Mixed lineage leukemias are being increasingly identified as use of larger numbers of immunophenotypic markers becomes widespread. These leukemias exhibit the phenotype of more than one, and sometimes more than two, lineages.<sup>83</sup> In most cases, this is the result of blasts that coexpress markers of several lineages; in other rare cases, blasts of different lineages coexist in the same patient.<sup>87</sup> In the former, more common cases, the blasts may be obviously derived from one lineage, based on morphologic, cytochemical, and immunophenotypic criteria; at the same time, the blasts express apparently aberrant markers from another lineage. Myeloid antigen-positive ALL and lymphoid antigen-positive AML occur frequently. In some cases, assignment of true lineage is more difficult. Scoring systems designed to weigh lineage-specific markers have been developed to assign lineage in these difficult cases ( Table 46.2-3).<sup>72</sup>

Lineage	1/2 Point	1 Point	2 Points
Myeloid lineage	CD13, CD14, CD15	CD15, CD13, CD14, morphology, cytochemistry	Myeloperoxidase
B lineage	Tdt, IgH rearrangement	CD19, CD19, CD24	cCD22, cy chain
T lineage	Tdt, CD7	CD2, CD5, TcR $\beta$ receptor rearrangement	cCD3

c, cytoplasmic; p, immunoglobulin M heavy chain; Tdt, terminal deoxyribonucleotidyl transferase.  
 IgH (heavy chain) rearrangement and TcR $\beta$  receptor are determined by Southern blot analysis. Any leukemia with two or more points from more than one lineage is scored as a mixed lineage.  
 (Adapted from ref. 72.)

**TABLE 46.2-3.** Assigning Lineage in Mixed Lineage Leukemias<sup>a</sup>

Although several clinical entities of leukemias with aberrant phenotypes have been described,<sup>82,84</sup> there is considerable overlap in the immunophenotypes, rendering such proposed subgroupings difficult to interpret. In addition, the aberrant markers found on AML blasts are associated with a variety of karyotypes and FAB subgroups.<sup>88,89</sup> The prognostic significance of mixed lineage phenotype or the expression of aberrant markers is unclear, but single aberrant antigens appear to hold little prognostic importance.

**CYTOGENETICS AND MOLECULAR GENETICS OF ACUTE LEUKEMIAS**

The frequent presence of nonrandom chromosomal translocations, oncogene mutations, and tumor suppressor gene abnormalities in leukemia cells has allowed substantial progress to be made in understanding the pathogenesis of acute leukemias,<sup>90,91,92,93</sup> and <sup>94</sup> in diagnosing and developing prognostic models for subtypes of leukemia,<sup>95,96,97</sup> and <sup>98</sup> and in assessing the effects of therapy or detecting early relapse.<sup>99,100</sup> The molecular genotype or karyotype is rapidly becoming the gold standard for diagnosis and prognosis in many subtypes of acute leukemia. A detailed discussion of the molecular biology of hematopoietic cancer is found in [Chapter 45.1](#).

In ALL, the presence of t(9;22), found in up to 30% of adults, t(4;11), -7 or +8, which are more infrequently seen, are poor prognostic signs. Abnormal karyotypes are seen in approximately 80% of patients with AML.<sup>98</sup> In AML, t(15;17), t(8;21), and inv(16) or t(16;16), have a favorable prognosis, whereas +8, -5, del(5q), -7, del(7q), -20, +11, +13, inv(3), and involvement of 11q23, are unfavorable. Distinct pathologic and clinical syndromes, such as APL, are strongly associated with t(15;17); AML-M2 with t(8;21); AML-M4EO with inv(16) or del(16p) and AML-M7 with t(1;22).<sup>98,101</sup> Chemotherapeutic agents that interfere with DNA topoisomerase II, such as epipodophyllotoxins or anthracyclines, can result in the balanced translocations described previously<sup>102,103</sup> and often appear 1 to 3 years after chemotherapy. In contrast, alkylating agents more typically yield -5, -7, and complex chromosomal abnormalities, 2 to 9 years later, frequently initiate as myelodysplastic syndromes and have a particularly poor prognosis.<sup>104,105</sup>

**PRINCIPLES OF THERAPY FOR ACUTE LEUKEMIA**

Despite advances, the majority of adult patients with acute leukemia die as a result of the disease (see [Fig. 46.2-1](#)).<sup>106</sup> Although most patients initially respond to chemotherapy, relapse is common. The goal of therapy in acute leukemia is the eradication of the leukemic clone with the restoration of normal hematopoiesis. This is usually accomplished by the use of profoundly myelosuppressive chemotherapy, which induces a period of relative bone marrow aplasia with the rapid reduction of leukemia cells. It is during the recovery from aplasia, that a state of clonal competition develops.

Normal stem cells gain a growth advantage and repopulate the bone marrow, establishing the predominance of polyclonal hematopoiesis. Leukemia cells are replaced by normal differentiated progeny, which are capable of providing vital life-sustaining functions. The disease process has been temporarily abated.

The transient nature of the initial clinical response is best understood in the context of the enormous size of the total leukemia burden and the limitations of the effect of modern chemotherapy on this critical mass. Based on data from animal models, it has been estimated that there are approximately 10<sup>12</sup> leukemia cells in the body at the time of diagnosis. Standard chemotherapy regimens generally result in a 2 to 3 log (99.0% to 99.9%) reduction in the total amount of tumor cells.<sup>107</sup> This places the residual leukemia burden below the level of clinical detection, and based on morphologic criteria, the patient has been placed into a complete remission. Laboratory and clinical evidence, however, would suggest that such a remission is far from complete for the great majority of patients. Although standard morphologic evaluation shows no evidence of residual leukemia, a state of minimal residual disease exists, with estimates for the remaining leukemia burden approaching approximately 10 billion cells. A number of laboratory techniques have been introduced in an effort to increase the resolution of detecting remaining leukemia cells ([Table 46.2-4](#)). Although none of the available assays are ideal, current studies of minimal residual disease are attempting to establish the clinical validity of such measures and whether the results from these assays may form the basis for therapeutic decisions in individual patients. The paradigm for this has been provided by the reverse transcriptase-based (RT) PCR assay for the PML/aRAR gene rearrangement used in APL (see [Acute Promyelocytic Leukemia](#), later in this chapter).<sup>71,81,85,97,108,109,110,111,112</sup> and <sup>113</sup>

Technique	Typical % of Cells Analyzed	Material Analyzed	Limit of Sensitivity (%)	Example
Morphology	100-200	Smear cells	1	Standard definition of complete response and relapse <sup>71</sup>
Clonality	25-50	Cells capable of cloning in culture	1-1	Im(Ph) in minimal bone marrow <sup>71</sup>
Response to alkylating agents	100-200	DNA	1-1	Downy (T to acute lymphoblastic leukemia) <sup>71</sup>
Antigen like	1,000,000	DNA	1-2	CD3 gene rearrangement <sup>71</sup>
Antigen receptor gene rearrangement	10,000-1,000,000	Smear cells	0.001	Immunoglobulin gene (IGH) <sup>71</sup>
Antigen receptor gene rearrangement	1,000,000	RNA	<0.001	PML, BCR in acute promyelocytic leukemia <sup>71</sup>

(Adapted from ref. 71.)

**TABLE 46.2-4.** Current Methods Used Frequently for Detection of Minimal Residual Disease

The primary goal of the initial chemotherapy in AML is to achieve a complete response (CR). Despite the limitations of morphologic evaluation, clinical standards have been adopted to define outcomes and establish reference points from which therapies can be compared.<sup>71</sup> CR is defined as less than 5% of blasts in the bone marrow normally regenerated as evidenced by both an acceptable level of cellularity (greater than 20% on bone marrow biopsy) and the restoration of normal hematopoiesis (as reflected by peripheral blood values of at least 1500 neutrophils per µL and 100,000 platelets per µL). Red cell parameters are not usually considered in this definition. The peripheral blood should not contain circulating blasts (in the absence of growth factor use), and there should be no evidence of extramedullary disease. These criteria must be sustained for a period of at least 4 weeks.

CR is the only significant form of clinical response in acute leukemia. The ability to achieve such a response has been directly correlated with survival and is a necessary first step in a curative treatment strategy. Although some research studies have chosen to categorize lesser responses and define partial remission (or response), the inability to morphologically clear leukemia cells from the bone marrow is a treatment failure with grave implications for the patient.

Current treatment strategies divide therapy into two basic parts: induction and postremission therapy. The purpose of remission induction is to achieve a CR. The goal of postremission therapy is to eradicate minimal residual disease, thus preventing relapse and effecting a cure. Different approaches to postremission therapy have been used and defined by a number of studies. Consolidation therapy is used to describe immediate postremission treatment regimens that are similar to induction therapy. The doses of the drugs are either equivalent or slightly attenuated. Intensification is the application of higher doses of active agents while in CR. Maintenance is defined as therapy given in greatly attenuated doses over extended periods.

Relapse is usually heralded by a change in a previously normal complete blood cell count. Reduction in normal cells or the reappearance of blasts in the peripheral blood occur frequently; isolated extramedullary relapse is infrequent. Examination of the bone marrow confirms the relapse by demonstrating more than 5% blasts. In situations in which there is only a borderline increase in blasts, it may be necessary to repeat the bone marrow examination in 1 to 2 weeks to confirm relapse.<sup>71</sup>

**PRINCIPLES OF CLINICAL MANAGEMENT OF ACUTE LEUKEMIA**

The care of the patient with acute leukemia requires the ability to support the individual through the expected complications of myelosuppressive therapy, most notably the period of pancytopenia, which may last for 2 to 5 weeks. Successful clinical management requires a detailed understanding of likely complications accompanied by early therapeutic intervention designed to minimize life-threatening toxicities. With regard to these principles, much of the improvement seen in the care of leukemia patients in the last few years can be directly attributed to advances in supportive care.

Infection and hemorrhage are the primary cause of death in patients with leukemia.<sup>114</sup> Many patients with acute leukemia initially present to the physician with fever and neutropenia. Virtually all patients develop these complications after treatment with chemotherapy. Untreated, infection in the neutropenic host can be rapidly fatal. Therefore, the early institution of antibiotic therapy is necessary.<sup>115,116</sup> Initial antibiotics must provide a broad spectrum of antibacterial coverage, with particular emphasis on gram-negative organisms. The epidemiology of a single center's flora may be instrumental in determining the particular antibiotics used as first-line therapy. Common regimens include an antipseudomonal penicillin or cephalosporin coupled with an aminoglycoside. Monotherapy with a third-generation cephalosporin, such as ceftazidime, or a carbapenem, such as imipenem, is an alternative.

Changes in the initial antibiotic coverage are based either on the sensitivities of the organisms isolated or persistence of fever. Continued fever, despite 4 to 6 days of antibacterial therapy usually requires empiric antifungal therapy with amphotericin B. Additionally, patients with indwelling central venous catheters or other prosthetic devices may require the early institution of vancomycin. Antimicrobial agents should be continued until the absolute neutrophil count has risen above 500/ $\mu$ L. Patients who have a documented bacterial source of infection should complete at least a 10- to 14-day course of therapy, whereas those patients with evidence of infection secondary to invasive mycoses may require a more protracted course of therapy.

Despite the accepted approach to empiric therapy in patients with leukemia and neutropenic fever, there is considerable controversy regarding infection prophylaxis, use of protected environments, reverse isolation, transfusion of granulocytes, or the use of hematopoietic growth factors to accelerate recovery.<sup>117,118</sup> and <sup>119</sup> Although the duration of neutropenia has consistently been shortened by the use of G-CSF or GM-CSF in a number of studies, the effect on infectious complications and mortality has been variable.<sup>120,121,122,123,124</sup> and <sup>125</sup> Careful attention to oral hygiene with regular use of oral rinsing and cleaning with soft tipped (sponge) devices to prevent gingival trauma may prove useful. Rectal or vaginal manipulations should be avoided.

Immediate access to blood products is critical to sustain the patient; the hemoglobin level should be maintained at 8 g/dL or higher in patients with other medical comorbidities (pulmonary disorders or coronary heart disease). There is a direct relationship between hemorrhage and reductions in the platelet count below 5000 to 10,000/ $\mu$ L. Hence, platelets are not only transfused in response to hemorrhage, but also to prevent hemorrhage. The routine use of platelet transfusions has had a significant effect on the incidence of hemorrhagic death. Patients with uncomplicated thrombocytopenia can be transfused when the platelet count falls below 10,000/ $\mu$ L. Patients who are either febrile or have other complicating medical conditions such as severe mucositis or ongoing coagulopathy, require prophylactic transfusions at higher levels.<sup>126,127</sup> and <sup>128</sup>

Some patients become refractory to platelet transfusions. This may result either from alloimmunization in the patients who have received multiple transfusions or may be secondary to other medical conditions such as persistent fever or disseminated intravascular coagulation. This refractoriness poses a particularly difficult management problem for the clinician. Current strategies to overcome alloimmunization include the prevention of sensitization by the use of single, related donor platelets or HLA-matched platelets as well as the use of leukocyte reduction filters.<sup>129</sup> Platelets from a potential bone marrow donor should be avoided in patients who are eligible for allogeneic BMT.

A bleeding diathesis or frank DIC may be present in addition to thrombocytopenia and may result in either hemorrhage or thrombosis. This complication is most frequently associated with APL, but may also be found in other subtypes of acute leukemia either at presentation or after the institution of cytotoxic therapy. The coagulopathy has been attributed to the release of procoagulants from the leukemia cells as they lyse. The contribution of increased fibrinolysis to this hemostatic disorder has come under scrutiny.<sup>130</sup>

The approach to the patient with leukemia-associated coagulopathy remains controversial. Laboratory tests that are useful as indicators of coagulopathy include the platelet count, prothrombin time, activated partial thromboplastin time, thrombin time, fibrinogen, fibrin split products, and d-dimer. Clinical management relies on frequent monitoring of the patient with intervention based on a deteriorating clinical status or worsening trend in a laboratory value such as fibrinogen. The former approach of managing the bleeding diathesis of APL with low-dose heparin (7 to 10 U/kg/h) has largely been replaced by early treatment with retinoids as well as aggressive blood product support.<sup>131,132</sup> Platelets and fresh frozen plasma are transfused multiple times daily to maintain platelet counts above 50,000/ $\mu$ L and fibrinogen levels above 100 mg/dL. The hemostatic abnormalities typically abate after the leukemia burden has been reduced.

Metabolic abnormalities can exist in the leukemia patient at presentation or with the institution of therapy.<sup>133,134</sup> Patients rarely present with disorders of potassium or calcium, but can develop electrolyte problems during treatment with aminoglycosides, amphotericin, or other agents that affect kidney function. Rapid leukemia cell death releases intracellular metabolites, notably uric acid, potassium, and phosphorus, causing a life-threatening metabolic condition known as the *tumor lysis syndrome*. Uric acid, a product of purine metabolism, may then deposit in the joints, causing a gouty arthropathy or, more important, in the renal parenchyma or collecting system, resulting in renal failure. Hyperuricemia may be detected. Prevention of these complications is usually accomplished by instituting vigorous hydration with a brisk urine output (greater than 150 mL/h) and administering allopurinol before beginning cytotoxic therapy. The dose of allopurinol ranges from 300 to 900 mg/d. Alkalinization of the urine by adding sodium bicarbonate to the intravenous fluids, administering a carbonic anhydrase inhibitor (such as acetazolamide), or both are recommended in extreme cases, or in patients allergic to allopurinol, to increase the solubility of the uric acid.

Complications, such as cardiac disturbances with hyperkalemia or the precipitation of calcium phosphate resulting in renal failure due to hyperphosphatemia, can be avoided in most cases with early attention to metabolic disturbances. Correction of these abnormalities is best accomplished by aggressive hydration with concomitant diuresis to wash out the toxic by-product of the dying leukemia cells. Additional benefit may be gained by using oral phosphate binders (aluminum hydroxide or calcium acetate) to minimize absorption of additional phosphate from dietary sources. In situations in which hyperkalemia is complicated by renal insufficiency, cation exchange resins (Kayexalate) may be indicated. Extreme circumstances may require renal dialysis to correct multiple abnormalities.

Tumor lysis syndrome most frequently complicates acute lymphoid leukemia (particularly Burkitt's type) and is most problematic in the setting of hyperleukocytosis (peripheral blast counts greater than 100,000/ $\mu$ L). Patients with AML are at a relatively reduced risk of tumor lysis, relative to ALL, but are at an increased risk for sludging of large myeloblasts in the microcirculation (leukostasis), resulting in cerebral or pulmonary compromise often associated with hemorrhage and, in extreme circumstance, leading to death. The ability to rapidly decrease the circulating blast number, however, is an important factor for survival in these patients. Leukapheresis can be used, but, at best, is only a temporizing measure. Instead, immediate treatment with chemotherapy should be undertaken with careful attention to the expected metabolic abnormalities discussed previously.

## TREATMENT OF NEWLY DIAGNOSED ACUTE MYELOGENOUS LEUKEMIAS

Untreated, AML is a uniformly fatal disease. Although it is possible to support patients for a period with supportive medical care, they ultimately succumb to the complications associated with bone marrow failure: infection or hemorrhage. Most patients seek medical attention for symptoms related to infection or bleeding, and these patients typically require immediate therapeutic intervention. Other patients are not candidates for cytotoxic therapy because of a poor performance status or other active severe medical comorbidities that complicate their care. In such settings, a supportive strategy may be most appropriate. The risks and potential benefits and alternatives should be carefully considered in each case and discussed with the patient and the family.

Several prognostic factors have been identified in AML ( [Table 46.2-5](#) ).<sup>114,135</sup> The difference in treatment results among various trials using similar chemotherapy may, in part, be explained by the frequency of these negative characteristics within a study population.<sup>136</sup> Age is inversely associated with the ability to achieve remission.<sup>137,138</sup> In patients older than the age of 60 years, standard therapy achieves CR in only 30% to 50% of treated individuals. AML that occurs as a consequence of prior cytotoxic therapy, or that has developed from an antecedent hematologic disorder (e.g., myelodysplastic syndrome) has a particularly poor outcome, with a lower incidence of achieving a CR and shorter duration of survival than for patients with *de novo* AML.<sup>139,140</sup> Multiple studies have demonstrated the prognostic importance of cytogenetic abnormalities in AML, making this the single most important predictor of outcome.<sup>141,142</sup> and <sup>143</sup> Patients with a good prognosis are those with t(15;17), t(8;21), or inv(16), whereas poor-risk patients have loss of all or part of chromosome 5 or 7, translocations involving 11q23, or trisomy 8.

Acute myelogenous leukemia  
 Age: Older age is associated with a reduced incidence of complete response  
 Antecedent hematologic disorder or secondary acute myelogenous leukemia: These subgroups have a lower incidence of complete response and a reduced overall survival  
 Cytogenetics: t(15;17), t(8;21), and inv(16) denote good prognostic subgroups; abnormalities of chromosome 5 or 7, trisomy 8, and t(9;11) denote poor prognostic subgroups  
 Acute lymphoblastic leukemias  
 White blood cell count: High count associated with poor prognosis  
 Leukemic cell immunophenotype: T cell has a favorable prognosis, pre-B cell has an intermediate prognosis, whereas mature B-cell disease has a poor prognosis with standard regimens  
 Age: Older age associated with worse prognosis  
 Philadelphia chromosome-positive disease has a worse prognosis  
 Time to complete response: Patients requiring more than 4 to 5 weeks to achieve a complete response have a lower likelihood of being cured

**TABLE 46.2-5.** Prognostic Features in Adult Acute Leukemia

Historically, the diagnosis of acute leukemia has left the physician with few therapeutic options. During the 1940s, Farber established the modern era of chemotherapy by effectively using antimetabolites in pediatric patients with ALL. Subsequently, a number of other single agents were demonstrated to have antileukemic activity at first in the laboratory and then later in the clinic. Many of the drugs initially used to treat adults with AML had been used in pediatric ALL, but they were not active in AML, and the early clinical results were disappointing. The introduction of cytarabine (Ara-C) dramatically changed the therapy of patients with AML.

Ara-C is the most important drug in use today for the treatment of AML. Much of the clinical investigation done since the 1970s has focused on increasing the efficacy of this drug by either combining it with other agents, escalating the dose, or changing the schedule of administration. Despite some minor modifications made in treatment in the last few years, Ara-C remains the cornerstone of AML therapy.

## INDUCTION

Standard induction therapy is based on the combination of Ara-C with an anthracycline or anthracenedione. CR rates in newly diagnosed AML patients younger than the age of 60 years range from 50% to 75%, depending on the patient population studied ( [Table 46.2-6](#)).<sup>136</sup> In the 1960s, investigators first demonstrated the ability of Ara-C alone to induce responses in approximately 20% to 30% of patients.<sup>144</sup> Ara-C was then tried in combination, at first with 6-thioguanine and later with daunorubicin, and found to increase the incidence of CR to approximately 40% to 50%.<sup>145</sup> When the dose of the Ara-C and daunorubicin used was increased, the response rates improved. Ara-C given for 7 days at 100 mg/m<sup>2</sup>/d as a continuous infusion with daunorubicin given at 45 mg/m<sup>2</sup>/d for 3 days became the standard regimen and is referred to as the 3 + 7 or 7 + 3 regimen. Patients who do not achieve a CR with one course of induction therapy may still be induced into a CR with a second cycle of this therapy. A randomized trial by the Cancer and Leukemia Group B (CALGB) reported a 59% CR rate using 3 + 7 induction therapy and found this response to be superior to a briefer course of similar therapy.<sup>138,146</sup>

Induction therapy Ara-C, 100 mg/m <sup>2</sup> IV q12h × 7 days 6-thioguanine, 100 mg/m <sup>2</sup> PO q12h × 7 days Daunorubicin, 60 mg/m <sup>2</sup> IV days 5, 6, and 7		
Patient Population	No. of Patients Achieving Complete Response	Percentage Complete Response
All patients (142)	74	52
Without patients unable to complete therapy (-20 patients)	74	61
Above without patients older than 70 years of age (-84 patients)	64	82
Above without patients with antecedent hematologic disorder (-5 patients)	62	85
Above without patients with secondary acute myelogenous leukemia (-5 patients)	62	91

(Modified from ref. 136.)

**TABLE 46.2-6.** Toronto Leukemia Study Group: Effect of Patient Subsets on Complete Response Rate

The initial success of increasing response rates through dose intensification prompted studies designed to improve the 3 + 7 combination by either adding agents or further increasing doses. Given the prior results with 6-thioguanine, this agent was added to the daunorubicin and Ara-C to form the DAT or TAD regimens. In a number of nonrandomized, single-arm studies, the CR rates were similar to those obtained with 3 + 7 regimen.<sup>147,148</sup> The CALGB conducted a randomized study between 3 + 7 and DAT and found the addition of 6-thioguanine provided no significant benefit.<sup>149</sup> The extension of the Ara-C infusion to 10 days was also found to be without an advantage. A subsequent study failed to show a statistical advantage to doubling the Ara-C dose during the 7-day infusion, although a greater number of treatment-related deaths were noted in patients younger than 60 years of age.<sup>150</sup>

As new drugs with antileukemic activity have been introduced into the clinic, trials have been undertaken in an attempt to improve on 3 + 7 induction ( [Table 46.2-7](#)). The substitution of doxorubicin for daunorubicin produced no significant benefit, but instead resulted in increased gastrointestinal toxicity.<sup>137</sup> In another study, the addition of etoposide to 3 + 7 produced an improved remission duration in a younger cohort of patients.<sup>151</sup> Mitoxantrone, amsacrine, rubidazole, and aclarubicin have all been substituted for daunorubicin in induction, but no clinical trial has demonstrated the unequivocal superiority of any of these second-generation regimens.<sup>152,153,154</sup> and <sup>155</sup>

Study	Study Group	Induction	Response	Complete Response	Median Survival	Comments
137	AML	3 + 7 + 6-TG	CR 52%	CR 52%	12.5 mo	Randomized trial comparing 3 + 7 + 6-TG to 3 + 7

**TABLE 46.2-7.** Representative Treatment Regimens in Acute Myelogenous Leukemias (AML)

Three randomized trials have compared idarubicin with daunorubicin and have demonstrated that the idarubicin regimens increased response rates in patients younger than 60 years of age.<sup>156,157</sup> and <sup>158</sup> More patients treated with idarubicin were able to achieve CR after only one course. The toxicity profiles between the two regimens were similar. In two of the studies, the idarubicin combination demonstrated a survival advantage. An update of these studies has suggested a survival advantage could still be detected in one trial (but not the other two) with a follow-up of 5 years.<sup>159</sup>

Despite these findings, the anthracycline of choice in the induction regimens remains controversial. Criticism of the idarubicin studies cited previously has centered on the issue of dose equivalency between the idarubicin dose (12 or 13 mg/m<sup>2</sup>) and the daunorubicin dose (45 or 50 mg/m<sup>2</sup>) used for comparison. The CR rate (58%,

58%, and 59%, respectively) in the daunorubicin arm was lower than other studies that used a standard 3 + 7 induction. Several nonrandomized trials have used higher doses of daunorubicin (70 mg/m<sup>2</sup>) and have described response rates similar to those seen with idarubicin, suggesting that the dose of the anthracycline used may be more important than the choice of anthracycline.<sup>147</sup> In addition, preliminary results of a large Eastern Cooperative Oncology Group (ECOG) trial that randomized elderly patients between induction regimens using daunorubicin, idarubicin, or mitoxantrone failed to show an advantage to using the newer agents.<sup>160</sup> Despite conflicting results, idarubicin has been widely adopted as part of current treatment regimens.

The ability of high doses of Ara-C to overcome drug resistance and induce remission has been demonstrated in relapsed disease. Such an approach has been applied to upfront induction therapy in an effort to improve response. Ara-C doses ranging from 0.5 to 6.0 g/m<sup>2</sup>/d for 3 to 8 days have been investigated. The effect of these regimens on treatment outcomes has been variable. A University of California, Los Angeles, study randomized patients between a 3 + 7 induction and an intermediate-dose Ara-C regimen and found that both remission rate and actuarial 4-year disease-free survival were similar in the two cohorts.<sup>161</sup> Two other randomized studies, however, have shown a benefit to high-dose Ara-C–based inductions, demonstrating an advantage not in the likelihood of achieving a CR but in producing more durable responses and a superior disease-free survival.<sup>162,163</sup> Toxicity was increased with the high-dose regimens and particularly evident during the postremission period when infections were increased and recovery times delayed.

Hematopoietic growth factors have been tested in clinical trials in an attempt to reduce the toxicities seen with dose-intensive treatments. In older patients, significant toxicity with standard therapy has prevented testing more dose-intensive regimens. Treatment-related mortality in patients older than the age of 60 years is higher compared with younger patients treated with similar therapy and remains a primary cause of treatment failure in this group.<sup>114</sup> As the hematopoietic growth factors had been used successfully to speed granulocyte recovery after chemotherapy in other malignancies, this approach was tested in older patients with AML. Initially, there was concern over using a myeloid growth factor in AML; however, a clinical trial conducted in patients with relapsed disease did not demonstrate stimulation of leukemia cells when growth factor was used in support of chemotherapy.<sup>119</sup> A number of small, nonrandomized studies have investigated the use of either G-CSF or GM-CSF after treatment in poor-risk populations and found an advantage in ameliorating treatment-related toxicity.<sup>164,165</sup> Other studies have explored a novel application of using growth factors to modify drug sensitivity in addition to their potential supportive role. Both G-CSF and GM-CSF have been used before chemotherapy (as priming) in an effort to increase leukemia cell proliferation and increase sensitivity to cell-cycle–specific agents.<sup>160,167,168</sup> None of these trials have demonstrated any benefit to such a strategy.

Given the conflicting data in the early studies, several large randomized trials were conducted in an attempt to clarify the role of growth factors in AML therapy.<sup>120,121,122,123,124</sup> and <sup>125</sup> Although these studies have generally demonstrated a decrease in the duration of neutropenia, the significance of this effect has remained controversial. A study from the ECOG was able to show a decrease in treatment-related mortality with GM-CSF, while another large randomized study from CALGB was not able to demonstrate any significant clinical benefit from this growth factor.<sup>120,121</sup> It should be noted that two different forms of the recombinant growth factor were used, which could account for the disparity in outcomes. Moreover, large numbers of patients were removed from treatment in the CALGB study, which may have altered the outcome. Using G-CSF, the French AML Cooperative Study Group demonstrated an increased CR rate but no survival benefit.<sup>122</sup> The Southwest Oncology Group also tested G-CSF in older patients (older than 55 years old) and found a reduction in time of neutrophil recovery and decreased duration of infection, but no difference in either CR rate or overall survival.<sup>124</sup> A separate European and Australian phase III study also showed similar response and survival rates in the G-CSF and control groups, but was able to demonstrate significant reduction in measures of morbidity such as duration of fever, requirements of antimicrobials, and duration of hospitalization.<sup>123</sup> This study was not confined to the older population but included all patients older than the age of 16 years with *de novo* AML seen during the study period. Hence, despite intensive investigation, there is still no consensus regarding growth factor use in AML therapy other than the observation that their use is safe and reduces the neutropenic period. More recently, cost-to-benefit considerations have been introduced into the equation, and future clinical trials may incorporate economic data when dealing with this question.<sup>168</sup>

## POSTREMISSION THERAPY

Although the exact form of postremission therapy is controversial, the need for such therapy is widely accepted. Induction therapy fails to provide adequate cell kill, and leukemia cells survive the initial treatment. The benefit of postremission therapy was established by two randomized multicenter trials that showed that maintenance therapy was superior to no further treatment in prolonging remission duration.<sup>169,170</sup> This concept of continuing low-dose therapy over a prolonged period was further modified by subsequent clinical trials. The CALGB addressed the question of the duration of maintenance in a randomized study that compared 36 months of therapy versus 8 months of therapy.<sup>149</sup> No benefit was found for the more prolonged duration of treatment. Additional studies have suggested that more intensive therapy delivered within a shorter period appeared to offer clinical benefit.<sup>171,172</sup> One study from ECOG randomized patients younger than 65 years of age to receive either one course of intensive consolidation versus 2 years of maintenance therapy and found superior survival in patients receiving the more intensive form of therapy.<sup>173</sup> This has led to the concept that state-of-the-art therapy of AML includes induction, intensive consolidations, but no maintenance ( [Table 46.2-8](#)). However, this concept has been challenged by the experience reported in APL (see [Acute Promyelocytic Leukemia](#), later in this chapter).

Acute myelogenous leukemia
Anthracycline- and cytarabine-based induction regimens
Intensive postremission therapy; either bone marrow transplant or high-dose cytarabine is required for prolonged remission
Maintenance therapy is not generally indicated, with the exception of acute promyelocytic leukemia
Acute promyelocytic leukemia
Retinoic acid and anthracycline- and cytarabine-based treatment
Management of disseminated intravascular coagulation
Administration of cryoprecipitate or fresh frozen plasma to maintain fibrinogen >100 mg/dL; platelet transfusions to maintain daily platelet counts >50,000/μL
Bone marrow transplant/high-dose cytarabine therapy reserved for relapsed disease
Acute lymphoblastic leukemia
Four- or five-drug induction regimens using anthracyclines, cyclophosphamide, and/or asparaginase in addition to vincristine and prednisone
Intensive consolidation therapy based on cytarabine combined with anthracyclines, epipodophyllotoxins, or antimetabolites
Prolonged maintenance therapy (approximately 2 years) based on oral methotrexate combined with mercaptopurine
Prophylactic intrathecal chemotherapy (with or without cranial radiotherapy) for central nervous system prophylaxis

**TABLE 46.2-8.** State-of-the-Art Treatment Programs for Adult Acute Leukemia

The logical progression of the experience that established consolidation was to further intensify the chemotherapy used in postremission treatment. The efficacy of high-dose Ara-C in treating patients with relapsed AML led to regimens for postremission therapy. A number of nonrandomized trials using Ara-C doses ranging from 1 to 3 g/m<sup>2</sup> (typically given every 12 hours for 6 to 12 doses) have reported 4-year disease-free survivals ranging from 30% to 40%.<sup>174,175</sup> These results appear to be superior to the 15% to 20% survival reported with standard consolidation regimens. The most compelling evidence for intensification, however, has been provided by a large randomized study conducted by the CALGB.<sup>80</sup> After achieving remission with a standard 3 + 7 regimen, patients with *de novo* AML were randomized to receive four courses of Ara-C at one of three dose levels: 100 mg/m<sup>2</sup>/d for 5 days by continuous infusion (standard-dose arm); 400 mg/m<sup>2</sup>/d for 5 days by continuous infusion (intermediate-dose arm); or 3 g/m<sup>2</sup> twice daily via a 3-hour infusion on days 1, 3, and 5 (high-dose arm). A subsequent analysis of this trial according to cytogenetic data underscored the importance of this prognostic factor, with 84% of the patients who had favorable cytogenetics [defined in this study as t(8;21) or inv (16)] able to have prolonged disease-free survival.<sup>176</sup> Although the results from this trial have been used to bolster the argument for single-agent high-dose Ara-C intensification, all patients received four courses of maintenance therapy in the form of attenuated doses Ara-C and daunorubicin in addition to the high-dose Ara-C intensification. The effect of such therapy on outcomes is uncertain, causing some speculation as to whether comparable results can be achieved by administering the high-dose Ara-C intensification alone. Still, the results from this trial compare favorably with studies using allogeneic BMT as postremission therapy and have heightened the debate regarding the standard of care in the postremission setting.

## ALLOGENEIC BONE MARROW TRANSPLANTATION

The use of bone marrow or stem cell transplantation as postremission therapy represents dose intensification carried to the extreme of myeloablation. High doses of chemotherapy with or without total body radiation are used in an effort to maximize leukemia cell kill. Hematopoiesis is restored by the infusion of stem cells harvested from an HLA-compatible donor, thereby rescuing the patient from the consequences of bone marrow failure. The donor bone marrow and peripheral blood stem cells (graft) may also have a number of immunologic effects. Because of differences in HLA composition, the graft may reject the host, resulting in graft-versus-host disease (GVHD). This complication may increase the risk of infection and represents a major source of morbidity and mortality in patients who undergo this procedure.<sup>177</sup> This

immunologic effect may, however, also translate into antileukemic activity as evidenced by the lower relapse rates observed in patients with GVHD. This graft-versus-leukemia effect is an evolving area of investigation and probably accounts for the lower relapse rates seen in allogeneic BMT as compared with syngeneic (or autologous) transplants in which similar conditioning regimens are used. <sup>178</sup>

Despite treatment-related complications, allogeneic BMT is effective antileukemic therapy. This was first established in a small number of heavily pretreated refractory AML patients who were successfully treated with allogeneic BMT. The concept that the efficacy of this therapy could be improved and its toxicity lessened if transplants were performed earlier in the course of the disease led to a number of nonrandomized trials from large centers or cooperative groups. These trials showed that allogeneic BMTs in first CR using HLA-compatible related donors resulted in 5-year disease-free survival of approximately 45% to 50%, with relapse rates ranging only from 10% to 20%. <sup>179</sup> A significant number of patients, however, succumb to such complications as GVHD, infection, or interstitial pneumonitis, affecting the overall survival of the group as a whole.

Therefore, the major criticism of allogeneic BMT in first CR is that although it is effective therapy with a relatively low incidence of relapse, it is quite toxic, expensive, and not necessarily better than other forms of dose-intensive therapy. The complication rate increases with age, and it is not standard practice to offer allogeneic BMT with a conventional graft to patients older than the age of 50 to 55 years. As the median age of patients with AML is approximately 65 years, it is clear that most patients with this disease are not eligible for this form of therapy. Because of entry criteria, BMT trials report results in younger groups of patients who may do well with other forms of dose-intensive therapy, but are generally not representative of the majority of patients with AML. In addition, only approximately 30% of eligible patients have an HLA-compatible donor. Despite meeting the minimum requirements of age and availability of a donor, a significant number of patients still fail to undergo transplantation. <sup>180</sup> Therefore, it has been estimated that allogeneic BMT is only applicable in 2% to 10% of patients with AML. <sup>106</sup> Strategies using unrelated HLA-matched or haplotype-mismatched individuals as alternative donors or using nonmyeloablative transplant regimens with reduced toxicity as part of a minitransplant for older patients have been introduced and are currently undergoing investigation. <sup>181,182</sup>

## AUTOLOGOUS BONE MARROW TRANSPLANTATION

Despite efforts to expand the donor pool for allogeneic BMT, the majority of patients do not have an acceptable HLA-matched donor and cannot undergo allogeneic BMT. In an attempt to allow such patients to undergo high-dose therapy with curative intent, investigators began to explore the use of the patient's own bone marrow, obtained while in CR, as a source of hematopoietic reconstitution. <sup>183</sup> Such an approach was thought to provide the antileukemic benefits associated with high-dose conditioning regimens yet avoid the toxic complications such as GVHD. One major disadvantage, however, is the potential contamination of the autologous graft by residual leukemia cells. The inability of currently available laboratory techniques to reliably detect minimal residual disease and predict outcome based on its presence represents a major problem in leukemia therapy. Hence, there is concern that despite the high-dose conditioning designed to eradicate residual leukemia cells in the body, patients will ultimately relapse because undetectable leukemia cells will be reinfused with the graft. One innovative study from St. Jude Children's Hospital attempted to address this important question. <sup>184</sup> Cells in an autologous bone marrow graft were marked with a neomycin-resistant gene before transplantation into two patients with AML. After clinical relapse of the patients, the neomycin-resistant gene marker was detected in the leukemia blast cells of both patients, implying that the remission marrow that had been reinfused contributed to disease recurrence.

Despite this laboratory evidence and the rationale for attempting to remove minimal residual disease from the stem cell graft, the clinical benefits of purging the graft remain unclear. Clinical trials using unpurged bone marrow as the source for hematopoietic reconstitution in first CR have reported treatment results comparable with studies using a purged graft. Results from these trials have generally reported disease-free survival of approximately 40% to 50%. <sup>183</sup> Relapse rates (50% to 60%) are higher than allogeneic BMT, but, as expected, the toxicities are less. In studies that have used either immunologic or pharmacologic methods to purge bone marrow, there has been a profound suppression of normal bone marrow progenitors, resulting in delayed engraftment and a prolonged period of hematologic recovery.

Given the experience in other malignancies using peripheral blood stem cells as the source of hematopoietic reconstitution after high-dose therapy, this approach has been investigated in patients with AML. <sup>185</sup> One potential advantage to this approach is the hypothesis that there is a difference between the normal stem cell and leukemia cell compartments in recovery rates after a priming stimulus such as chemotherapy. The normal cells are thought to have a temporary competitive growth advantage so that the cells that initially repopulate the peripheral blood are more likely to be normal progenitors instead of clonogenic leukemic stem cells. Therefore, collecting stem cells early in the priming process may be thought to provide the graft with a kinetic purge, making it relatively free from contamination by residual leukemia cells. Some evidence to support this hypothesis has been provided by a study that used standard cytogenetic analysis to assay for contamination of residual leukemia cells and failed to detect them early in the collection process. <sup>186</sup> Further support for the feasibility of this approach as been provided by the experience of harvesting pure populations of progenitor cells after chemotherapy in CML and myelodysplastic syndromes. <sup>187</sup> Studies using newer, more sensitive techniques, such as PCR or multiparameter flow cytometry, will continue to address the issue of graft contamination by minimal residual disease. <sup>188</sup>

The clinical results using peripheral blood stem cells have generally shown a decrease in the duration of neutropenia and thrombocytopenia. The effect on treatment outcomes, however, has been less clear, with some groups reporting relapse rates comparable with trials using unpurged bone marrow grafts. <sup>189</sup> Other studies have shown superior leukemia-free survival using purged bone marrow grafts. Although no studies have appeared, as yet, using purged peripheral stem cells, there has been great interest in intensifying the chemotherapy before collection of these stem cells and, in effect, achieving a form of *in vivo* purging. <sup>190</sup> This approach has been applied in both peripheral stem cell and bone marrow grafts, with the most compelling evidence provided by the results from the Medical Research Council (MRC) AML 10 trial (discussed in the following section). <sup>191</sup>

## ASSESSING THE OPTIONS FOR POSTREMISSION THERAPY IN ACUTE MYELOGENOUS LEUKEMIAS

Currently, the options for postremission therapy in younger patients with AML involve three forms of dose-intensive treatments: allogeneic or autologous transplantation and high-dose chemotherapy. These can be applied either alone or in combination. A number of studies have compared the different approaches in an effort to establish the optimal therapy. Although the initial comparisons reported the superiority of allogeneic BMT over chemotherapy, these studies used standard-dose attenuated consolidation regimens. <sup>179</sup> In the modern era, many would consider this suboptimal postremission therapy for patients younger than 60 years of age. More recent studies, however, have compared outcomes in patients who have undergone allogeneic BMT from HLA-compatible donors with those who have received either dose-intensive chemotherapy or autologous BMT. <sup>192,193</sup> and <sup>194</sup> The results from several of these studies are summarized in [Table 46.2-9](#). These trials have consistently reported decreased relapse rates with higher treatment-related morbidity and mortality in the BMT groups, but no significant benefit in survival. In fact, a large U.S. intergroup study showed a marginally better overall survival in the cohort treated with a single course of high-dose Ara-C after a standard Ara-C/idarubicin consolidation. <sup>194</sup> In contrast, the MRC 10 trial found a decreased relapse rate with a survival benefit for patients who received autologous BMT after three cycles of intensive postremission chemotherapy. <sup>191</sup> It should be noted that these two studies differed in the amount of therapy patients received before autologous BMT, as well as the conditioning regimen used for the autologous transplant.

Author	Comparison	Outcomes
Barnes <sup>192</sup>	Autologous BMT (unpurged) versus observation	Superior DFS and OS at 7y in autologous BMT group
Titus <sup>193</sup>	Allogeneic BMT versus autologous BMT (unpurged) versus IC	DFS best with allogeneic BMT versus equivalent OS
Harcos <sup>194</sup>	Allogeneic BMT versus autologous BMT (unpurged) versus IC	No difference in DFS or OS
Gaske <sup>195</sup>	Allogeneic BMT versus autologous BMT (purged) versus IC	No difference in DFS, marginal advantage in OS for IC

BMT, bone marrow transplantation; DFS, disease-free survival; IC, intensive chemotherapy; OS, overall survival.

**TABLE 46.2-9.** Randomized Comparisons of Dose-Intensive Postremission Regimens

The results from these randomized studies have failed to provide a clear answer to the postremission question, but have caused many centers to reevaluate the approach to AML patients in first remission. Although some institutions still recommend allogeneic BMT for suitable candidates with HLA-compatible donors, other

centers reserve BMT for relapse. This strategy is based on the relative equivalence of treatment outcomes. Despite a higher risk of relapse with chemotherapy, BMT can salvage some patients who fail chemotherapy-based consolidation, leading to equivalent overall survival while avoiding unnecessary toxicity in those patients who may be cured by chemotherapy alone. Patients should have either a potential donor identified or stem cells (bone marrow or peripheral blood) harvested and cryopreserved during first remission, in the event relapse occurs and a salvage strategy becomes necessary.<sup>194,195</sup> Treatment options are limited in patients who are not candidates for BMT, who are the largest fraction of patients.

## TREATMENT OF RELAPSED ACUTE MYELOGENOUS LEUKEMIAS

The majority of patients with AML relapse and ultimately die from the consequences of resistant disease. Chemotherapy is generally not curative in this setting. The data from multiple trials suggest median survivals of only a few months after a second remission is obtained.<sup>196</sup> Both allogeneic and autologous BMT have been reported to provide prolonged disease-free survival in 30% to 40% of patients treated in first relapse or second CR.<sup>197,198</sup> Therefore, suitable patients who have relapsed should undergo BMT as this represents the best chance for cure.

The timing of BMT in relapsed disease is controversial. Previous strategies have relied on the ability of salvage chemotherapy to decrease the leukemia burden and induce a second CR. However, a significant proportion of patients are unable to achieve a second CR, and the ability to proceed to allogeneic BMT may be compromised by the additional morbidity seen with such therapy. This is particularly true as high-dose regimens have been moved up front, limiting the treatments available on relapse. Data from the Fred Hutchinson Cancer Center have suggested that allogeneic BMT performed early in first relapse yields similar results to those transplants performed after a second CR has been obtained.<sup>197</sup> Although a number of centers have adopted this strategy, it requires that patients are able to proceed to allogeneic BMT in a timely manner. The feasibility of this approach, however, is often problematic as the readiness of the transplant facility or the availability of the donor may instead require the patient to receive some form of chemotherapy before allogeneic BMT. Further complicating the application of this relapse strategy has been disagreements over the definition of early relapse and concern regarding the maximal level of leukemia burden that will allow a successful transplantation to take place.

A similar strategy may be used for patients proceeding to autologous BMT.<sup>198</sup> Patients who relapse and previously had stem cells (either peripheral blood or bone marrow) harvested and cryopreserved, may proceed directly to autologous BMT. If no provision has been made for the patient and stem cells have not been collected in first CR, a second remission must be obtained. A number of studies have reported durable disease-free survival of approximately 30% in patients who have received autologous BMT in second CR and approximately 20% in third CR.<sup>199,200</sup> Results were not dependent on whether purged or unpurged marrow was used as the source of hematopoietic reconstitution.

Most patients, however, are not candidates for either type of BMT. For such patients, the goal in treating relapse is to induce a second remission. The ability to achieve a second remission is primarily dependent on the duration of the first remission.<sup>196,201</sup> Several groups have found that the response rates to salvage therapies are lower in patients with first remission durations of 6 to 12 months. Patients with an exceptionally short remission duration (less than 6 months) are unlikely to respond to any of the standard agents now available. In such patients, the use of investigational approaches are appropriate.<sup>202</sup> Alternatively, patients who relapse after 2 years in remission may achieve a second CR by repeating the original induction regimen. Because of the potential cumulative toxicity of the anthracyclines, patients who receive up to three cycles of such chemotherapy require evaluation of cardiac function before additional re-treatment with these agents.

Because most patients with relapsed disease, however, do not respond to repetition of the original induction regimen, research efforts have sought to define the underlying basis for clinical drug resistance with the ultimate goal of identifying new therapeutic approaches. One suspected mechanism of clinical drug resistance that has received much attention is the multidrug-resistant (MDR) phenotype. This laboratory phenomenon describes the observation that cell lines can become cross-resistant to unrelated, structurally diverse chemotherapeutic agents. The mechanism of resistance is linked to a 170- to 180-kD glycoprotein that functions via decreasing the intracellular accumulation of drugs, resulting in decreased cytotoxicity of these agents. The MDR phenotype has been observed in approximately 70% of patients with relapsed or refractory disease but also in 25% to 30% of patients with untreated disease.<sup>203</sup> The variable correlation of clinical response with expression of MDR phenotypes suggests alternative mechanisms may be active in determining resistance of AML cells to current chemotherapy.<sup>204,205</sup> In addition, other potential mediators of drug resistance, such as lung resistance protein, have been described, and the relationship of this resistant phenotype to MDR and outcome remains under investigation.<sup>206</sup> The emphasis on the MDR data may be explained by the potential to use modulators that alter the phenotype and restore chemotherapy sensitivity. Several trials have been undertaken that attempt to use the cyclosporin derivative, PSC-833, in an effort to reverse the MDR phenotype.<sup>207</sup> These studies are ongoing in both relapsed disease and up front as part of a strategy to increase CR rate and improve outcomes. Although such an approach has been shown to be feasible, efficacy remains to be established. A major criticism of this approach is that resistance to the most important antileukemia agent, Ara-C, is not affected by MDR, and that these studies basically ignore a common yet important mechanism of failure. Several investigators, however, have attempted to modify Ara-C efficacy in several different ways: increasing the intracellular concentration of the drug by giving high-dose Ara-C or combining Ara-C with fludarabine or attempting to exploit the cytokinetic properties of hematopoietic growth factors to recruit leukemia cells into cell cycle, thereby increasing the sensitivity to the drug.<sup>167</sup>

Among the drugs tested in the relapsed setting, high-dose Ara-C, either alone or in combination, has consistently been found to have the greatest antileukemic activity.<sup>208,209</sup> Although the dose and schedule of Ara-C has varied somewhat between studies, high-dose Ara-C is usually given at 2 to 3 g/m<sup>2</sup> every 12 hours for eight to 12 doses. Several centers now administer the Ara-C once daily or twice daily on an every other day schedule in an effort to decrease toxicity. Responses to such regimens have ranged from approximately 30% to 50%. Other active agents, such as daunorubicin, mitoxantrone, idarubicin, and etoposide, have been combined with high-dose Ara-C, but the therapeutic advantage of these combinations remain unclear. Substantial differences in treatment results between trials containing similar agents may be explained by patient selection and the small numbers of patients enrolled on these trials.

Patients who fail to achieve CR after receiving two courses of standard dose therapy are considered to have primary refractory disease. The prognosis for such patients is exceptionally poor, and response to salvage regimens is rare. Approximately 20% to 40% of these patients who are able to undergo allogeneic BMT can be rendered free of disease with durable remissions.<sup>210</sup> This ability to salvage primary refractory patients underscores the importance of identifying potential donors early in the therapy of patients who may be eligible for BMT. Patients who are not transplant candidates are best enrolled in investigational studies.

As more patients receive some form of high-dose therapy as their initial treatment, the options at relapse have changed. For some patients relapsing after high-dose Ara-C postremission therapy, studies suggest that either autologous BMT or allogeneic BMT can be curative. Those patients who are not BMT candidates may undergo therapy with alternative salvage regimens. Although the initial reports of potentially non-cross-resistant combinations, such as mitoxantrone/etoposide or carboplatin, were encouraging, subsequent studies have shown that these regimens are relatively ineffective.<sup>211,212</sup> The combination of cyclophosphamide and etoposide, given in near myeloablative doses, has been shown to induce CR in approximately 30% of patients who are refractory to regimens containing high-dose Ara-C.<sup>213</sup> Similar to the experience with other chemotherapy-based salvage regimens, such responses are usually short-lived.

Relapse of AML after allogeneic BMT poses a difficult and frustrating management problem,<sup>214,215</sup> with a median survival of 3 to 4 months. However, results are not significantly improved with current available therapy. Treatment options are determined by the performance status of the patient as well as the interval from transplant to relapse. Although a CR rate of approximately 35% has been reported to standard induction regimens, patients who relapse within the first 100 days after BMT are unlikely to respond and have a high treatment-related mortality. Selected young patients who relapse after 1 year may be candidates for a second allogeneic BMT, but the survival at 3 years has been reported to be approximately 10%. Therapeutic approaches, including the use of G-CSF, modulation of the graft-versus-leukemia effect by discontinuing immunosuppressives such as cyclosporin, or infusing donor leukocytes have been reported to induce remission in this setting.<sup>216</sup> Although donor leukocyte infusions have received much attention, most of the data have been generated in patients with CML and the results of such therapies in AML have been disappointing, although investigations continue.

## ACUTE PROMYELOCYTIC LEUKEMIA

APL represents a distinct entity among the myeloid leukemias. The unique biology that characterizes the disease also serves to make it the paradigm for targeted antineoplastic therapy. Historically, the importance of the prompt recognition of this subtype of AML has been stressed because of the coagulopathy associated with the disease and the potential for lethal hemorrhage with the institution of cytotoxic chemotherapy. The incorporation of all-*trans*-retinoic acid (ATRA) into up-front therapy further underscores the importance of rapid and accurate diagnosis.

When treated with standard Ara-C/anthracycline-based chemotherapy, there is a higher rate of periinduction mortality in APL than in the other AML subtypes.<sup>217,218</sup> A variety of supportive interventions have been introduced in an effort to control the hemorrhagic diathesis of the disease, but these complications remain a source of

significant morbidity and, even with best available therapy, constitute a major reason for induction failures. Despite the early hazards associated with cytotoxic treatment, the long-term survival in APL with this therapy is far superior to the other subtypes of AML. In groups that have emphasized dose intensity of the anthracycline, long-term disease-free survival as high as 60% has been reported.<sup>219</sup>

The clinical use of ATRA changed the emphasis from cytotoxic therapy and established differentiation therapy as an effective modality in the therapy of human cancer. The initial experience with this agent was reported by Huang et al. and subsequently confirmed by other groups.<sup>220,221</sup> and <sup>222</sup> ATRA is not a cytotoxic agent but instead causes a proliferation of the abnormal clone coincident with maturation, eventual terminal differentiation, and ultimately, apoptotic cell death. CR is obtained in 90% to 95% of newly diagnosed cases of APL without inducing aplasia and without the toxic effects associated with standard chemotherapy. Instead of worsening APL-related coagulopathy, there is stabilization and improvement of the condition within days of the institution of ATRA therapy. The biologic effects of ATRA are not restricted to *de novo* disease but are also seen in patients who have relapsed after chemotherapy as demonstrated by CR rates between 85% and 90% in this population.<sup>221,223</sup>

Despite the many advantages of ATRA therapy, it is not without potential complications. Although there is prompt improvement of coagulopathy with ATRA, many trials continue to report a 10% to 15% periinduction mortality due to both thrombosis and hemorrhage as well as the occurrence of a newly recognized toxicity named the *retinoic acid syndrome* (RAS). Approximately 25% of patients develop symptoms consistent with a capillary leak syndrome with features similar to acute respiratory distress syndrome or endotoxic shock.<sup>224</sup> Therefore, RAS is characterized by fever, dyspnea, peripheral edema with resultant weight gain, pleural and pericardial effusions, hypotension, and occasionally renal failure. Untreated, RAS can lead to rapid clinical deterioration and death.

The pathogenesis of RAS and its relationship to the other biologic effects observed with ATRA remain unclear. The description of a similar symptom complex in patients with APL who have not received ATRA has raised the hypothesis that this syndrome is directly related to the underlying disease process.<sup>225</sup> Leukocytosis, which is seen in up to 40% of patients with the institution of ATRA and may be an indicator of a biologic response, has, in some series, been associated with RAS.<sup>226</sup> This observation has led some investigators to advocate the early institution of cytotoxic chemotherapy with ATRA in patients who initially present with a high WBC count (greater than 5000/ $\mu$ L) or who demonstrate a rapid increase in WBC count during therapy (5000/ $\mu$ L by day 6 ATRA; 10,000/ $\mu$ L by day 10; or 15,000/ $\mu$ L by day 15). Although this strategy has been highly successful in reducing the incidence of RAS, it does expose a significant proportion of these patients to early chemotherapy.<sup>227</sup> Because RAS may occur in as many as one-third of the cases regardless of leukocytosis, alternative strategies have been developed. Early therapy with a short course of high-dose corticosteroids (dexamethasone, 10 mg IV twice a day for 3 or more days) at the first onset of symptoms can effectively halt the progression of RAS and has markedly reduced the mortality from this complication.<sup>223,228</sup> Other investigators have proposed corticosteroid prophylaxis be used with ATRA therapy to avoid the RAS.

Although highly successful in inducing remission, ATRA alone is insufficient therapy for APL.<sup>223</sup> If left on a continuous schedule of ATRA, patients eventually develop resistance to this agent. They are unable to sustain adequate plasma concentrations of the drug and generally relapse within a few months. In addition, most patients have persistent minimal residual disease and remain positive for the PML/RAR- $\alpha$ , the molecular signature of APL, after ATRA monotherapy. These observations have led to the incorporation of standard chemotherapeutic agents to the treatment of APL.

Initially, ATRA, in conjunction with anthracycline/Ara-C-based postremission regimens, were used as sequential therapy in phase II studies and resulted in improved disease-free survival compared with historical controls treated with similar chemotherapy given without the retinoid. Large randomized studies from both Europe and North America demonstrated the superiority of ATRA-containing regimens over chemotherapy alone.<sup>227,229</sup>

In an effort to exploit the known sensitivity of APL to anthracyclines, extend the durability of remissions obtained with ATRA chemotherapy-based regimens, and reduce ATRA-related toxicity, the Italian cooperative groups, GIMEMA-AIEPO, moved the chemotherapy up to induction by including idarubicin with ATRA (AIDA).<sup>230</sup> Ninety-five percent of patients achieved CR with AIDA induction and, when followed by three courses of postremission chemotherapy, the actuarial event-free survival at 2 years was reported to be 79%. Only 2.5% of patients developed RAS. Sequential ATRA chemotherapy was subsequently compared with simultaneous administration during induction in a large randomized study conducted by the European APL study group.<sup>231</sup> Although the actuarial relapse rates at 2 years were marginally better in the ATRA-plus chemotherapy group, the estimated 2-year survival was statistically similar. In addition, patients who received maintenance in the form of either chemotherapy or intermittent ATRA had superior overall survival. This is in sharp contrast to the other forms of AML in which maintenance therapy after a dose-intensive course of consolidation is generally without benefit.

The unique disruption of the RAR- $\alpha$  locus results in novel fusion proteins that given the current level of sophistication in the laboratory, are readily detectable and provide a useful tool for the clinician. The PML/RAR- $\alpha$  transcript defines sensitivity to ATRA, and the ability of RT-PCR to readily detect the PML/RAR- $\alpha$  fusion product allows for rapid genetic confirmation of the diagnosis, which given the various morphologic variants can be difficult even for the experienced eye.<sup>95,100</sup> In addition to helping in the diagnosis and planning an effective treatment strategy, RT-PCR has facilitated the detection of minimal residual disease and has made APL a paradigm for the use of molecular techniques to monitor therapy.<sup>232</sup>

Despite the spectacular CR rates and the equally impressive survival results, approximately 30% of patients treated in the large randomized studies relapse. Similar to the experience in other AML subtypes, such patients are generally incurable with chemotherapy alone and achieving a second remission may be difficult. Many are resistant to rechallenge with the retinoid, particularly if the disease relapses early (within 6 to 12 months). Arsenic trioxide has been used to achieve CR in heavily pretreated patients.<sup>233</sup> For those patients who are able to obtain a remission, both allogeneic and autologous BMT have been reported to offer a chance for cure. The results with autologous transplantation are dependent on the pretransplant status of minimal residual disease with 75% of patients who were PCR-negative before the autograft in molecular and clinical remission with a median follow-up of 28 months.<sup>234</sup>

The therapy of APL in the modern era is marked by great clinical success accompanied by a new understanding of the fundamental biology of the disease. The promise for future progress in AML may lie in mechanism-based drug design. The observation that arsenic trioxide leads to increased expression of caspases resulting in enhanced apoptosis has prompted investigators to combine this agent with the differentiating effects of ATRA in an attempt to amplify the effect of each agent by exploiting the different mechanisms of action. *In vitro*, this combination has been found to be synergistic, and the investigation of arsenic and ATRA has been undertaken in animal models.<sup>41</sup> The interaction between PML/RAR- $\alpha$  fusion products, corepressor binding proteins, and histone deacetylation have been implicated in the pathogenesis of APL. This has led to interest in a class of drugs, the histone deacetylase inhibitors, that may usher in a new era in the drug therapy of leukemia.

## GENERAL PRINCIPLES FOR THE TREATMENT OF ADULT ACUTE LYMPHOBLASTIC LEUKEMIAS

Treatment of adults with ALL has been modeled on therapy developed for childhood ALL. The similarity between the childhood and adult forms of this disease allows for inferences to be drawn from experience in the pediatric population. However, adults with ALL have a far poorer outcome when compared with children. Some of this difference can be attributed to differences in ability to tolerate intensive therapy coupled with an increased incidence of unfavorable cytogenetic subgroups [particularly t(9;22) and t(4;11)] and a decreased incidence of favorable cytogenetic subgroups [such as hyperdiploidy or t(12;21)]. Despite these mitigating features, the distinctly different outcomes of therapy have led to questions regarding how advances in pediatrics can be used in adult ALL. A broad review of the St. Jude experience in pediatric ALL demonstrated a dramatic stepwise improvement in treatment results since the 1970s.<sup>235</sup> However, adults with ALL have not shared in this remarkable success story.<sup>236</sup>

Treatment of adult ALL is typically divided into four broad categories: induction, consolidation, maintenance, and CNS prophylaxis. At presentation, many patients are quite ill with active infection, hemorrhage, or both, and induction regimens for adult ALL have typically emphasized relatively myeloid-sparing cytotoxic agents.

Consolidation therapy is administered at a relatively higher level of intensity to patients already in complete remission. Before beginning this phase of therapy, patients have normal blood counts and generally a good performance status. They are therefore able to tolerate significant myelosuppression with acceptable toxicity.

Maintenance therapy is administered to patients in remission after the more intensive consolidation therapy. It is administered at a low level of intensity, but for a protracted period. Current opinion is that 2 years of maintenance therapy is required for optimal results.

The fourth category of treatment is CNS prophylaxis. This is administered concurrently with systemic chemotherapy. Despite aggressive systemic therapy, the CNS remains a sanctuary site and without specific meningeal-directed therapy approximately 35% of adult patients develop CNS disease.

To understand the natural history of adult ALL and to assign specific therapy, the FAB subclassification (see [Morphology and Cytochemistry](#), earlier in this chapter) is less useful than an immunophenotypic subclassification, which recognizes three major groups: The most common subtype is pre-B-cell ALL, which represents approximately 70% of patients. The term pre-B refers to the fact that these cells are committed to the B-cell lineage, as manifested by immunoglobulin gene rearrangement and expression of typical early B-cell markers such as CD19 and terminal deoxyribonucleotidyl transferase, but do not express the hallmark of the mature B cell, surface immunoglobulin. In addition to CD19 and terminal deoxyribonucleotidyl transferase, the lymphoblasts of patients with pre-B-cell ALL typically express CD10, which was previously known as common ALL antigen (CALLA).

The second subtype of ALL is T-cell disease. T-cell ALL and lymphoblastic lymphoma are essentially the same disease. This disease typically affects young adults and has a significant male predominance. The malignant process begins as a rapidly growing mediastinal mass with early dissemination to the bone marrow. Patients present with symptoms related to their mediastinal mass (cough, dyspnea, chest pain) or to bone marrow involvement (infection and bleeding). Patients without evident bone marrow involvement at diagnosis are said to have lymphoblastic lymphoma. Those with scant bone marrow involvement are said to have stage IV lymphoblastic lymphoma and those with significant (greater than 30%) bone marrow involvement are said to have T-cell ALL. These distinctions are largely semantic and are without important clinical implications. All patients with lymphoblastic lymphoma/T-cell ALL require therapy as for ALL.

The third and least common subtype (approximately 5% of adult ALL) is mature B-cell ALL. As the name implies, these leukemic cells are slightly more mature than their pre-B-cell counterparts and express surface immunoglobulin. The typical patient is a young man who presents with a rapidly growing abdominal mass (initial sites are typically the appendix and the ileocecal valve) and early dissemination to the bone marrow. The most common presentation is with symptoms related to the abdominal mass (pain, bloating, and small bowel obstruction) or to bone marrow involvement (infection and bleeding). Patients who present to medical attention without evidence of bone marrow involvement are said to have Burkitt's lymphoma. Once significant bone marrow infiltration occurs, this disease is called *mature B-cell ALL*. In contrast to pre-B-cell ALL and T-cell ALL, mature B-cell ALL requires a different treatment regimen for optimal results (see [Treatment of Mature B-Cell Acute Lymphoblastic Leukemia](#), later in this chapter).

## PROGNOSTIC FEATURES IN ADULT ACUTE LYMPHOBLASTIC LEUKEMIA

There have been several evaluations of prognostic features in adult ALL. The two most widely accepted multivariate analyses were performed by the German multicenter group and the Memorial Sloan-Kettering group.<sup>237,238</sup> Other analyses have in general supported these two studies and have led to five widely accepted prognostic features: WBC count, age, leukemic cell immunophenotype, Philadelphia chromosome-positive disease, and time to achieve CR (see [Table 46.2-5](#)).

Multivariate analyses indicate that a high WBC count at diagnosis is associated with poor prognosis. There is both a reduced likelihood of achieving a CR as well as shorter duration of remission (and overall survival) for those who achieve a CR. An increased WBC count probably has prognostic significance in part on the basis as a measure of tumor burden, but also because of its correlation with adverse cytogenetics [e.g., t(4;11) and t(9;22)]. A high WBC count is probably a continuous variable (the higher the count, the worse the prognosis), and different studies have used different levels of elevated WBC count as their cutoff for an adverse feature. In the Memorial Hospital study, WBC counts greater than 10,000/ $\mu$ L were associated with a lower frequency of achieving a CR, whereas counts greater than 20,000/ $\mu$ L were associated with a shorter duration of CR. The German study indicated that WBC counts greater than 30,000/ $\mu$ L carry an adverse prognosis.

Older age is also associated with a worse prognosis. Age is probably a continuous variable (the older the patient, the worse the prognosis). In pediatric series, adolescent patients typically have the worst prognosis, though in adult series this is almost always the most favorable group. Different studies have defined different ages as having a poor prognosis, the two most important being age 35 years from the German group and age 60 from the Memorial Hospital study.

The immunophenotype of the leukemic cell also carries prognostic implication.<sup>237,238</sup> and <sup>239</sup> T-cell disease has a favorable prognosis, pre-B-cell (common) ALL has an intermediate prognosis, whereas mature B-cell disease has a poor prognosis when treated with standard regimens. It should be noted that modern regimens designed specifically for mature B-cell ALL improve the prognosis for this subtype significantly. Previously, null cell ALL was considered to have a poor prognosis. Modern immunophenotyping has essentially eliminated this entity. It is possible that in the past some acute leukemias now classified as AML-M0 would have been considered null cell ALL; not surprisingly these would fare poorly with vincristine/prednisone-based therapy.

Philadelphia chromosome-positive disease carries a poor prognosis. Adult patients with this entity are essentially never cured by chemotherapeutic regimens. A minority of patients with this disease may be cured if they undergo allogeneic transplant in first CR.<sup>240</sup> Other cytogenetic abnormalities also have prognostic implications, but their frequency is not sufficient to be noted in multivariate analysis. Most notable of these is the poor prognosis associated with t(4;11).

Time to achieve a CR during induction therapy carries significant prognostic implications. Patients requiring more than 4 weeks<sup>70,241</sup> or 5 weeks<sup>238</sup> to achieve a CR have a lower likelihood of being cured. It is not clear if this reflects an innate sensitivity to (and curability by) the chemotherapeutic agents used or rather that rapid cytoreduction of the leukemic cell mass minimizes the opportunity for drug resistance to develop and ultimately allows for cure of the patient.

## TREATMENT OF NEWLY DIAGNOSED ADULT PATIENTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA

A variety of different treatment regimens for adults with ALL have been developed since the 1970s. These regimens, which borrow heavily from advances made in childhood ALL, have many features in common. Current therapy can induce complete remission in approximately 65% to 85% of adults. However, the majority of these patients subsequently relapse, and overall only 20% to 30% of adults with ALL prove to be cured of their disease (see [Fig. 46.2-1](#)).<sup>242,243,244,245,246,247,248</sup> and <sup>249</sup> The mainstay of induction therapy for ALL has been the combination of vincristine and prednisone. Vincristine and prednisone achieves a CR in approximately 50% of patients. Addition of an anthracycline to induction therapy was demonstrated in a randomized trial to increase the likelihood of achieving a CR (83% vs. 47%).<sup>250</sup> This increased incidence of CR did not translate into improved survival for the patients randomized to receive the anthracycline. Although lacking support from randomized clinical trials, further intensification of induction therapy with cyclophosphamide or L-asparaginase, is widely accepted as improving remission induction, and one or both of these drugs are therefore included in essentially all induction regimens. Current induction regimens are therefore labeled as *four drug* (vincristine, prednisone, anthracycline, and cyclophosphamide or asparaginase) or *five drug* (vincristine, prednisone, anthracycline, cyclophosphamide, and asparaginase) regimens. There are no data currently available to favor one of these induction regimens over another.

Consolidation therapy has evolved over time to include several drugs given in varying sequence. Though there is no standard consolidation therapy, some generalizations can be made. The drug most prominently used in consolidation of adult ALL is Ara-C. Consolidation regimens include Ara-C combined with other drugs, most typically anthracyclines, epidophyllotoxins, or antimetabolites (such as methotrexate or thioguanine). Multiple studies seem to indicate the value of such consolidations. Most of these studies are uncontrolled phase II studies or comparisons with historical controls.<sup>243,246,248,249</sup> The experience at M. D. Anderson is typical in this regard in which implementation of such therapy increased 3-year survival from 15% to 40%.<sup>251</sup> A randomized phase III trial demonstrating the importance of cytarabine-containing consolidations was reported by Fiere et al.<sup>242</sup> In this study, after remission induction, patients were randomized to receive consolidation therapy with cytarabine, doxorubicin, and asparaginase or to immediately receive maintenance therapy. Three-year disease-free survival in the consolidation arm was markedly superior (38%) to the no consolidation arm (0%) ( $P < .005$ ). Although most authors accept that intensive consolidations are beneficial, there is a report by Ellison et al. of a randomized trial that failed to show significant benefit to cytarabine-based consolidation.<sup>252</sup>

Protracted maintenance therapy is a feature unique to treatment strategies for ALL. All other chemotherapeutically curable human malignancies are typically cured with 3 to 6 months of therapy. In pediatric ALL, maintenance therapy is clearly necessary, and most regimens prescribe 2 to 3 years of such treatment. In adults, the necessity of maintenance therapy has been less clearly addressed. Only a few studies have failed to use maintenance therapy, and the low reported disease-free survival seen in the CALGB study (18% at 3 years) and the ECOG study (13% at 4 years) suggests the importance of maintenance therapy in adult ALL.<sup>253,254</sup> The two most important drugs in maintenance chemotherapy are a combination of oral methotrexate and mercaptopurine. In pediatric ALL, these two drugs alone can be sufficient for maintenance therapy; in adults, however, most maintenance regimens are intensified by incorporating other active agents such as vincristine, prednisone, anthracyclines, and cyclophosphamide.

The CNS, along with the eye and the testis, are viewed as sanctuary sites. These are areas where penetration of systemically administered cytotoxic agents is compromised, leading to the potential of localized relapse. In adults, ocular relapse is extremely rare. Testicular disease occurs occasionally in patients with mature B-cell ALL, less frequently in patients with Philadelphia chromosome-positive ALL, and is extremely uncommon in other adults with ALL. Of the three sanctuary sites, CNS relapse is by far the most common. The incidence of CNS disease at presentation in adult ALL is typically 5% to 10%. Risk factors for developing CNS disease include high WBC count at diagnosis and mature B-cell immunophenotype. Patients who do not receive prophylactic therapy have a cumulative risk of approximately

35% of developing CNS involvement during the course of their disease. Prophylaxis with intrathecal chemotherapy (with or without whole brain irradiation) effectively reduces the cumulative incidence to approximately 10%. Intrathecal chemotherapy can be delivered by lumbar puncture or intraventricularly via Ommaya reservoir. If whole brain irradiation is used, intrathecal chemotherapy can be delivered by lumbar puncture (and requires fewer treatments) to achieve acceptable results. Patients not receiving whole brain irradiation as part of their prophylaxis require a greater number of intrathecal treatments and should have these treatments administered via an Ommaya reservoir. Patients should achieve a complete remission of their systemic disease before having an Ommaya reservoir placed to avoid this surgery in the subset of patients who have primary refractory disease or die during induction therapy. Intrathecal chemotherapy does not require adjustments for body surface area, and a typical adult dose is 12 mg of methotrexate (or 60 mg of cytarabine). A variety of administration schedules have been used, but for patients not receiving brain irradiation, we recommend six doses during the first 2 months of treatment, two doses per month during consolidation therapy, and two doses for every 3 months of maintenance therapy. The addition of whole brain radiotherapy to intrathecal chemotherapy can reduce the amount of intrathecal chemotherapy required for adequate CNS prophylaxis (and obviate the need for an Ommaya reservoir); however, concerns of late toxicity, including loss of cognitive function and leukoencephalopathy, <sup>255</sup> have led many investigators to omit whole brain radiotherapy from prophylactic regimens. CNS prophylaxis, although effective at reducing the incidence of CNS relapse, has no demonstrable effect on systemic relapse or overall survival. <sup>256</sup>

Features common to state-of-the-art treatment programs for adult ALL are summarized in [Table 46.2-8](#). Since the 1970s, treatment regimens that incorporate these features have been developed at many centers. Multiple formulations have been tested that vary the drug dose and schedule during induction, the number and intensity of chemotherapy cycles during consolidation, and the sequencing and duration of maintenance. Despite years of experience with multiple variations of this treatment strategy, no single formulation appears to be superior to the others. The wide variation in reported outcomes of clinical trials would superficially suggest the superiority of certain regimens ([Table 46.2-10](#)). Closer inspection, however, does not support this view. Interpretation of the literature is complicated primarily by differences in patient mix and duration of follow-up. It is easy to understand how duration of follow-up affects disease-free survival. [Figure 46.2-1](#) indicates overall survival for the 272 adult patients with ALL treated at Memorial Sloan-Kettering Cancer Center on several sequential treatment protocols. All of these treatment regimens were designed according to the principles listed in [Table 46.2-7](#). Although 2-year survival is almost 50%, the survival curve continues to fall and a plateau is not reached until 6 years out at approximately 24%. Therefore, studies that report only 2- or 3-year survival markedly overestimate their actual results and can appear superior to regimens that report 5-year survival.

Author	No. of Patients	Median Age	Complete Response (%)	Disease-Free Survival Percentage	At Year

**TABLE 46.2-10.** Clinical Chemotherapy Studies in Adult Acute Lymphoblastic Leukemia

The prognostic features of patients treated on a particular study are as important as duration of follow-up in interpreting the results of clinical trials in adult ALL. Certain patients with adult ALL, such as those with Philadelphia chromosome–positive disease have little likelihood of long-term survival. Because these patients may constitute 15% to 30% of unselected adults with ALL, their inclusion in clinical trials can have a major effect on reported results. Age is another important selection criteria that can vary from study to study with a major effect on reported survival. An analysis by Ohno of the relationship between median age and disease-free survival in 18 published studies of adult ALL reveals a tight correlation between the median age of the patients treated and the long-term disease-free survival. <sup>257</sup> This suggests that the apparent differences in results among published studies likely reflect patient mix rather than differences in treatment regimen.

The uniformity of results seen with vincristine/prednisone-based regimens has led to exploration of new induction approaches in adults. A phase II study at Memorial Sloan-Kettering Cancer Center used an induction regimen of cytarabine combined with a high single dose of mitoxantrone (80 mg/m<sup>2</sup>). Vincristine and prednisone were not used during induction therapy. When compared with historical controls, this regimen demonstrated a higher incidence of CR (  $P = .056$ ), a lower incidence of failure with resistant disease (  $P = .028$ ), a significantly reduced time to CR (  $P = .003$ ), and a trend to improved survival. <sup>258</sup> This regimen appeared to have particularly good activity in patients with Philadelphia chromosome–positive disease. A prospective multicenter randomized trial comparing this regimen to a standard four-drug induction regimen is currently ongoing.

#### TREATMENT OF RELAPSED OR REFRACTORY ADULT PATIENTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA

Most current induction regimens obtain CRs in 65% to 85% of newly diagnosed patients. Early deaths account for some of the induction failures, but in most studies 10% to 25% of patients have disease resistant to vincristine/prednisone-based regimens. In addition to these primary refractory patients, 60% to 70% of patients achieve a CR relapse. Treatment of relapsed and refractory patients is therefore an important and common problem. Numerous regimens have been reported in the setting of relapsed ALL. The most important regimens can be divided into two main groups: those that repeat the regimens used for newly diagnosed patients (this strategy is obviously not used for primary refractory patients) and those that involve high-dose chemotherapy. High-dose regimens appear to obtain a greater incidence of second CRs when compared with reinduction with vincristine/prednisone-based regimens. The high-dose regimens with the greatest likelihood for inducing a second CR are high-dose cytarabine-based regimens.

High-dose cytarabine has been used alone and in combination with a number of different agents. In combination with L-asparaginase, <sup>259,260</sup> and <sup>261</sup> doxorubicin, <sup>262</sup> idarubicin, <sup>263</sup> and <sup>264</sup> or mitoxantrone, <sup>265,266,267</sup> and <sup>268</sup> CRs as high as 72% have been reported in relapsed patients with ALL. Issues of patient mix make it difficult to assess if a specific regimen is superior to others, but in general a combination of high-dose cytarabine and an anthracycline has the greatest likelihood of achieving a second CR in relapsed patients (or a first CR in refractory patients). The toxicity of these regimens should be balanced against the benefits of achieving a CR. However, second CRs are difficult to maintain and typically each succeeding response is briefer than the preceding one. Patients with a suitable allogeneic transplant option should probably be referred for such a transplant in second CR. <sup>269</sup> The role of autologous or matched unrelated transplants in relapsed adult ALL has not been clearly established and should be considered investigational.

#### CENTRAL NERVOUS SYSTEM RELAPSE IN ADULT ACUTE LYMPHOBLASTIC LEUKEMIA

CNS relapse occurs in approximately 10% of patients who have received appropriate prophylaxis. In the majority of patients, simultaneous bone marrow relapse can be documented. In occasional patients, CNS relapse may occur without demonstrable systemic relapse (so-called isolated CNS relapse); however, this event almost always predicts subsequent bone marrow relapse, and patients with isolated CNS relapse should receive reinduction chemotherapy as well. Treatment of established CNS disease requires a combination of radiotherapy and intrathecal chemotherapy. Radiotherapy should consist of 1800 to 2400 cGy (in 150- to 200-cGy fractions) administered to the whole brain. Higher doses should be avoided because of the risk of late toxicity and the fact that some patients may later require total body irradiation as part of a conditioning regimen for an allogeneic transplant. Despite encouraging results in children, spinal radiotherapy should be avoided in adults because the dose of radiotherapy to marrow-bearing areas subsequently limits the ability to administer necessary systemic chemotherapy. Intrathecal therapy with methotrexate (12 mg) for patients with established CNS disease should be administered intraventricularly via an Ommaya reservoir. Intrathecal chemotherapy can be administered as often as two or three times per week until the CSF is cleared of leukemic blasts, then twice a week for 3 weeks, and twice a month for 2 or 3 additional months. Patients who develop CNS disease despite prophylaxis with intrathecal methotrexate, or those who do not clear the blasts from the CSF promptly (within two treatments) with methotrexate, should receive intraventricular therapy with cytarabine at a dose of 60 mg.

#### BONE MARROW TRANSPLANT FOR ADULT ACUTE LYMPHOBLASTIC LEUKEMIA

HLA identical sibling BMTs have been used in adults with ALL in a variety of settings. This dose-intense treatment approach has the ability to eradicate leukemia in a subset of patients with disease refractory to conventional chemotherapy. However, the lack of availability of HLA-matched donors and the toxicity and mortality seen

with transplant limits the utility of this approach. There is significant controversy over the use and timing of allogeneic transplant in adult ALL. Analysis of patterns of failure highlight a fundamental difference in the use of this modality for ALL compared with AML. Patients with AML (in first or second CR) treated with allogeneic transplant tend to fail therapy because of treatment-related mortality (infectious complications, GVHD, and so forth). Failure because of relapsed AML after allogeneic transplant (for patients in first or second CR) is relatively uncommon. The results for ALL, however, indicate that even for patients who survive the transplant, there is a significant relapse rate, and overall few patients are long-term disease-free survivors. The ability of allogeneic transplants to cure malignant diseases rests in part on the ability of the transplanted (donor) immune system to eliminate residual leukemic cells; this is known as the *graft-versus-leukemia effect*. There is evidence to suggest that this effect may be less important in ALL than in either AML or in CML. Data from the International Bone Marrow Transplant Registry compared identical twin to HLA identical sibling transplants.<sup>270</sup> Presumably, graft-versus-leukemia should be more pronounced in the HLA identical sibling transplants as compared with the identical twin transplants. In this study, there was a significantly higher relapse rate in the identical twin transplants for AML and CML, but not for ALL. This implies that graft-versus-leukemia is less important in ALL. A second indication that graft-versus-leukemia is less active in ALL comes from an analysis of studies of donor T-cell infusions used to treat leukemia that has relapsed after allogeneic BMT. In this study, donor lymphocyte infusions produced CRs in 73% of patients with CML, 29% of patients with AML, and in 0% of patients with ALL.<sup>219</sup> The lack of graft-versus-leukemia in ALL may in part explain the high relapse rate and the relatively low incidence of long-term disease-free survival after allogeneic transplant for adult ALL.

A review of the published experience of allogeneic BMT in adult ALL reveals that only a small fraction of patients are cured by this modality. The results of 192 adults with ALL transplanted at the Fred Hutchinson Cancer Center report a 5-year disease-free survival of only 15% for patients transplanted in second CR or beyond.<sup>269</sup> Another study that suggested more favorable results is difficult to interpret because this study presents combined results for pediatric and adult patients or patients in first CR (who may already be cured) with higher risk patients.<sup>271</sup>

The ability to cure a small subset of relapsed patients with allogeneic transplant has led investigators to test this modality in first CR. However, two large comparisons of allogeneic transplant versus standard chemotherapy for patients in first CR have failed to demonstrate an improved survival for the transplant arm.<sup>272,273</sup> In one of these studies, subset analysis suggests a benefit for certain high-risk patients.<sup>272</sup> This benefit was not confirmed in the other study.<sup>273</sup> Currently, the only group for whom allogeneic transplant in first CR can be routinely recommended is patients with t(9;22) and t(4;11) disease. For other adult patients, allogeneic transplant should be reserved for second CR.

Autologous transplant for adult ALL is even less effective than allogeneic transplant.<sup>274</sup> The extremely poor results for patients in second CR or beyond has led to this modality being tested in first CR. However, both a nonrandomized<sup>244</sup> and randomized trial<sup>275</sup> showed no benefit for autotransplant compared with maintenance chemotherapy. This modality should be considered experimental and not routinely performed in first CR.

## TREATMENT OF MATURE B-CELL ACUTE LYMPHOBLASTIC LEUKEMIA

Mature B-cell ALL is an uncommon disorder that accounts for approximately 5% of all patients with ALL. This disease has an extremely poor prognosis when treated with traditional ALL regimens such as those described previously. Studies indicate that a majority of patients with mature B-cell ALL can be cured with certain intensive regimens. The important features of regimens for this disease are rapid cycling of drugs, fractionated cyclophosphamide, high-dose methotrexate, and intensive CNS prophylaxis. Maintenance therapy is not used in these regimens. A retrospective review of the French experience with this form of therapy indicates that 12 of 22 (55%) patients older than the age of 18 years were cured in this poor-risk group of patients.<sup>276</sup>

## GRANULOCYTE SARCOMAS, LEUKEMIA CUTIS, AND OTHER EXTRAMEDULLARY LEUKEMIC INVOLVEMENT

Acute leukemia cells may diffusely infiltrate any organ of the body during the course of disease, or may form collections and large masses known as *granulocytic sarcomas* or *chloromas*, due to their green hue from the myeloperoxidase. Diffuse involvement of the skin by acute leukemia cells is referred to as *leukemia cutis* and should be distinguished from Sweet's syndrome, which is an infiltration of the skin by neutrophils. The initial presentation of acute leukemia at a primary extramedullary site with normal marrow and blood findings is extremely rare.<sup>278</sup> However, if extramedullary leukemia is misdiagnosed as carcinoma or lymphoma and treated without leukemia-specific therapy, the prognosis is poor; overt leukemia usually appears within a year, and death occurs at a median of 3 months later. In contrast, granulocytic sarcomas may occur secondarily in approximately 5% of patients, especially in those with (8;21) or (9;11) translocations or inv(16) chromosome abnormalities, and in patients with other monocytic leukemias.<sup>277,278 and 279</sup>

The occurrence of extramedullary disease virtually always heralds systemic relapse and should be treated as such.<sup>278</sup> Specific therapy directed at the extramedullary disease, unless it is located in the CNS, is usually not indicated. Treatment of CNS leukemia is discussed earlier in this chapter (see [Central Nervous System Relapse in Adult Acute Lymphoblastic Leukemia](#)). The prognostic significance of extramedullary disease is usually negative even when it is associated with other good prognostic signs [e.g., t(8;21)].<sup>279</sup> Extramedullary disease is treated by systemic therapy of the kind used to consolidate or intensify systemic leukemia. Leukemia cutis has been treated by external electron beam therapy, but this has been associated with fatal dermatitis in patients who had also received anthracyclines commonly used to treat AML.<sup>280</sup>

Involvement of the CNS is rare at presentation in AML, in contrast to ALL, in which it occurs more frequently; therefore, in the absence of symptoms of neurologic involvement, examination of the CSF in patients with AML is not indicated at presentation. In patients with ALL, the CSF should be examined routinely during the initiation of treatment and prophylactic intrathecal chemotherapy should be administered; more aggressive therapy should be initiated if the CSF is involved (as described previously). In AML, CNS disease is more common in patients with high blast counts in the blood and with monocytic leukemias, especially the M4EO variant.<sup>281 and 282</sup> Cranial neuropathies, when present, are most likely to involve the fifth or seventh nerves.<sup>283</sup> Leukemic infiltration of the cranial nerves can occasionally be detected by computed tomography; magnetic resonance imaging is a better choice, but the diagnosis is usually made by demonstration of leukemia blasts in the CSF. Some patients may not display positive CSF findings; emergency treatment with irradiation and intrathecal methotrexate is sometimes indicated even without diagnostic CSF.

Neurologic symptoms, such as headache or confusion, may also be the consequence of leukostasis and microemboli in the cerebral microvasculature; this is a rare occurrence except in myeloid leukemias with blood blast counts in excess of 100,000/ $\mu$ L.<sup>284</sup> In these cases, urgent therapy (either by leukopheresis or chemotherapy) to lower the blast count is indicated.

## BIOLOGIC AND IMMUNOLOGIC THERAPIES OF ACUTE LEUKEMIAS

Modern attempts to treat acute leukemias with agents designed to alter the biology and growth of the leukemia cells or to kill the cells via immunologic means have met with variable success.<sup>285,286 and 287</sup> Early work focused on nonspecific immunostimulators such as interferon, IL-2, and linomide in the setting of advanced disease; more recently these agents have been proposed for use after induction therapy to eliminate residual leukemia.<sup>288,289,290,291,292 and 293</sup> Interferon has demonstrated sporadic and limited success in inducing remissions in ALL of children, but has never achieved the consistent results observed in hairy cell leukemia or chronic myelogenous leukemia.<sup>122,285,288,289</sup> Moreover, the lack of potency and requirement for prolonged use to achieve effects, combined with the marked toxicity of interferons (including fever, malaise, myalgia, neurologic disorders, and cytopenias), make chronic use as a long-term agent for postremission or maintenance therapy difficult. A mechanism of action of interferon in treating acute leukemia has not been demonstrated.

IL-2, which promotes the growth of T cells and natural killer cells and activates natural killer cells to become lymphokine-activated killer cells, has demonstrated potent activity *in vitro* in stimulating autologous effector cells to kill leukemia blasts, and to block leukemia cell growth in culture *in vitro* and in mouse models.<sup>286,287,290,291,292 and 293</sup> Clinical trials of IL-2 have shown significant antileukemia effects in inverse relationship to the leukemic burden<sup>291,293,294</sup>; therefore, studies have focused on the use of IL-2 in patients in remission or posttransplantation. There is some preliminary evidence that relapse rates may be reduced in AML but not in ALL.<sup>274,292,295</sup> IL-2 is also under investigation as a means to enhance specific therapy with monoclonal antibodies directed to AML cells, because of its ability to enhance antibody-dependent cellular cytotoxicity.<sup>296,297</sup>

Specific monoclonal antibody therapy of acute leukemia has been under investigation since 1981 using passively infused murine monoclonal antibodies, radiolabeled monoclonal antibodies, immunotoxins, and, most recently, genetically engineered humanized monoclonal antibodies.<sup>286,287,296,297,298,299,300,301,302 and 303</sup> Passive serotherapy in relapsed ALL and AML has generally not been effective because of the lack of antibody potency, rapid loss of the target antigen from the leukemia cell surface, and development of human antimurine antibody responses. Attempts to use genetically engineered humanized antibodies, which have greater potency and can be repeatedly infused, have begun to show activity in the setting of residual disease, particularly in APL.<sup>287,297,298,300,301</sup> A new drug-conjugated antibody and an

alpha-emitting construct appears to have significant activity in relapsed AML as well. [302](#) and [303](#) Randomized trials to assess the effectiveness of these approaches are in progress. The application of radiolabeled monoclonal antibodies as an ablative agent before BMT in patients with acute leukemia is also under study. [287](#), [304](#), [305](#) and [306](#) CR rates approaching 100% have been achieved using these combined modalities, without detriment to engraftment or significant worsening of toxicity associated with the transplant; the demonstration of a therapeutic advantage of this approach in survival awaits randomized studies.

Antibody therapy can also be used *ex vivo* to purge bone marrow of residual leukemia before autologous reinfusion. [286](#), [287](#), [288](#), [289](#), [290](#), [291](#), [292](#), [293](#), [294](#), [295](#), [296](#), [297](#), [298](#), [299](#), [300](#), [301](#), [302](#), [303](#), [304](#), [305](#), [306](#) and [307](#) Though initial clinical results are encouraging, no randomized studies confirming the efficacy of this approach have been reported.

Active specific immunotherapy (vaccine therapy) has been explored for its potential in the treatment of leukemias. In principle, peptide sequences derived from oncogene products and translocated fusion proteins may serve as leukemia-specific targets for stimulated cytolytic T cells. [38](#), [308](#) Such approaches are most likely to be effective in the setting of minimal disease or transplantation.

## CONCLUSIONS

Two decades of empiric therapy in leukemia have led to long-term cures in a fraction of adult patients with acute leukemia. Advances in the molecular genetics, immunology, and biology of normal and neoplastic hematopoiesis have produced significant progress in understanding the pathogenesis of acute leukemia. This knowledge is leading to an explosion of new, sensitive molecular assays for minimal disease, new diagnostic and prognostic tests, and to more specific, and less toxic therapies. However, there is still a large gap between the patients who initially achieve remission and those who are ultimately cured. The appropriate care of patients with leukemia requires specialized resources and remains a difficult and complicated task with significant morbidity and mortality. Patients with acute leukemias should continue to be referred to cancer centers and enrolled in investigational treatment protocols until a greater fraction of patients achieve long-term survival.

## INTRODUCTION

Chronic myelogenous leukemia (CML) is a clonal myeloproliferative disorder of a pluripotent hematopoietic progenitor cell. It is characterized by excessive proliferation of marrow granulocytes, erythroid precursors, megakaryocytes, and connective tissue-forming cells. Clonal proliferation and transformation of myeloid progenitor cells usually dominate the clinical picture. The CML cells harbor a distinctive cytogenetic abnormality, the Philadelphia chromosome (Ph). It results from a translocation between the long arms of chromosomes 9 and 22. Segments of the *ABL* gene on chromosome 9 are fused to segments of *BCR* on chromosome 22. The *BCR-ABL* fusion genes are translated into chimeric proteins with increased tyrosine kinase activity such as p210. Downstream signaling events, which heavily involve ras pathways, eventually activate genes responsible for the uncontrolled proliferation of the leukemic clone.

CML is divided into three clinical phases. The benign or chronic phase may last for a few years. Transformation through an accelerated phase into a blastic phase typically follows. Whereas outcome in the transformed phases is still unsatisfactory, advances in stem cell transplantation (SCT), interferon-based therapies, and supportive care have had a major effect on prognosis in chronic phase disease. Novel treatments based on immunomodulation and our increasing understanding of signal transduction pathways in the leukemic cells have generated new targets for therapy that are currently being investigated in clinical trials.

Current state-of-the-art therapies result in increasing numbers of patients who achieve complete cytogenetic remissions. However, highly sensitive molecular assays such as fluorescence *in situ* hybridization (FISH) or polymerase chain reaction (PCR) frequently detect *BCR-ABL* rearrangements in these patients. In many cases, these patients stay in remission for many years, raising the question of the significance of *molecular cures versus functional cures* and the mechanisms that sustain these remissions. Thus, CML has not only become a paradigm for our understanding of leukemogenesis and targeted drug development, but is also an ideal model for the study of minimal residual disease in hematologic malignancies.

## EPIDEMIOLOGY

Some 4000 to 5000 patients are diagnosed with CML in the United States annually. The incidence of CML is 1 to 2 per 100,000 population with a male to female ratio of 1.4 to 2.2:1.0. CML accounts for 7% to 15% of leukemias among adults. The median age at presentation is between 45 and 55 years. One-third of the patients are older than 60 years.<sup>1</sup> This incidence used to be higher in earlier studies and the more recently reported decrease may be a consequence of earlier detection, referral of younger patients to large centers, and exclusion of patients with CML-like conditions such as chronic myelomonocytic leukemia, Ph-negative CML, or other myeloproliferative disorders. Nevertheless, the proportion of patients over age 60 is important when considering therapeutic options such as allogeneic SCT, which is associated with a high treatment-related mortality, or interferon- $\alpha$  (IFN- $\alpha$ ), which has more side effects in older patients. CML is uncommon in children and adolescents in whom it accounts for less than 5% of the leukemias.

## ETIOLOGY AND PATHOGENESIS

### ETIOLOGY

The etiology of CML is unknown. There is little evidence for genetic factors linked to CML. Lack of concordance in monozygotic twins and the demonstration of Ph in hematopoietic progenitor cells only, suggest that CML is an acquired disorder.<sup>2</sup> Offspring of parents with CML do not have a higher incidence of CML than the general population. The incidence of CML is higher among survivors of the atomic bomb explosions in Hiroshima and Nagasaki.<sup>3</sup> Effects of therapeutic doses of radiation on the development of CML are disputed. No association has been established with infectious agents.

### MOLECULAR PATHOGENESIS

More than 90% of patients with the clinical picture of CML demonstrate Ph in 95% to 100% of marrow cell metaphases. Through a reciprocal translocation between the long arms of chromosomes 9 and 22, a large 3' segment of the *ABL* gene on chromosome 9q34 is fused to a 5' segment of the *BCR* gene on chromosome 22q11, creating a hybrid *BCR-ABL* gene on 22q11 and, in two-thirds of patients, a reciprocal *ABL-BCR* gene on chromosome 9q+.<sup>4,5</sup> In most cases, *ABL* exons 2 to 11 (also referred to as *a2 to a11*) are transposed into the major breakpoint cluster region (M-bcr) of *BCR* between exons 13 or 14 (also called *b2 or b3*). The *BCR-ABL* fusion mRNA extends over 8.5 kb and contains a b2a2 or b3a2 junction. It is translated into a chimeric protein of 210 kD called p210.<sup>6,7</sup> In most cases, CML cells express either b2a2 or b3a2 transcripts, but in approximately 5% alternative splicing causes expression of both forms. No significant difference exists with respect to response to treatment, prognosis, or clinical features, except for a higher platelet count in patients with b3a2 transcripts.<sup>8,9</sup>

In rare cases of CML, but in 50% of adults and up to 80% of children with Ph-positive acute lymphoblastic leukemia, the breakpoint on chromosome 22 is located centromeric to M-bcr between exons e1 and e2 referred to as the minor breakpoint cluster region (m-bcr). The e1a2 fusion gene is translated into a protein of 190 kD termed p190.<sup>10</sup> A third breakpoint location occurs telomeric from M-bcr, creating a fusion transcript with an e19a2 junction and a protein of 230 kD termed p230 ( [Fig. 46.3.1-1](#)).<sup>11</sup> Expression of p190 in CML has been associated with monocytosis, and of p230 with the chronic neutrophilic leukemia variant and with thrombocytosis.<sup>12</sup>

**FIGURE 46.3.1-1.** Probability of survival after human leukocyte antigen–identical sibling stem cell transplantation for chronic myelogenous leukemia in chronic phase by age, 1991 through 1997. (International Bone Marrow Transplant Registry data, with permission.)

In approximately two-thirds of cases, the reciprocal *ABL-BCR* rearrangement can be detected on the derivative chromosome 9q+. The 5' remnant of *ABL* exon 1 is transposed to the 3' tail of *BCR* exons 14 or 15 (b3 or b4). No pathogenetic role in CML has been documented for this rearrangement.<sup>13</sup>

Both *in vitro* and *in vivo* animal experiments using transgenic mice and retrovirus-mediated gene transfer into murine hematopoietic cells have demonstrated that expression of *BCR-ABL* can imitate the clinical manifestations of CML, including the progression from chronic to blastic phase. Thus, the combined data from animal experiments support the role of *BCR-ABL* and its fusion proteins as central mediators of myeloid proliferation and transformation in CML.<sup>14</sup>

Whereas *ABL* encodes a nonreceptor tyrosine kinase (p145) whose activity is rigorously controlled and which is involved in signal transduction and regulation of cell growth, p210 and p190 show increased and uncontrolled kinase activity. Constitutive activation of the kinases initiates downstream signaling pathways that up-regulate transcription of genes mediating proliferation and transformation of CML hematopoietic progenitor cells. A central element of *BCR-ABL* signaling is Ras. Activation of Ras is mediated through a series of adapter proteins that in turn also connect p210 to other kinases and signal transduction systems.<sup>7,15</sup>

## CELLULAR PATHOGENESIS

CML is dominated by expansion of myeloid progenitor cells at various stages of maturation, their premature release into the circulation, and their tendency to home to extramedullary sites. Clonal expansion may also involve the erythroid, megakaryocytic, and B- as well as occasionally T-lymphoid lineages. The disorderly expansion of leukemic progenitors in chronic phase may reflect both alterations in their proliferative activity and shifts in the balance of self-renewal and differentiation. Although Ph-positive primitive hematopoietic cells (long-term culture-initiating cells) are found in lower frequencies than are colonies of normal progenitor cells and have a longer generation time, they may undergo additional cell divisions.<sup>16</sup> Leukemic progenitor mass is also increased by altered regulation at the stem cell level, shifting the balance between self-renewal and differentiation toward the differentiating cell pool, a process that has been referred to as *discordant maturation*.<sup>17</sup> Stem cells become part of the proliferating compartment, causing the neoplastic population to expand exponentially in later maturational compartments. At this stage, leukemic progenitor cells may also be less responsive to growth regulatory signals from either cytokines or the bone marrow microenvironment.<sup>16,17</sup> and <sup>18</sup> Defective adherence of CML progenitors to bone marrow stromal elements further facilitates their premature release into the peripheral blood.<sup>19</sup> Although differentiation remains relatively unaffected during chronic phase disease, transforming events in accelerated and blastic phase substantially deregulate the delicate balance between normal and leukemic progenitor colonies, leading to maturation arrest similar to events observed in acute leukemias.

## DIAGNOSIS AND CLINICAL COURSE

### CLINICAL MANIFESTATIONS

CML is a triphasic disease (Table 46.3.1-1). At diagnosis, more than 90% of patients are in chronic phase. Symptoms at presentation reflect the increase in mass and turnover of the CML hematopoietic progenitor cells. Patients may complain of lethargy and weakness, night sweats, and weight loss. Increase in abdominal girth and abdominal discomfort may be due to an enlarged spleen. Less frequently, easy bruisability and bleeding are recorded due to platelet dysfunction. Ten percent to 20% of patients from older series and as many as one-half of patients in more recent studies have no symptoms and are diagnosed by routine blood tests. Presentations in accelerated or blastic phases occur in 5% to 10%. Splenomegaly occurs in up to 50% and is the most common finding on physical examination. Generalized lymphadenopathy and fever, rare in chronic phase, may indicate an accelerated disease course.<sup>20,21</sup>

Chronic Phase	Accelerated Phase	Blastic Phase
No symptoms (if treated)	Wt ↓; Anemia	Wt ↓; Anemia
Year of the characteristic of accelerated or blastic phase	Peripheral blood/platelets and granulocytes (GPI)	Peripheral blood/platelets and granulocytes (GPI)
	Platelet count (100 × 10 <sup>9</sup> /L) continued to change	Platelet count (100 × 10 <sup>9</sup> /L) continued to change
	Cytopenic resolution	Cytopenic resolution
	WBC count (100 × 10 <sup>9</sup> /L) increased with use of broad spectrum antibiotics	WBC count (100 × 10 <sup>9</sup> /L) increased with use of broad spectrum antibiotics
	Rapid doubling time of WBC (10 days)	Rapid doubling time of WBC (10 days)
	(20% blast in peripheral blood marrow)	(20% blast in peripheral blood marrow)
	(20% blast and granulocytes in peripheral blood)	(20% blast and granulocytes in peripheral blood)
	(20% blast and granulocytes in peripheral blood)	(20% blast and granulocytes in peripheral blood)

**TABLE 46.3.1-1.** Phases of Chronic Myelogenous Leukemia

## LABORATORY TESTS

### Peripheral Blood and Bone Marrow

Myeloid hyperplasia in the marrow associated with neutrophilic leukocytosis, thrombocytosis, and basophilia in the peripheral blood are typical chronic phase CML laboratory features. Peripheral blood leukocytosis exceeding  $100 \times 10^9/L$  occurs in 70% to 90% of patients. Anemia of varying degrees is frequent. The marrow is markedly hypercellular with a myeloid to erythroid ratio between 9:1 to 15:1. Myeloid cells display all stages of maturation, with a preponderance of myelocytes and promyelocytes. Megakaryocytes are frequently increased, especially in accelerated phase. Marrow fibrosis is focal in early disease stages and may progress to a more diffuse pattern with disease evolution.<sup>22</sup>

### Cytogenetic Analysis

Cytogenetic analysis is the gold standard for demonstration of the Ph translocation and other abnormalities that occur frequently with disease progression (clonal evolution).<sup>23</sup> Cytogenetic analysis is tedious and time-consuming, and only 20 to 25 metaphases per sample are examined. In approximately 10% of patients with CML, no t(9;22) is detected by cytogenetic analysis. However, in up to one-third of these patients, molecular studies detect *BCR-ABL* rearrangements. The remaining patients are Ph and *BCR-ABL* negative. These patients carry a worse prognosis and have to be distinguished from typical CML (Table 46.3.1-2).<sup>24</sup>

Condition	Characteristics
Indolent myeloid	Total white blood cell count <math>100 \times 10^9/L</math> <math>10^4</math> ABL on peripheral blood differential does not exceed granulocyte neutrophils Absence of basophils <math>C</math>-myeloid leukocytes (neutrophils, D16a leukocytes) Absence of eosinophils Usual clinical features of chronic phase Usual leukocyte morphology (neutrophils, basophils, eosinophils, monocytes, lymphocytes, other leukocytes)
Other myeloproliferative disorders (essential thrombocythemia, polycythemia vera)	Lower degree of leukocytosis Larger spleen Leukocytosis without peripheral blood smear (rare atypical cells) Established criteria for diagnosis
Myeloid chronic myeloproliferative disorders	Significant changes in leukocytes of peripheral blood; bone marrow No basophils
Chronic eosinophilic leukemia	Leukocytosis usually consisting of mature eosinophils No basophils High leukocyte alkaline phosphatase
Chronic myelomonocytic leukemia, myeloproliferative	Increase in absolute and relative monocyte counts Minimal leukocyte changes in leukocytes No basophils Presence of atypical acute promyelocytes
Jervell chronic myeloid leukemia	Presence of children of acute cell Hypersegmented neutrophils common at presentation Markedly increased leukocyte counts

**TABLE 46.3.1-2.** Differential Diagnosis of Philadelphia Chromosome and *BCR-ABL*-Negative Chronic Myelogenous Leukemia

### Molecular Analysis

Molecular assays are used in the diagnosis of CML and the assessment of response to therapeutic modalities. PCR, Southern and Northern blot, and immunoprecipitation can determine the exact breakpoints of the fusion genes, detect *BCR-ABL* transcripts at the RNA level, and demonstrate the p210 protein using antibodies against the N-terminal region of BCR and the C-terminal region of ABL.

Patients on therapy are frequently monitored by PCR and FISH.<sup>26</sup> FISH allows analysis of metaphase and nondividing interphase cells and is easily quantifiable. Interphase FISH can be performed on peripheral blood specimens.<sup>26</sup> However, it overestimates the degree of cytogenetic responses at high Ph-positive percent values and has a false-positive rate of up to 10%. Hypermetaphase FISH is as time efficient as interphase FISH, does not generate false-positive results, but cannot be done on peripheral blood samples.<sup>27</sup> The use of double color probes for FISH is being investigated and may have superior sensitivity and specificity.<sup>28</sup>

### PROGRESSION OF CHRONIC MYELOID LEUKEMIA

When treated with chemotherapeutic agents such as hydroxyurea or busulfan, CML invariably progresses into an accelerated phase that is followed after 3 to 18 months by a blastic transformation. Criteria for the definition of accelerated and blastic phase disease have been proposed (see [Table 46.3.1-1](#)).<sup>29,30</sup>

Whereas Ph predominates throughout chronic phase, up to 80% of patients develop additional cytogenetic abnormalities when they progress (clonal evolution). Common changes during clonal evolution of CML are trisomy 8, isochromosome i(17q), trisomy 19, and an additional Ph. Trisomy 8 and isochromosome i(17q) are common during myeloid transformation.<sup>23</sup> Alterations of molecular markers during clonal evolution include *p53*, *RB1*, *c-MYC*, *p16*, *Ras*, and AML/EVI-1, a fusion protein resulting from translocation t(3;21)(q26;q22). Abnormalities of *p53* occur in 20% to 30% of patients and are mainly associated with myeloid transformation.<sup>31,32</sup> Loss of function of *p53* has been associated with suppression of apoptosis and progression into blastic phase. Abnormalities of *RB1* have been associated with lymphoid transformation.

### TREATMENT

Criteria for assignment of response to therapies are summarized in [Table 46.3.1-3](#). A number of poor prognostic features have been identified, and prognostic systems have been developed in CML ([Table 46.3.1-4](#)). These systems allow patients to be categorized into good-, intermediate-, and poor-risk groups with respective median survivals of 6, 3 to 4, and 2 years in patients receiving conventional therapy. These models are useful in evaluating the effect of new strategies within different risk groups (see [Table 46.3.1-4](#)).

Response	Parameters
Complete hematologic response	Complete normalization of peripheral count (WBC <math>10^4</math> /L, platelets <math>100 \times 10^9</math> /L, no immature cells like blast, promyelocytes, metamyelocytes) No signs and symptoms of disease; disappearance of palpable splenomegaly
Cytogenetic response (in patients in complete hematologic response)	Complete: No Ph-positive cells (major) Partial: <math>1-5\%</math> Ph-positive cells (major) Minor: <math>5-9\%</math> Ph-positive cells
Partial hematologic response	As for complete hematologic response, except for (1) persistence of immature cells, or (2) platelets <math>100 \times 10^9</math> /L or <math>10^4</math> /L, or (3) persistent splenomegaly for >math>10\%</math> of patients

Ph, Philadelphia chromosome.

**TABLE 46.3.1-3.** Criteria for Cytogenetic and Hematologic Remissions in Chronic Myelogenous Leukemia

	Sokal Model	Sybilis Model
Characteristics	Age Platelet count Spleen size Percentage blast cells	Poor-prognosis characteristics Age >math>60</math> years Spleen >math>210</math> cm below costal margin Blasts >math>2\%</math> in blood or marrow Basophils >math>2\%</math> in blood or >math>25\%</math> in marrow Platelets <math>100 \times 10^9</math> /L
Risk group <sup>a</sup>	Low risk (1-3) Intermediate risk (3.5-12) High risk (14-21)	Accelerated phase characteristics Clonal evolution Blood blasts >math>2\%</math> Blood blasts and promyelocytes >math>20\%</math> Blood basophils >math>25\%</math> Platelets <math>100 \times 10^9</math> /L

<sup>a</sup>Risk is based on hazard ratio values in Sokal's model<sup>31</sup> and on summation of poor-prognosis factors in Sybilis model.<sup>32</sup>

**TABLE 46.3.1-4.** Prognostic Models in Chronic Myelogenous Leukemia

### HISTORICAL AND CONVENTIONAL TREATMENTS FOR CHRONIC MYELOGENOUS LEUKEMIA

The median survival of patients with CML used to be 3 years, and less than 20% of patients were alive 5 years after diagnosis. Nowadays, patients in chronic phase can expect a median survival time of 5 to 7 years, and up to 9 years in good-prognosis patients. Five and 10-year survival rates are 60% to 70% and 30% to 40%, respectively. Earlier diagnosis, better supportive care, and more effective anti-CML therapies account mostly for this change.<sup>33</sup>

The use of arsenicals (Fowler's solution) was first advocated for the treatment of CML in 1856. In the early 1900s up to approximately 1950, total body or splenic radiation therapy was shown to be effective in controlling the signs and symptoms of CML. Its benefit was, however, short-lived and the overall survival was not affected significantly. It is a rarely used modality today.

In the early 1950s, oral alkylating agents such as busulfan became the new mainstay of treatment.<sup>35</sup> Busulfan is inexpensive and allows long periods of hematologic

control, but may be associated with serious side effects such as delayed myelosuppression and pulmonary toxicities ( Table 46.3.1-5). Busulfan was replaced by hydroxyurea in the 1970s.<sup>36</sup> Hydroxyurea is a cell-cycle-specific inhibitor of DNA synthesis that allows rapid hematologic control and is well tolerated (see Table 46.3.1-5). Both hydroxyurea and busulfan cause complete hematologic remissions in up to 80% of patients. Cytogenetic remissions occur, but are rare, and neither agent has any notable effect on the natural course of the disease. In a large randomized study, both median survival (56 vs. 44 months) and median duration of chronic phase (47 vs. 37 months) were significantly longer in patients treated with hydroxyurea compared with busulfan.<sup>37</sup> Busulfan therapy before allogeneic SCT has also an adverse outcome on posttransplant survival (3-year disease-free survival of 61% for patients treated with hydroxyurea vs. 45% for patients on busulfan).<sup>38</sup>

Drug	Dosage	Side Effects
Busulfan	1.1 mg/kg PO bid and 100 mg intravenous in 30% dose when due to 30% maintain 100 mg twice daily if > 10%.	Acute: prolonged neutropenia (30%); splenomegaly; pulmonary fibrosis (median long); fibrosis of the esophagus; splenomegaly; osteoporosis.
Hydroxyurea	1000 mg (100 mg/kg)	Acute: neutropenia; skin changes (rash, alopecia, dryness, etc.)
	1000	34
	40-80	43
	10-20	54
	10-20	53
	10-20	15-28
	10-20	18-15
	10-20	63-18

Maintain 100 mg twice daily if > 10%.

1000 mg twice daily.

**TABLE 46.3.1-5.** Dosage and Side Effects of Hydroxyurea and Busulfan in the Management of Patients with Chronic Myelogenous Leukemia

While other agents (dibromomannitol, melphalan, 6-mercaptopurine, 6-thioguanine, cyclophosphamide, chlorambucil) have also been used in the treatment of CML, they have been associated with worse outcome. Uncontrolled thrombocytosis on therapy with hydroxyurea may respond to anagrelide, the addition of IFN- $\alpha$ , or intermittent therapy with thiopeta (75 mg/m<sup>2</sup> intravenously every 2 to 4 weeks).

Splenectomy may benefit occasional patients with persistent and symptomatic splenomegaly and refractory cytopenias. Splenectomy pretransplant reduces the time to marrow recovery, but does not influence long-term prognosis.<sup>39</sup>

## STEM CELL TRANSPLANTATION

### Matched Related Allogeneic Stem Cell Transplantation

SCT has become an effective treatment for CML and can cure a substantial proportion of carefully selected patients with suitable donors. In most studies of chronic phase CML, projected actuarial 3-year to 5-year survival rates range between 50% and 60%, with values up to 80% in large centers. Relapses occur in 15% to 30%, and plateau at 5 to 7 years after transplantation, suggesting a cure for some patients. Late relapses 10 to 12 years posttransplant can occur. Allogeneic SCT is limited by availability of matched siblings and age restrictions. Less than 30% of patients in Europe and North America receive SCT from matched sibling donors.<sup>40</sup>

Transplant-related mortality ranges between 10% and 40%, but can be as high as 68% in subgroups of patients who receive marrows from mismatched or unrelated donors. Several variables influence transplant outcome.<sup>41</sup>

**AGE.** Younger patients do best (see Fig. 46.3.1-1): Disease-free survival is from 60% to 70%, transplant-related mortality 10%, and probability of relapse 20%. Above age 20, patients appear to have a continuous and inverse relationship between age and survival. Older patients do worse mainly because of an increased treatment-related mortality in this age group; the relapse rates are similar. One center reported favorable outcomes for carefully selected patients above age 50: The 2-year estimated survival rate among 57 such patients was 80%.<sup>42</sup> Results from other transplant centers or registry studies are worse. In the International Bone Marrow Transplant Registry (IBMTR) studies, the 5-year survival rate for patients above age 50 was only 30%. In the European Bone Marrow Transplant Registry (EBMTR), patients over age 45 had a treatment-related mortality of 47% and a 5-year disease-free survival rate of 25%.<sup>43,44</sup>

**PHASE OF DISEASE.** The largest effect of treatment is achieved in the chronic phase of CML. Disease free survival rates decrease from 40% to 60% in chronic phase to less than 15% in blastic phase (Fig. 46.3.1-2).<sup>21,38</sup> Transplantation in transformed CML phases is accompanied by increased rates of leukemia relapse and treatment-related mortality. Posttransplant outcome in accelerated phase is better when clonal evolution is the single criterion for disease acceleration: Disease-free survival up to 60% has been reported in these patients.<sup>45</sup> Timing of transplantation in chronic phase is more controversial. Based on earlier data, most centers propose transplantation in early chronic phase CML (i.e., within 1 year of diagnosis) (Fig. 46.3.1-3).<sup>38</sup> However, updates of these data suggest similar rates for 5-year disease-free survival for transplants performed within 12 to 24 months from diagnosis and a critical prognostic cut-off point at around 2 years from diagnosis is suggested.<sup>44,46</sup>

**FIGURE 46.3.1-2.** Probability of survival after human leukocyte antigen-identical sibling stem cell transplantation for chronic myelogenous leukemia by disease status pretransplant, 1991 through 1997. (International Bone Marrow Transplant Registry data, with permission.)

**FIGURE 46.3.1-3.** Probability of survival after human leukocyte antigen-identical sibling stem cell transplantation for chronic myelogenous leukemia in chronic phase by disease duration, 1991 through 1997. (International Bone Marrow Transplant Registry data, with permission.)

**PRETRANSPLANT CHEMOTHERAPY.** Anti-CML therapy before transplantation influences posttransplant outcome. Disease-free survival at 5 years is significantly higher in chronic phase patients pretreated with hydroxyurea than with busulfan (61% vs. 45%). Prior therapy with IFN- $\alpha$  does not appear to affect outcome of matched related SCT. The influence of IFN- $\alpha$  on matched unrelated donor transplantation is more controversial. <sup>47,48,49 and 50</sup>

**PREPARATIVE REGIMENS.** Results are conflicting regarding the best preparative regimen. Virtually all regimens produce toxic effects, with severe mucositis of the gastrointestinal tract being most common. The combination of busulfan with cyclophosphamide appears as effective as the combination of cyclophosphamide with total body irradiation, except for the more unfavorable toxicity profile of the latter. <sup>51</sup>

**GRAFT-VERSUS-HOST DISEASE PROPHYLAXIS.** Acute graft-versus-host disease (GVHD) occurs in 8% to 63% of patients and is the cause of death in up to 13%. <sup>38</sup> The rates for chronic GVHD can be as high as 75% with a mortality of up to 10%. The use of methotrexate with cyclosporine has resulted in better outcomes than single methotrexate or methotrexate in other combinations. <sup>52</sup> T-cell depletion pretransplant improves tolerance and reduces treatment-related mortality. However, this advantage is offset by increased leukemia relapse, indicating the importance of immune-mediated effects (e.g., graft-versus-leukemia effect) in maintaining remission in CML. <sup>53,54</sup>

The incidence of relapse posttransplant ranges from 10% to 70%. It is lowest in patients transplanted in chronic phase and highest in blastic phase. <sup>55</sup> Second transplants from human leukocyte antigen (HLA)-identical sibling donors can achieve disease-free survival rates up to 30%. Results, however, depend on the time interval between transplant and relapse and are most favorable in the setting of a long first remission duration. <sup>56</sup> IFN- $\alpha$  may induce long-lasting cytogenetic remissions in 20% to 40% of patients with cytogenetic relapse in chronic phase postallogeic SCT. <sup>57</sup> Donor lymphocyte infusions (DLI) have generated cytogenetic and complete hematologic response rates in 60% to 80% of patients. Disease-free survival at 3 years is between 40% and 85%. Responses are considerably less frequent and short-lived in transformed CML phases. A strong correlation exists between development of GVHD and response to DLI, which supports a role for the graft-versus-leukemia activity generated by infused donor T lymphocytes. DLI toxicity can be substantial and includes myelosuppression and severe GVHD. <sup>58</sup>

### **Matched Unrelated Donor Transplants**

It is possible to identify HLA-compatible unrelated donors for approximately half the patients who lack an HLA-matched sibling through the National Marrow Donor Program in the United States and similar transplant registries throughout the world. The median time from donor search to transplant is approximately 6 months. Although encouraging results have been obtained with matched unrelated donor transplants, they are associated with significant treatment-related morbidity and mortality depending on age and degree of matching. <sup>59,60</sup> Graft failure as well as severe acute and extensive chronic GVHD contribute to a treatment-related mortality above 50% in some groups of patients. Good-risk patients for matched unrelated donor transplants are younger (less than 30 years), in early chronic phase, cytomegalovirus seronegative, and have received non-T-cell-depleted marrow infusions. <sup>60</sup> Molecular matching is emerging as a highly significant parameter of treatment outcome. The EBMT group analyzed the effect of HLA class II matching on results of matched unrelated donor transplants in 366 patients, two-thirds of whom had been transplanted in chronic phase. <sup>61</sup> Matching at the HLA-DRB1 locus was the most significant factor influencing overall survival, disease-free survival, and treatment-related mortality. Patients transplanted in first chronic phase, with non-T-cell-depleted marrows, and a matched HLA-DRB1 locus had a 2-year survival of 51%, a treatment-related mortality of 47%, and a relapse rate of 2%. Treatment-related mortality was 80% for HLA-DRB1 mismatches.

In carefully selected patients, 5-year survival rates may be as high as 70%, relapse rates less than 10%, rates of graft failure below 10%, and rates of severe acute GVHD below 50%. Until experience with matched unrelated donor transplants has matured, it should be offered preferentially to younger patients in chronic phase who are resistant to IFN- $\alpha$  and who have a fully matched donor available. <sup>60</sup>

### **Intensive Chemotherapy and Autologous Transplantation**

Autografting with unpurged autologous marrow generates transient cytogenetic responses, but a survival advantage has not been proven. <sup>62</sup> Relapse due to reinfused, Ph-positive cells may occur. <sup>63</sup>

To reduce contaminating Ph-positive cells, several purging strategies have been developed. These include *in vitro* manipulations with cyclophosphamide derivatives and biologic response modifiers (interferon- $\gamma$ , interleukin-2), tyrosine kinase inhibitors, antisense oligonucleotides, ribozymes, positive or negative selections based on phenotype determination or long-term bone marrow cultures, and high-dose combination chemotherapy.

Intensive chemotherapy, to eradicate Ph-positive clones, was patterned after acute leukemia programs. Cytogenetic remissions were induced in 60% to 70% of patients and were complete in 35% to 50%. However, the cytogenetic responses were brief and not improved by maintenance with IFN- $\alpha$ . <sup>64</sup> Intensive chemotherapy has been used preceding autologous SCT as a method for *in vivo* purging that allows collection of Ph-negative marrow and peripheral blood stem cells during early hematopoietic recovery. <sup>65,66</sup>

### **INTERFERON- $\alpha$**

IFNs are a complex group of naturally occurring proteins produced by eukaryotic cells in response to various stimuli. They have pleiotropic biologic activities including inhibition of cellular proliferation, regulation of cytokine expression, and modulation of the immune system. IFNs consist of three distinct groups of peptides: IFN- $\alpha$ , IFN- $\beta$ , and IFN- $\gamma$ . IFN- $\alpha$  and IFN- $\beta$  are acid stable, bind to the same receptor, and are produced by leukocytes and fibroblasts, respectively. IFN- $\gamma$  is an acid-labile, structurally distinct molecule that binds to a different receptor and is produced mainly by T lymphocytes. <sup>67</sup> IFN- $\alpha$  has been used most commonly in the treatment of solid and hematologic malignancies. The mechanism of action of IFN- $\alpha$  is not known. While antiproliferation is thought to be important, other possible mechanisms include (1) restoration of cytoadhesion of hematopoietic cells to marrow stroma; (2) immunomodulation; and (3) antiangiogenesis.

### **Single-Arm Studies of Interferon- $\alpha$ in Chronic Myelogenous Leukemia**

The clinical activity of interferons in CML was first demonstrated with partially purified IFN- $\alpha$  (Finnish Red Cross, Helsinki), given at doses of 3 to 9 million U/d to early chronic phase patients. Preliminary studies showed that laboratory indices of disease activity (elevated lactate dehydrogenase and B<sub>12</sub> levels, increased bone marrow cellularity) normalized among responding patients. Subsequently, cytogenetic responses with various degrees of Ph suppression were found in 41% of the patients. <sup>68</sup> In the original studies at M. D. Anderson Cancer Center, patients received IFN- $\alpha$  at a dose of 5 million U/m<sup>2</sup> or the maximally tolerated lower dose daily. <sup>69</sup> Complete hematologic response rates were 80% and cytogenetic response rates 58%. The estimated median survival was 89 months. Achieving a cytogenetic response after 12 months of therapy conferred a significant survival benefit by landmark analysis: 5-year survival rates from 12 months into therapy were 90% with a complete cytogenetic response, 88% with a partial cytogenetic response, 76% with a minor cytogenetic response, and 38% in other response categories ( $P < .001$ ) (Fig. 46.3.1-4). The benefit of cytogenetic response was identified by multivariate analysis, introducing it as a time-dependent variable. It was also observed within each risk group. The 4-year survival dated from the 12-month landmark analysis in good-risk patients was 79% with cytogenetic response versus 62% without cytogenetic response ( $P < .01$ ); in the intermediate-risk group the rates were 82% versus 35% ( $P < .01$ ); and in the poor-risk group these rates were 83% versus 39% ( $P < .01$ ). This study confirmed the independent effect of achieving a cytogenetic response on prolongation of survival, and supported efforts aimed at suppressing Ph-positive clones. Among patients with good-risk disease (50% of patients), the median survival was 102 months, and the major cytogenetic response rate 50%.

**FIGURE 46.3.1-4.** Probability of survival of patients in chronic phase chronic myelogenous leukemia on interferon- $\alpha$  (1983 through the present) compared with historical control groups.

Three other trials reported similar results (Table 46.3.1-6). The high hematologic and cytogenetic response rates observed with IFN- $\alpha$  were dose-dependent. Furthermore, survival was significantly influenced by achieving a complete hematologic response at 3 months and a cytogenetic response at 12 months of treatment with IFN- $\alpha$  (see Fig. 46.3.1-4).<sup>70,71,72 and 72a</sup>

Study	No. of Patients	Complete Hematologic Response (%)	Cytogenetic Response (%)		Survival (mo)
			Any	Major

Ozer et al. <sup>71</sup>	107	59	—	29	66
Mahon et al. <sup>72</sup>	116	80	—	43	60
Kantarjian et al. <sup>72a</sup>	274	80	58	38	89

**TABLE 46.3.1-6.** Single Arm Studies with Interferon- $\alpha$

### Randomized Studies

In four randomized trials from Japan, the United Kingdom, Italy, and Germany patients treated with IFN- $\alpha$  achieved higher rates of major and complete cytogenetic responses than with conventional chemotherapy (Table 46.3.1-7).<sup>73,74,75 and 76</sup> Achievement of cytogenetic response was associated with prolonged survival in the Italian and Japanese trials and in an updated report of the Medical Research Council data from the United Kingdom.<sup>77</sup> An updated report from the Italian Cooperative Study Group on CML with prolonged follow-up (range, 95 to 129 months) demonstrated continued significantly better survival for patients on IFN- $\alpha$  versus chemotherapy.<sup>78</sup> Median and 10-year survival of low-risk patients were 104 months versus 64 months and 47% versus 30% ( $P = .03$ ), and 69 months versus 46 months and 16% versus 5% for intermediate and high-risk patients ( $P = .006$ ), respectively. The German trial found a survival benefit with both IFN- $\alpha$  and hydroxyurea therapy compared with busulfan, but no difference between IFN- $\alpha$  and hydroxyurea.<sup>75</sup> When the data were updated for patients who were on IFN- $\alpha$  for more than 3 months and when *intended* versus *actually delivered* therapy was considered, survival was better with IFN- $\alpha$  than with hydroxyurea.<sup>79</sup>

Study	Complete Hematologic Response (%)	Cytogenetic Response (%)		Survival Advantage with Interferon- $\alpha$
		Any	Major	
Hehlmann et al. <sup>73</sup>	31	18	10	++
Italian Cooperative Study Group <sup>74,75</sup>	62	55	19	+
Allan et al. <sup>77</sup>	68	22	11	+
Ohnishi et al. <sup>76</sup>	39	44	9	+

\*The study of Hehlmann et al.<sup>73</sup> showed a survival advantage of interferon- $\alpha$  versus busulfan, but not versus hydroxyurea. In a subsequent intent-to-treat analysis, Amari et al.<sup>79</sup> demonstrated a survival advantage for patients on interferon- $\alpha$  versus both busulfan and hydroxyurea.

**TABLE 46.3.1-7.** Randomized Studies with Interferon- $\alpha$

A metaanalysis compared IFN- $\alpha$  with chemotherapy in CML and suggested better survival with IFN- $\alpha$  (57% at 5 years) than with either hydroxyurea ( $P = .001$ ) or busulfan ( $P = .00007$ ) (42% at 5 years).<sup>80</sup>

### Interferon- $\alpha$ in Combination with Cytosine Arabinoside

IFN- $\alpha$  alone in late chronic and accelerated phases of CML yielded modest results. In a study from M. D. Anderson Cancer Center, 140 patients with Ph-positive early chronic phase CML received IFN- $\alpha$  (5 million U/m<sup>2</sup>) in combination with low-dose Ara-C, 10 mg subcutaneously daily, or intermittent Ara-C (7 d/mo).<sup>81</sup> With daily IFN- $\alpha$  and daily Ara-C, complete hematologic responses were seen in 92% of patients and cytogenetic responses in 74% (major 50%, complete 31%). The estimated 4-year survival rate was 70%. The median time to achievement of a major cytogenetic response was also significantly shorter with daily Ara-C ( $P < .01$ ).

In a French trial, 721 patients in early chronic-phase CML received either hydroxyurea (50 mg/kg), and IFN- $\alpha$  (5 million U/m<sup>2</sup>/d) alone, or with monthly courses of Ara-C (20 mg/m<sup>2</sup> for 10 d/mo).<sup>82</sup> The complete hematologic response rate was 66% in the IFN- $\alpha$  plus Ara-C group and 55% in the IFN- $\alpha$  group ( $P = .003$ ). Patients treated with IFN- $\alpha$  and Ara-C survived significantly longer than did patients treated with IFN- $\alpha$  (3-year survival rate 86% vs. 79%,  $P = .02$ ). This difference remained independently significant by multivariate analysis. Patients achieving a cytogenetic response with either IFN- $\alpha$  alone ( $P < .001$ ) or with IFN- $\alpha$  plus Ara-C ( $P < .001$ ) had a significantly longer survival than those who did not achieve a cytogenetic response.

The Italian Cooperative Study Group on CML randomized 540 patients in chronic phase CML to IFN- $\alpha$  alone (median dose, 3.65 million U/m<sup>2</sup>/d) versus IFN- $\alpha$  (median dose, 3.8 million U/m<sup>2</sup>/d) with low-dose Ara-C (40 mg/kg/d subcutaneously  $\times$  10 d/mo).<sup>83</sup> Cytogenetic responses were observed in 54% of patients on IFN- $\alpha$  plus Ara-C versus 47% in the IFN- $\alpha$  group. The rate of major and complete cytogenetic responses was significantly higher in the combined treatment arm (28% vs. 19%,  $P = .01$ ). At a median follow-up of 24 months, the study demonstrated a significantly higher survival rate among good-risk patients with IFN- $\alpha$  plus Ara-C versus IFN- $\alpha$  alone (3-year survival rates 85% vs. 80%,  $P = .03$ ).

### Toxicities of Interferon- $\alpha$ and Clinical Management

Toxicities are common with IFN- $\alpha$ . Almost all patients experience some constitutional side effects, up to 50% of patients require dose reductions, and discontinuation of treatment due to toxicity is necessary in up to 18%.<sup>84</sup> Early adverse effects consist of flu-like symptoms and include fever, chills, postnasal dripping, and anorexia. These are usually not dose limiting, can be managed symptomatically (Table 46.3.1-8), and abate once tachyphylaxis develops within 1 to 2 weeks. Common chronic side effects are fatigue, depression, insomnia, weight loss, alopecia, reduced libido, and impotence. Neurotoxicity (lack of concentration, depression, psychosis) is more common in patients with psychiatric problems and those 60 years and older. Autoimmune phenomena occur in less than 5% of patients: hemolytic anemia and thrombocytopenia, Raynaud's phenomenon, collagen vascular disorders, hypothyroidism, and nephrotic syndrome. Cardiac arrhythmias and manifestations of congestive heart failure are rare but mandate discontinuation of therapy as do severe autoimmune phenomena, severe neurotoxicity, and refractory depression.<sup>85</sup>

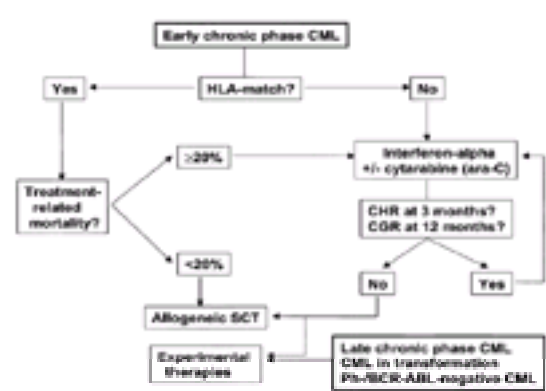

TABLE 46.3.1-8
<p><b>Side Effects</b></p> <p>Start treatment with interferon <math>\alpha</math> at a dose of 3 to 6 million IU 3 times a week for 2 to 3 weeks, then starting 3 to 6 million IU 3 times a week and increase gradually to 9 million IU 3 times a week for 3 to 7 days, then 3 million IU 3 times a week as tolerated.</p> <p>Other patients are more sensitive to side effects of IFN-<math>\alpha</math> and may not tolerate full dose.</p> <p>Precautions with immunosuppression may increase risk of infection.</p> <p>Common chronic side effects include a state of fatigue, depression, and insomnia. Toxicity abates over a few days (e.g., anorexia).</p> <p>Side effects at a dose of 3 to 6 million IU 3 times a week may be of benefit. Neurotoxicity consultation can be helpful in some cases.</p> <p>In the setting of a dose of 3 to 6 million IU 3 times a week, the side effects of IFN-<math>\alpha</math> are usually not dose limiting.</p> <p>The grade 1 and 2 toxicity, both dose and course, are 30% for grade 2 patients versus 10% for grade 1.</p> <p>Start IFN-<math>\alpha</math> for patients with intermediate disease.</p>

<p>Abbreviations: WBC, white blood cell count.</p>

**TABLE 46.3.1-8.** Side Effects and Guidelines for Therapy with Interferon- $\alpha$  in Chronic Myelogenous Leukemia

The use of IFN- $\alpha$  during pregnancy is controversial. IFN- $\alpha$  has antiproliferative and antiangiogenic activities that may affect the placenta and fetal development. Mutagenicity *in vitro* and teratogenicity in animal studies are not documented with IFN- $\alpha$ , but IFN- $\alpha$  caused abortions in rhesus monkeys at dose levels above those used clinically.<sup>86</sup> Case reports of uncomplicated pregnancies with successful delivery of healthy newborns on IFN- $\alpha$  given either at the time of conception or during pregnancy may not be representative, since adverse outcomes may be less frequently reported, and possible damaging consequences for fetal development by IFN- $\alpha$  cannot be excluded.<sup>87</sup> Alternative treatments of pregnant patients with CML are supportive care or pheresis in the first 3 months, then hydroxyurea until delivery, and resumption of IFN- $\alpha$  thereafter.

### TREATMENT DECISION ANALYSIS: INTERFERON- $\alpha$ VERSUS STEM CELL TRANSPLANTATION

SCT can be curative. However, treatment-related mortality and disabling morbidity can be substantial, especially in older patients and those with other comorbid conditions. Therapy with IFN- $\alpha$  can effectively suppress the Ph-positive clone and induce durable cytogenetic responses. Any treatment decision should be based on weighing potential benefits of one treatment approach against its disadvantages. An example of this approach is shown in Figure 46.3.1-5.<sup>88,89</sup>

**FIGURE 46.3.1-5.** Clinical decision making in chronic myelogenous leukemia (CML). For patients in early chronic phase CML, allogeneic stem cell transplantation (SCT) and interferon- $\alpha$  are possible first-line therapies. The decision depends on several factors: (1) availability of a matched sibling; (2) age and performance status of the patient; (3) presence of other comorbid conditions; and (4) socioeconomic situation. For patients who have a matched sibling donor and whose physical condition allows SCT with an acceptable treatment-related morbidity and mortality (less than 20%), allogeneic SCT should be the first choice. For other patients, a trial with interferon- $\alpha$  may be preferable given the manageable side-effect profile with absence of treatment-related mortality. Furthermore, a prospective study on 840 patients below age 56 with chronic phase CML found increased survival with matched sibling allogeneic transplant only in those patients who were younger than 32 years and had intermediate- or high-risk CML. Patients in late chronic phase or accelerated phase should be offered investigational therapies or undergo allogeneic transplantation.<sup>88,89</sup> CHR, cytogenetic response; CHR, complete hematologic response; HLA, human leukocyte antigen.

Delaying allogeneic SCT in favor of IFN- $\alpha$  has raised concerns including worse transplant outcome in late chronic phase CML, adverse effects of prior IFN- $\alpha$  therapy on SCT, risk of sudden disease transformation while on IFN- $\alpha$ , and the fact that almost all patients treated with IFN- $\alpha$ , even in complete cytogenetic remission, express the *BCR-ABL* transcript compared with only one-third after successful transplantation. However, studies have shown that postponing allogeneic SCT up to 2 years into chronic phase does not adversely affect outcome. Likewise, prior IFN- $\alpha$  therapy, if discontinued for more than 3 months before transplantation, has no adverse effects on transplantation. The risk of sudden disease transformation is low during the first 3 years.<sup>90</sup> The significance of persisting *BCR-ABL* transcripts is unknown. Patients in long-term complete cytogenetic remission in whom IFN- $\alpha$  has been discontinued and who are still PCR-positive for *BCR-ABL* have been reported.<sup>91</sup> This observation is consistent with the situation in many other malignant conditions that are considered to be cured despite persistent expression of molecular markers of disease [translocation (14;18), *inv*(16), translocation (8;21)]. Moreover, long-term cytogenetic responders on IFN- $\alpha$  may become negative.<sup>92</sup>

### MANAGEMENT OF ACCELERATED AND BLASTIC PHASE CHRONIC MYELOGENOUS LEUKEMIA

Treatment results in the transformed phases of CML are unsatisfactory.<sup>93</sup> Disease-free survival of selected patients after SCT is less than 15%. IFN- $\alpha$  has no effect on the disease course. Control of elevated white cell counts may be achieved by increasing doses of hydroxyurea and combination with other cytotoxic drugs in the short-term. Symptomatic splenomegaly may be treated with splenectomy. Anemia and thrombocytopenia can be managed with transfusions. New agents and combinations of drugs are being developed and can be offered on investigational protocols.

In one-third of the patients, blastic phase is of lymphoid phenotype with expression of markers such as terminal deoxynucleotidyl transferase (TdT), CD19, CD20, or CD10 common acute lymphoblastic leukemia antigen (CALLA). Most cases with lymphoid blastic phase (80%) coexpress myeloid markers (CD13, CD14, CD33). The remaining two-thirds have an acute myeloblastic or undifferentiated leukemia-like phenotype and form a heterogeneous group. Patients with lymphoid blastic phase respond better to treatment with regimens active against acute lymphoid leukemia. The complete remission rate is 60%, one-half of the patients may have suppression of Ph-positive cells (cytogenetic response), and the remission duration is 9 to 12 months. Patients with myeloid blastic phase have a low objective response rate of 20% to 30%, may respond to high-dose cytosine-arabioside, other antiacute myeloid leukemia regimens, or to hypomethylating agents such as 5'-deoxyazacitidine (decitabine), and to *BCR-ABL* tyrosine kinase inhibitors.<sup>94,95</sup>

### NEW AGENTS AND APPROACHES

## Tyrosine Kinase Inhibitors

Although many molecules along the signaling cascade can be targeted (blockade of SH3, farnesyl transferase, Ras, further downstream targets), inhibition of phosphotyrosine kinase activity has been studied most extensively. Natural inhibitors of tyrosine kinases (herbimycin A, genistein, erbstatin, lavendustin A), extracted from fungal sources, have only broad specificity for a variety of enzyme substrates. To improve target specificity, synthetic compounds have been modeled after the naturally occurring kinase inhibitors. They have been called tyrphostins, and more than 20 of them are known today. Analysis of some of these compounds (AG1112, AG568) showed a growth-inhibitory effect on CML cell lines *in vitro*, inhibition of the tyrosine kinase activity of p210, and induction of differentiation and death in a CML cell blast crisis cell line K562.<sup>96,97</sup> Identification of the crystal structure of several protein kinases allowed the generation of more specific tyrosine kinase inhibitors. In preclinical studies, signal transduction inhibitor 571 (STI571), formerly known as CGP57148B, was found to (1) inhibit the ABL tyrosine kinase at submicromolar concentrations; (2) inhibit the proliferation of BCR-ABL expressing cell lines; (3) inhibit colony formation of BCR-ABL-positive hematopoietic cell lines; and (4) only minimally inhibit the formation of normal bone marrow colonies. Based on these promising results, phase I clinical studies have been conducted in patients with CML in chronic and in transformed phases. Among 54 patients with chronic phase CML who have failed therapy with IFN- $\alpha$  and received STI571 at doses of 300 mg orally daily and more, 96% achieved a complete hematologic remission and 33% a cytogenetic response. After about 3 months of therapy, the cytogenetic response rate is anticipated to exceed 50%, being complete in over 20% to 30%. Responses in *de novo* patients treated with STI571 may be even higher.<sup>98</sup> In 46 patients with CML in blastic phase (32 myeloid, 14 acute lymphoid leukemia or lymphoid blast crisis), 18 (39%) patients had a complete clearance of blood and bone marrow leukemic cells. The marrow complete response rate for patients with myeloid blast crisis was 29%, but responses were often transient. In accelerated phase, the hematologic response is about 70%, cytogenetic responses have been noted in 20%, and responses appear durable.<sup>99</sup> STI571 was well tolerated and no dose-limiting toxicity has yet been reached except for myelosuppression at doses of 300 to 800 mg orally daily. Side effects included nausea, vomiting, diarrhea, and muscle cramps, mostly mild in nature.

## Antisense Oligonucleotides

Antisense oligonucleotides are short DNA sequences modified to bind target RNA sequences within the cell, preventing translation of the RNA message into functional proteins. Effective targets for antisense approaches are *BCR-ABL* itself, Ras, PI-3-kinase, c-Myb, and c-Myc. *BCR-ABL* antisense oligonucleotides alone or in combination with sequences targeted against additional oncogenes reduce the level of p210 *bcr-abl* in CML cells and slow the rate of growth and proliferation. Antisense sequences directed against *BCR-ABL* for *ex vivo* purging in autologous SCT are of interest.<sup>100</sup>

## Polyethylene Glycol Interferon

Polyethylene glycol interferon is a modified IFN- $\alpha$  molecule that is covalently attached to polyethylene glycol. Polyethylene glycol interferon has a significantly longer half-life than its parent compound and can be given once weekly instead of daily. Early data suggest an improved side-effect profile compared with IFN- $\alpha$ . Complete hematologic remissions and cytogenetic responses have been reported. Results with polyethylene glycol interferon are promising, and further investigations are required to validate its role in the treatment of CML.<sup>101</sup>

## Homoharringtonine

Homoharringtonine (HHT) is a plant alkaloid derived from the *Cephalotaxus fortunei* tree. Used in a low-dose continuous infusion schedule (2.5 mg/m<sup>2</sup> for 14 days for remission induction followed by a 7-day monthly infusion as maintenance), HHT resulted in complete hematologic remission in two-thirds of patients and cytogenetic response in one-third (one-half of which were major).<sup>102</sup> More than one-half of the patients were resistant to prior therapy with IFN- $\alpha$ . In early chronic phase disease, HHT was given for six cycles as remission induction followed by IFN- $\alpha$  maintenance: Complete hematologic remission rate was 92% and cytogenetic response rate was 68%.<sup>103</sup> Combinations of HHT with IFN- $\alpha$  and Ara-C in the clinical setting, including early chronic phase CML, are in progress with promising results.<sup>104</sup>

## 5-Aza-2'-Deoxycytidine

5-Aza-2'-deoxycytidine (decitabine) is a potent hypomethylating cytidine analogue. Decitabine produced response rates of 25% in blastic phase and 53% in accelerated phase. Further clinical trials are in progress including decitabine in combination with busulfan and cyclophosphamide as part of a preparative regimen for allogeneic SCT, and as salvage therapy together with stem cell rescue after relapse from allogeneic SCT.<sup>105</sup>

## Adoptive Immunotherapy

That leukemic cell proliferation is under the control of the immune system is based on several observations: (1) there is an increased frequency of disease recurrence with T-cell depleted SCTs; (2) DLIs in patients who relapse after an allogeneic transplant reestablish cytogenetic remissions in a high percentage of patients; (3) there is a positive correlation between GVHD and reduced risk of relapse after transplant; and (4) cytogenetic response correlates with IFN-associated autoimmune phenomena. Response to DLIs suggests a pivotal role for graft-versus-leukemia activity generated by infused donor T lymphocytes in suppressing Ph-positive clones.

Research is focusing on identification of (1) specific T-cell clones able to eliminate leukemic progenitors and (2) proteins that can serve as targets, even though only a few tumors express structures unique to them. CML is a good model because p210 is uniquely associated with the Ph translocation. Minor histocompatibility antigens, overexpressed normal antigens, and other leukemia-restricted antigens are studied as further immunologic targets.<sup>106</sup> In one study, cultures of CD34-positive CML progenitor cells incubated with granulocyte-macrophage colony-stimulating factor, interleukin-4, and tumor necrosis factor stimulated the formation *in vitro* of dendritic cells, leukemic-antigen-presenting cells that are strong inducers of T-cell responses *in vitro*.<sup>107</sup> Identification of leukemia-specific antigens and stimulation of leukemia-specific T-cell responses may allow us to use immunogenicity of CML cells in approaches such as immune gene therapy and peptide vaccination.

Investigational combined modalities using T-cell-depleted allogeneic SCT upfront (to reduce GVHD and treatment-related mortality), followed by periodic incremental doses of selected T-cell subsets for DLIs (to eradicate minimal residual disease), may render allogeneic SCT safer and more effective and extend its use to older patients and those with unrelated or mismatched donors.

## CONCLUSIONS

CML is one of the most extensively studied human malignancies and a prime example of how advances in our understanding of molecular biology can be translated into novel and effective treatment strategies. The most beneficial treatment for the patient in early chronic phase, transplantation versus IFN- $\alpha$ -based therapy, has to be decided on an individual basis. Numerous patient- and treatment-related factors have to be considered, particularly the acceptable threshold of transplant-related mortality, which may be different for different patients. Socioeconomic and logistic factors may play an increasing role in choosing the most appropriate therapy. These recommendations may change drastically as data mature on the efficacy of new investigational treatments, particularly the BCR-ABL tyrosine kinase inhibitor (STI571), and on the safety of new SCT approaches (e.g., mini-SCT). The effect of current treatments in accelerated phases of CML is modest at best, making investigational therapies the best option for these patients.

## INTRODUCTION

Chronic lymphocytic leukemia (CLL) is the most common form of leukemia affecting adults in Western countries. The current annual incidence estimates vary from approximately 8100 to 12,500 new cases in the United States.<sup>1,2</sup> An apparent decrease from 3.3 in 100,000 population in 1973 to 2.3 in 100,000 in 1990 may reflect an improved ability to distinguish CLL from other chronic lymphoid leukemias. CLL occurs more often in males, with a relative frequency of 1.3:1 to 2.6:1. The median age at diagnosis of CLL is 62 years; approximately 10% to 15% of patients with CLL present younger than 50 years of age, and 20% are younger than 55 years.<sup>3</sup> A 10-year-old child with CLL has been reported.<sup>4</sup> The increase in younger patients most likely represents the more routine use of automated blood counts and differentials. Although younger patients with stage 0 disease may survive as long as a normal age-matched population, those with more advanced stages of the disease have a median survival comparable to older patients when corrected for non-CLL-related causes of death.<sup>3,5</sup> CLL occurs more commonly in Jewish people of Russian or Eastern European ancestry, and it is infrequent in Japan, China, and Asian countries.<sup>6,7</sup>

No clear etiologic factors exist for CLL, although few carefully conducted studies have been performed.<sup>8</sup> CLL is one of the few leukemias that does not appear to be associated with prior exposure to ionizing radiation, chemicals, or drugs, and it was the only leukemia not associated with atomic bomb explosions.<sup>9,10,11 and 12</sup>

A clear familial incidence of CLL has been established. Approximately 20% of patients with this disease have relatives with CLL or another lymphoid malignancy, although no genetic linkage has yet been identified. Rare sets of twins have been affected.<sup>13,14</sup> A lack of concordance of oncogene expression was reported in monozygous twin sisters who both had CLL.<sup>15</sup> Immigrants from Japan to the United States maintain their low incidence of CLL. The occurrence in spouses has been observed.<sup>16</sup>

## CELL OF ORIGIN

The precise origin of the CLL lymphocyte has not been clearly defined. CLL lymphocytes have been assumed to be the malignant counterpart of normal lymphocytes because of their similar morphology. However, whereas B-CLL cells share some immunologic features with normal B cells, marked molecular and immunologic differences distinguish the two cell populations.

CLL cells express pan-B antigens (e.g., HLA class II, CD19, CD20), as well as activation antigens (e.g., CD5, CD23, CD25, CD71), but not terminal differentiation antigens exhibited by plasma cells.<sup>17</sup> This profile supports the hypothesis that the B-CLL cell is an "activated" B lymphocyte, meaning that the cells can be activated without dividing, but it does not suggest that they are in a state of active proliferation. Overexpression of BCL-2 is restricted to the malignant cells. CLL B cells express a restricted repertoire of V<sub>H1</sub> genes, which is distinct from that of normal B cells.<sup>18</sup>

Two major features that distinguish CLL cells from normal B cells is their expression of CD5 and the barely detectable amount of surface immunoglobulins. Although CD5 was formerly considered to be a restricted T-cell antigen, CD5+ B cells are normally present in the mantle zone of normal lymph nodes, and small numbers can be found in the peripheral blood of normal individuals. CD5+ B cells are found in increased numbers in patients with autoimmune disorders (e.g., rheumatoid arthritis, Sjögren's syndrome, and systemic lupus erythematosus), immune thrombocytopenic purpura, and after allogeneic bone marrow transplantation.<sup>19,20</sup> These observations have led to the current theory that B-CLL is a monoclonal proliferation of mantle zone-based anergic CD5+ self-reactive B cells devoted to the production of polyreactive autoantibodies.<sup>21</sup> A wide variety of growth factors have been implicated in the disordered proliferation and differentiation of B cells in CLL, including tumor necrosis factor,<sup>22</sup> interleukin-2 (IL-2),<sup>23,24</sup> IL-4,<sup>25,26</sup> IL-6,<sup>27</sup> IL-7,<sup>28</sup> IL-8, IL-10, IL-11, IL-12, IL-13, interferon-g (IFN-g), granulocyte-macrophage colony-stimulating factor, transforming growth factor- $\beta$ , and others.<sup>29,30,31,32,33 and 34</sup>

## IMMUNE FUNCTION AND AUTOIMMUNITY IN CHRONIC LYMPHOCYTIC LEUKEMIA

CLL is characterized by an accumulation of immunologically incompetent B cells. These cells produce reduced amounts of normal immunoglobulins in response to antigenic stimuli.<sup>21</sup> Quantitative and qualitative abnormalities of normal B cells, T cells, and natural killer (NK) cells also have been reported, with a reduction in the number and function of normal T cells and the function of NK cells, and impaired complement activation.<sup>35,36</sup> Elevated levels of circulating IL-2 receptor (IL-2R) may down-regulate helper T-cell function and may play a role in the pathogenesis of the immunodeficiency.<sup>23,24</sup> B-CLL cells express CD40, which down-modulates CD40 ligand (CD154) on CD4+ T cells. Because CD40 ligand allows B cells to respond to T cells, this effect may contribute to the immune incompetence in CLL.<sup>37</sup>

## CYTOGENETICS

Conventional banding techniques detect cytogenetic abnormalities in more than 50% of cases of CLL. <sup>38,39</sup> and <sup>40</sup> More recently, fluorescent *in situ* hybridization has identified cytogenetic abnormalities in more than 80% of cases. <sup>41,42</sup> and <sup>43</sup> The most common cytogenetic abnormality in CLL appears to be deletion of 13q, which is present in 55% of cases. Patients with 13q14 abnormalities tend to experience a more benign course with a normal lifespan. Whether deletion of the breast cancer gene BRCA2 at 13q12 is involved is controversial. <sup>44,45</sup>

Deletions of 11q23 are detected in 18% of cases and are associated with massive lymphadenopathy that is often out of proportion to the increase in peripheral blood lymphocyte count. Trisomy 12 occurs in 16% of cases and is associated with atypical morphology and a poor outcome. Lymphocytes with trisomy 12 tend to have unmutated immunoglobulin variable ( $V_H$ ) genes, whereas those with 13q14 have evidence of somatic mutations. <sup>46</sup> Mutations or deletions of p53 at 17p13.3 have been reported in approximately 15% of patients. Chromosome 17 abnormalities are found more frequently in cases of atypical CLL and are associated with a higher likelihood of Richter's transformation and a poor prognosis. <sup>47</sup>

BCL-3 translocations, t(14;19)(q32.3;q13.2), are uncommon and, in approximately one-half of cases, occur in association with trisomy 12. These patients tend to be young and have rapidly progressive disease. Of note is the lack of translocations in patients with CLL.

## MOLECULAR BIOLOGY AND GENETICS

Lymphocytes from approximately one-half of patients with CLL contain  $V_H$  genes that are mutated postgerminal center B cells [immunoglobulin D (IgD)<sup>-</sup>, CD38<sup>+</sup>], whereas the other half are naïve and unmutated (IgD<sup>+</sup>/IgM<sup>+</sup>, CD38<sup>-</sup>). <sup>48,49</sup> and <sup>50</sup> These two populations are characterized by markedly different clinical outcomes, with the unmutated group having a significantly shorter survival rate. Studies of gene use in CLL have indicated that there may be nonrandom differential usage of  $V_H$  and  $V_L$  genes used in the cell of origin, with an apparent increase in the usage of the  $V_{H1-69}$  (51p1) gene from the  $V_{H1}$  family. <sup>46,51</sup>

No single oncogene has been implicated in the pathogenesis of CLL. Early reports of cases with the BCL-1 translocation were more likely mantle cell lymphoma (MCL). <sup>52,53</sup> and <sup>54</sup> The translocations associated with BCL-2 [t(14;18)(q32;q21)] and BCL-3 [t(14;19)(q32;q13.1)] have been detected in only 5% to 10% of cases. <sup>55,56</sup> However, overexpression of the BCL-2 gene is present in more than 70% of cases, even in the absence of the chromosome rearrangement. <sup>57</sup> The ratio of the antiapoptotic gene BCL2 to the proapoptotic gene BAX is increased in CLL cells, which favors cell survival. Deletions of 13q have been identified using molecular techniques, even in cases without cytogenetic changes. This abnormality was thought to be at the site of the retinoblastoma (RB) suppressor gene but has since been shown to be telomeric to that region with a novel suppressor gene referred to as *DBM* (disrupted in B-cell malignancy). <sup>58</sup> An apparent correlation exists between the antiapoptotic protein Mcl-1 and resistance to chemotherapy. <sup>59</sup>

Considerable interest has focused on the *ATM* gene, which is mutated in patients with ataxia telangiectasia, who are at an increased risk for developing lymphoid neoplasms. The *ATM* gene is located at chromosome 11q22-23 and encodes for a high-molecular-weight protein that is involved in cell-cycle control, DNA repair, and DNA recombination. However, only a subset of patients with deletions at 11q22-23 show mutations in the coding region of the remaining ATM allele, <sup>60</sup> suggesting a pathogenetic role for other genes.

Abnormalities of p53 occur in at least 15% of patients and are associated with a higher percentage of prolymphocytes, advanced stage, chemoresistance, and a poorer outcome. <sup>61,62</sup> and <sup>63</sup>

## DIAGNOSIS

Most patients with CLL are asymptomatic at presentation, and the diagnosis is often made when lymphocytosis is noted at the time of a routine complete blood cell count. Physical examination is normal in 20% to 30% of patients at presentation. As the disease progresses, however, generalized adenopathy and splenomegaly are common.

The diagnosis of CLL requires more than 5000 per  $\mu$ L of small, mature-appearing lymphocytes circulating in the peripheral blood that are unexplained by other clinical disorders. The bone marrow aspirate and biopsy are infiltrated by at least 30% lymphocytes. A bone marrow aspirate and biopsy are rarely required to make the diagnosis of CLL, but they may provide prognostic information and are valuable for assessing response to therapy. <sup>64,65</sup>

The immunophenotype of CLL cells readily distinguishes CLL from other disorders associated with increased numbers of circulating atypical lymphoid cells [e.g., prolymphocytic leukemia (PLL), hairy cell leukemia (HCL), and hairy cell variant (HCL<sub>v</sub>)], from non-Hodgkin's lymphomas (NHL) in a leukemic phase (e.g., lymphoplasmacytic lymphomas; marginal zone NHL, including splenic lymphoma with villous lymphocytes; mantle cell NHL), and from plasma cell leukemia <sup>66</sup> (Fig. 46.3.2-1). CLL lymphocytes are monoclonal B cells that express CD19, CD20, CD23, and CD5, along with low levels of surface immunoglobulin (slg). T-cell antigens (e.g., CD2, CD3) are absent. <sup>66</sup> Mouse red blood cell rosettes on peripheral blood lymphocytes are characteristic of CLL, but this test is no longer routinely performed. In an occasional patient, CLL B cells express additional antigens more characteristic of hairy cells, monocytes, or myeloid cells. <sup>17,67</sup> Immunoglobulin heavy-chain gene rearrangements are invariably present but are not required to make the diagnosis. <sup>68</sup> Disorders characterized by CD5<sup>-</sup> chronic lymphocytosis should not be considered CLL because they differ in immunologic, molecular, and functional features. <sup>69</sup>

**FIGURE 46.3.2-1.** Morphologic and immunophenotypic characteristics, respectively, of **(A)** chronic lymphocytic leukemia (small, compact nucleus; no visible nucleoli; homogeneous cells; slg dim, CD19<sup>+</sup>, CD20<sup>+</sup>, CD23<sup>+</sup>, CD5<sup>+</sup>, CD103<sup>-</sup>, CD10<sup>-</sup>); **(B)** prolymphocytic leukemia (larger, prominent nucleoli; mixed population; slg<sup>+</sup>, CD19<sup>+</sup>, CD20<sup>+</sup>, CD5<sup>+/-</sup>, CD23<sup>+/-</sup>, CD103<sup>-</sup>, CD10<sup>-</sup>); **(C)** hairy cell leukemia (filamentous projections; slg<sup>+</sup>, CD19<sup>+</sup>, CD20<sup>+</sup>, CD23<sup>-</sup>, CD5<sup>-</sup>, CD103<sup>+</sup>, CD10<sup>-</sup>); **(D)** follicular small cleaved cell lymphoma (small, cleaved cells; Slg<sup>+</sup>; CD19<sup>+</sup>, CD20<sup>+</sup>, CD5<sup>-</sup>, CD10<sup>+/-</sup>, CD23<sup>-</sup>); and **(E)** mantle cell lymphoma (small to medium cleaved; slg<sup>+</sup>, CD19<sup>+</sup>, CD20<sup>+</sup>, CD23<sup>-</sup>, CD5<sup>-</sup>, CD103<sup>-</sup>, CD10<sup>+</sup>). slg, surface immunoglobulin.

## CLINICAL FEATURES

### CLINICAL PRESENTATION

Patients with CLL are generally symptomatic at presentation, and the diagnosis is often made incidentally when a lymphocytosis is noted at the time of a routine evaluation. Physical examination is normal at presentation in 20% to 30% of patients, with lymphadenopathy or hepatosplenomegaly, or both, noted in an additional 40% to 50% of patients. As the disease progresses, however, generalized adenopathy and splenomegaly become common features of this disease ( Fig. 46.3.2-2).

Pulmonary and central nervous system involvement are uncommon.<sup>70,71</sup>

**FIGURE 46.3.2-2.** Pronounced cervical, supraclavicular, and axillary lymphadenopathy in a patient with chronic lymphocytic leukemia.

## INFECTIONS

Hypogammaglobulinemia is common in CLL, especially in patients with advanced disease. The increased susceptibility to infections reflects an inability to produce specific antibodies and abnormal activation of the complement system.<sup>36</sup> Historically, the most common pathogens were those that require opsonization for bacterial killing, such as *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae*. The increased use of immunosuppressive agents, such as fludarabine, 2-chlorodeoxyadenosine (2-CdA), and 2'-deoxycytidine (DCF), has markedly altered the spectrum of pathogens encountered in patients with CLL, with an increase in infections seen with opportunistic organisms such as *Candida*, *Listeria*, *Pneumocystis carinii*, *Cytomegalovirus*, *Aspergillus*, Herpesvirus infections, and others that were rarely encountered before the widespread use of nucleoside analogues.<sup>72,73,74</sup> and <sup>75</sup> A febrile patient with CLL receiving one of the new nucleoside analogues can no longer be assumed to have a common bacterial pathogen, and aggressive diagnostic measures may be required. Prophylactic antimicrobial regimens cannot be routinely recommended for all fludarabine-treated patients because the broad spectrum of potential pathogens would require multiple, potentially toxic drugs. However, such regimens should be considered for patients with extensive prior therapy, who have failed fludarabine, who have a history of recurrent infections, or are on corticosteroids.<sup>75,76</sup>

High-dose intravenous immunoglobulins have been evaluated for their ability to prevent infections in CLL.<sup>77</sup> Although a reduction in the total number of bacterial infections is reported with this treatment, these are primarily of trivial to moderate severity, with no decrease in the total number of major infections, either viral or fungal, or in the number of patients experiencing an infection, and with no improvement in overall survival. The prophylactic use of intravenous immunoglobulins is not cost-effective<sup>78</sup> and should be reserved for select patients with documented, repeated bacterial infections.<sup>79</sup>

Whether myeloid growth factors can protect against chemotherapy-induced myelosuppression has not yet been demonstrated.<sup>80</sup> In one study,<sup>81</sup> the use of granulocyte colony-stimulating factor to support fludarabine therapy reduced the occurrence of pneumonias but not other forms of severe infections.

## AGGRESSIVE TRANSFORMATION

Approximately 3% to 15% of CLLs evolve into a more aggressive lymphoid malignancy. The most common of these is Richter's syndrome, which was initially described in 1928 by Maurice Richter.<sup>82</sup> He reported a 46-year-old man with CLL who experienced a rapid clinical deterioration characterized by lymphocytosis, massive and diffuse adenopathy, hepatosplenomegaly, and abdominal discomfort. At autopsy, large abdominal and retroperitoneal lymph nodes were infiltrated not only by small lymphocytes, but with larger cells, which reflected the large cell lymphoma component. Additional cases were subsequently reported by Lortholary et al.,<sup>83</sup> who designated the entity as Richter's syndrome. Richter's syndrome develops in approximately 5% of CLL patients.<sup>84</sup> Patients characteristically present with increasing lymphadenopathy, hepatosplenomegaly, fever, abdominal pain, weight loss, progressive anemia, and thrombocytopenia, with a rapid rise in the peripheral blood lymphocyte count. A lymph node biopsy reveals a large cell lymphoma. This transformation is not clearly related to either the nature or the extent of prior therapy. The large cell lymphoma shares immunologic, cytogenetic, and molecular features with the original CLL clone in one-half of the cases.<sup>85,86</sup> and <sup>87</sup> Nucleic acid sequence analysis of the heavy- and light-chain-variable region supports the theory that Richter's syndrome is derived from the same malignant clone in most patients.<sup>88,89</sup> Response of patients with Richter's syndrome to systemic therapy is poor, with a median survival of 4 to 5 months using alkylating agents, but may be longer with nucleoside analogue-based regimens.<sup>84,90</sup>

CLL may also evolve over the years into PLL. This transformation is associated with progressive anemia and thrombocytopenia, with at least 55% polymphocytes in the peripheral blood.<sup>91</sup> Clinical features include lymphadenopathy, hepatosplenomegaly with a wasting syndrome, and an increasing resistance to therapy.

Anecdotal reports have been published of a transformation to acute lymphoblastic leukemia, plasma cell leukemia, multiple myeloma, or Hodgkin's disease.<sup>91,92</sup> and <sup>93</sup>

## AUTOIMMUNITY

A positive Coombs' antiglobulin test may be present in 20% to 30% of cases of CLL, with clinical hemolysis in 10% to 25% of patients.<sup>94,95</sup> The frequency of immune thrombocytopenia appears to be approximately 2%.<sup>94,95</sup> The immune hemolysis is more often related to a warm-reactive than a cold antibody. In most cases, these antibodies are polyclonal and, therefore, not produced by the malignant B cells.<sup>21,96</sup> This phenomenon probably reflects impaired interactions among the malignant B cells, normal B cells, and T cells.<sup>21</sup> However, two  $V_H$  genes have been shown to be preferentially expressed in cells from CLL patients with warm-reacting antibodies: 51p/DP-10 gene and a DP-50 gene.<sup>97,98</sup> These observations suggest that, whereas the antibodies that are produced by the CLL are not involved in the red blood cell destruction, they may still be involved in the pathogenesis of the autoimmune hemolytic anemia.

Autoimmune anemia, or thrombocytopenia, generally responds to corticosteroids, such as prednisone, 60 to 100 mg/d, which may be tapered after 1 or 2 weeks after evidence of response. Patients who are unresponsive to corticosteroids may respond to high-dose intravenous immunoglobulins using an initial loading dose daily for 5 days followed by 0.4 g/kg every 3 weeks. Splenectomy may be considered when systemic approaches fail.<sup>99</sup> Splenic irradiation induces only transient responses. Rituximab has been associated with dramatic responses (B. Cheson, unpublished observation).

## PURE RED BLOOD CELL APLASIA

Pure red blood cell aplasia has been reported to occur in up to 6% of cases of CLL, although that figure is likely an overestimate.<sup>100</sup> This complication is characterized by severe anemia (hematocrit generally less than 21%) without a reticulocyte response or bone marrow normoblasts and in the absence of neutropenia or thrombocytopenia. Corticosteroids may induce transient responses. Chemotherapy increases the hematocrit in the majority of patients with a response of the CLL. Cyclosporine A, with or without concurrent corticosteroids, may also achieve responses, often within 2 to 3 weeks and without requiring a reduction in tumor mass.<sup>101</sup>

## SECOND MALIGNANCIES

Secondary malignancies occur with increased frequency in patients with CLL, related both to the immune defects of the disease as well as the consequences of therapy.<sup>102,103,104,105,106,107</sup> and <sup>108</sup> The most common tumors are lung cancers and melanomas; others include Hodgkin's disease, essential thrombocythemia, multiple myeloma, and acute myeloid leukemia. Coincidence of CLL and chronic myeloid leukemia also has been observed<sup>109,110</sup> (B. Cheson, unpublished observation).

## STAGING AND PROGNOSTIC FACTORS

## STAGING SYSTEMS

CLL patients have markedly differing outcomes and may require different therapeutic approaches. Over the years, a number of classification systems have been developed to organize CLL patients into risk groups.<sup>111,112</sup> and <sup>113</sup> The first widely accepted attempt to identify various prognostic groups of patients was the five-stage Rai classification (Table 46.3.2-1): Stage 0 includes patients with only lymphocytosis (median survival, more than 12.5 years); stage I patients also have lymphadenopathy (median survival, 8.5 years); stage II is characterized by splenomegaly with or without hepatomegaly (median survival, 6 years); stage III includes anemia (not related to hemolysis) (median survival, 2 to 4 years); and stage IV includes thrombocytopenia (median survival, 2 to 4 years).<sup>114</sup> This system was subsequently simplified to three stages: low risk (stage 0), intermediate risk (stages I–II), and high risk (stages III–IV)<sup>115</sup> (Fig. 46.3.2-3). In Europe a few years later, Binet described his three-stage stage system: Stage A patients have fewer than three node-bearing areas (median survival, more than 10 years); stage B patients have three or more node-bearing areas (median survival, 5 years); and stage C patients have anemia and/or thrombocytopenia (median survival, 2 years)<sup>116</sup> (Table 46.3.2-2). The Rai classification is the most commonly used in the United States, whereas the Binet system is often applied in Europe. A major difference between the two systems is the failure of the Binet system to identify Rai stage 0 patients, who have a 10-year survival rate of approximately 60%. Binet stage A patients include all Rai 0, two-thirds of Rai I, and one-third of Rai II. Neither system identifies patients with lymphocytosis and splenomegaly without lymphadenopathy. Nevertheless, the two systems have similar prognostic value. Other staging systems do not appear to provide an advantage over the two already in widespread use.<sup>117,118</sup>

Rai Stage	Three-Stage System	Clinical Features	Median Survival (Y)
I	Low risk	Lymphocytosis in blood and marrow only	>11
II	Intermediate risk	Lymphocytosis + lymphadenopathy + splenomegaly + hepatomegaly	7
III, IV	High risk	Lymphocytosis + anemia + thrombocytopenia	2-4

TABLE 46.3.2-1. Modified Rai Staging System for Chronic Lymphocytic Leukemia

FIGURE 46.3.2-3. Simplification of the five-stage Rai classification into three risk groups based on survival. Stage 0, low risk; stages I and II, intermediate risk; stages III and IV, high risk.

Stage	Clinical Features	Median Survival (Y)
A	Fewer than three areas of clinical lymphadenopathy; no anemia or thrombocytopenia	12
B	Three or more involved node areas; no anemia or thrombocytopenia	7
C	Hemoglobin $\leq$ 10 g/dL and/or $<$ 100,000 platelets per $\mu$ L.	2

TABLE 46.3.2-2. Binet Staging System for Chronic Lymphocytic Leukemia

At diagnosis, approximately 20% to 30% of patients are Rai stage 0, and 70% to 80% of patients are in low- or intermediate-risk groups in both the Rai and Binet classifications.<sup>5,106,114,116,118,119,120,121</sup> and <sup>122</sup>

## PROGNOSIS

Clinical features and laboratory studies are used to predict survival in CLL. Montserrat and coworkers<sup>123,124</sup> were the first to use the term *smoldering CLL* to distinguish patients with early-stage disease who were unlikely to progress from those who were more likely to require treatment. The laboratory features included a hemoglobin of 12 g% or higher, a lymphocyte count of less than 30,000 cells per  $\mu$ L, a platelet count of more than 150,000 cells per  $\mu$ L, and a nondiffuse pattern of bone marrow involvement with fewer than 80% lymphocytes.

A rapid lymphocyte doubling time appears to be a better predictor of a poor outcome than the absolute number of circulating lymphocytes.<sup>124,125</sup>

In more than one-half of CLL cases, the bone marrow is diffusely infiltrated by small lymphocytes; in the remaining patients, the pattern of infiltration is nodular, interstitial, or a mixture of the two. The diffuse pattern has been suggested to be a strong independent adverse prognostic factor,<sup>121</sup> although this finding does not clearly add to clinical stage.<sup>5,126,127,128</sup> and <sup>129</sup>

Additional features associated with a shorter survival include male gender, black race, poor performance status, abnormal liver chemistries, decreased serum albumin, and vertebral bone marrow involvement detected by magnetic resonance imaging.<sup>106,118,130,131</sup>

Of the numerous immunologic characteristics that have been evaluated, soluble CD23 and serum b<sub>2</sub>-microglobulin appear to have a particularly strong predictive value.<sup>132,133,134,135,136</sup> and <sup>137</sup> Others include the function of various lymphocyte subpopulations,<sup>138</sup> expression of surface IgM, FMC7, loss of CD23, increased serum levels of soluble CD54,<sup>139,140,141,142,143,144</sup> and <sup>145</sup> and soluble IL-2 receptors.<sup>23,24</sup>

A serum or urine paraprotein can be detected in more than 60% of cases of CLL, including the presence of Bence Jones proteinuria,<sup>146,147</sup> but the level of paraprotein does not appear to have prognostic value. There has been no consistent relationship between hypogammaglobulinemia and survival among series.<sup>118,142,148,149</sup>

Cytogenetic and molecular studies best predict outcome in CLL. Patients with 13q abnormalities experience the longest survival and rarely require therapy, whereas complex abnormalities are associated with the poorest outcome.<sup>43</sup> Deletions of the long arm of chromosome 11 (11q21-25) tend to occur in patients who are younger and have more aggressive disease; peripheral, abdominal, and mediastinal adenopathy; advanced stage; and a shorter survival. Trisomy 12 has a prognosis that is intermediate between the two. Cytogenetic studies are not recommended as part of the routine evaluation of the patient with CLL because they are expensive, difficult to perform, and most important, we do not yet know how to apply the information to treatment decisions.

Although BCL-2 expression has not uniformly correlated with outcome, the ratio of BCL-2 to BAX favors survival in CLL cells with enhanced *in vitro* cell survival and correlates with clinical resistance to chemotherapy and clinical outcome.<sup>150,151</sup> and <sup>152</sup> P53 deletions predict for poor response to therapy with fludarabine or pentostatin.<sup>62</sup>

Studies<sup>49,50</sup> have shown a strong independent correlation between V<sub>H</sub> gene mutations, CD38 expression, and survival. The V<sub>H</sub> mutation status distinguishes more primitive from more mature B cells and appears to separate CLL patients into markedly distinct prognostic groups ( Fig. 46.3.2-4).

**FIGURE 46.3.2-4.** Patients with chronic lymphocytic leukemia can be separated into survival groups on the basis of the mutational status of the immunoglobulin variable gene **(A)** and CD38 expression **(B)**. (From ref. 50, with permission.)

## THERAPY

Patients with low-risk CLL often do not require therapy for many years after diagnosis and eventually die of apparently unrelated causes. Anecdotal reports of transient spontaneous remissions also have been published.<sup>153,154</sup> Many patients with intermediate-risk disease may remain stable for many years as well, whereas others may die from disease-related complications within a few months of diagnosis, despite appropriate therapy. Most patients with high-risk CLL need treatment at diagnosis.

### INITIAL APPROACH TO THE PATIENT WITH CHRONIC LYMPHOCYTIC LEUKEMIAS

Currently available therapies do not cure patients with CLL<sup>155</sup> ( Fig. 46.3.2-5), yet they may be associated with substantial toxicities. Moreover, early intervention has not been shown to benefit patients with early-stage disease.<sup>107,156,157,158</sup> and <sup>159</sup> The French Cooperative Group on CLL conducted two studies in patients with Binet stage A disease.<sup>107,158</sup> In the first study, patients were randomized to daily oral chlorambucil or observation. In the second trial, patients received either intermittent chlorambucil plus prednisone or no initial treatment. Neither study detected an advantage to early intervention. Moreover, a greater number of fatal, secondary solid tumors were reported in the first study, which was not noted in the study using an intermittent drug schedule.<sup>158</sup> Therefore, therapy should not be initiated in patients with early-stage CLL without specific indications, which include disease-related symptoms (e.g., fevers, chills, weight loss, pronounced fatigue); increasing bone marrow failure with anemia and/or thrombocytopenia, autoimmune anemia, or thrombocytopenia; massive or progressive hepatosplenomegaly or lymphadenopathy; and recurrent infections.<sup>65</sup> An elevated lymphocyte count alone is not sufficient to prompt therapy; however, a lymphocyte doubling time of less than 6 months may support the decision to treat.<sup>5,125</sup>

**FIGURE 46.3.2-5.** Survival of 741 previously untreated patients seen at the M. D. Anderson Cancer Center over three decades, ending in 1990, demonstrating a lack of any incremental improvement in survival with therapies available during that period. (From ref. 155, with permission.)

### SINGLE-AGENT CHEMOTHERAPY

The most active classes of chemotherapy drugs in CLL are alkylating agents, such as chlorambucil and cyclophosphamide, and the nucleoside analogues fludarabine, 2-CdA, and DCF (pentostatin).<sup>155,160,161</sup> When chlorambucil is administered orally, either at a dose of 4 to 8 mg/m<sup>2</sup> daily for 4 to 8 weeks, or as pulses of 15 to 30 mg/m<sup>2</sup> every 2 to 4 weeks, responses are attained in approximately 30% to 70% of previously untreated patients, although few of these are complete responses.<sup>157,162,163</sup> The activity of cyclophosphamide appears to be similar to chlorambucil, but it is generally used only when chlorambucil has failed or is poorly tolerated, and in combination regimens.

Corticosteroids are less active than alkylating agents in CLL and should be reserved for patients with autoimmune complications because of the risks of bacterial, viral, and fungal infections; diabetes; and osteoporosis.

### PURINE ANALOGUES

Fludarabine (2-fluoro-ara-adenosine monophosphate) is the most active agent for the treatment of CLL ( Table 46.3.2-3). The currently recommended schedule of administration of fludarabine is as an intravenous bolus of 25 mg/m<sup>2</sup> daily for 5 consecutive days once a month. Patients failing to respond to two or three courses should be switched to an alternative treatment. Patients who achieve a complete response probably do not warrant additional treatment. For those patients with a partial response, therapy is continued to best response plus two additional courses, not exceeding 1 year of therapy because of concerns of cumulative myelotoxicity.

Other schedules have not been as active.<sup>185,186</sup> and <sup>187</sup> The oral bioavailability of fludarabine is 50% to 60%, and an oral formulation is in clinical trials. <sup>188</sup>

Study	Fludarabine CR/RR	Chlorambucil CR/RR	DFS	OS
International Working Group on CLL (IWCLL) <sup>169</sup>	70%	43%	+	-
Rai et al. 1996 <sup>165</sup>	70%	43%	+	-
Lepoerier et al. 1997 <sup>170</sup>	69%	43%	+	±
Spriano et al. 1999 <sup>166</sup>	150	43%	+	NR

**TABLE 46.3.2-3.** Purine Analogues in Chronic Lymphocytic Leukemia

Fludarabine induces complete remissions in approximately 30% of previously untreated patients, with an overall response rate higher than 70%.<sup>163,165,166,169,170</sup> In a long-term follow-up of a large, single institution series, the median time to progression of responders was 31 months, and the overall median survival was 74 months.<sup>189</sup> Those who achieve an immunophenotypic and molecular complete remission appear to experience a longer survival than those with only a clinical and hematologic remission.<sup>190</sup>

Fludarabine has been compared with an alkylating agent-based regimen in several phase III trials<sup>163,169,170,191</sup> (Table 46.3.2-4).

Study	Number of Patients	CR/RR	DFS	OS
IWCLL <sup>169</sup>	100	-	+	-
Rai et al. 1996 <sup>165</sup>	544	+	+	-
Lepoerier et al. 1997 <sup>170</sup>	695	+	+	±
Spriano et al. 1999 <sup>166</sup>	150	+	+	NR

+, significant fludarabine advantage; -, no difference; ±, borderline; CR, complete response; DFS, disease-free survival; IWCLL, International Working Group on Chronic Lymphocytic Leukemia; NR, not reported; OS, overall survival; RR, rate response.

**TABLE 46.3.2-4.** Comparisons between Fludarabine and Alkylating Agent Regimens as Initial Therapy of Chronic Lymphocytic Leukemia

In a North American Intergroup study, 544 untreated patients with advanced-stage, active disease were randomized to either fludarabine at the standard dose, chlorambucil (40 mg/m<sup>2</sup> single dose), or a combination of the two agents (fludarabine 20 mg/m<sup>2</sup> daily for 5 days; chlorambucil 20 mg/m<sup>2</sup> day 1) every 4 weeks for up to 12 months. Patients who were unsuccessful with one of the single agents were crossed over to receive the alternate drug. The 167 patients in the fludarabine group had an overall response rate of 70%, including 27% complete remissions, which was significantly higher than with chlorambucil (43% responses, 3% complete remissions;  $P < .0001$ ). The duration of response was 32 months with fludarabine versus 18 months with chlorambucil ( $P = .0002$ ), with a median progression-free survival of 27 months with fludarabine and 17 months for chlorambucil ( $P < .0001$ ). However, no apparent prolongation of survival was reported, related in part to the crossover design of the study. The combination arm was prematurely closed because it was more toxic with no likelihood of being more effective than fludarabine alone.

A European collaborative group randomized 196 patients with stage A (2), B (104), or C (89) to either fludarabine or one of two anthracycline-based regimens [cyclophosphamide, doxorubicin, and prednisone (CAP) or cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP)].<sup>169</sup> A higher response rate was attained with fludarabine in the untreated patients, although the difference was not significant. The advantage for fludarabine was significant for remission duration, with a trend toward a survival advantage ( $P = .087$ ). In a subsequent trial by the International Working Group on CLL, including 486 stage B and 209 stage C patients,<sup>170</sup> a complete hematologic remission was observed in 37% of the fludarabine group, 28% of the CHOP group, and 13% of the CAP-treated patients. The differences were significant between fludarabine and CAP and between CHOP and CAP ( $P < .0001$ ) in response and survival, but not between fludarabine and CHOP ( $P = .15$ ). Nevertheless, fewer deaths were reported in the fludarabine group, resulting in a significant survival advantage ( $P = .05$ ).

These results establish fludarabine as the preferred initial treatment for most patients with CLL. However, for patients who are elderly or those who have a reduced performance status or an active infection, chlorambucil may be a reasonable first-line treatment option. Another alternative is a 3-day schedule of fludarabine, which appears to be almost as active but has fewer associated toxicities.<sup>187</sup>

The major toxicities associated with fludarabine at the currently used schedules are moderate myelosuppression and severe immunosuppression, with occasional neurotoxicity, particularly at higher than recommended doses.<sup>74,192,193</sup> Lymphocyte counts decrease within weeks, particularly CD4 cells, which do not return to normal for 1 year or longer after treatment has been discontinued.<sup>74,166</sup> Fludarabine has not been found to be more myelotoxic but has been associated with more opportunistic infections than alkylating agent regimens.<sup>163,169</sup>

Tumor lysis syndrome is a rare complication of treatment of CLL with alkylating agents, radiation, combination chemotherapy, or fludarabine.<sup>194</sup>

Approximately 55% to 85% of patients who are treated with 2-CdA as their initial therapy respond to this agent, but only 10% to 15% achieve complete remissions, and the duration of response appears to be shorter than reported for fludarabine<sup>176,177,195</sup> (see Table 46.3.2-3). Data with pentostatin as initial therapy are insufficient to assess its level of activity<sup>161</sup> (see Table 46.3.2-3).

### COMBINATION REGIMENS

Combination regimens are not clearly superior to single-agent therapy for CLL.<sup>157,169,196,197,198,199,200,201</sup> and <sup>202</sup> The most commonly used multiagent regimens include chlorambucil plus prednisone (CP) or cyclophosphamide, vincristine, and prednisone (CVP). CP and CVP induce responses in fewer than 10% to more than 60% of previously untreated patients, although few of these responses are complete, and the median survival is shorter than 2 years.<sup>157,162,196,197</sup> and <sup>198,203</sup> The French Cooperative Group randomized 151 patients with Binet stage B CLL to indefinite daily oral chlorambucil and 140 patients to cyclophosphamide, Oncovin, and prednisone (COP). No difference was noted in response rate, reduction in clinical stage, or overall survival.<sup>204</sup>

More aggressive regimens that include multiple alkylating agents or anthracyclines also have not shown an advantage over less intensive programs.<sup>170,201,202,205,206</sup> One small randomized trial suggested a survival advantage for an attenuated CHOP regimen (including doxorubicin at 25 mg/m<sup>2</sup> every 4 weeks) over COP in a small number of patients with stage C disease.<sup>199</sup> Moreover, data from the same investigators suggest an advantage for CHOP over CAP.<sup>170</sup> However, several other randomized trials and a metaanalysis have not confirmed superiority for anthracycline-containing regimens.<sup>157,159,198,200</sup>

Combinations of fludarabine with chlorambucil, anthracyclines or related compounds, cytarabine, and IFN- $\alpha$  are not clearly better than fludarabine alone.<sup>163,207,208,209,210,211,212,213</sup> and <sup>214</sup> The addition of prednisone to fludarabine does not increase the response rate but is associated with more frequent opportunistic infections.<sup>72,75,166</sup> Preliminary encouraging data with combinations of fludarabine and cyclophosphamide have led to phase III studies.<sup>215,216</sup>

DCF has been combined with alkylating agents and steroids with high response rates but considerable toxicity.<sup>217</sup>

## SECOND-LINE THERAPY

Treatment decisions for relapsed and refractory patients should be based on criteria similar to those used for initial management.<sup>65</sup> Because therapy is palliative in this setting, treatment should not be initiated unless it is clearly needed.

Patients with CLL who relapse after or are refractory to initial treatment should be referred to a clinical trial. For patients who are not eligible for or are unwilling to participate in clinical research, salvage therapy is determined by the initial treatment and response to that treatment. Alkylating agents and fludarabine remain the most widely used drugs in this setting. Most other cytotoxic drugs have failed to show activity.<sup>218,219</sup>

Patients who initially respond to an alkylating agent can often be successfully retreated with that agent; however, the quality of the subsequent response and its duration are usually inferior to the initial treatment.<sup>196,201,205</sup> Response rates with multiple alkylating agents of anthracycline-containing regimens are significantly lower as second-line therapy, with few complete remissions.<sup>169,201,205</sup>

Fludarabine has become the standard agent for treating patients unsuccessful with alkylating agents.<sup>164,166,167</sup> and <sup>168,172,185,220,221</sup> Grever et al.<sup>164</sup> were the first to report activity for fludarabine in a series of 32 previously treated patients. Although they achieved only 3% complete responses and 9% partial responses, a large number of other patients experienced major clinical improvement. When current response criteria were applied, the overall response rate was 45%.<sup>65</sup> Keating and coworkers<sup>155,165,220,222</sup> reported 57% complete responses and 36% partial responses of 28 relapsed patients, and 28% complete responses and 10% partial responses of 50 refractory patients (63% of complete responses had residual lymphoid nodules in the bone marrow) (see [Table 46.3.2-3](#)). The median time to progression was 18 months for patients who were refractory to alkylating agents and 17 months for patients who had relapsed after prior treatment. Lower response rates and durability of response were noted in patients with advanced-stage disease, extensive prior therapy, and poor performance status.<sup>171,172</sup> When compared with CAP as second-line therapy,<sup>169</sup> fludarabine was associated with a significantly higher response rate as well as a longer remission duration and survival, although these differences were not significant.

Re-treatment with fludarabine is successful in one-half of those patients whose initial response to fludarabine lasted 1 year or longer.<sup>165,189</sup> On the other hand, few effective therapeutic options are available to patients whose disease is refractory to fludarabine.<sup>163,165</sup>

### **2-Chlorodeoxyadenosine**

In general, response rates with 2-CdA for relapsed and refractory patients are in the range of 30% to 40%, but with few complete remissions.<sup>160,174,177</sup> Saven et al.<sup>160</sup> reported 4% complete responses and 40% partial responses of 90 relapsed and refractory patients with CLL, with a median duration of response of 4 months (see [Table 46.3.2-3](#)). Variability in response rates among series reflect differences in drug administration schedule, patient selection, response criteria, and other factors.

2-CdA has limited activity in fludarabine failures.<sup>223,224</sup>

### **2'-Deoxycoformycin (Pentostatin)**

Almost one-fourth of alkylating agent failures respond to DCF, although few of these responses are complete or durable.<sup>161,181,183,184,193,225,226</sup> and <sup>227</sup> (see [Table 46.3.2-3](#)).

A few reports of combinations of DCF with other cytotoxic or biologic agents in CLL in relapsed patients have been published.<sup>217,228</sup>

## OTHER CHEMOTHERAPY AGENTS

Despite the lack of single-agent data for cisplatin and cytarabine, these drugs have been incorporated into multidrug regimens, although their contribution to those regimens is unclear.<sup>229,230</sup> and <sup>231</sup> Theophylline appears to synergize with chlorambucil in vitro in inducing apoptosis and has shown clinical activity.<sup>232,233</sup> and <sup>234</sup>

Several newer agents are currently under investigation in CLL. Compound GW506U78, a prodrug for ara-G, is a new nucleoside analogue with impressive activity in a variety of hematologic malignancies.<sup>235</sup> Responses have been reported in patients with chronic B-cell and T-cell leukemias, even after failure with fludarabine and alkylating agents.<sup>236,237</sup> Interest in the use of arsenicals in CLL stems from several preclinical studies suggesting that arsenic induces apoptosis of malignant lymphocytes at clinically achievable doses.<sup>238,239</sup> The protein kinase C inhibitors bryostatin and UCN-01, the cyclin inhibitor flavopiridol, and the histone deacetylase inhibitor depsipeptide are being evaluated as single agents and in combinations.<sup>240,241,242,243</sup> and <sup>244</sup> A variety of in vitro observations suggest a potential role for antiangiogenesis agents.<sup>245</sup>

## BIOLOGIC THERAPY

### **Interferon- $\alpha$**

IFN- $\alpha$  has limited activity in CLL, with transient partial responses in patients with limited-stage disease.<sup>246,247,248</sup> and <sup>249</sup> Preliminary data suggesting benefit for IFN maintenance after a response to induction chemotherapy with alkylating agents<sup>246</sup> were not confirmed in studies with fludarabine.<sup>250,251</sup>

### **Monoclonal Antibodies**

Early studies with monoclonal antibodies targeting CD5 did not show adequate activity to pursue in larger trials.<sup>252,253</sup> and <sup>254</sup> However, several newer antibodies have shown considerable promise.

The CAMPATH-1H monoclonal antibody recognizes the CD52 antigen, which is present on B cells as well as T cells. This antibody has shown impressive activity against both in CLL and PLL.<sup>255,256,257,258</sup> and <sup>259</sup> Responses occur in approximately one-third of patients who have been unsuccessful with other treatments, including fludarabine.<sup>260</sup> This agent appears to be more active against peripheral blood and bone marrow involvement than nodal disease.

Rituximab (Rituxan) is an anti-CD20 antibody C2B8 with major activity against follicular lymphomas.<sup>261</sup> However, its activity using the recommended dose and schedule has not been impressive in patients with small lymphocytic leukemia or CLL, with response rates in the range of 10% to 15% and no complete remissions.<sup>261,262,263,264</sup> and <sup>265</sup> This lack of activity may reflect the dim expression of CD20 on CLL cells. Attempts are being made to improve on this activity by increasing the dose, altering the schedule of administration, or augmenting CD20 expression.<sup>264,266,267</sup> and <sup>268</sup> Rituximab may sensitize tumor cells to chemotherapy agents, and combinations of the antibody with fludarabine are in development. Patients with CLL who are treated with this antibody are at risk for potentially life-threatening toxicities characterized by cytokine release syndrome or rapid tumor clearance.<sup>264,269</sup>

The development of antibodies conjugated to radioisotopes, such as iodine 131 or yttrium 90, will be more difficult because of concerns that antibody localization in the bone marrow results in significant myelotoxicity.<sup>270,271</sup>

thrombocytopenia (fewer than 100,000 cells per mm<sup>3</sup>, 53%), anemia (hemoglobin less than 12 cells per dL, 71% to 77%), and neutropenia (absolute neutrophil count less than 500 cells per mm<sup>3</sup>, 32% to 39%).

The hairy cells generally have an eccentric, spongiform kidney-shaped nucleus, with characteristic filamentous cytoplasmic projections. Bone marrow biopsy is generally required to make the diagnosis, because the aspirate is often not obtainable. The malignant cells are of B-cell origin, expressing CD19, CD20, and the monocyte antigen CD11c. Perhaps the most specific marker is CD103. It is most difficult to distinguish HCL from HCLv; the latter is often associated with a high circulating white blood cell count, cells containing bilobed nuclei with prominent nucleoli, and a typical bone marrow histology with interstitial infiltration of clumped cells.<sup>299</sup> An important distinguishing, almost diagnostic, feature is the resistance of this disease to treatment with IFN- $\alpha$ , cladribine, and pentostatin.<sup>299</sup>

HCL may be an indolent disorder, and 10% of patients may never require treatment. In most patients, however, treatment is eventually warranted because of massive or progressive splenomegaly, worsening blood counts, recurrent infections, more than 20,000 hairy cells per  $\mu$ L of peripheral blood, or bulky lymphadenopathy. Until the early 1980s, splenectomy was the standard treatment for HCL. In most patients, this procedure improves symptoms related to splenomegaly and peripheral blood counts, often for prolonged periods, but it does not affect the disease itself. Splenectomy now plays a minor role in the management of HCL and is reserved for the rare patient who is refractory to treatment and has splenomegaly that is either symptomatic or is resulting in cytopenias.

The first systemic therapy to demonstrate activity in HCL was IFN. At doses of  $2 \times 10^6$  U/m<sup>2</sup>/d or  $3 \times 10^6$  U three times per week, IFN produces responses in 80% of patients; however, only 10% of these are complete responses. Although responses generally occur within 3 to 4 months, it may take more than 1 year of therapy to achieve the maximal response. The leukemia invariably recurs after IFN therapy is discontinued, and maintenance therapy is associated with excessive toxicity and expense without any apparent survival benefit. Many patients who recur will again respond when retreated. IFN is associated with flu-like symptoms (fevers, myalgias, malaise) in almost all patients. Other toxicities include rash; application site disorders; and gastrointestinal symptoms, with nausea, vomiting, and anorexia. Reduced doses are associated with less toxicity but lower response rates.

The purine analogues have revolutionized the treatment of patients with HCL.<sup>300,301</sup> In 1984, Spiers et al.<sup>302</sup> first reported complete responses in patients with HCL treated with pentostatin. DCF at doses of 4 mg/m<sup>2</sup> intravenously every other week for 4 to 6 months achieves complete responses in 60% to 89% of previously treated or untreated patients, including those who have been unsuccessful with IFN, with overall response rates of 80% to 90%. Moreover, only 25% of patients have relapsed with more than 5 years of follow-up. In an intergroup trial, 350 previously untreated patients with HCL were randomized to IFN or DCF; the complete response rate was approximately 11% for IFN compared with 76% for DCF, with a significant advantage to DCF in the durability of response.<sup>300</sup>

In 1990, Piro et al.<sup>301</sup> reported 11 complete responses of 12 patients with HCL who had received a single 7-day continuous infusion of 2-CdA. Numerous studies have now confirmed that the original schedule or a 2-hour infusion for 5 to 7 days achieves responses in 80% to more than 90% of patients, including 65% to 80% complete remissions. These responses tend to be durable, with 20% to 30% of patients relapsing with prolonged follow-up. Relapse can be predicted by the demonstration of minimal residual disease using sensitive immunohistochemical methods.<sup>303</sup> In many cases, relapse is characterized only by an increase in bone marrow hairy cells, with no indication for treatment. Most patients who require re-treatment achieve a second durable response.

The results with DCF are equivalent to those with 2-CdA. However, the shorter duration of treatment makes 2-CdA somewhat more attractive, although no advantage exists with regard to toxicity.

New monoclonal antibodies have shown promise for patients with HCL who are unsuccessful with purine analogue therapy or for those with HCL.<sup>304,305</sup>

## NON-HODGKIN'S LYMPHOMA IN A LEUKEMIC PHASE

Patients with NHL may present with or subsequently develop a leukemic picture,<sup>306,307</sup> most commonly those with a follicular small-cleaved cell histology, MCL, or marginal zone lymphoma. Although morphologic differences exist among these cells, immunophenotyping is necessary to distinguish among these entities.<sup>66</sup> Follicular NHL in a leukemic phase is characterized by cells that are small, with clefts and little or no visible cytoplasm, called *buttock cells*. These cells strongly express slg, are positive for FMC7, CD22, and CD10, and are negative for CD5 and CD23.<sup>17,66</sup> The leukemic manifestation of MCL is characterized by a mixture of small- to medium-size lymphocytes with nuclei that are generally cleaved but may be nearly round, leading to a misdiagnosis of CLL or PLL and small lymphocytic leukemia. MCL cells also express CD5, but in contrast to CLL cells, they strongly express slg but not CD23.<sup>66</sup>

Leukemic follicular small-cleaved cell lymphomas and mantle zone lymphomas have a median survival rate of 2.0 to 3.5 years and 2 years, respectively, whereas those derived from a large cell NHL have a median survival of only 1 to 3 months. Patients tend to respond poorly to therapy, including aggressive regimens such as CHOP. Anecdotal reports suggest activity for fludarabine in leukemic forms of low-grade NHL.

Splenic lymphoma with villous lymphocytes is a marginal-zone NHL that generally presents with significant splenomegaly, often with circulating cells exhibiting villous projections.<sup>308,309</sup> The diagnosis may not be apparent until the spleen is examined histologically after splenectomy. The malignant cells are larger than CLL cells and often contain a prominent nucleolus. They tend to stain positively for acid phosphatase, which is not tartrate resistant and which distinguishes them from HCL. The cells express B-cell markers, including CD19, CD20, CD22, Slg, and FMC-7. In contrast to CLL, they are negative for CD5 and CD23. Anemia and thrombocytopenia are common. A small concentration of an IgG or IgM monoclonal gammopathy can be detected in either the serum or urine from most cases. Fludarabine is active in this disorder.<sup>310</sup>

## CHRONIC T-CELL LEUKEMIAS

The mature (postthymic) T-cell leukemia disorders consist of large granular lymphocytic leukemia (LGL), T-PLL, adult T-cell leukemia/lymphoma, and the Sézary syndrome. The chronic T-cell leukemias are a heterogeneous group of rare disorders that differ significantly from B-CLL with respect to their immunophenotype, virology, biology, morphology, and response to therapy. The term *T-cell CLL* is no longer used in current classification systems.<sup>66</sup>

### Large Granular Lymphocytic Leukemia

LGL is the most common chronic T-cell leukemia.<sup>311</sup> The etiology of this clonal disorder is unknown. It is often diagnosed in the setting of an incidental T-cell lymphocytosis with more than 2000 circulating T cells per  $\mu$ L. The peripheral blood lymphoid cells demonstrate characteristic azurophilic granulation. Monoclonal antibodies directed against the V-gene region of the T-cell receptor gene and the p58 family on NK cells may help make the diagnosis.<sup>312</sup>

Proliferations of LGL may be either CD3+ (T-LGL) or CD3- (NK-LGL). Approximately 95% are CD4-/CD8+, although some cases may be CD4-/CD8-. T-LGL is the most common of these entities and occurs more often in women, with a median age of 57 years. Physical examination is notable for splenomegaly. Neutropenia is common and may be severe, with recurrent infections in 40% of patients. Peripheral blood NK cells are often decreased in numbers. The bone marrow is involved in almost all patients. There is a 30% incidence of rheumatoid arthritis, often with Felty's syndrome. Polyclonal hypergammaglobulinemia, rheumatoid factor, antinuclear antibodies, and circulating immune complexes are often present.<sup>313</sup> Pure red blood cell aplasia also has been reported. More than two-thirds of cases eventually require therapy, primarily because of recurrent infections. Responses may be achieved with alkylating agents, corticosteroids, or cyclosporine A. DCF and 2-CdA have shown activity.<sup>314,315</sup> Splenectomy is generally not associated with long-term benefit.

Disorders associated with an increase in NK cells form a spectrum, from more indolent NK-cell lymphocytosis to an aggressive NK-LGL leukemia/lymphoma. Chronic NK-cell lymphocytosis is a clonal disorder characterized by a sustained increase in cells with a CD3-/CD16+/CD2-/CD8+ phenotype.<sup>316</sup> The bone marrow is usually involved. The median age of patients with NK-LGL is 60 years, and the disease appears to be more common in men. Most patients note constitutional symptoms, but lymphadenopathy or splenomegaly are not common at presentation. Associated diseases include pure red blood cell aplasia and vasculitis syndromes. The outcome is similar to that of T-LGL. However, vasculitis and cytopenias may be life-threatening. Cyclophosphamide may be effective in controlling the vasculitis syndrome.<sup>316</sup> NK-LGL leukemia/lymphoma is an aggressive disease characterized by constitutional symptoms and splenomegaly. Response to therapy is poor, and the median survival rate is only a few months.

### T-Cell Prolymphocytic Leukemia

T-PLL is characterized by massive splenomegaly, lymphadenopathy in 40% of patients, and skin infiltration in 20%.<sup>317</sup> The presenting white blood cell count often exceeds 100,000 cells per  $\mu\text{L}$ . The malignant cells generally express CD3, CD4, CD5, and CD7, but are negative for CD8– and CD25–, although one-third of cases are CD4+/CD8+ or CD4–/CD8+. There are no apparent clinical differences among these subsets. A consistent abnormality of chromosome 14 has been reported with two breakpoints at 14q11 and 14q32.<sup>317</sup>

The prognosis of T-PLL is poor, with a median survival of 7 months. The purine analogues are active agents; DCF has achieved complete responses in up to 10% of patients, with partial responses in one-third.<sup>296,314</sup> Response rates of more than 70% have been reported in small series with CAMPATH-1H in T-PLL, including almost 60% complete responses.<sup>256</sup>

### Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma occurs most commonly in patients from the Caribbean and southwestern islands of Japan.<sup>318</sup> This uncommon lymphoid malignancy is associated with infection with human T-cell leukemia virus type 1. The immunophenotype of the malignant cells includes CD2+, CD3+, CD5+, CD4+, CD8–, CD25+/, and CD56/57–. The disease exhibits a clinical spectrum ranging from an indolent disease that may not require treatment for several years to an extremely aggressive disease characterized by anemia, hypercalcemia, bone lesions, splenomegaly, skin infiltration, central nervous system involvement, opportunistic infections, circulating leukemia cells, and a very poor outcome.<sup>319,320</sup> DCF has been used with modest success.<sup>321,322</sup>

### Sézary Syndrome

One-third of patients with mycosis fungoides will have circulating malignant cells at diagnosis. The peripheral blood of patients with skin patches may reveal circulating cerebriform cells in 0% to 22%, in 9% to 30% of those with plaques, in 27% to 50% with skin tumors, and in 90% to 96% of those with erythroderma. The presence of circulating cells may be an independent negative prognostic factor. Treatment of this disorder is discussed in [Chapter 45.4](#).

## INTRODUCTION

Plasma cell neoplasms represent a spectrum of diseases characterized by clonal proliferation and accumulation of immunoglobulin-producing cells that are terminally differentiated B cells. The spectrum includes clinically benign conditions, such as monoclonal gammopathy of unknown significance (MGUS) and rare disorders such as Castleman's disease and a heavy-chain disease; indolent conditions such as Waldenström's macroglobulinemia; the more common malignant entity, plasma cell myeloma, a disseminated B-cell malignancy; and a more aggressive form, plasma cell leukemia, with circulating malignant plasma cells in the blood. All of these disorders share common features in the form of plasma cell morphology, production of immunoglobulin molecules, and immune dysfunction. A plasma cell neoplasm is considered to originate from a single B cell, with resultant monoclonal protein secretion that characterizes its type. Occasional oligoclonal or polyclonal protein abnormalities are observed in conditions such as Castleman's disease. Current laboratory data based on complementarity determining region III (CDRIII) confirm the monoclonal origin of this disease.<sup>1</sup>

There are five major classes of immunoglobulin synthesized by normal B cells and plasma cells: IgG, IgA, IgM, IgD, and IgE. The dysfunctional plasma cells secrete one of these molecules or, in some instances, produce only k or l light chain molecules.<sup>2,3 and 4</sup> Usually, intact immunoglobulin molecules are secreted by the plasma cells; however, there may be a discrepancy in the production of the heavy and light chains leading to an imbalance, with an excess of free light chain that is excreted in the urine (Bence Jones proteinuria). Occasionally, plasma cells do not secrete any paraproteins (nonsecretory type myeloma); however, they usually have cytoplasmic immunoglobulin and produce low levels of immunoglobulins undetectable by current methods. Although myeloma can be associated with any of the immunoglobulin subtypes, the IgM type is predominately associated with other malignant conditions such as Waldenström's macroglobulinemia and chronic lymphocytic leukemia (CLL).

The clinical manifestations of plasma cell dyscrasias range from total absence of any symptoms in subjects with MGUS to formation of tumors, paraproteinemia, hypogammaglobulinemia due to decreased levels of the uninvolved immunoglobulins, bone disease, especially osteolytic lesions, hematopoietic and immune dysfunction, kidney function abnormalities, and infectious problems. These clinical manifestations are the result of a variety of pathogenic mechanisms, including cytokine production by the tumor or by the microenvironment, effect of the tumor mass itself, the deposition of the M protein into various organs, suppression of the T- and B-cell functions, and occasionally autoimmune disorders.

## HISTORY

The earliest evidence of myeloma has been reported from the Egyptian mummies; however, the first published clinical description of the disease was reported in 1850 in England. A patient, Thomas Alexander McBean, presented with symptoms of episodes of fatigue, diffuse bone pain, and urinary frequency to Dr. William Macintyre of London in 1845. The urinalysis test results detected a urinary protein with the heat properties often observed for urinary light chains and McIntyre called it "mollities and fragilitas ossium" based on the patient's bony symptoms.<sup>5</sup> Later that year, Dr. Henry Bence Jones also tested urine specimens provided by Macintyre and corroborated the heat properties of urinary light chains. Bence Jones thought that the protein was the "hydrated deuterioxide of albumin" (now called *Bence Jones proteins*) and published his findings several years before Macintyre published his case report.<sup>6</sup> Bence Jones also emphasized the potential importance of looking for this urinary protein in other cases with mollities ossium. After the patient died in 1846, a surgeon, Dr. John Dalrymple, examined several bones and made gross and microscopic observations.<sup>7</sup> His drawings are consistent with morphology of myeloma cells.

The term *multiple myeloma* was coined by Rustizky in 1873 following his independent observation in a similar patient with multiple bone lesions.<sup>8</sup> Kahler in 1889 published a review on this condition and the disease became known, particularly in Europe, as Kahler's disease.<sup>9</sup> Ellinger, in 1899, described the increased serum proteins and sedimentation rate in myeloma.<sup>10</sup> In 1900, Wright described the involvement of plasma cells in this neoplasm instead of original belief of its origin from the red marrow and for the first time he used roentgenographic abnormality in myeloma, which to date remains one of the diagnostic tests.<sup>11</sup>

The development of bone marrow aspiration in 1929,<sup>12</sup> electrophoresis to separate serum proteins in 1937,<sup>13</sup> and a later report of a specific spike in the g globulin region<sup>14</sup> enhanced the diagnosis and understanding of myeloma. Identification of the heavy and light chains in the monoclonal protein by immunoelectrophoresis was described by Grabar in 1953, confirming the monoclonality of immunoglobulin in this disease.<sup>5</sup> Other developments from 1960s to 1980s include a staging system,

role of several cytokines such as interleukin-1 (IL-1) and IL-6, and significance of chromosome 13 changes in myeloma.

No effective systemic therapy existed before 1947, when urethan was reported to show initial results in a few patients.<sup>16</sup> However, a subsequent randomized trial indicated that the survival of patients receiving urethan was inferior to that observed with a placebo.<sup>17</sup> The first successful use of chemotherapeutic agent in myeloma was reported in 1958 by Blokhin and colleagues with the use of a racemic mixture of  $\alpha$ - and L-phenylalanine mustards (Sarcodyline). Subsequently, the  $\alpha$ - and L-isomers of phenylalanine mustard were tested separately, and the antimyeloma activity was found to reside in the L-isomer, melphalan. In 1962, Bergsagel and colleagues of the Southwest Oncology Group reported remissions in approximately one-third of myeloma patients with melphalan.<sup>18</sup> Administration of high doses of the glucocorticoid was first reported to induce remissions in relapsing or refractory myeloma in 1967.<sup>19</sup> The use of melphalan in combination with prednisone was then studied extensively.<sup>20</sup> The role of high-dose therapy was investigated by McElwain and Powles in 1984, and addition of bone marrow transplantation with improved safety and further dose escalation was reported in 1986 by Barlogie et al.<sup>21,22</sup> Since then, numerous developments have taken place including activity of tandem transplant and the role of bisphosphonates and thalidomide.

## EPIDEMIOLOGY

According to the most recent data from the Surveillance, Epidemiology, and End Results program, multiple myeloma is a relatively uncommon malignancy in the United States, representing 1.0% of all malignancies in whites and 2.0% in African Americans. Among hematologic malignancies, it constitutes 10% of the tumors and ranks as the second most frequently occurring hematologic cancer in the United States after non-Hodgkin's lymphoma. At any one time, the prevalence of myeloma is around 40,000 and approximately 14,000 new patients are diagnosed each year, with 11,000 people dying each year from myeloma. The disease is more common in men and has average annual age-adjusted (1970 U.S. standard) incidence rates per 100,000 among whites of 4.7 in men and 3.2 in women, whereas for African Americans the incidence is 10.2 in men and 6.7 in women. The increased incidence in African Americans is not explained by factors such as social or economic condition, household size, or family income.<sup>23</sup> The incidence data for other ethnic groups including native Hawaiians, female Hispanics, American Indians from New Mexico, and Alaskan natives also show higher myeloma rates relative to U.S. whites in the same geographic group; however, the Chinese and Japanese populations have a lower incidence than whites. The incidence of multiple myeloma has slowly increased in the U.S. white population since 1970; however, the incidence among African Americans has increased more prominently during the 1970s, 1980s, and 1990s.

The incidence of myeloma and other plasma cell disorders increases with advancing age. The median age of onset is 68 years. The mortality pattern also closely follows the incidence curves for age distribution with median age at death in men of 70 years and women of 71 years. As seen in [Figure 46.4-1](#), fewer than 2% of patients are younger than 40 years, whereas more than 40% of the patients are older than 70 years.<sup>24</sup> A similar age distribution is also observed in other related plasma cell disorders including MGUS and Waldenström's macroglobulinemia.

**FIGURE 46.4-1.** Multiple myeloma average annual age-, sex-, and race-specific incidence per 100,000 in the United States, 1992 to 1996. Increase in incidence is noted with advancing age, and higher incidence is observed in male than female subjects and in African American than white populations.

## ETIOLOGY

### ENVIRONMENTAL EXPOSURE

Exposure to ionizing radiation is the strongest single factor linked to an increased risk of multiple myeloma.<sup>25</sup> This has been documented in atomic bomb survivors with a five times greater incidence than the control group and a latent period of approximately 20 years from exposure.<sup>26</sup> People exposed to low levels of radiation also demonstrate an increased incidence of myeloma, including radiologists, people employed in the nuclear industry, or those handling radioactive materials.<sup>27</sup> An increase in myeloma risk with increasing numbers of diagnostic radiographs was demonstrated without an increased risk of leukemia or lymphoma, suggesting that even a low level of radiation may be a risk factor for myeloma. An association between exposure to various chemicals and the risk of multiple myeloma remains ill defined. Exposure to metals, especially nickel; agricultural chemicals; benzene and petroleum products; other aromatic hydrocarbons; and silicon have been considered as potential risk factors.<sup>25,28,29,30,31,32</sup> and <sup>33</sup> Alcohol and tobacco consumption has not been clearly linked to myeloma. Among medications, only mineral oil used as a laxative has been reported to be associated with an increased risk of multiple myeloma in some patients.<sup>34,35</sup>

Hereditary and genetic factors may predispose to myeloma development.<sup>36,37</sup> Among 37 families with at least two family members who had myeloma, occurrence among siblings was reported in 25 of the families. However, direct genetic linkage has not been established.<sup>38</sup> Myeloma risk also appears to be enhanced by the presence of HLA-Cw2 in both African American and white populations.

MGUS has been considered a premalignant condition; however, the rate of conversion to myeloma remains extremely small and often associated with additional genetic changes.<sup>39,40</sup> Repeated infections or antigenic stimulation of the plasma cell compartment has also been proposed as a possible predisposing condition for myeloma. In one interesting patient report in the literature, a prior therapy with horse antiserum against tetanus lead to subsequent development of MGUS, which lasted for three decades before conversion to multiple myeloma. At the time of myeloma diagnosis, the serum IgG component was found to react specifically against horse  $\alpha_2$ -macroglobulin.<sup>41</sup> This report suggests an initial antigen-driven stimulation of monoclonal protein-producing plasma cells, eventually becoming malignant after acquiring additional genetic alterations.<sup>42</sup>

Epidemiologic studies have not been able to conclusively establish an association between multiple myeloma and infectious or autoimmune diseases. The human herpes virus (HHV-8; Kaposi's sarcoma herpes virus) has been shown to be present in the bone marrow dendritic cells of the majority of patients with multiple myeloma.<sup>43,44</sup> Its association with other lymphoproliferative diseases, such as Castleman's disease,<sup>45</sup> body cavity lymphoma,<sup>46</sup> and Kaposi's sarcoma,<sup>47</sup> has been previously demonstrated. Although this association has been reported by some,<sup>44,48,49</sup> others have failed to identify HHV-8 in dendritic cells from various sources including mobilized peripheral blood stem cells.<sup>50,51,52,53,54,55,56,57,58,59,60,61</sup> and <sup>62</sup> In the initial report, 100% of myeloma patients demonstrated evidence of ORF26 sequences in dendritic cells, compared with zero in normal controls. However, one study reports that 60% of 30 myeloma samples were positive for ORF26, with 44% of 25 normal controls demonstrating positive results. This study also failed to show positivity for the viral genes ORF72 and 75 in both myeloma and control samples.<sup>49</sup> Antibodies against HHV-8 have not been observed in multiple myeloma. Since HHV-8 produces unique gene products, including possible growth-promoting factors for myeloma such as IL-6, insulin-like growth factor-1, and an IL-8-like molecule, the possible linkage of HHV-8 to myeloma is intriguing, with infection of the stromal cell elements, part of the tumor microenvironment, exerting cell survival or antiapoptotic signals on the tumor cells.<sup>63,64</sup>

## PATHOGENESIS

Myeloma occurs not only in humans, but also in mice, canines, and hamsters. In fact, genetic susceptibility to plasma cell tumors has been demonstrated in an inbred strain of mice. A common factor in various species has been considered to be the prevalence of endogenous retroviruses.<sup>65,66</sup> Animal models are now providing a basis for understanding the role of various molecular events, including the activation of oncogenes, tumor suppressor genes, and various cytokines, and the role of

the microenvironment not only in causing bone destruction but sustaining and promoting growth, survival, drug resistance, and genetic instability.

## MURINE MODEL

C57BL/Ka strains of inbred mice spontaneously develop monoclonal gammopathies without tumor formation in 16% of the mice by 2 years.<sup>65,67,68</sup> Other strains, such as BALB/c, have a low spontaneous incidence of monoclonal gammopathies. In BALB/c mouse, however, induction of plasmacytoma or myeloma is easily observed after intraperitoneal injection of mineral oil or its clinically defined component, pristane.<sup>65</sup> Production of such tumors can be blocked by administration of indomethacin and accelerated by subsequent infection of the mice with Abelson's virus. The plasmacytomas develop within the oil or other foreign body-mediated granulomas with lymphoplasmacytic infiltration. Plasmacytoma progression is associated with dysregulated expression of c-MYC as a result of translocation analogous to t(8;14) in humans. These plasmacytomas produce IgA immunoglobulins, and a growth factor present in the peritoneal fluid has been confirmed to be IL-6. Interestingly, however, the C57BL/Ka strain with a high incidence of spontaneous monoclonal gammopathies is relatively resistant to induction of plasmacytoma by mineral oil.

An association between antigenic stimulation of normal B cells and development of plasmacytoma has been demonstrated in the pristine oil-treated BALB/c mouse model. When animals are raised in a germ-free environment, incidence of myeloma after mineral oil stimulation is markedly reduced, whereas that of other lymphoid neoplasms increases.<sup>65</sup> These studies suggest an important role of immune stimulation toward myeloma development.

Human myeloma cell lines can grow and disseminate in a severe combined immunodeficiency (SCID) mouse model, providing a unique opportunity to study this disease in an *in vivo* setting.<sup>69,70</sup> and <sup>71</sup> The introduction of fetal human bone into SCID mice (SCID-Hu) has allowed engraftment and proliferation of primary human myeloma cells in more than 80% of mice with human myeloma-specific immunoglobulin and light chains detected in murine blood samples.<sup>72,73</sup> In this murine model of primary human disease, the fetal bone undergoes osteoporotic and osteolytic change as a consequence of clonotypic plasma cell proliferation and production of human cytokines.<sup>74</sup> Interestingly, the murine bones remain uninvolved at least in the early stages of the disease. This model provides a unique opportunity to study the importance of stromal cell–myeloma cell interaction and the cytokines, chemokines, and various genetic and molecular mechanisms critical for myeloma growth and dissemination. This model also can provide clues to the origin of myeloma stem cells, as well as the opportunity to evaluate new treatment approaches, such as antiangiogenesis therapy.

## CYTOGENETIC AND MOLECULAR GENETIC ALTERATIONS

Myeloma karyotypes are complex, with an average of 11 numeric and structural abnormalities per cell.<sup>75,76</sup> and <sup>77</sup> The relative incidence of gain or loss of various chromosomes and its p and q arm are shown in Figure 46.4-2. The inherent problem in the low proliferative activity of the tumor cells and possible clonal evolution have been obstacles to identify specific chromosomal and molecular changes in myeloma. However, the newer techniques of multicolor fluorescent *in situ* hybridization (FISH) and spectral karyotyping along with refined G-banding techniques in a large number of patients have identified many nonrandom changes.<sup>78,79</sup>

**FIGURE 46.4-2.** Summary karyotypic abnormalities in 158 patients with evaluable abnormal cytogenetics from study of 492 patients demonstrating *chromosomal chaos*. **A:** Numeric changes with trisomies (gain) and monosomies (loss). **B:** Structural changes involving short (p) and long (q) arms. (Courtesy of Jeffery R. Sawyer.)

Partial or complete deletion chromosome 13 q arm confers a poor prognosis, even with high-dose therapy, and suggests a putative tumor suppressor gene.<sup>80</sup> Using the RB1 gene as a probe, FISH analysis reveals RB-1 deletion in more than 40% of these patients.<sup>81</sup> On detailed analysis of the 13q chromosome with a 11 probe panel of FISH probes, more than 80% of 50 patients showed molecular deletions, with 13q14 representing a critical region most frequently involved.<sup>82</sup> Additionally, constitutive phosphorylation of pRB is reported in myeloma cells, which is further enhanced by IL-6.<sup>83</sup> Cyclin D, cyclin-dependent kinases (CDK) and CDK inhibitors p15 and p16 (ink), p21 and p27 (cip), and p57 (kip) have also been investigated in myeloma based on their effect on pRB phosphorylation. Abnormalities in p16 in 75% and p15 in 67% of myeloma patients have been reported, suggesting an important defect in the pRB regulatory pathway.<sup>84,85,86</sup> and <sup>87</sup>

The immunoglobulin heavy-chain gene at 14q32 is involved in translocation in 20% to 30% of myeloma by conventional cytogenetics and higher percentage by molecular techniques.<sup>75,76,88</sup> Demonstration of this abnormality in MGUS may suggest its involvement in the initial step of the transformation.<sup>89</sup> The most common translocation involving 14q32 is t(11;14), resulting in overexpression of cyclin D.<sup>88,90</sup> Additional interesting partners are 4p, 16q, and chromosome 9. Involved in the 4p16 region are fibroblast growth factor receptor III (FGFR3) and MMSET genes. Mutated FGFR3 has been shown to confer resistance to caspase 3–related apoptosis.<sup>91,92</sup> With the help of spectral karyotyping a nonrandom involvement of t(14;16) (q32;q22-23) has been described. Molecular analysis of the locus at chromosome 16q22 shows fusion of immunoglobulin heavy chain with the sequence near the cMAF oncogene.<sup>93</sup> Additionally, t(9;14) involving PAX5 gene and t(6;14) involving IRF4 genes have been described.<sup>94,95</sup> In the majority of the cases, however, the translocating partner chromosome locus is not identified. Although, 14q32 is one of the common translocation points, its real significance remains unclear in relation to myelomagenesis because of the variety of partner chromosomes involved and lack of prognostic implications.

One of the commonly altered genes in many malignancies is p53. However, in myeloma, abnormalities in p53 in early disease are detected in only 10% of patients.<sup>96,97</sup> and <sup>98</sup> However, it represents an important late event associated with progression to an aggressive form of the disease. A study of frequency of p53 gene mutations in a series of 52 patients with myeloma in different clinical phases showed 7 of 52 patients with abnormalities, all with an advanced and clinically aggressive acute leukemic form of multiple myeloma (7 of 16, 43%). Three of these cases with mutated p53 had been evaluated earlier during the indolent form of the disease and were negative for p53 mutations.<sup>96</sup> One study showed poor prognosis in patients with p53 gene deletion, as assessed by FISH when treated with standard-dose therapy.<sup>97</sup> The effect of p53 deletion in relation to high-dose therapy has not yet been evaluated. In contrast to primary patient samples, mutations in p53 are more commonly detected in myeloma cell lines, which are usually derived from patients with aggressive myeloma. MDM2, an important inhibitor of p53 function, is overexpressed in the majority of myeloma cell lines; however, its abnormality is infrequently observed in primary myeloma cells.<sup>99</sup> Changes in another important cell-cycle regulatory gene, c-myc, are also observed in a majority of patients in the form of either abnormal size transcript or high level of expression.<sup>100,101</sup>

An important antiapoptotic gene, BCL-2, is uniformly overexpressed in low-grade non-Hodgkin's lymphoma. In this family of genes, BCL-2 and BCL-XL are antiapoptotic genes, while BAX, BAD, and BCL<sub>XS</sub> are proapoptotic genes. A balance between these genes determines cell survival. The t(14;18) translocation involving the BCL-2 gene is quite rare (2% to 3%) in myeloma. However, numerous myeloma cell lines as well as primary cells express high levels of BCL-2.<sup>102,103</sup> Its relation with development of drug resistance as well as radiation resistance in myeloma cells is also well described.<sup>104,105,386</sup> The relation of BCL-2 expression and prognosis remains controversial as one small study failed to correlate it with short survival. Another study in 63 patients, however, showed a significant correlation between BCL-2 expression and resistance to therapy with interferon but not melphalan and prednisone.<sup>106</sup> BCL-XL is up-regulated in myeloma cells after exposure to IL-6 through activation of STAT-3.<sup>107,108</sup> It confers a drug-resistant phenotype and in conjunction with BCL-2 leads to increased genetic instability. These and other molecular changes involving gp130, NF-κB, and STATs combined lead to the development and progression of myeloma.<sup>109</sup>

High telomerase activity has also been demonstrated in myeloma cells compared with normal cells, as well as other malignant cell lines.<sup>110</sup> The clinical implication of

this activity remains under investigation; however, telomerase activity provides an additional target for therapeutic intervention.

## DISEASE EVOLUTION

Multiple myeloma is a germinal center-derived tumor with mainly a post-switch B-cell phenotype characterized by extensive Ig gene hypermutation in the CDRs, which interacts with the antigen. This is reflected in the exceedingly rare occurrence of IgM myeloma. Somatic mutations of other loci, such as BCL-6, have also been reported in the B cells along with the immunoglobulin gene rearrangement.<sup>111</sup> Similar mechanisms may also be affecting other cell-cycle control genes important for cell proliferation and malignant transformation.

As in most malignancies, pathogenesis of multiple myeloma appears to be associated with dysregulated expression and the function of multiple key cellular genes controlling apoptosis, cell growth, and proliferation. Understanding the evolution of myeloma from MGUS has provided a background for a multistep process involving alterations in various oncogenes and tumor suppressor genes. One report suggests the presence of 14q32 abnormalities in patients with MGUS and an additional chromosome 13 change, with a transformation to overt multiple myeloma.<sup>88</sup> This has led to a theory that a subset of myeloma may originate from prior MGUS with a high incidence of monosomy 13 and a second group of *de novo* myeloma in which other genetic abnormalities may be involved.<sup>89</sup>

## CYTOKINES

IL-6 is an important cytokine originally identified as a B-cell differentiation factor that causes proliferation of plasmablastic cells and induces terminal differentiation of B cells into antibody-producing cells. Several studies have confirmed its activity as an autocrine and paracrine growth factor for myeloma cell lines and primary cells.<sup>112,113,114</sup> and <sup>115</sup> Evidence supporting this includes *in vitro* myeloma cell growth in the presence of recombinant IL-6,<sup>83</sup> IL-6 production by some of the myeloma cells themselves,<sup>116</sup> expression of high levels of IL-6 receptors,<sup>112</sup> and suppression of *in vitro* myeloma cell proliferation by anti-IL-6 antibodies.<sup>117</sup> Close cell-cell contact between myeloma cells and the bone marrow stromal cells triggers a large amount of IL-6 production by stromal cells, which supports the growth of myeloma cells and protects them from apoptosis induced by dexamethasone or other chemotherapeutic agents.<sup>118,119</sup> Correlation has been reported between serum IL-6 levels or C-reactive protein (CRP) levels, an indirect measurement of IL-6 activity, and disease severity as well as extent of bone marrow plasmacytosis<sup>120</sup>; frequent lytic bone lesions; and some tumor-associated symptoms such as fever, fatigue, and weight loss. In addition, indirect evidence of the role of IL-6 in B-cell disorders is provided through IL-6 transgenic mice. These animals have a high incidence of polyclonal plasmacytosis. Transduction of the IL-6 gene in hematopoietic cells in mice leads to a disorder resembling Castleman's disease.<sup>121</sup> IL-6, however, is not an absolute requirement for myeloma cell growth as some of the myeloma cells do not proliferate in response to IL-6, nor do they require IL-6 for their continued growth. Therapy with anti-IL-6 antibody has also not provided significant clinical benefit.<sup>122,123</sup>

Expression by myeloma cells of IL-1b, tumor necrosis factor-b (TNF-b), and hepatocyte growth factor has been described, resulting in development of resistance to therapy, possibly through activation of NF-kB.<sup>124,125,126</sup> and <sup>127</sup> Myeloma cells express a variety of cytokine receptors that play a significant role in cell-cell interactions as well as autocrine and paracrine growth control. A majority of myeloma cell lines and primary cells express IL-6-related receptors gp80 and gp130.<sup>128,129</sup> Additionally, receptors are expressed for TNF-a, IL-11, IL-1, IL-2, IL-7, granulocyte-macrophage colony-stimulating factor (GM-CSF), stem cell factor, leukocyte inhibitory factor, oncostatin-M, and insulin-like growth factor-1 and -2.<sup>130,131,132,133</sup> and <sup>134</sup> These findings suggest that in addition to IL-6, interferon-g, IL-1, IL-2, IL-7, GM-CSF, TNF, and insulin growth factor have at least a direct biologic effect on myeloma cells.

The soluble cytokines can be used *in vitro* to expand the pre-B cells to mature plasma cell stage with cytoplasmic immunoglobulin expression. An important combination of cytokines in this regard is IL-6 and IL-3. However, secretion of immunoglobulin requires contact between marrow stromal cells and myeloma cells; this occurs through adhesion molecules on the surface of the myeloma cells and their counterparts on the stromal cell or extracellular matrix in the bone marrow.<sup>135</sup>

The role of angiogenesis in myeloma has been investigated, showing that advanced-stage myeloma is associated with high microvessel density in bone marrow compared with indolent myeloma or MGUS.<sup>136,137</sup> An association between increased bone marrow microvessel density at diagnosis with poor event-free and overall survival has also been reported.<sup>138</sup> Angiogenic factors such as vascular endothelium growth factor-1 (VEGF-1) and fibroblast growth factor are expressed by myeloma cells.<sup>139</sup> This observation has led to an evaluation of thalidomide as antiangiogenic therapy in myeloma with encouraging results.<sup>140</sup>

## ADHESION MOLECULES

Adhesion molecules, especially those expressed by myeloma cells and the bone marrow stromal cells, play an important role in mediating the interaction between the host and tumor cells to regulate tumor growth and migration of these cells *in vivo*. It is believed that after class switching in lymph nodes, myeloma cells home to the bone marrow through acquisition of a variety of adhesion molecules including syndecan-1 (CD138), CD44, very late antigen-4 (VLA-4) (CD49d) and VLA-5 (CD49e), lymphocyte function-associated antigen-1 (LFA-1), intracellular adhesion molecule-1 (CD54), neural cell adhesion molecule (NCAM) (CD56), and MPC-1.<sup>141,142</sup> The homing to the marrow leads to binding of myeloma cells to bone marrow stromal cells, which in turn mediates signal transduction events including IL-6 production by the stromal cells.<sup>72</sup> The adhesion molecules in the bone marrow that myeloma cells bind to, and require for their homing, include heparan sulfate proteoglycan, intracellular adhesion molecule-1, and vascular cellular adhesion molecule-1 (VCAM-1) on the bone marrow stromal cell, as well as fibronectin and type I collagen in the extracellular matrix.<sup>143,144,145</sup> and <sup>146</sup> With further progress of the disease, CD56 (NCAM), syndecan-1 (CD138), and VLA-5 are down-regulated; in the case of syndecan-1, this occurs in response to IL-6. Some of these changes may allow circulation of clonotypic plasma cells in blood. The acquisition of CD11b may also help in invasion and metastatic spread through its interaction with the endothelium. All plasma cells express CD38, which is a receptor for CD31, expressed on endothelial cells with potential implications for trafficking of myeloma cells through blood vessels. Interestingly, the majority of the plasmacytic myeloma cells, but not plasmablastic and plasma cell leukemia cells, have also been reported to express CD31.<sup>147</sup> Other than syndecan-1, matrix metalloproteinase (MMP), especially MMP-2 and MMP-9, have also been implicated in myeloma cell proliferation and spread.<sup>136,148,149</sup> Serum syndecan-1 levels are reflective of tumor burden as is hepatocyte growth factor.<sup>127,150</sup> *In vitro* and *in vivo* studies have documented a role of syndecan-1 in cell-cell and cell-matrix adhesion and in inducing myeloma cell apoptosis.<sup>144</sup> Syndecan-1 expressed by myeloma cell may also serve to trap the growth regulatory molecules such as fibroblast growth factor and insulin-like growth factor as well as angiogenic molecules, such as VEGF and fibroblast growth factor.<sup>149</sup> Expression of different adhesion and surface molecules on normal plasma cells, myeloma cells, and plasma cell leukemia cells are listed in [Table 46.4-1](#).

TABLE 46.4-1. Adhesion Molecule Expression on Normal Plasma Cells and Multiple Myeloma Cells

## PHENOTYPE

Myeloma cells display heterogenous phenotypes with differences in the molecules among different patients expressed on the cell surface as well as differences within the same patient at different disease stages.<sup>135</sup> In general, all myeloma cells express high levels of CD38 with immature plasma cell additionally expressing CD45 and the IL-6 receptor.<sup>116,151,152</sup> and <sup>153</sup> More mature myeloma cells do not express CD45 and lack the IL-6 receptor expression.<sup>154</sup> A subpopulation of myeloma cells may also express CD10, CD56, or CD49e (VLA-5).<sup>154,155,156</sup> and <sup>157</sup> CD28 expression is associated with more aggressive disease<sup>158,159</sup> and CD20 expression is present in 20% of

myeloma patients, which can be further up-regulated with interferon- $\alpha$ .<sup>160</sup> The phenotypic heterogeneity of myeloma cells in fact describes the differentiation process that is an important part of the disease development. The identity of the myeloma stem cell still remains an enigma. B cells expressing CD19 and CD11b can be induced to mature with the help of stromal cells into monotypic plasma cells, suggesting that this cellular compartment may comprise myeloma cell progenitors.<sup>161</sup> Using the allele-specific oligonucleotide PCR and the SCID-hu model, the myeloma stem cell will be better defined in the future.

## IMMUNOSUPPRESSION

Myeloma patients present with suppressed immune function from a variety of factors. The most significant observation is suppression of uninvolved immunoglobulins (e.g., in patients with IgG myeloma there is suppression of serum IgA and IgM levels).<sup>162</sup> The factors causing such suppression include the direct role of monoclonal immunoglobulin, increased soluble Fc-receptor or Fc-expressing cells, suppression of helper cell functions through the effect of monoclonal immunoglobulin, and an ill-defined macrophage-related factor that affects B-cell maturation to plasma cell.<sup>163</sup> Recovery of uninvolved immunoglobulin following effective therapy has been associated with improved survival as well as protection from infectious complications. In regard to T-cell function, deficiency of T<sub>4</sub> helper cell is most pronounced.<sup>164</sup> The total T-cell count may be decreased; however, in a substantial number of patients it could be normal with no significant change in CD8 cells.<sup>165,166,167</sup> and <sup>168</sup> There has been demonstration of a stage-dependent suppression of NK cells.<sup>169</sup> Antiidiotypic T-cell response has been demonstrated in the majority of the patients with higher Id-specific T-cell frequency in MGUS and early-stage myeloma compared with advanced disease.<sup>170</sup> This has led to a provocative hypothesis that in the early stage of the disease immunologic response plays an important role in controlling proliferation of the malignant clone, and at some point the system is overwhelmed or fails, leading to an overt or more aggressive form of the disease. This also provides a scientific basis to develop idiotype-specific T-cell response through vaccination or *in vitro* production of idiotype or myeloma-specific cytotoxic T lymphocytes for therapeutic purpose.<sup>171</sup>

## CLINICAL MANIFESTATIONS

Patients with multiple myeloma may be entirely asymptomatic and could be diagnosed on routine blood work or may present with a myriad of symptoms, including hematologic manifestations, bone-related problems, infections, various organ dysfunctions, neurologic complaints, or bleeding tendencies ( [Table 46.4-2](#)). These signs and symptoms result from direct tumor involvement in the bone marrow or location of various plasmacytomas in the body, the effect of the protein produced by the tumor cells and deposited in various organs, production of cytokines by the tumor cells or by the bone marrow microenvironment, and the effect on the immune system.

Symptoms	Common Cause
Bone pain	Pathologic fracture
Easy fatigability	Anemia
Polyuria	Hypercalcemia
Nausea and vomiting	Renal failure, hypercalcemia
Recurrent infections	Low uninvolved Ig, low CD4 count
Paraplegia	Cord compression
Confusion, central nervous system symptoms	Hyperviscosity or hypercalcemia
Neurologic symptoms	Nerve compression, amyloidosis, POEMS syndrome

POEMS, polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes.

**TABLE 46.4-2.** Clinical Features of Multiple Myeloma

## ANEMIA

A normochromic normocytic anemia is usually observed in myeloma patients and it may originate from tumor cell involvement in the marrow as well as inadequate erythropoietin responsiveness. Anemia gives rise to fatigue, weakness, and occasionally shortness of breath. In addition to the decreased production of red cells due to marrow infiltration, the effect of various cytokines on erythropoiesis and the effect of renal dysfunction on erythropoietin production may account for some of these effects. High immunoglobulin levels aggravate the anemia due to dilutional effects. In the Durie-Salmon staging system, the level of anemia is considered as one of the criteria to determine the tumor mass load.

## RENAL FAILURE

Nephropathy is one of the serious adverse complications that can be observed at the time of clinical presentation. The etiology of renal failure can be multifactorial. However, the most common cause is development of light chain tubular casts leading to interstitial nephritis (myeloma kidney).<sup>172</sup> Another common cause of renal dysfunction is development of hypercalcemia and hypercalciuria leading to osmotic diuresis and volume depletion and prerenal azotemia. Other modes of kidney involvement in myeloma are light chain deposition disease, which is more commonly associated with k light chain proteins with impaired glomerular filtration; and AL amyloidosis, which is more frequently associated with l light chain, especially l light chain subtype VI, and may have an initial presentation as nephrotic range proteinuria, and renal calcium deposition leading to interstitial nephritis.<sup>173,174,175</sup> and <sup>176</sup> The presence of l light chain in the urine is also more commonly associated with myeloma kidney when compared with k light chain. Bence Jones proteins bind to a common peptide segment of Tom-Horsfall glycoprotein to promote heterotypic aggregation.<sup>177,178</sup> and <sup>179</sup> Tom-Horsfall protein deposition in the kidney and its measurement in the urine may be a sensitive measure to predict renal dysfunction.<sup>180</sup> Additional factors complicating the renal failure in myeloma patients includes use of nonsteroidal antiinflammatory drugs for pain control, hyperuricemia, nephrotoxic chemotherapeutic agents, intravenous contrast for radiographic studies, and calcium deposition and stones in the kidney.<sup>181</sup> The proteinuria observed in patients with amyloidosis is more often nonspecific, which can help differentiate it from typical myeloma-related kidney problems in which patients have excessive light chain excretion.<sup>182</sup> A demonstration of the development of pathologic renal changes similar to human myeloma-related nephropathy in an IL-6 transgenic mice expressing IL-6 under metallothionein-1 promoter indicates a relationship between constitutive high IL-6 expression in the liver inducing dysproteinemia and long acute-phase response and renal changes.<sup>183</sup>

## HYPERCALCEMIA AND BONE DISEASE

The mechanism of bone abnormalities, especially destruction, in myeloma is an unbalanced process of increased osteoclast activity and suppressed osteoblast activity. These changes are exerted by an increase in osteoclast-activating factors produced predominantly by the bone marrow microenvironment but additionally contributed by the myeloma cells.<sup>126,184</sup> These factors include IL-1b, TNF-b (lymphotoxin), and IL-6.<sup>124,125,387</sup> Newly identified factors such as osteoprotegerin and its ligand TRANCE and RANK ligand, which acts as a decoy receptor for TRANCE, have been implicated in the development of bone changes in myeloma.<sup>185,186</sup> TRANCE is a member of the TNF family and was originally discovered to be secreted by T cells to induce maturation of dendritic cells. TRANCE is also secreted by stromal cells and osteoblasts and induces differentiation and maturation of osteoclast progenitors. Its production is elicited by factors such as parathyroid hormone, parathyroid hormone-related protein, and osteoclast-activating factors. Radiographic findings of such destruction are shown in [Figure 46.4-3](#).<sup>184,187</sup> All of these changes lead to the development of osteoporotic changes and subsequent development of lytic bone lesions. These bone changes frequently involve the vertebral column, leading to compression fracture and lytic bone lesions that lead to pain-related complications in this disease. A new onset of back pain or other bone pain is a frequent presenting symptom in myeloma patients. These changes in the cytokine milieu and bone destruction may also lead to development of hypercalcemia, which is observed in approximately 25% of patients at some stage of the disease. It may reflect a high tumor burden and the presence of symptoms related to high calcium, which include mental status changes, lethargy, constipation, and vomiting. High paraprotein levels, low albumin levels, or both, commonly observed in patients with myeloma require measurement of ionized calcium rather than total calcium to reliably diagnose hypercalcemia. Hypercalcemia also contributes to renal failure and should be considered an oncologic emergency requiring prompt intervention.

**FIGURE 46.4-3.** Biology of bone destruction in multiple myeloma (MM): 1. MM cells adhere to stroma. 2. Stromal cells secrete osteoclast-activating factors. 3. Osteoclast-activating factors elicit stroma and osteoblasts to secrete TRANCE. 4a. TRANCE is blocked by osteoprotegerin (OPG); OPG levels are reduced in MM due to syndecan trapping OPG. 4b. Excess TRANCE is available to stimulate osteoclast differentiation and maturation. 5. Increased osteoclastic activity leads to increased cytokine release from the bone matrix. 6. These cytokines stimulate MM cell growth, which increases process 1. 7. These cytokines also cause release of parathyroid hormone-related protein (PTHrP) from MM cells, which activates stromal cells to secrete additional TRANCE. FGF-1 and 2, fibroblast growth factor-1 and 2; IGF-1 and 2, insulin growth factor-1 and 2; IL, interleukin; PDGF, platelet-derived growth factor; TGF- $\beta$ , transforming growth factor- $\beta$ ; TNF- $\alpha$ , tumor necrosis factor- $\alpha$ . (Adapted from ref. 187.)

## INFECTIONS

Myeloma patients are at risk for developing recurrent bacterial infections due to deficiencies in both humoral and cellular immunity.<sup>163,188,189 and 190</sup> Various factors including high monoclonal immunoglobulin levels, soluble Fc receptor in serum, and transforming growth factor- $\beta$  lead to suppression of B-cell function, which in turn leads to depressed uninvolved immunoglobulins.<sup>191,192 and 193</sup> This impairment in patients' abilities to mount humoral responses predisposes patients to bacterial infections that are ordinarily opsonized by specific antibodies against the bacterial antigens. Patients also have profound T-cell dysfunction originating from various immunosuppressive cytokines such as transforming growth factor- $\beta$  secreted by the microenvironment and fas ligand present on the membrane of the myeloma cells. The therapy for myeloma, which frequently includes high-dose corticosteroids, also increases the infection-related risks in these patients.

## NEUROLOGIC SYMPTOMS

The most common cause of neurologic abnormalities is related to a tumor mass effect, especially compression of the spinal cord or cranial or spinal nerves. This may present as motor or, less frequently, sensory problems. Depositions of amyloids in the paraneural or *vasa nervorum* may lead to polyneuropathies. An interesting group of symptoms described as POEMS syndrome (*polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes*) is observed in osteosclerotic myeloma with prominent sensory neuropathy.<sup>194,195,196,197 and 198</sup> The biologic and cellular basis of these manifestations is not yet well understood. Leptomeningeal involvement in myeloma has been described, usually in the late phase of the disease and with manifestations involving the CNS.<sup>199,200</sup> Paraneoplastic CNS syndromes have also been described, possibly related to an immune mechanism directed at proteins present in the CNS including the cerebellum. Additionally, neurologic symptoms may occur as a consequence of hypercalcemia or hyperviscosity.

## HYPERVISCOSITY

The M components in myeloma can lead to circulatory problems when the serum immunoglobulin levels exceed certain levels. Such effects require sufficient concentration of an M protein; the incidence is highest in Waldenström's macroglobulinemia with IgM, followed by IgA myeloma, and is least common in IgG myeloma.<sup>201,202 and 203</sup> It can also be observed when the immunoglobulins have a self-aggregation property leading to increased viscosity. The syndrome is observed usually when serum viscosity exceeds 4.0 centipoise (cp) units relative to normal serum and it usually manifests with circulatory problems involving the CNS, kidneys, and pulmonary function and may also be associated with bleeding complications. Due to varying characteristics of idiotypes, the same level of increased viscosity may produce different severity of symptoms in different patients. Its incidence in IgA myeloma is 25% of the patients, whereas in IgG myeloma it is observed in less than 10% of the patients. In IgG myeloma, the IgG3 subclass is more commonly associated with hyperviscosity.<sup>204</sup> As prompt plasmapheresis can alleviate the symptoms and possibly other irreversible organ damage, a high level of suspicion for this syndrome is important in any patient with paraproteinemia and either mental changes or pulmonary distress.

## COAGULOPATHY

Myeloma patients may acquire coagulation abnormalities related to a high level of paraprotein interfering with the normal coagulation cascade or exhibit specific antibody activity leading to a clinical syndrome similar to acquired deficiency of factor VIII.<sup>205,206 and 207</sup> Additional factors such as thrombosis in capillary circulation associated with hyperviscosity and anoxia may lead to coagulation-related complications in 15% of patients with IgG myeloma and in more than 33% of the patients with IgA myeloma. Although platelet counts are not suppressed in the early stages of myeloma, functional abnormalities of platelets have been described and may contribute to bleeding-related problems.

Patients may also present in a hypercoagulable state related to acquired deficiencies in protein C, protein S, or lupus anticoagulants, leading to thromboembolic complications.<sup>208</sup>

The Fab fragment of the antibody of the myeloma protein binds to fibrin and may prevent its aggregation. This may represent one of the common mechanisms of coagulopathy in myeloma.<sup>209</sup> Additionally, factor X deficiency is reported in patients with systemic AL amyloidosis.<sup>210</sup> However, an inhibitor has not been demonstrated *in vitro* to account for this manifestation.

## EXTRAMEDULLARY DISEASE

Extramedullary disease manifestations are uncommon in patients with myeloma at presentation. However, with more aggressive therapy and improved survival an increasing frequency of such manifestations has been observed. Solitary or multiple extramedullary plasmacytomas have been described in the liver, spleen, lymph nodes, kidneys, subcutaneous tissues, and brain parenchyma. Such extramedullary involvement may be suspected in patients who have more aggressive features of myeloma including high lactate dehydrogenase levels, immunoblastic morphology, high tumor cell labeling index, and complex karyotypic features.<sup>211</sup>

## DIAGNOSIS

As myeloma patients present with a variety of symptoms not specific to the disease, the diagnosis of myeloma is quite often delayed. An older patient with a new onset of unexplained back pain or bone pain, recurrent infection, anemia, or renal insufficiency should be screened for myeloma. Additional findings such as hyperproteinemia or proteinuria, anemia, hypoalbuminemia, low immunoglobulin levels, or marked elevation of erythrocyte sedimentation rate should prompt a further complete evaluation for diagnosis of plasma cell myeloma.

The initial evaluation includes a hemogram, complete skeletal radiographic survey, serum and urine protein electrophoresis and immunofixation, quantitative immunoglobulin levels, urinary protein excretion in 24 hours, and bone marrow aspiration and biopsy ( [Table 46.4-3](#) ). The diagnostic criteria for MGUS, smoldering and indolent myeloma, and multiple myeloma are shown in [Table 46.4-4](#).

<b>Presence and characterization of monoclonal protein</b>
Serum protein electrophoresis
Quantitative immunoglobulins
2D-E serum total protein and Bence Jones protein immunoelectrophoresis of urine and serum
<b>Medullary evaluation</b>
Skeletal survey
Magnetic resonance imaging with short time inversion recovery images
Bone densitometry
Computed tomography to rule out solitary plasmacytoma
<b>Laboratory evaluation</b>
Complete blood cell count with reticulocyte and differential count
Chemistry panel (renal, calcium, albumin, uric acid, lactate dehydrogenase)
$\beta_2$ -Microglobulin, C-reactive protein
<b>Bone marrow</b>
Aspirate and biopsy
Cytogenetics
Flow cytometry (DNA, Ig)
Plasma cell labeling index
<b>Specialized studies for selected patients</b>
Abnormal fat panel or renal biopsy for amyloid
Referral to a bone marrow transplant center
Serum viscosity if IgM component or high IgA levels or serum M component $> 7$ g/dL
<b>Fig. Immunoglobulin</b>

### STAGING AND RISK ASSESSMENT

Following preliminary investigation, more detailed cellular and molecular studies are required to stage myeloma and evaluate other prognostic variables that determine the patient's probable outcome.

### PROTEIN ELECTROPHORESIS

Among patients with myeloma, 70% have IgG, whereas 20% have IgA subtype with an additional 5% to 10% having production of monoclonal light chains only. A small proportion, less than 1%, of patients produce monoclonal IgD, IgE, IgM or have nonsecretory myelomas. Suppression of uninvolved immunoglobulins (e.g., IgM and IgA in IgG myeloma) is present in the majority of the patients at diagnosis. Suppression of all of the three major classes of immunoglobulin should raise the possibility that the patient may have light chain only disease or a nonsecretory disease. When multiple immunoglobulin class suppression is associated with small M peak on serum protein electrophoresis, a less common variety of myeloma involving IgD or IgE may be suspected. Patients producing intact immunoglobulin can also have excess light chain production with excretion in the urine ( Fig. 46.4-4 ). The distribution of k and l light chains in the majority of myeloma cases is similar except in IgD myeloma in which l light chain is more common. Currently, there is no difference in therapeutic approach between the different types of myeloma; however, patients with IgA myeloma, despite a higher initial response rate, have poorer survival outcomes.

**FIGURE 46.4-4.** Serum (SPE) and urine protein electrophoresis ( *left* ) showing abnormal monoclonal protein bands ( *arrows* ). Quantitation of the M protein is performed by nephelometric measurement of the band. Identification of serum and urine M component by immunofixation electrophoresis (IFE) ( *right* ). The labels indicate the specificity of the antiserum used in developing the immunofixation pattern. The top is immunoglobulin (IgG) A-g in serum and bottom is free g light chain in urine.

Myeloma plasma cells usually produce a single, abnormal, unique, monoclonal antibody with a constant isotype and light chain restriction. Rare occurrences of biclonal and triclinal cases have been reported at the time of diagnosis.<sup>212</sup> Occurrence of isotype switch and appearance of abnormal protein bands have, however, been reported in myeloma patients after therapy, especially high-dose therapy.<sup>213</sup> This appears to be related to recovery of normal immunoglobulin production rather than alteration in disease biology. This change is also associated with improved survival. Occasionally, patients with initially intact immunoglobulin production relapse with only Bence Jones proteinuria (light chain escape), nonsecretory disease, or high lactate dehydrogenase disease, and this change has been correlated with more aggressive disease.<sup>214</sup>

Further analysis of a unique variable region in the myeloma-related idiotype (e.g., CDRIII) provides information on the monoclonal nature of the protein and also provides a tool to investigate minimal residual disease by polymerase chain reaction using allele-specific oligonucleotide, thus allowing determination of molecular complete remissions.<sup>215</sup>

### BONE MARROW EXAMINATION

Various degrees of bone marrow infiltration are observed in myeloma, with the majority of the patients having an excess number of plasma cells (more than 5%). The pattern of bone marrow involvement (diffuse vs. nodular) is important, as patients with nodular disease seem to have poorer outcomes (in contrast to CLL).<sup>216</sup> The morphology of the plasma cell seems to be an important factor determining severity of the disease. This is based on histologic examination (Bartl grade) in which grade I suggests a slow-growing disease, whereas grade III represents plasmablastic disease with an aggressive course.<sup>217</sup> There is also an increased incidence of cytogenetic abnormalities in patients with Bartl grade III when compared with grade I. As plasma cells contain cytoplasmic immunoglobulins with a constant heavy and light chain, its frequency can be evaluated by flow cytometric analysis using immunohistochemical staining of the plasma cells.<sup>218</sup> When coupled with DNA staining using propidium iodide, two-parameter analysis can detect changes in DNA content in the myeloma cells ( Fig. 46.4-5 ). DNA aneuploidy is observed in the bone marrow of more than 80% of patients, suggesting the existence of chromosomal abnormalities in the majority of patients.<sup>218,219 and 220</sup> This also provides an objective marker for evaluation of therapy and to distinguish reactive from clonal plasmacytosis, especially in nonsecretory disease. A hypodiploid tumor cell has also been

associated with refractoriness to standard-dose therapy.

**FIGURE 46.4-5. A:** Bone marrow plasma cells in a patient with immunoglobulin G myeloma showing neoplastic plasma cells at various stages of differentiation. **B:** Two-parameter flow cytometry of DNA content of bone marrow cells; abscissa (propidium iodide), and cytoplasmic immunoglobulin (ordinate, anti-k or g FITC). At diagnosis approximately 45% hyperdiploid tumor cells with k light chain restriction are seen (*left panel*); at the time of maximal response no hyperdiploid light chain restricted cells are seen (*middle panel*); at the time of early relapse reappearance of small hyperdiploid and k light chain–restricted population (<1%) is indicative of reemergence of a small number of clonal cells that may not yet be apparent on cytologic examination of the bone marrow (*right panel*).

## CYTOGENETICS

As the myeloma cell represents a mature differentiated cell with low proliferative activity, cytogenetic abnormalities are not frequently found. Abnormalities are detected in only one-third of the patients at the time of diagnosis; however, repeated analysis improves the yield to almost one-half of the patients. The normal karyotypic pattern observed in the remaining half most likely originates from dividing normal hematopoietic cells.<sup>75</sup>

As described previously, a complex karyotypic pattern is frequently observed and its distribution is shown in [Figure 46.4-2](#). Although a predominant constant cytogenetic abnormality has not been identified, certain recurrent changes have been noticed. These include the common B-cell tumor-related changes in the 14q32 region involving the IGH region, chromosome 1q, and chromosome 13–related changes.<sup>221,222 and 223</sup> A longitudinal analysis in patients undergoing high-dose chemotherapy has shown clinical evolution including changes involving chromosome 5 and 7, commonly associated with myelodysplastic syndrome.<sup>224</sup> Acquisition of such changes in the myeloma karyotype appears to portend poor prognosis. Detection of chromosome 13 deletion abnormalities at diagnosis as well as after high-dose chemotherapy has now been reported to carry a poor prognosis. The application of FISH technology has improved our ability to detect genetic changes by using interphase cells. The Rb-1 probe detects an abnormality on the 13q14 region, and its deletion has been reported in 40% of patients by interphase FISH, also suggesting a prognostically poor-risk group of patients treated by standard-dose therapy.<sup>225</sup> Interphase FISH analysis for numeric chromosomal aberrations has identified chromosomes 6, 9, and 17 as also carrying favorable outcomes.<sup>79</sup> Plasma cell leukemia has been reported to frequently contain a t(11:14); however, this translocation has also been detected in patients with MGUS without any prognostic relevance.<sup>226</sup>

## LABELING INDEX

The proportion of myeloma cells in the cell cycle is small early in the disease. A study of cycling myeloma cells with bromodeoxyuridine or tritiated thymidine methods shows a median of 1% cycling cells at diagnosis. The labeling index has important prognostic significance as patients with more than 1% cells in S phase in bone marrow have worse outcomes.<sup>218,227,228,229 and 230</sup>

## RADIOGRAPHIC EVALUATION

The radiographic survey of the bone is a standard diagnostic workup, which shows osteopenia in an early phase of the disease and, with increasing tumor burden, lytic punched out lesions ([Fig. 46.4-6](#)). Osteosclerotic lesions are observed in POEMS syndrome.<sup>194,195,196 and 197</sup> Due to the predominant osteolytic activity with osteoblastic inactivity, bone scans are seldom positive unless a recent fracture has occurred and not useful in the diagnosis of multiple myeloma.<sup>231</sup>

**FIGURE 46.4-6.** Typical skeletal changes on roentgenogram. **A:** Example of punched-out lytic lesions in skull. **B:** Small lytic lesions in the left femur. **C:** Large lytic lesion in sacrum (*arrows*). **D:** Fine-needle aspiration biopsy of the vertebral lesion. (Courtesy of Hemendra Shah.)

As demineralization of bone (osteoporosis) is one of the common manifestations of myeloma, measurement of bone mineral density (BMD) by dual-energy x-ray absorptiometry is an important evaluation at diagnosis.<sup>232</sup> In a study of 66 patients at diagnosis, majority of the patients had decreased BMD: lumbar mean BMD value (Z score)  $-1.24 \pm 1.45$ . Following standard-dose therapy, lumbar BMD increased 0.7%, while in a group treated with high-dose therapy the improvement was 4.6% ( $P = .02$ ).<sup>233</sup> Similar improvements in BMD have also been noted in patients undergoing high-dose therapy with addition of bisphosphonates<sup>234</sup> and show differential effects of pamidronate on cortical and cancellous bones in patients with myeloma undergoing autotransplants.<sup>233,234</sup>

Magnetic resonance imaging (MRI) of bone marrow provides a better assessment of tumor burden and is essential in the workup of a patient with solitary plasmacytomas of bone.<sup>235</sup> More than 95% of myeloma patients have MRI abnormalities: one-third have diffuse involvement of the bone marrow, one-third have focal lesions, while the other one-third have heterogenous marrow with both focal and diffused involvement. As myeloma is well recognized as a macrofocal disease, random bone marrow sampling may not be entirely diagnostic or predictive of disease status. MRI short tau inversion recovery images (STIR) provide a better assessment of tumor load in myeloma.<sup>236,237,238 and 239</sup> A focal marrow plasmacytoma can be further analyzed through computed tomographically (CT)-guided fine-needle aspiration allowing cytologic diagnosis, which can be combined with further risk assessment through evaluation of cytogenetic and FISH analysis as well as labeling index. As therapies become more effective, the MRI pattern may change as seen in [Figure 46.4-7A](#), [Figure 46.4-7B](#), and [Figure 46.4-7C](#); a diffuse involvement of the marrow may unravel into a focal disease. Normalization of MRI abnormalities may provide a better definition of complete responses as the therapy for this disease with autologous or allogeneic transplantations aims toward cure. Positron emission tomography scanning has been evaluated in a small number of studies and may provide a better functional definition of the lesions observed on MRI or CT and allow selection of lesions for biopsy.<sup>240</sup>

**FIGURE 46.4-7. A:** Magnetic resonance imaging (MRI) pattern in multiple myeloma at diagnosis. T1-weighted and short tau inversion recovery (STIR) imaging shows approximately one-third of patients each presenting with heterogeneous pattern (A), focal plasmacytoma lesions (B), or diffuse homogeneous hyperintense marrow pattern (C). Hyperintensity of marrow on short inversion time inversion recovery image is suggestive of uniform marrow involvement by myeloma. Few patients have a hypointense and homogenous pattern also seen in normal individuals (D). **B:** The hyperintense marrow pattern (*arrows*) suggestive of extensive marrow involvement pretherapy (left) changes to hypointense pattern following complete response and normalization of marrow (right). **C:** MRI is useful in differentiating myelomatous involvement from amyloidosis or infection. The active plasmacytoma appears as bright on a STIR image (A, *arrow*), whereas amyloidosis appears as a dark lesion (B, *thick arrow*). A bright shadow above the amyloid (*thin arrow*) is suggestive of associated small plasmacytoma. Fine-needle aspiration examination in 72 patients with MRI focal disease showed tumor in 92%, indicating that MRI focal lesions in myeloma represent tumor. (Courtesy of Ramesh Avva.)

## DIFFERENTIAL DIAGNOSIS

In the presence of lytic bone lesions and greater than 30% marrow plasmacytosis, the myeloma diagnosis can be readily established. However, in the absence of lytic bone lesions or diffused osteoporosis, other criteria have to be fulfilled to differentiate overt myeloma from MGUS.<sup>242</sup> These include anemia, high levels of monoclonal protein in serum and urine, and marrow plasmacytosis as described in [Table 46.4-4](#).<sup>241,242</sup> Distinguishing smoldering myeloma and monoclonal gammopathy may be difficult as this distinction is essentially based on levels of serum monoclonal proteins and marrow plasmacytosis.<sup>243</sup> The differentiating features are shown in [Table 46.4-5](#), and in the majority of the patients with monoclonal gammopathy, anemia, bone lesions, or MRI abnormalities are absent. Conventional cytogenetic results are usually negative in MGUS; however, monoclonal plasma cells in some cases with MGUS may be aneuploid. Patients with nonsecretory myeloma are diagnosed based on marrow plasmacytosis and bone lesion. MRI abnormalities and CT- or MRI-guided fine-needle aspiration biopsy are important for follow-up of the disease.

	Monoclonal Gammopathy of Unknown Significance	Smoldering Multiple Myeloma	Multiple Myeloma
Monoclonal protein	<3 g/dL	>3 g/dL, stable	>3 g/dL
IgG	<3 g/dL	>3 and <12 g/dL, stable	>3 g/dL
IgA	<2 g/dL	>2 and <10 g/dL, stable	>2 g/dL
Light chain only	<2 g/dL	>2 g/dL	>2 g/dL
Plasma cells in marrow biopsy	<5%	>5% but <10%	>10%
Bone lesions on skeletal survey	No lesions	No bone lesions	Lytic lesions or osteoporosis
Myeloma response imaging	No focal lesions	Focal lesions can be present	—
β <sub>2</sub> -microglobulin level	Normal	Normal	High or normal
Plasma cell labeling index	<1%	<1%	Can be >1%
Renal failure, hypocalcemia, anemia, hypergammaglobulinemia	Absent	Absent	Present

**TABLE 46.4-5.** Major Diagnostic Criteria among Monoclonal Gammopathy of Unknown Significance, Smoldering Multiple Myeloma, and Multiple Myeloma

Diagnosis of solitary plasmacytoma of bone or soft tissue requires intense investigation to rule out systemic disease. Bone marrow examination in a true solitary lesion is negative with no clonal cell population on DNA clg examination. MRI evaluation for myelomatous involvement of the bone marrow helps detect early lesions before their detection by standard roentgenographic examination. Detection of such lesions and cytologic confirmation through CT- or MRI-guided fine-needle aspiration biopsy may help confirm solitary plasmacytoma and its genetic makeup. In case of MGUS, such detection may change the diagnosis to solitary or multiple myeloma. It is important to note that patients with MGUS or solitary plasmacytoma seldom have suppression of uninvolved immunoglobulins.

Besides plasma cell neoplasms, various other conditions can present with monoclonal immunoglobulin secretion. These conditions include other B-cell neoplasms such as CLL and B-cell non-Hodgkin's lymphoma; autoimmune conditions such as cold agglutinin diseases, mixed cryoglobulinemia, hypergammaglobulinemia, and Sjögren's syndrome; inflammatory or storage diseases such as lichen myxedematous, Gaucher's disease, sarcoidosis, and cirrhosis; and rarely other malignancies such as chronic myelogenous leukemia, and colon, breast, or prostate cancer.

Protein deposition disease involving various organs requires additional special diagnostic procedures. Deposition of amyloid protein (amyloidosis) can be clinically suspected based on macroglossia, vascular fragility (*raccoon's eyes*, periorbital subcutaneous hemorrhages), carpal tunnel syndrome, organomegaly, nephropathy, and cardiomegaly with arrhythmia. Detection of Congo red–positive amyloid in perivascular area and in subcutaneous fat, bone marrow, or rectal biopsy and classic apple-green birefringence when visualized under polarized light are diagnostic of AL amyloid. Electrocardiography may reveal a low voltage, and echocardiographic evaluation shows thickening of the interventricular septum or classic spackled pattern in the myocardium. Endomyocardial biopsy may establish the diagnosis of cardiac amyloid. Another manifestation of amyloid deposition includes autonomic dysfunction due to amyloid deposition in the vasa nervorum of the autonomic nerves, leading to orthostatic hypotension. Deposition in adrenal glands leads to hypoadrenalism. Amyloid deposition in spleen may lead to hyposplenism with observation of thrombocytosis. Deposition in liver may be suspected based on elevated alkaline phosphatase and g-glutamyl transpeptidase, and deposition in gastrointestinal tract leads to malabsorption syndrome. Renal dysfunction needs to be further investigated with a renal biopsy, as diagnosis of light chain cast nephropathy or light chain deposition disease may be reversible following aggressive therapy while deposition of amyloid would require a different therapeutic approach. As deposition of immunoglobulin and light chain can mimic many manifestations of AL amyloid, immunofluorescence analysis of unfixed tissue is important for diagnosis.

## PROGNOSTIC VARIABLES

Patients with multiple myeloma have variable disease courses with survival ranging from less than 1 year with aggressive disease to more than 10 years with indolent presentation of sensitive disease. Various characteristics have been identified to predict the possible course of the disease. Evaluation of prognostic factors is important to define therapeutic strategies, permit comparison of clinical trial results, and predict life expectancy after diagnosis. As shown in [Table 46.4-6](#), prognostic factors are related to tumor burden, intrinsic property of the tumor, host and microenvironmental influences, and treatment intervention–related factors.

Variable	Definition
Stage I	Monoclonal protein or immunoglobulin levels in serum, light chain excretion in a 24-hour urine sample, presence of hypercalcemia, anemia, extent of bone lesions, and presence or absence of renal failure.
Stage II	Similar to Stage I but with additional criteria.
Stage III	Similar to Stage I but with additional criteria.

TABLE 46.4-6. Prognostic Variables

Studies measuring *in vitro* immunoglobulin production by patients' myeloma cells have led to the development of clinically applicable methods to estimate tumor mass. A clinical staging system developed by Durie and Salmon for multiple myeloma using standard laboratory measurements has been applied to predict clinical outcomes after standard-dose chemotherapy.<sup>244,245</sup> As shown in Table 46.4-7, this system uses monoclonal protein or immunoglobulin levels in serum, light chain excretion in a 24-hour urine sample, presence of hypercalcemia, anemia, extent of bone lesions, and presence or absence of renal failure. In a study by National Cancer Institute Canada, overall survival with standard-dose therapy in patients with low-disease burden (stage I) was 49 months and with high-tumor burden (stage III) was 25 months. Including the renal failure in the staging system, patients with stage IIIa disease had a median survival of 30 months and stage IIIb disease, 15 months.<sup>246</sup> The accuracy and predictive value of the Durie-Salmon system is less pronounced in patients undergoing high-dose chemotherapy.<sup>247</sup> The high-dose chemotherapy is probably able to treat the disease burden more successfully, with the patient's outcome depending more on tumor biology factors. As the Durie-Salmon system considers tumor burden variables and depends on subjective interpretation of lytic bone lesions, additional other variables have been investigated to better assess patients' risk.

Stage	Criteria
Stage I	Monoclonal protein or immunoglobulin levels in serum, light chain excretion in a 24-hour urine sample, presence of hypercalcemia, anemia, extent of bone lesions, and presence or absence of renal failure.
Stage II	Similar to Stage I but with additional criteria.
Stage III	Similar to Stage I but with additional criteria.

TABLE 46.4-7. Myeloma Staging System

b<sub>2</sub>-microglobulin (b<sub>2</sub>m) has been identified as one of the most important predictors of survival in plasma cell myeloma. b<sub>2</sub>m is the light chain gene of the class I histocompatibility antigens expressed on the surface of all nucleated cells and shed into the blood. Its renal excretion explains its elevation in renal failure. In multiple myeloma it reflects both tumor burden and renal function.<sup>248,249</sup> High b<sub>2</sub>m (greater than 2.5 mg/L) levels carry a poor prognosis with both standard-dose and high-dose therapy.<sup>247</sup> Other independent factors associated with poor prognosis include elevated CRP and less consistently serum IL-6 activity and sIL-6R and IgA isotype.<sup>250</sup> Because CRP levels reflect IL-6 activity and elevated levels can be associated with various acute-phase reactions including inflammation and infections, its predictive value is important only when other possible causes of elevated CRP are ruled out.

The bone marrow plasmacytosis reflects tumor burden and has been considered in prognosticating survival. Peripheral blood monoclonal plasma cell has also been reported as a predictor of survival in myeloma. In a study of 254 patients, blood monoclonal plasma cell count was greater than or equal to 4% in 57% of patients, with median survival of 2.4 years compared with 4.4 years in patients with a count less than 4%.<sup>251</sup>

Among the various other disease biology variables, Bartl grading of tumor cells correlates with survival even in patients undergoing high-dose chemotherapy. Flow cytometry of DNA and cytoplasmic immunoglobulin (DNA-clg) can identify hypodiploid tumor cells, associated with resistance to standard-dose chemotherapy, which can be overcome by high-dose chemotherapy.<sup>252</sup> The plasma cell proliferation rate as measured by the labeling index is a valuable prognostic factor, with an index of greater than 2% predicting inferior survival. One study combining b<sub>2</sub>m and labeling index identified a low-risk group with both parameters low, intermediate-risk group with one parameter high, and high-risk group with both parameters high, with median survival of 71 months, 40 months, and 15 months, respectively.<sup>230</sup>

Cytogenetic analysis has now been identified as a major prognosticator in plasma cell myeloma. Abnormalities involving chromosome 13 carry a poor prognosis with short survival as well as inferior response to high-dose chemotherapy. Additional tumor-related factors associated with inferior survival include increased soluble IL-6 receptor level, elevated serum lactate dehydrogenase level usually associated with extramedullary disease, and increased mitotic activity (greater than one per high power field).

Among the microenvironment-related factors, bone marrow microvessel density has been identified as an important prognosticator. High microvessel density in the bone marrow (greater than or equal to four per high power field) at the diagnosis confers shorter event-free (2.7 vs. 4.3 years; *P* = .03) and overall survival (7.9+ vs. 4.3 years; *P* = .006) after high-dose chemotherapy.<sup>138</sup> This may be reflective of increased VEGF expression by myeloma cells or other microenvironmental factors.<sup>139</sup> An increased level of serum syndecan-1 has been described as carrying poor prognosis. Soluble CD16 levels have been correlated with disease activity, with significantly reduced levels of soluble CD16 found in sera from patients with multiple myeloma as compared with MGUS patients and normal controls; a stage-dependent decrease in soluble CD16 was observed in myeloma.<sup>253</sup>

Among therapy- and intervention-related prognostic factors, more than 12 months of prior standard-dose therapy affects survival most significantly in patients undergoing high-dose chemotherapy. Additionally, the tandem transplant and the time between the two transplants are also significantly correlated with superior event-free and overall survival.<sup>247</sup> Age over 65 years has been reported to be associated with inferior survival using standard-dose therapy; however, with high-dose therapy, age does not appear to predict poor survival.<sup>254</sup>

As high-dose therapy is able to overcome the problems related to increased disease burden as well as to some other biologic features associated with drug resistance, some traditional prognostic factors are no longer predictive of survival after high-dose chemotherapy. With this background, in a study of 1000 patients receiving high-dose chemotherapy with melphalan, 200 mg/m<sup>2</sup>, the three most significant adverse variables associated with a shorter survival were the presence of chromosome 13 abnormality, b<sub>2</sub>m greater than 2.5 mg/L at the time of transplant, and more than 12 months of preceding conventional-dose therapy. When patients are divided into groups with none of the previously mentioned risk factors, presence of one of the risk factors, or presence of both the risk factors, inferior prognosis is associated with an increase in the number of risk factors. As shown in Figure 46.4-8, even among these three groups presence of chromosome 13 abnormality predicts inferior survival, confirming its overriding influence. Additional molecular studies with FISH analysis as well as expression of various proteins such as BCL-family proteins, p53, and activation of STAT and NF-κB pathways in the future may provide new insight into the understanding of predictive factors important for prognostication.

**FIGURE 46.4-8.** Multivariate analysis of 972 patients undergoing at least one high-dose melphalan with autologous peripheral blood stem cell rescue showed chromosome 13 abnormality, b<sub>2</sub>-microglobulin (b<sub>2</sub>m) >4.0 mg/L, and C-reactive protein >3 mg/L to be the most significant predictors of poor outcome, followed by >12 months of prior therapy. Patients were divided into three groups based on their b<sub>2</sub>m and C-reactive protein values; those with both values normal (risk 0), those with one of the two values abnormal (risk 1), and those with both the values abnormal (risk 2). These patients were evaluated for event-free (EFS) (left) and overall survival (OS) (right) and divided into those with (top) or without (bottom) chromosome 13 abnormality. As seen in the figure, patient groups divided based on b<sub>2</sub>m and C-reactive protein show significantly superior EFS and OS as the number of risk factors increases (risk 0 to 2). However, within each group the presence of chromosome 13 abnormality (upper panel compared with lower panel) predicts significantly inferior EFS and OS, suggesting adverse effect of chromosome 13 abnormality irrespective of other risk factors.

## TREATMENT

The diagnosis of a monoclonal protein does not always require immediate treatment of the patient. Although multiple myeloma is generally a disseminated disease, patients can present with solitary plasmacytomas that can be treated with local therapy or they may present with indolent asymptomatic myeloma, which can smolder for a long period of time before becoming symptomatic and requiring treatment.

### SOLITARY PLASMACYTOMA

Solitary plasmacytoma requires specialized techniques for more accurate staging including a CT scan and MRI to exclude more disseminated disease. Solitary plasmacytomas of the bone involve vertebral bodies in one-third of the patients and frequently affect men (70%) at a younger age (median, 56 years).<sup>255</sup> A measurable monoclonal protein in the serum is observed in 24% to 54% of the patients and in a large proportion, no detectable monoclonal protein is observed, even on immunofixation. Extramedullary plasmacytomas are diagnosed less frequently and require a complete workup including MRI and positron emission tomography scanning to rule out any additional site or disseminated disease. The optimal therapy for true solitary plasmacytoma is curative-dose radiotherapy with 4000 to 5000 cGy.<sup>256,257</sup> and<sup>258</sup> With such a dose, the local tumor recurrence rate has been less than 10%, and 30% of patients with solitary bone lesions compared with more than 70% of patients with solitary extramedullary plasmacytomas have a long disease-free survival.<sup>259,260</sup> The monoclonal protein disappears after radiotherapy in 25% to 50% of the patients, suggesting possible eradication of all detectable disease. Reappearance of monoclonal protein predicts recurrence of disease. It can be anticipated that with better staging with MRI true solitary plasmacytoma of the bone can be cured in a high proportion of patients.<sup>261</sup>

### INDOLENT MYELOMA

Myeloma patients with a low tumor mass and slowly progressive disease may present without specific symptoms. These patients generally have less than 20% bone marrow plasmacytosis and low monoclonal protein levels as shown in [Table 46.4-5](#).<sup>243,262</sup> They have no lytic bone lesions, no hypercalcemia or renal disease, and hemoglobin greater than 10 g/dL. In patients with indolent light chain disease, Bence Jones proteinuria does not exceed more than 10 g/d. These patients do not present with cytogenetic abnormalities using conventional karyotyping and do have a low labeling index and low b<sub>2</sub>m. Features predictive of early progression to symptomatic myeloma include lytic bone lesions, high serum myeloma protein levels (greater than 3 g/dL IgG or greater than 2 g/dL IgA), and focal MRI abnormalities.<sup>263</sup> Median time to progression is 26 months for all patients, 10 months in patients with bone lesions and high monoclonal protein, and 61 months for those without any of these features. Such indolent myeloma patients are typically not treated with chemotherapy until disease progression, onset of symptoms, or development of new lytic bone lesions. However, pamidronate has been used as *soil-directed* treatment to delay the onset of bone-related complications. Additionally, cytogenetic analysis of bone lesions through CT-guided biopsy provides important prognostic information that may dictate the need for early chemotherapeutic intervention.

### SYMPTOMATIC MULTIPLE MYELOMA

#### Standard-Dose Therapy

Since the observation of induction of remission defined as greater than or equal to 50% decrease in paraprotein levels with melphalan in one-third of the myeloma patients studied, various standard-dose chemotherapeutic combinations have been evaluated. Oral melphalan and prednisone was the first successful combination chemotherapy for myeloma and in subsequent years various other single agents and combinations have been investigated and reported to have significant antimyeloma activity.

**MELPHALAN AND PREDNISONE.** Treatment with oral melphalan and prednisone was introduced 30 years ago and has remained the standard of therapy, providing symptomatic relief as well as tumor mass reduction.<sup>264</sup> A partial response as defined by greater than 50% reduction in monoclonal protein has been observed in 50% to 60% of the patients and between 3% and 5% of patients achieve a complete response. The absorption of oral melphalan is unpredictable, requiring its ingestion on empty stomach and increase in dose if the patient does not develop cytopenia.<sup>265</sup> With availability of the intravenous formulation, dose and pharmacokinetics are now predictable. In patients receiving melphalan and prednisone, a prompt response was associated with a poor survival, reflecting possibly a highly proliferative tumor. The median response duration was 18 months and overall survival was 24 to 36 months. One of the frequent complications of melphalan and prednisone therapy was the development of cytopenia and eventually myelodysplastic changes in the marrow. With successful treatment with high-dose therapy, melphalan and prednisone are not being used as induction therapy because the ability to mobilize adequate numbers of stem cells decreases with prolonged use of this combination; the incidence of treatment-related myelodysplastic syndrome and acute myeloid leukemia increases and partial resistance even to high-dose chemotherapy develops.

**OTHER ALKYLATING AGENT-BASED COMBINATIONS.** Various chemotherapeutic combinations have been investigated in myeloma, including vincristine (V), cyclophosphamide (C), carmustine (BCNU; B), melphalan (M), doxorubicin (Adriamycin; A), and prednisone (P). Commonly used combinations include VBMCP or VMCP/VBAP.<sup>266,267,268,269,270,271,272,273,274,275,276,277</sup> and<sup>278</sup> These combinations in randomized studies achieved similar response rates and event-free and overall survival when compared with melphalan and prednisone. Results from large studies evaluating standard-dose chemotherapy regimens are listed in [Table 46.4-8](#) and [Table 46.4-9](#). In the majority of the studies, there was no benefit of any of these combinations over melphalan and prednisone, and the toxicity problems, including bone marrow stem cell damage, remained the same. A metaanalysis of 18 published studies with 3814 patients randomized to receive melphalan and prednisone or various other chemotherapeutic combinations showed that melphalan and prednisone and other chemotherapeutic combinations are equivalent.

**VINCRIStINE , ADRIAMYCIN, AND DEXAMETHASONE AND HIGH-DOSE DEXAMETHASONE.** The role of high-dose corticosteroids was initially investigated in the late 1960s with an observation of therapeutic benefit in small numbers of patients. Glucocorticoids down-regulate IL-6 production and induce apoptosis *in vitro*. The molecular mechanism of corticosteroid-induced apoptosis in myeloma involves a decrease in NF- $\kappa$ B activity through I $\kappa$ B activation. Interestingly, myeloma cells can be rescued from glucocorticoid-mediated killing by addition of IL-6 to *in vitro* cultures or by coculturing them with stromal cells, which are a source of IL-6 *in vivo*. High-dose dexamethasone was evaluated in combination with vincristine and Adriamycin. The dosages of these agents (VAD) were vincristine at 0.25 mg/m<sup>2</sup> and Adriamycin at 9 mg/m<sup>2</sup> given by continuous infusion over 24 hours for 4 days, along with dexamethasone, 40 mg orally on days 1 to 4, 9 to 12, and 17 to 20, with the cycle repeated every 5 weeks.<sup>279,280</sup> More than 50% of refractory myeloma patients showed rapid and marked response, defined as greater than 75% cytoreduction, with better efficacy in patients responsive to prior therapy. Response with VAD was much faster, with the median tumor halving time of 21 days compared with greater than 6 weeks for other combination therapies. The advantages of this combination include quick response, effectiveness in hypercalcemia, quick relief of bone pain, applicability in patients with renal failure, and no cumulative bone marrow stem cell damage, allowing subsequent successful mobilization of stem cells. Studies using high-dose dexamethasone alone given in doses similar to the VAD regimen have shown response rates almost similar to those observed with VAD in primary resistant myeloma but higher in relapsing disease, indicating that dexamethasone is clearly an important agent in VAD. In a study evaluating glucocorticosteroid dose intensity, chemotherapy regimens with higher glucocorticosteroid dose intensity yielded higher response rates and improved survival (  $P = .02$ ).<sup>281</sup> VAD is associated with minimal bone marrow toxicity, and continuous infusion of Adriamycin prevents cardiac toxicity. Randomized comparisons between VAD and other chemotherapeutic combinations have failed to show any survival benefit for VAD; however, lack of stem cell damage provides an advantage in using VAD for initial cytoreduction before stem cell mobilization and transplant. Addition of cyclophosphamide to VAD (CVAD) has been shown to achieve responses in up to 40% of VAD-refractory patients.

**INTERFERON.** The role and efficacy of interferon in the management of myeloma remains controversial. It has been shown to have up to a 20% response rate in relapsed myeloma patients. Its mode of action remains multifactorial; direct growth inhibitory action as well as its antiangiogenic and immunomodulatory activity may contribute to its overall action. However, in combination with other chemotherapeutic regimens, it has failed to demonstrate beneficial effect.<sup>282</sup> In a metaanalysis of 16 trials involving 2286 patients, response rate was 45.9% in the chemotherapy alone group versus 54.4% for the chemotherapy with interferon group.<sup>283</sup> The difference in overall survival was 5 months. Its role in maintenance therapy after standard-dose therapy has generally been more positive, with demonstration in some of the studies of significant prolongation of survival for groups receiving interferon- $\alpha$ .<sup>282,284</sup> However, other studies have failed to show benefit. A metaanalysis of eight trials involving 929 patients randomized to interferon versus no treatment showed prolongation of relapse-free survival by 7 months and overall survival by 5 months. However, in younger patients and those with lower tumor burden interferon was more effective.<sup>283</sup> Its role, if any, after high-dose therapy is entirely unclear.<sup>285</sup> It is associated with flu-like symptoms, weight loss, impotence, depression, mental status changes, and cytopenia, and its prolonged use has been associated with inability to mobilize stem cells.

### Radiation Therapy

Radiation therapy was considered the mainstay of the treatment for myeloma before availability of chemotherapeutic options. However, with more effective chemotherapy, especially high-dose chemotherapy, the role of radiation has now been limited.<sup>286</sup> A definitive role remains in patients with solitary bone and extramedullary plasmacytoma. In this setting, it provides excellent local control, and in a subset of patients it provides long-term disease-free survival when a solitary lesion is confirmed through extensive radiographic workup. Patients with solitary bone plasmacytoma following definitive radiation therapy (4000 to 5000 cGy) have progression-free survival of 30% compared with extramedullary plasmacytoma in which progression-free survival is around 70%.<sup>256,257,258,259</sup> and <sup>260</sup> The indication for radiation therapy in multiple myeloma remains palliative in cases of impending pathologic fracture and spinal cord compression. In patients with bone pains or symptomatic soft tissue masses, radiation is only considered when patients have failed chemotherapeutic options.<sup>287,288</sup> Radiation to the extensive marrow-containing area, such as the pelvic bone, should be considered carefully in light of the need for collection of stem cells. The dose for palliative radiation therapy has been substantially lower, in the range of 1500 to 2500 cGy. Studies to date have failed to show any benefit of hemibody radiation in multiple myeloma. However, total body radiation has been used in relation with allogeneic transplantation as well as autologous transplantation. More recent studies have demonstrated that total body irradiation does not provide additional cytoreductive potential and it actually increases treatment-related morbidity and mortality and delays immune recovery following high-dose therapy possibly affecting disease control. Total body irradiation as part of conditioning for allogeneic transplantation is especially important in the optimal regimen for achieving engraftment; however, its role in cytoreduction in this setting also remains questionable. Newer studies are evaluating low-dose radiation therapy with or without chemotherapy in nonmyeloablative conditioning regimens that may be associated with lower morbidity and still achieve tumor control through graft versus myeloma effect.

### High-Dose Therapy with Peripheral Blood Stem Cell Support

The low incidence of complete response with standard induction chemotherapy, even in newly diagnosed patients, suggests a marked drug resistance that is possibly acquired during a prolonged subclinical course of the disease evidenced by the presence of complex karyotypic aberrations and multiple molecular changes. This observation led to a pilot study by the late Tim McElwain and his colleagues at the Royal Marsden Hospital where they evaluated role of melphalan dose escalation (140 mg/m<sup>2</sup>). They reported complete remissions in refractory patients.<sup>21</sup> However, treatment-related mortality was high due to bone marrow toxicity. Bone marrow support in the subsequent studies improved the treatment-related mortality<sup>22</sup> and further dose escalation of melphalan to 200 mg/m<sup>2</sup> and by added total body irradiation provided further improvement in response.<sup>289,290</sup>

**HIGH-DOSE THERAPY WITH AUTOLOGOUS HEMATOPOIETIC STEM CELL SUPPORT IN NEWLY DIAGNOSED PATIENTS.** Initial demonstration of activity of high-dose melphalan therapy has led to series of evaluations by various institutions of this treatment with stem cell support to avoid prolonged cytopenia ( [Table 46.4-10](#)). A large

transplantation may lead to increased drug resistance, as well as further genetic changes resulting in more aggressive disease. An ongoing Intergroup trial in the United States randomizing patients to up-front high-dose therapy or standard therapy with high-dose therapy as a salvage treatment should also further define the role of high-dose therapy.

**HIGH-DOSE REGIMEN.** High-dose melphalan (140 to 200 mg/m<sup>2</sup>) with or without total body irradiation is the most common conditioning regimen used in myeloma.<sup>250,289,302,306,307,308 and 309</sup> Melphalan's predominant myelotoxicity and metabolism independent of renal function is ideal for multiple myeloma patients who commonly have renal function abnormalities. Melphalan seems to be superior to thiotepa when given with total body irradiation, with patients achieving longer relapse-free and overall survival duration.<sup>310</sup> A combination regimen containing high-dose carboplatin with etoposide and Cytosan (cyclophosphamide) or a combination with CBV has also been investigated in resistant patients with only occasional responses.<sup>311,312 and 313</sup> However, no regimen has shown marked superiority over others. The addition of total body irradiation has not been shown to improve cytoreduction, and in fact it increases morbidity and treatment-related mortality. A poor outcome in one study using total body irradiation was considered to be related to delayed immune recovery.

**STEM CELL PURGING.** Myeloma cell contamination as evaluated by polymerase chain reaction or sensitive immunofluorescence is universally observed in stem cell products. Purging of tumor cells by positive selection of CD34+ cells leads to a 3- to 5-log reduction in contamination.<sup>314,315 and 316</sup> Negative selection by the monoclonal antibody cocktail containing CD10 (common acute lymphoblastic leukemia antigen); CD20 (a pan B-cell antigen); and PCA-1, (plasma cell-associated antigen) or peanut agglutinin (PNA) and anti-CD19 antibodies results in undetectable myeloma cells by conventional flow cytometry.<sup>298</sup> The early follow-up results from these studies have not revealed any significant advantage in responses or survival, but they consistently show a delay in engraftment posttransplantation. Even when cells were purged using fluorescence-activated cell sorting of early hematopoietic stem cells (CD34+, Thy1+, Lin-) devoid of any clonal B cells, relapses were frequent and patients had delayed hematopoietic engraftment and suppressed immune status for prolonged periods of time.<sup>317,318</sup> These effects lead to infectious complications. As complete responses are observed in 30% to 50% of patients, greater emphasis needs to be placed on achieving better tumor cytoreduction in the patient.

**HEMATOPOIETIC STEM CELL SOURCE.** Mobilized peripheral blood stem cells provide faster engraftment compared with bone marrow. Myeloma patients with less than 1 year of prior therapy had faster granulocyte and platelet recovery after peripheral blood stem cell transplants compared with bone marrow autografts.<sup>319</sup> The duration of prior chemotherapy, especially with stem cell-damaging agents (melphalan, BCNU, and high-doses of cyclophosphamide) along with radiation to bone marrow-containing areas, significantly affects the ability to procure adequate quantities of peripheral blood stem cells and engraftment kinetics posttransplant.<sup>320</sup> Differential mobilization with cyclophosphamide and GM-CSF of normal hematopoietic stem cells during the first 3 days of leukapheresis is observed, while peak levels of myeloma cell contamination are present on subsequent days. These myeloma cells show a higher labeling index and a more immature phenotype (CD19+).<sup>321</sup>

### Transplantation in Older Patients

Because myeloma is a disease of older patients, the role of high-dose chemotherapy has been evaluated in patients older than 65 years of age. No significant differences in clinical characteristics have been observed between younger and older patients. Age does not impair stem cell mobilization or engraftment.<sup>254</sup> In a study of patients over the age of 65 years (range, 65 to 83 years) undergoing high-dose melphalan with stem cell transplant, 22% complete responses were achieved. A pair-mate analysis was conducted for these patients and patients younger than 65 with similar high-dose therapy who were matched for relevant prognostic features. Results showed no significant difference in event-free survival (2.1 vs. 1.5 years;  $P = .2$ ) and overall survival (3.9 vs. 3.7 years;  $P = .4$ ) for younger versus older patients, respectively (Fig. 46.4-10). In a study involving 71 older patients (age greater than 60 years) receiving intermediate-dose melphalan at 100 mg/m<sup>2</sup> with stem cell support applied two to three times, the older patients were compared with 71 pair-mates matched for age and b<sub>2</sub>m and treated with oral melphalan and prednisone. Complete response rates were observed in 47% versus 5% ( $P < .001$ ), median event-free survival was 34 versus 17.7 months ( $P < .001$ ), and median overall survival 56+ versus 48 months ( $P < .01$ ) in patients receiving high-dose therapy and melphalan and prednisone, respectively.<sup>322</sup>

**FIGURE 46.4-10.** Outcome of 67 patients over the age of 65 and undergoing high-dose chemotherapy with autologous stem cell rescue were compared with a matched pair of patients with age less than 65 and similar prognostic features including chromosome 13 abnormality, C-reactive protein, b<sub>2</sub>m, and months of prior therapy and treated with similar high-dose chemotherapy. There is no difference in overall (OS) and event-free survival (EFS) between the two groups, suggesting that when myeloma patients are treated with high-dose therapy older age does not predict for poor outcome.

### Transplant in Patients with Renal Failure

One-third of multiple myeloma patients have renal dysfunction in the initial stage of the disease, and one-half of them recover renal function after correction of hypercalcemia, improved hydration, or effective chemotherapy.<sup>323</sup> Melphalan<sup>324</sup> and busulfan,<sup>325</sup> both active agents in myeloma, are pharmacokinetically independent of renal function, allowing high-dose administration in myeloma patients with renal dysfunction. Thirty-six patients with severe renal insufficiency (creatinine clearance less than 40 mL/min), including eight patients on chronic hemodialysis, were treated with high-dose melphalan followed by peripheral blood stem cell rescue. No effects on median half-life, area under the curve, and clearance of melphalan were observed in patients with renal failure compared with patients who had normal renal function. Renal insufficiency did not affect posttransplant engraftment or overall survival. However, the patients with renal insufficiency required longer hospitalization due to prolonged mucositis and anorexia.

### Myelodysplastic Syndrome after High-Dose Therapy in Myeloma

Treatment-related myelodysplastic syndrome and acute myeloid leukemia are well-recognized complications following alkylating agent therapy. Myeloma patients with their advanced age may have coexisting myelodysplastic syndrome at a preclinical stage detected by cytogenetic changes that may be exacerbated by alkylating agent therapy<sup>224</sup> and may be further affected by high-dose melphalan and stem cell transplant. In myeloma following high-dose therapy and stem cell support increased incidence of cytogenetically detected myelodysplastic syndrome is observed. The increase observed after 2 years was lowest in patients less than 50 years age and with less than 12 months of prior standard-dose therapy (1% to 2%); and it increased to 7% to 10% in older patients (>50 years) with more than 12 months of prior therapy, especially when CD34 mobilization was impaired (Fig. 46.4-11). Thus, in the background of older age and cumulative DNA damage caused by standard-dose alkylating agent therapy, the hematopoietic reconstitution following high-dose therapy may lead to excess telomeric shortening with genomic instability and an increased chance of myelodysplastic syndrome and acute myeloid leukemia.<sup>326,327</sup>

**FIGURE 46.4-11.** Development of myelodysplasia using cytogenetic criteria (-5 or del 5q, -7 or del 7q, trisomy 8, del 20q11) following autologous hematopoietic stem cell–supported high-dose therapy with melphalan, 200 mg/m<sup>2</sup> (one or two cycles). Cumulative incidence of cytogenetic myelodysplastic syndrome in relationship to months of prior therapy ( $\le 12$  vs.  $>12$  months) and age ( $\le 50$  vs.  $>50$  years). Patients with no more than 12 months of prior therapy and aged 50 years or younger had the lowest risk of myelodysplastic syndrome compared with the three other groups.

### Allogeneic Transplantation

Patients with identical siblings have an option of syngeneic transplantation with true tumor-free graft. <sup>328</sup> In the setting of maximal cytoreductive therapy data from the European Bone Marrow Registry involving 16 patients undergoing syngeneic transplant, a complete response rate of 50% and median event-free and overall survival of 32 and 60 months were seen.

HLA-matched sibling donor transplantation enables myeloma patients to achieve 15% to 30% long-term disease-free survival, as shown by various large groups and summarized in Table 46.4-11. <sup>298,329,330,331</sup> and <sup>332</sup> In this study, between 30% and 50% of patients achieved a complete remission; however, an extremely high 1-year mortality (up to 50%) has been reported (Fig. 46.4-12). This unusually high treatment-related mortality compared with other diseases, including chronic myelogenous leukemia and acute leukemia, might be related to the older patient population, an immunosuppressed state due to the disease, corticosteroid treatment leading to higher bacterial and fungal infections, and the prior long duration of chemotherapy. <sup>333</sup> Definitive evidence of graft-versus-myeloma effect has been demonstrated and is considered responsible for the reduced probability of disease progression. <sup>334,335</sup> However, outcome after allografts are poor compared with autografts both as primary and salvage therapy. European Bone Marrow Transplant Registry retrospective analysis in a matched pair setting showed superior overall survival after autotransplants (34 vs. 18 months). <sup>336</sup> Surprisingly, even autograft performed as salvage in patients with resistant or relapsed disease resulted in superior overall survival (32 vs. 20 months), compared with allotransplant. <sup>337</sup> This is mainly due to excessive treatment-related mortality associated with allografts. Newer approaches are now being investigated with nonmyeloablative transplants, TK gene–transduced donor lymphocyte infusion, and CD6-depleted transplants and CD4+ donor lymphocyte infusion to reduce treatment-related mortality and improve overall survival. <sup>298</sup>

### Salvage Therapies

Patients unresponsive or relapsing after standard alkylating agent therapies such as melphalan and prednisone are responsive to high-dose dexamethasone pulsing alone or in combination with drugs such as VAD or CVAD. <sup>306,338,339</sup> and <sup>340</sup> Such patients still remain candidates for high-dose melphalan with peripheral blood stem cell rescue if adequate quantities of stem cells can be procured after salvage therapies. Patients relapsing after prior VAD and autotransplant have been treated with combination chemotherapy consisting of dexamethasone in a pulsing fashion and cyclophosphamide, 400 mg/m<sup>2</sup>/d, etoposide, 40 mg/m<sup>2</sup>/d, and cisplatin, 15 mg/m<sup>2</sup>/d by continuous infusion for 4 days (DCEP). In a study of 57 patients relapsing after tandem transplant, more than 40% achieved greater than or equal to 75% tumor mass reduction, including true complete remission in 13% patients. <sup>341</sup> The responses were seen in high-risk disease settings, including chromosome 13 abnormalities and high labeling index. The efficacy of thalidomide in this setting (see [Thalidomide](#), later in this chapter) has led to the evaluation of a combination of DCEP with thalidomide and Adriamycin (DTPACE) followed by G-CSF administration as induction therapy before transplantation. The preliminary results of this combination appear to be extremely promising, with more than 75% of previously treated patients achieving partial response after two cycles. These combinations, with success in the salvage setting, are now being evaluated as induction therapy and posttransplant consolidation. In fact, superior overall and event-free survival have been reported in high-risk patients (chromosome 13 abnormalities) receiving posttransplant DCEP consolidation. <sup>342</sup>

### Newer Phase I Agents

**BISPHOSPHONATES.** The second- and third-generation bisphosphonates, pamidronate and zoledronate, reduce skeletal complications and bone pain in myeloma (Table 46.4-12). <sup>343,344</sup> The mechanism of action includes down-regulation of osteoclast activity, decreased IL-6 production, and induction of apoptosis of osteoclasts through inhibition of farnesyl and geranyl-geranyl transferase activity. <sup>345,346</sup> Besides reducing bone-related problems, continued administration over 21 months showed

**TABLE 46.4-13.** Immunophenotype of Waldenström's Cells

Chromosomal changes have been reported in a small number of patients with Waldenström's macroglobulinemia, mainly due to low proliferative potential of this disease. Complex karyotypic changes include trisomies, deletions, and structural abnormalities of various chromosomes.<sup>365</sup> As with myeloma and other B-cell tumors, translocations involving 14q32 are reported with various partners.<sup>366,367</sup> These includes chromosome 18 (BCL-2), 8 (c-myc), 11 (PRAD-1), and importantly, chromosome 9 involving PAX5 gene, which is expressed at a higher level in normal pre-B cells, and its expression decreases as the cells become plasma cells.<sup>368</sup>

The clinical presentation is variable and is related to high IgM levels and lymphoplasmacytic cell infiltration of various organs.<sup>369</sup> The usual manifestations related to tissue infiltration include pulmonic symptoms with cough and dyspnea, gastrointestinal infiltration with diarrhea and bleeding, skin plaques, and periorbital exophthalmos and nerve palsies. The large molecular size of IgM leads to higher serum viscosity than seen with comparable levels of IgG or IgA. Hyperviscosity is seldom seen with IgG or IgA levels less than 5 g/dL, whereas IgM levels of greater than 3 g/dL may lead to clinical manifestations. Relative plasma viscosity above 5 cp is usually associated with symptoms. Hyperviscosity may present with fatigue, blurred vision, headache, shortness of breath, mucosal bleeding, and mental status changes or coma. Type I cryoglobulinemia, which is caused by physicochemical interactions with the paraprotein and observed in small numbers of patients, may present with purpura, urticaria, Raynaud's phenomenon, acrocyanosis, malleolar ulcers, or necrosis.<sup>370</sup> Cryoglobulinemia type II, which is due to antibody reactivity, may present with arthralgia, proteinuria, renal failure, polyneuropathy, and mononeuritis.<sup>364,371</sup> Additional special presentation may be related to the presence of cold agglutinins leading to a mild hemolytic anemia or exacerbation of Raynaud's phenomenon. Severe demyelinating sensorimotor neuropathies is observed in 10% of the patients. One-half of these patients have detectable antibodies against myelin-associated glycoprotein (anti-MAG antibodies).<sup>372,373,389</sup> Sensory or ataxic neuropathy is observed more commonly in patients with anti-MAG antibodies. The frequency of common presenting features is listed in [Table 46.4-14](#).

Clinical Findings	Frequency (%)
<b>SYMPTOMS</b>	
Severe fatigue	85
Bleeding	60
Neurologic	17
Bone pain	10
<b>SIGNS</b>	
Lymphadenopathy	40
Hepatomegaly	30
Splenomegaly	30
Hepatosplenomegaly	25

**TABLE 46.4-14.** Clinical Manifestations in 260 Patients with Waldenström's Macroglobulinemia

Laboratory evaluation usually shows anemia; however, early leukopenia and thrombocytopenia in untreated patients is uncommon. Elevated erythrocyte sedimentation rate, monoclonal IgM protein in serum with occasional light chains in the urine, and elevated b<sub>2</sub>m in a subset of patients is observed. Bone marrow shows typical lymphoplasmacytic infiltration with the presence of mast cells. CT scan evaluation of chest, abdomen, and pelvis may show the presence of lymphadenopathy with enlargement of liver, spleen, or both. Skeletal survey is done to rule out IgM myeloma as bone lesions are not seen in Waldenström's macroglobulinemia. Depending on clinical findings of immunologic effects or involvement of other organs, specialized test are required. Tissue infiltration may require confirmation with biopsies.

Asymptomatic presentation of Waldenström's macroglobulinemia does not require immediate cytoreductive therapy as it does not alter the outcome and delays chemotherapy-related bone marrow suppression. Patients with preserved hemoglobin and low b<sub>2</sub>m are ideal candidates for observation. Patients with high IgM-related symptoms, such as hyperviscosity, hemolytic anemia, neuropathy, and cryoglobulinemia, benefit from plasmapheresis without conventional chemotherapy.<sup>374,375 and 376</sup>

Patients who are symptomatic from the disease or have marked hepatosplenomegaly, cytopenia, or progressive disease have been treated with alkylating agents. Chlorambucil alone or with corticosteroids produces response rates as defined by greater than 50% drop in paraproteins and tumor mass in 60% to 75% of previously untreated patients, and complete responses observed in less than 5% of the patients.<sup>377</sup> Responses are slow and may take up to 12 to 18 months from the beginning of treatment. Treatment is continued until maximal reduction is observed. Median survival from diagnosis is more than 10 years. More aggressive combination therapy with multiple agents has achieved more than 80% response rate. However, there is no improvement in overall survival. Prolonged alkylating agent therapy has led to development of myelodysplastic syndrome or acute myeloid leukemia in up to 10% of the patients.

Purine analogues fludarabine at a dose of 25 mg/m<sup>2</sup> intravenously for 5 days every 4 weeks and cladribine at a dose of 0.1 mg/kg by continuous infusion for 7 days have produced responses in up to 80% of previously untreated patient populations and complete responses in 10% of patients. Effectiveness of purine analogues in previously treated patients has been in the range of 30%, with higher responses in patients relapsing after cessation of prior therapy and less frequent responses in patients with resistant relapse.<sup>263,390,391,392,393 and 394</sup> Patients relapsing after receiving one purine analogue do not usually respond to another purine analogue. In a large prospective multicenter study by the Southwest Oncology Group in newly diagnosed patients, however, fludarabine showed only 39% response rate.<sup>378</sup> Younger patients are shown to respond better than older patient populations. Anemia, b<sub>2</sub>m greater than 2.5 mg/dL, and IgM greater than 4 g/dL were predictive of poor outcome in that study. The major side effects with purine analogues are prolonged cumulative cytopenia and immunosuppression leading to opportunistic infections. Nonchemotherapeutic treatment options include Rituxan (anti-CD20 mo-ab) with 20% to 30% responses in small studies,<sup>364</sup> and interferon- $\alpha$  with a 30% response rate.<sup>395,396,397 and 398</sup> High-dose dexamethasone pulsing has produced some responses in refractory patients.<sup>379,380</sup> There have been reports of occasional responses following splenectomy.<sup>381,382</sup> The role of high-dose chemotherapy has been evaluated in six patients with extensive prior therapy showing five patients achieving a partial response and one patient achieving a complete response.<sup>383</sup> However, as prolonged prior therapy affects stem cell mobilization, especially after purine analogues and chlorambucil, mobilization, at an earlier stage of the treatment, is necessary. The role of thalidomide in this disease remains under investigation.

## PERSPECTIVE

New discoveries in molecular biology, better understanding of B-cell development and immune regulation, and improved imaging techniques have advanced our understanding of the biology of multiple myeloma and related plasma cell neoplasms in the last decade. A new entity of multiple myeloma with chromosome 13 abnormalities has been recognized, carrying an extremely adverse prognosis even with high-dose chemotherapy. A putative tumor suppressor molecule is under investigation and a risk-based therapeutic approach is applied with more aggressive treatment in this subgroup of patients, including up-front allogeneic transplantation. High-dose chemotherapy has been clearly shown to be effective in improving complete response rates and event-free and overall survival in comparison with standard-dose therapy. It has been successfully applied in older patients or in the presence of renal dysfunction. Over 40% of patients now achieve complete remission compared with 5% with standard-dose therapy a decade ago, and for the first time durable complete responses have been reported in patients without standard risk factors and absence of chromosome 13 abnormalities. MRI with inversion recovery images provides better assessment of bone marrow involvement with myeloma cells and CT- and MRI-guided fine-needle aspiration biopsies provide cytologic and molecular diagnosis of the residual bone lesions. Progress is being made in better defining complete responses and now includes normalization of MRI (MRI complete response). Preliminary investigations appear to predict superior survival in such patients. Allogeneic transplants continue to remain difficult, with up to 50% 1-year mortality. However, nonmyeloablative allogeneic transplant regimens are being evaluated to decrease treatment-related mortality while at the same time using graft-versus-myeloma effect to achieve disease control, especially in patients with chromosome 13 changes. The demonstration of the role of neoangiogenesis in myeloma has led to identification of an effective new agent, thalidomide, in refractory myeloma patients. With its different spectrum of adverse effects, it may be an ideal drug to be combined with chemotherapeutic agents. Soil-directed therapy with the use of bisphosphonates has shown antitumor effects along with improvement in bone density and a decrease in skeletal events.

Future directions include investigation of thalidomide in induction as well as maintenance therapy, evaluation of post-high-dose chemotherapy consolidation with chemotherapeutic agents, development of tumor cell-specific cytotoxic T lymphocytes, and safe administration of allogeneic transplantation. Better understanding of the molecular mechanism of the disease, especially of factors that prevent apoptosis with the help of subtractive libraries and micro array chips, should provide newer tools to effectively and specifically treat this disease.

## INTRODUCTION

The myelodysplastic syndromes (MDS) are heterogeneous clonal hematopoietic stem cell disorders grouped together because of the presence of dysplastic changes in one or more of the hematopoietic lineages.<sup>1,2</sup> Dysplasia signifies abnormal or discordant nuclear cytoplasmic maturation and is the morphologic hallmark of apoptosis. Indeed, MDS is associated with apoptosis<sup>3,4,5</sup> and<sup>6</sup> and excessive proliferation, resulting in the paradoxical picture of peripheral cytopenias and cellular marrows. The common findings in MDS include anemia-associated problems, infections and bleeding, generally in elderly patients, frequent exposure to carcinogens or leukemogenic agents, a wide range of transformation rates (10% to 80%) to acute leukemia, and a high incidence of cytogenetic abnormalities associated with poor prognoses.<sup>7</sup> The MDS were previously referred to as *smoldering leukemia* or *preleukemia*, *oligoblastic leukemia*, or *hematopoietic dysplasia*,<sup>8</sup> implying an indolent course. More recent studies have emphasized the aggressive nature and poor prognosis of some subsets of *high-risk* MDS, defined by excess marrow or peripheral blasts, cytogenetic abnormalities, or both.<sup>9,10</sup>

## INCIDENCE

The estimated incidence of MDS is 7000 to 12,000 new cases in the United States annually.<sup>11</sup> With a median survival of 1 to 3 years, the estimated prevalence is 10,000 to 25,000 cases. The true incidence of MDS is probably underestimated, because the diagnosis is often overlooked or not reported. Those cases often receive no specific therapy because of older age, complicating medical illnesses, and unavailability of effective low-risk treatment modalities. Some MDS may be misdiagnosed as other entities such as hypoplastic or aplastic anemia (hypoplastic MDS), acute myelogenous leukemia (AML) (high blast percent), or myeloproliferative disorders (high white blood cell counts).

## ETIOLOGY

The etiology of most MDS cases is unknown. Smoking and exposures to ionizing irradiation, organic chemicals, heavy metals, herbicides, pesticides, fertilizers, stone and cereal dusts, exhaust gases, nitroorganic explosives, petroleum and diesel derivatives, alkylating agents, benzene, solvents other than benzene (e.g., toluene, xylene), chloramphenicol, and marrow-damaging agents including chemotherapeutic agents may increase the risk of developing MDS.<sup>12,13,14,15</sup> and<sup>16</sup> Patients with clear exposure to such agents are referred to as having *secondary MDS* or *treatment-related MDS* and constitute approximately 20% to 30% of MDS cases. Their proportion is increasing as more patients with other cancers are exposed to and cured with such treatments. Secondary MDS accounts for 30% of MDS cases referred to M. D. Anderson Cancer Center since 1990, compared with 15% before 1990. Alkylating agents (melphalan, chlorambucil, cyclophosphamide, procarbazine) and radiation therapy are associated with the highest risk of development of MDS.<sup>17</sup> Their effects are synergistic, particularly in older patients. Patients with Hodgkin's disease and other lymphomas, myeloma, breast and ovarian cancers, and those undergoing stem cell transplantation (SCT) are often exposed to such treatments.<sup>17,18</sup> Among patients with Hodgkin's disease or lymphoma undergoing autologous SCT with high-dose cyclophosphamide and total body irradiation, the estimated cumulative risk of developing MDS at 5 to 6 years is 11% to 18%, the risk being higher with use of total body irradiation, with increasing age, with longer time from first treatment to transplant, and with low platelet counts at time of SCT.<sup>18</sup> X-chromosome inactivation analysis has shown replacement of polyclonal hematopoiesis with clonal hematopoiesis preceding the development of MDS in some patients. Patients with MDS are older than those with AML and have a higher incidence of unfavorable chromosomal abnormalities, including losses of parts or all of chromosome 5 or 7.

There is no known association between viral or other infections and development of MDS. There may be an increased risk of MDS in families of patients with MDS. Rare familial forms of MDS or AML and monosomy 7 have been described.<sup>19</sup> Studies of the frequency of specific polymorphism in enzymes activating, detoxifying, or both activating and detoxifying carcinogens in MDS patients versus normal controls may help in understanding the disease pathophysiology and identifying individuals at risk for developing MDS.

## CLASSIFICATION AND RISK GROUPS

The French-American-British (FAB) classification categorizes patients with MDS based on the percentage of marrow and peripheral blasts and the presence of monocytosis and Auer rods. Categories include refractory anemia (RA), RA with ringed sideroblasts (RARS), RA with excess blasts (RAEB), and RAEB in transformation (RAEBT). Chronic myelomonocytic leukemia (CMML), a hybrid disorder of excessive myeloid proliferation, monocytosis, and dysplastic changes in the erythroid and megakaryocytic series, is sometimes considered as a fifth MDS category or as a separate disorder ([Table 46.5-1](#)).<sup>20,21</sup>

Myelodysplastic Syndrome Category	Percentage of Marrow Blasts			Percentage of Myeloid Dysplasia Syndromes	
	French-American-British	French-American-British	Other	French-American-British	French-American-British
Refractory anemia	<5	5	—	10-40	10-20
Refractory anemia with ringed sideroblasts	<5	5	>15 ringed sideroblasts	10-20	10-15
Refractory anemia with normoblasts	5-20	5	—	10-20	10
Refractory anemia with normoblasts in non-ferrous	5-20	5	keratin	10-20	10-15
Chronic myelomonocytic leukemia	<5	5	Monocytosis >10%	10-20	10

(From ref. 21 with permission.)

**TABLE 46.5-1.** French-American-British Classification of Myelodysplastic Syndromes

The FAB classification of MDS has shortcomings.<sup>22</sup> For example, Auer rods, which characterize RAEBT, have been associated with favorable rather than poor prognosis.<sup>23</sup> Confusion arises when monocytosis is present with 5% to 29% blasts as to whether such cases should be referred to as *RAEBT* (if blasts more than 20%) or as a separate category of accelerated-phase CMML. Finally, there is great variability in prognosis within a single FAB subtype, indicating the need to incorporate further information into the FAB system.<sup>24</sup> Investigators have attempted to improve on the classification by including prognostically relevant variables such as the percentage of marrow blasts, chromosomal abnormalities, and cytopenias (anemia or thrombocytopenia).<sup>25,26</sup>

An International Prognostic Scoring System (IPSS) was developed that assigns points to each of several prognostic factors (Table 46.5-2).<sup>27</sup> It divides patients into low, intermediate-1, intermediate-2, and high-risk groups with median survivals of 5.7, 3.5, 1.2, and 0.4 years, respectively. Although it is an improvement over the FAB system, the IPSS also suffers from variability within single-risk groups. For example, the median survivals of patients with IPSS low and intermediate-1 groups referred to M. D. Anderson were only 2.1 and 1.2 years, respectively, significantly different from those reported in the IPSS study (5.7 and 3.5 years, respectively), despite similar therapeutic measures (Table 46.5-3).<sup>24,27</sup> The IPSS was derived from newly diagnosed untreated patients, and survival was calculated from diagnosis. However, patients referred to tertiary centers have often had prior therapy, the patients were referred because of some need for therapy, and their survival was measured from the referral date. Thus, latent variables, unrecognized by the prognostic models and related to the referral, might account for differences in prognosis of different study groups categorized in the same IPSS risk groups. Investigations of aberrant cellular or molecular events in MDS (e.g., RAS mutations, apoptosis, clonality, loss of suppressor genes, methylation, and others) may yield new clinically relevant biologic prognostic factors.

Prognostic Variable	Score Value				
	0	0.5	1.0	1.5	2.0
Marrow Blast (%)	<5	5-10	—	11-20	21-30
Karyotype*	Good	Intermediate	Poor		
Cytopenias†	0-1	2-3			

International Prognostic Scoring System Risk Group	Score Value	Survival Median/5% Percentage	Percentage 5.7 Years Median/Leukemia Transformation
Low	0	5.7/93	15
Intermediate-1	0.5-1.0	3.5/93	30
Intermediate-2	1.5-2.0	1.2/7	45
High	2.5	0.4/0	100

\*Good, normal; I, del(17p), del(20q); poor, complex (≥3 abnormalities), chromosome 7 anomalies, unbalanced, others.  
†Cytopenias: hemoglobin <10 g/dL, granulocytes <1.3 × 10<sup>9</sup>/L, platelets <100 × 10<sup>9</sup>/L.

## BIOLOGY AND PATHOPHYSIOLOGY

Preclinical studies have provided insight into different pathophysiologic processes in MDS, and several models of MDS evolution have been proposed.<sup>28,29</sup>

The clonal nature of MDS appears restricted to hematopoietic population subsets.<sup>30,31</sup> Primitive progenitors (CD34+, Thy 1+) and T cells, perhaps in the earlier MDS phases, appear nonclonal. Late-stage hematopoietic cells of myeloid and erythroid lineage, as well as B-cell lymphocytes, were often clonal.<sup>30,31,32,33,34</sup> and <sup>35</sup> Hematopoietic recovery in remission marrows is frequently nonclonal.<sup>35,36</sup>

In some patients, nonclonal CD8+ T cells directed against HLA class I-restricted antigens may suppress normal hematopoiesis, as evidenced by enhanced *in vitro* growth of granulocyte-macrophage colony-forming units following T-cell depletion (cyclosporin, anti-CD8).<sup>37</sup> This provides the rationale for the use of immunosuppressive therapy in MDS.

*In vitro* colony formation is generally reduced in MDS and correlates with survival.<sup>8,38</sup> Addition of growth factors [erythropoietin, granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin-3 (IL-3)] increases colony formation. This provided hope that at least some patients in early MDS phases or with mild lineage involvement may benefit from such therapy. Serum levels of growth factors (e.g., erythropoietin) were inversely correlated with the degree of cytopenia, indicating appropriate host compensatory mechanisms. Cytopenias may be improved with pharmacologic doses of growth factors.

Dysplasia appears to signify high apoptotic rates, explaining the unilineage or multilineage peripheral cytopenias.<sup>3,4,5</sup> and <sup>6</sup> According to one hypothesis, the primary lesion in MDS is the high cell death rate, which is counterbalanced by a compensatory early phase of excessive hematopoiesis. This is supported by studies demonstrating both increased apoptosis and proliferation<sup>3,4,5</sup> and <sup>6</sup> and may explain the apparent paradox of peripheral cytopenia and hypercellular marrows. Increased apoptosis has also been observed in the marrow microenvironment cells, suggesting that the primitive stem cell involved is a progenitor to both hematopoietic and stromal cells.<sup>5</sup>

What might contribute to increased apoptosis? High levels of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) or other proapoptotic cytokines, and the effect of TNF- $\alpha$  on induction of Fas expression on CD34+ cells, may be pathophysiologic.<sup>39,40</sup> Elevated TNF- $\alpha$  levels in MDS may be restricted to the earlier phases (RA, RARS) and were not found in normal control subjects or in patients with AML.<sup>41,42</sup> The source of TNF- $\alpha$  production may be the increased marrow macrophages in MDS, which may be stimulated by elevated macrophage colony-stimulating factor (M-CSF) levels, through point mutations in c-fms, which encodes the M-CSF receptor.<sup>43,44</sup> and<sup>45</sup> That TNF- $\alpha$  production in MDS is relevant is suggested by (1) enhanced *in vitro* colony growth in MDS by incubation with TNF- $\alpha$  neutralizing antibodies<sup>46</sup>; and (2) the correlation of TNF- $\alpha$  levels with severity of anemia, poor response to erythropoietin, and increased apoptosis.<sup>5,41,47</sup> Strategies to suppress TNF- $\alpha$  levels may help therapeutically.

Other proapoptotic cytokines of interest include interferon- $\gamma$  and IL-1 $\beta$ . Interferon- $\gamma$  production appears to be important in aplastic anemia but less so in MDS.<sup>42</sup> IL-1 $\beta$  levels are highest in RA, tend to correlate with apoptosis but not proliferation, and may be due to deficient production of the receptor antagonist in MDS stromal cells, which increase IL-1 $\beta$  levels and thus apoptosis.<sup>48</sup>

Involvement of the Fas/Fas ligand system in MDS apoptosis has also been proposed,<sup>4,5</sup> as well as a role for other molecular events including Ras mutations or aberrations in the RAS pathways that may be dysfunctional without Ras mutations.<sup>49</sup> Understanding the pathophysiology of RAS in MDS and CMML (10% to 25% with Ras mutations) may result in rational intervention approaches with RAS inhibitors (antisense, farnesyl-transferase inhibitors). Antiapoptotic signaling pathways, including bcl-2 overexpression, and shortening of telomeres may be important in advanced MDS states.<sup>4,5,50</sup>

Chromosomal abnormalities may serve as *fingerprints* for the molecular abnormalities. Chromosome 5 abnormalities (losses in the long arm, 5q-) are common. Many hematopoietic growth regulatory genes have been mapped to this region.<sup>51</sup> These include M-CSF, GM-CSF, IL-4 and IL-5, CD-14, interferon regulatory factor-1, the receptors for platelet-derived growth factor and M-CSF (Fms), and others. Fms is a tyrosine kinase protooncogene, and the viral form of Fms (v-Fms) has transforming properties. Fms point mutations have been described in patients with MDS and AML and those receiving chemotherapy, suggesting its possible role in MDS pathogenesis.<sup>45,52</sup> Other abnormalities include mutations in p53, overexpression of bcl-2 and c-mpl, deletions of IRF-1, methylation of p15<sup>INK4b</sup> and others.<sup>53,54,55,56</sup> and<sup>57</sup> C-mpl expression was low in low-risk MDS and high in RAEB, RAEBT, and CMML (40% to 45%). In RAEB and RAEBT, c-mpl expression correlated with other adverse features and with poor survival ( $P = .02$ ).<sup>54</sup>

How do these observations fit into a general multistep pathophysiologic process in MDS? It is possible that an initial injury results in suppression of normal hematopoietic stem cell growth and differentiation, directly or through stimulation of an immunologic response of polyclonal T cells. The cytotoxic suppressor T cells induce hematopoietic suppression through production of proapoptotic cytokines including TNF- $\alpha$  and the Fas/Fas ligand system. The roles of increased M-CSF, c-fms mutation, increased macrophages and contribution to TNF- $\alpha$  production, and interferon- $\gamma$  and IL-1 $\beta$  need further elucidation. These processes are more prominent in the early phase of MDS (RA, RARS), producing excessive apoptosis and cytopenias, and are more amenable to therapeutic approaches including growth factors, antiapoptotic strategies (e.g., against TNF- $\alpha$ ), and immunomodulation (e.g., cyclosporin A, antithymocyte globulins [ATG], corticosteroids). As compensatory proliferation continues, and perhaps mediated by the process of telomeric shortening and genomic instability, the hematopoietic progenitor cells allow the escape and growth advantage of clonal malignant hematopoiesis. This process may predominate in MDS advanced phases (RAEB, RAEBT, CMML), in which proliferation and maturation arrest (rather than apoptosis) are frequent, and in which a new set of molecular events dictate the pathophysiology, including enhanced Bcl-2 and p53 mutations, RAS mutations and dysfunction, and hypermethylation of p15<sup>INK4b</sup> (leading to suppression of tumor suppressor genes). In these stages, more appropriate investigations include AML-like strategies to suppress the abnormal clone, or ones directed against specific molecular targets including hypomethylating agents or RAS inhibitors.

Thus, MDS might appropriately be divided into two distinct entities, early and late MDS, which are governed by different sets of pathophysiologic processes and in which different directed strategies should be investigated.

## CLINICAL MANIFESTATIONS

The median age in MDS is 65 to 75 years, with a clear-cut age-related incidence. Younger patients who develop MDS have generally had exposure to leukemogenic agents. There is a male preponderance with a male to female ratio of 1.3:1.0. Presenting manifestations are due to cytopenia-associated problems including fatigue, pallor, infections, and bleeding (Table 46.5-4). Lymphadenopathy and hepatosplenomegaly are uncommon, occurring in less than 10% to 20% of patients. Central nervous system involvement is rare.

Characteristic	Category	Percentage
Age (yr)	600 (median)	64 (94.7)
Splenomegaly	Yes	11
Hepatomegaly	Yes	6
Hemoglobin (g/dL)	<10	56
Platelets ( $\times 10^9/L$ )	<50	43
Granulocytes ( $\times 10^9/L$ )	50-100	21
French-American-British category	R1	37
	Refractory anemia with ringed sideroblasts	0
	Refractory anemia with excessive blasts	20
	Refractory anemia with excessive blasts in transformation	30
	Chronic myelomonocytic leukemia	13
Neutropeny	Neutrophils $< 1.5 \times 10^9/L$	48
	Neutrophils $< 1.0 \times 10^9/L$	5.9
	Chloroacetate Esterase T abnormality	30
	Smudge B	3
	WBC	2
	Other abnormalities	12
	Transferrin receptor	7

Infections	Yes	19
Bleeding	Yes	6

TABLE 46.5-4. Presentation of Myelodysplastic Syndrome (M. D. Anderson, 1980–1999, 1358 Patients)

## LABORATORY FEATURES

Anemia is the most common finding; neutropenia and thrombocytopenia are frequent. Monocytosis greater than  $10^9/L$  in the peripheral blood, in the setting of other MDS features, leads to a diagnosis of CMML. Smears of the bone marrow and blood show various degrees of dysplasia (mild, moderate, severe) in one or more lineages (myeloid, erythroid, megakaryocytic). While the degree and lineage involvement by dysplasia have been correlated with prognosis, assessment of dysplasia may be subjective. Blasts in MDS are myeloid in origin as determined by histochemistry (myeloperoxidase-positive, positive monocytic stain results) and by immunophenotyping (CD13, CD14, CD33 positivity); some cases exhibit B-lineage lymphoid (CD19 or CD10) or mixed-lineage morphologies.

Bone marrow biopsies or aspirates are usually hypercellular, but may be normocellular or hypocellular. Twenty percent of cases may have a cellularity below 20%, which may be important in the context of immune-mediated mechanisms and of immunomodulatory strategies. Other abnormalities include hypogranulation or hyposegmentation (Pelger-Huët-like) of granulocytes; anisocytosis, poikilocytosis, and macrocytosis of peripheral red cells; and marrow dyserythropoiesis including ringed sideroblasts, asynchronous maturation, abnormal nuclear shapes, and chromatin clumping. Peripheral platelet dysplasia may be noted with large abnormally granular platelets or hypogranular platelets. Marrow micromegakaryocytes are also frequent.

Cytochemical stains of importance in the workup of MDS include stains for (1) iron to identify ringed sideroblasts, (2) myeloperoxidase to identify abnormal granulation of myeloblasts, (3) periodic acid–Schiff to identify abnormal erythroblasts, (4) reticulin to define the degree of fibrosis, and (5) platelet antibodies to mark micromegakaryocytes.<sup>58</sup>

Blood chemistries should include B<sub>12</sub> and folic acid levels to exclude vitamin deficiency–induced MDS-like changes. Serum and urinary lysozymes may be increased in CMML. Hypokalemia (lysozyme-induced renal tubular loss), renal dysfunction (leukemic involvement), and hyperuricemia may be present. Testing for the human immunodeficiency virus excludes MDS-like changes associated with human immunodeficiency virus–positive disease.<sup>59</sup>

Additional abnormalities observed in MDS include polyclonal gammopathies in up to one-third of patients, monoclonal gammopathies or hypogammaglobulinemia, the

presence of autoimmune antibodies, and B- or T-cell abnormalities.

Cytogenetic studies demonstrate karyotypic abnormalities in 40% to 75% of patients. These are more common in higher risk MDS and secondary MDS and often involve chromosome 5 or 7 abnormalities, trisomy 8, 20q-, and complex abnormalities (see [Table 46.5-4](#)).<sup>7,51,60</sup> A characteristic chromosomal abnormality involving 5q23, or the 5q- syndrome, is often associated with an indolent form of RA.<sup>51</sup> Patients with MDS may infrequently demonstrate *favorable* chromosomal abnormalities such as t(8;21) or inversion 16.<sup>61</sup>

## DIFFERENTIAL DIAGNOSIS

Dysplastic changes in the bone marrow are not pathognomonic for MDS, and the first concern is to exclude more treatable conditions associated with cytopenias. These include B<sub>12</sub> or folic acid deficiencies; exposure to antibiotics, chemotherapy, ethanol, benzene or lead; or a regenerating bone marrow following hypoplasia induced by drugs or infections. Patients with human immunodeficiency virus–positive disease, chronic inflammation, tuberculosis, liver disorders, hypersplenism, Hodgkin's disease, lymphomas, and metastatic disease to the marrow may present with cytopenias and marrow dysplastic changes. In these situations, appropriate tests and an observation period clarify the diagnosis.

Hypoplastic MDS with a marrow cellularity of less than 10% to 20% may be confused with aplastic or hypoplastic anemia.<sup>62</sup> Cytogenetic studies may help in the differential diagnosis, but some aplastic conditions may also be clonal or associated with cytogenetic abnormalities.<sup>63</sup> MDS with maturation arrest at the promyelocytic stage may be confused with acute promyelocytic leukemia; this is clarified by the characteristic promyelocytic blastic morphology and appropriate cytogenetic and molecular studies. Predominance of myelofibrosis in MDS may confuse it with myelofibrosis<sup>64</sup> or occasionally with hairy cell leukemia, because of the constellation of cytopenia, dry marrow aspiration, fibrosis, and splenomegaly in an elderly man. A high blast percentage may result in difficulty classifying MDS-RAEBT versus AML, but this distinction may not be critical for therapeutic choices or prognosis.

## SIGNIFICANCE OF THE 30% BLAST CUTOFF TO DISTINGUISH HIGH-RISK MYELODYSPLASTIC SYNDROMES FROM ACUTE MYELOID LEUKEMIA

The 30% blast cutoff has been traditionally proposed by the FAB classification to distinguish MDS from AML. The original intent was to avoid misdiagnosis and treatment of benign conditions as AML. This was supported by the view that MDS are indolent disorders often observed or treated with supportive care.

More recent studies have shown that high-risk MDS has as poor a prognosis as AML, and that other factors, some known, such as cytogenetic abnormalities, and others yet to be discovered (apoptotic, proliferative, angiogenesis, and methylation patterns, molecular abnormalities), may provide more rational methods to classify AML and MDS. In multivariate analysis, when account was taken of cytogenetics, patients with AML and high-risk MDS had similar outcomes following the use of anti-AML chemotherapy, independent of the blast percent.<sup>9,65</sup> Thus, the use of 30% marrow blasts to distinguish and to assign different treatments to AML versus high-risk MDS may not be relevant. A committee of the World Health Organization has recommended that patients with 20% or more marrow blasts be treated as they would for AML.<sup>66</sup>

## SPECIFIC SUBTYPES OF MYELODYSPLASTIC SYNDROMES

### 5Q SYNDROME

This syndrome is often found in elderly women who present with isolated anemia.<sup>51</sup> The median age is 65 years; the female to male ratio is 3:1. The disease presents as RA or RARS, has an indolent course, rarely transforms to AML, and is associated with a median survival longer than 5 years. The peripheral blood shows macrocytic anemia and normal or slightly elevated white blood cell and platelet counts. The bone marrow may show characteristic monolobulated megakaryocytes. Cytogenetic studies usually demonstrate 5q23 as the single abnormality. Additional chromosome abnormalities, when present, are associated with a worse prognosis. Since repeated transfusions are a major component of supportive care, iron-chelating therapy (desferioxamine) is important in these patients, particularly if they have received more than 20 units of packed red cells, or when serum ferritin levels exceed 400 to 800 mg/L.

### OTHER MYELODYSPLASTIC SYNDROME SUBTYPES

Hypoplastic MDS,<sup>62</sup> like aplastic anemia, may respond to immunomodulatory therapy such as corticosteroids, cyclosporin A, or ATG. Some cases may have disease induced by T-cell suppression of normal hematopoiesis. Myelofibrosis may predominate in some MDS cases<sup>64</sup> and raises the differential diagnosis of acute or chronic myelofibrosis, AML-M7 (megakaryocytic leukemia), and occasionally hairy cell leukemia.

Rarely, MDS may present with prominent eosinophilia or monocytosis without fulfilling the criterion of 10<sup>9</sup>/L peripheral monocytes. These are referred to as *MDS with eosinophilia* or *with monocytosis*. The latter is probably a variant of CMML without excessive myeloproliferation.

### CHRONIC MYELOMONOCYTIC LEUKEMIA

Originally categorized as MDS, CMML is now recognized as a hybrid disorder characterized by increased myeloid proliferation with monocytosis and erythroid and megakaryocytic dysplasia.<sup>67,68</sup> Thus, it shares characteristics of both MDS and myeloproliferative disorders in different lineages. The median age of patients is 65 to 75 years; there is a male predominance with a ratio of 2:1. Anemia and thrombocytopenia are common; hepatosplenomegaly is present in 25% to 50%; extramedullary disease involves the skin and subcutaneous tissues. Gingival or central nervous system involvement is rare. Patients with CMML and significant leukocytosis may present with organ infiltration and dysfunction including pulmonary insufficiency, cardiac decompensation, and renal failure. This may be exacerbated once treatment has started, and patients may develop bilateral lung infiltrates (leukemic cell necrosis and inflammation) and a picture resembling adult respiratory distress syndrome. Subtle renal dysfunction at the start may worsen transiently on therapy as tumor lysis complications develop. Patients presenting with severe leukocytosis, monocytosis, and organ dysfunction may benefit from leukapheresis, measures to prevent tumor lysis (allopurinol, alkalization, hydration, oral aluminum hydroxide to bind calcium), corticosteroids, and, at times, early hemodialysis for renal failure. Cytogenetic abnormalities are less frequent than in MDS. When present, they involve monosomy 7, trisomy 8, or other structural changes including 12p. Ras mutations are more common in CMML than in MDS (30% to 40%). The median survival of patients with CMML is approximately 18 months. Characteristics associated with shorter survival include increased marrow blasts, anemia, thrombocytopenia, cytogenetic abnormalities, and perhaps older age and excessive monocytosis.

## THERAPY

### BACKGROUND

The standard of care in MDS is generally accepted to be supportive care. This practice reflects (1) the older age and concomitant medical problems of MDS patients, making AML-like combination regimens risky; (2) the lack of effective nontoxic modalities; and (3) the prevailing notion that MDS is an indolent disorder. However, as discussed, the 30% blast cutoff is arbitrary, and survival of patients with high-risk MDS is similar to that of patients with AML. Hence, the same treatment considerations in elderly AML patients also apply to MDS. The belief that MDS is incurable except with allogeneic SCT is now contradicted by studies using AML-type therapy and intensive supportive care for patients with MDS. In such studies, the overall 3-year complete response duration rates of 25% were similar, among comparable age groups, to patients undergoing allogeneic SCT.<sup>9,69</sup>

There is marked heterogeneity in MDS. An indolent course is generally seen only in patients with RA or RARS, or low- and intermediate-1 IPSS risk groups. Other patients, making up the majority of referrals to specialized centers, have a poor prognosis and estimated median survivals of 1 year or less, similar to patients with AML. Low-risk MDS generally refers to RA and RARS in the FAB classification and to the low-risk IPSS group. High-risk patients include RAEB and RAEBT in the FAB classification and the high- and intermediate-2 IPSS risk groups. The intermediate-1 IPSS categorization depends on the population under study, being *lower* risk in community-based studies, and *higher* risk in studies from specialized centers (see [Table 46.5-3](#)).

## GENERAL TREATMENT PRINCIPLES

Treatment strategies should be individualized to the patient's condition and disease manifestations. MDS may be appropriately divided into two generally distinct entities pathophysiologically and for therapeutic purposes: low-risk and high-risk MDS. Patients with low-risk MDS and minimal findings should be observed. If they develop significant cytopenias and complications, growth factor support, as single agents or in combinations, may be indicated depending on patient's symptoms and frequency of transfusions and infections. For patients with low-risk MDS, trials of high doses of vitamins (e.g., B<sub>6</sub>) or androgens could benefit occasional patients. Immunomodulatory therapy with corticosteroids, cyclosporin A, and ATG may benefit 30% to 50% of selected patients. Low-risk patients may also be offered investigational single-agent chemotherapy, cytokines, antiapoptotic, or targeted modalities. Because of the poor prognosis of high-risk MDS, efforts should be made to involve patients in investigational studies including novel single chemotherapeutic agents, cytokines, gene or other targeted approaches (e.g., RAS-inhibitors, monoclonal antibodies), or AML-type combination regimens.

## SUPPORTIVE CARE

Most patients succumb to complications of marrow failure and cytopenias before transformation has occurred. Patients with anemia may be transfused with packed red cells when symptoms develop. If the frequency of transfusions increases (e.g., more than 1 to 2 per month), trials of vitamins, androgens, erythropoietin alone or in combinations, and immunomodulatory strategies may be indicated. With granulocytopenia and repeated infectious episodes (e.g., two or more) antibiotic prophylaxis with or without G-CSF appears reasonable, although not established in randomized studies or in high-risk patient subsets.

Thrombocytopenia may be managed with platelet transfusions when platelets are reduced below  $10 \times 10^9/L$  or if bleeding occurs. Patients may become refractory to platelet transfusions; investigational strategies with cytokines, immunomodulation, new agents, or chemotherapy combinations should then be considered.

## VITAMINS, ANDROGENS, DIFFERENTIATING AGENTS, AND INTERFERON

Although occasional patients may benefit from vitamin B<sub>6</sub>, androgens, and corticosteroids, the approaches have had a low success rate. Differentiating agents have been investigated including vitamin D, vitamin A, retinoids, hexamethylene bisacetamide, and sodium phenylbutyrate. These were associated with low response rates,<sup>70,71,72,73,74</sup> and 75 as did interferon alone or with chemotherapy and vitamins.<sup>76</sup>

## HEMATOPOIETIC GROWTH FACTORS

Erythropoietin has improved anemia and reduced transfusion requirements in 16% to 25% of selected patients, despite elevated endogenous erythropoietin levels in 85% of patients.<sup>77</sup> Better responses are noted in RA and RAEB compared with RARS (22% vs. 7%), in patients without transfusion requirements, in the absence of ringed sideroblasts, or with low to normal serum levels of endogenous erythropoietin (below 2000 U/L). Erythropoietin, 10,000 U, 3 times weekly, or 40,000 U weekly, may show benefit within 8 weeks of therapy.

G-CSF and GM-CSF improve neutropenia in 70% to 80% of patients and occasionally in other lineage cytopenias. Randomized studies comparing supportive care with G-CSF or GM-CSF have not shown them to reduce infectious episodes, prolong survival, or influence the rate of transformation to acute leukemia.<sup>78,79</sup> Combinations of G-CSF and erythropoietin may synergize in improving cytopenias.<sup>80,81</sup> Other cytokines investigated include IL-3 alone and in combinations, IL-6, and IL-11, and thrombopoietins for thrombocytopenia.<sup>82,83,84</sup> and 85 Growth factors with low-dose cytarabine were not better than chemotherapy alone.<sup>86</sup>

## LOW-DOSE CYTARABINE

Large-scale analyses of cytarabine, 10 to 20 mg/m<sup>2</sup> daily for up to 3 weeks, in MDS showed response rates of 10% to 15%.<sup>87</sup> Cytotoxicity, rather than differentiation, was the anti-MDS mechanism. Morbidity and mortality were substantial, and survival was not improved. Randomized studies of low-dose cytarabine, one with GM-CSF, versus supportive care did not show a survival benefit with cytarabine.<sup>88,89</sup>

## ACUTE MYELOID LEUKEMIA–TYPE COMBINATION REGIMENS

In the early 1980s, two retrospective studies showed that regimens used to treat AML could induce complete response in patients with MDS.<sup>90,91</sup> Since then, several studies reported on the use of intensive chemotherapy in MDS<sup>92,93,94,95,96,97,98,99,100</sup> and 101 (Table 46.5-5). Remission rates have ranged from 40% to 60% and mortality from 20% to 40%. Appropriate supportive care measures and prophylactic antibiotics have reduced this mortality to 6% to 20%. Complete response rates were 70% to 80% with favorable or normal karyotypes, and 40% to 50% with unfavorable karyotypes. Cytogenetic remissions generally accompanied complete responses.<sup>35,36</sup> Factors influencing outcome were age, karyotype, and FAB diagnosis. Patients most likely to benefit were younger than 50 years, had normal karyotypes, and had RAEBT<sup>95</sup> (Table 46.5-6). Long-term event-free survival was possible with intensive chemotherapy: Among age-comparable groups, the 3-year complete response and survival rates were similar with intensive chemotherapy versus allogeneic SCT<sup>69</sup> (see Table 46.5-6).

Study	Treatment	No. Evaluated	Percentage Complete Response	Percentage Mortality	Median Survival (mo)

## ALLOGENEIC STEM CELL TRANSPLANTATION

Allogeneic SCT is applicable to a small subset of MDS patients because of age restrictions, concomitant medical conditions, and donor availability. Disease-free survival rates of 30% to 50% have been reported.<sup>102,103</sup> and <sup>104</sup> Results were better in younger patients, with low-risk MDS, and if transplant was applied within 1 year from diagnosis.<sup>102</sup> Failure was primarily due to transplant-associated mortality in low-risk MDS and to disease recurrence in high-risk MDS. In the latter disorders, the long-term follow-up to studies showed 3-year survival rates of 23%, similar to those with intensive chemotherapy.<sup>69,102</sup> Allogeneic SCT after tumor reduction to less than 5% blasts in high-risk MDS produced better results, but may have selected inherently better patients.<sup>103</sup> In an update of the Seattle experience, patients were evaluated by the IPSS.<sup>104</sup> The disease-free survival rates were 60% in low-risk, 36% in intermediate-1, and 28% in intermediate-2 risk groups. This is compared with 5-year survival rates of 55%, 35%, and 7%, respectively, for unselected patients not receiving SCT. Considering the risk to benefit ratios (early transplant mortality but potential event-free survival) and the comparison of disease-free survival versus survival rates, it appears that SCT may benefit high-risk MDS patients.

While autologous SCT has been advocated as a treatment for MDS, this applies to patients who have achieved complete response, could be harvested, and were candidates for the procedure. The 2-year survival rate was only 39%, despite the highly selected nature of the patients.<sup>105</sup>

Improvement in results of SCT may occur through (1) targeted marrow ablative approaches (e.g., radiolabeled monoclonal antibodies against CD33 or CD45); (2) reductions in SCT-related mortality (e.g., mini-SCT); (3) preallogeneic and postallogeneic SCT-effective chemotherapy or immunomodulation; and (4) broader application of safer procedures in the setting of matched unrelated donor transplant.<sup>106</sup>

## NOVEL AGENTS AND STRATEGIES

### Topotecan

Topotecan, a topoisomerase I inhibitor, given as a single agent at 2 mg/m<sup>2</sup> by continuous infusion daily for 5 days every 4 to 6 weeks, produced complete response in 31% of patients.<sup>107</sup> Side effects were severe mucositis and diarrhea (23% and 17%, respectively).

Combinations of topotecan, 1.25 mg/m<sup>2</sup> daily × 5 and Ara-C 1 g/m<sup>2</sup> over 2 hours daily × 5, every 4 to 6 weeks, were given with intensive supportive care, prophylactic antibiotics, and the use of the protected environment among patients 50 years or older. Eighty-six patients have been treated (59 MDS, 27 CMML). Their median age was 64 years; 35% had prior therapy and 50% had unfavorable chromosomal abnormalities. Complete response was observed in 56% and induction mortality in 7%.<sup>35</sup> Complete response rates were higher with RAEB than with RAEBT and CMML (complete response rate of 80% vs. 47% vs. 44%; *P* = .01), but were similar by different age groups and cytogenetic abnormalities. Median complete response duration was 8 months, and median survival was 14 months. Severe mucositis or diarrhea occurred in only 3%. This suggested a possible role for topotecan in patients with poor prognoses (older, poor cytogenetics), who have a high incidence of expression of the multidrug resistance phenotype and may benefit from agents that are not multidrug resistance-dependent, such as topoisomerase I inhibitors. Investigations to improve prognosis include (1) addition of cyclophosphamide to topotecan and Ara-C; (2) consolidation strategies in complete response (targeted therapies, immunomodulation, anticytokines); (3) newer topoisomerase I inhibitors<sup>108,109</sup>; and (4) different dose schedules (e.g., oral topotecan in lower dose, longer exposure schedules).

### Hypomethylating Agents

DNA site-specific methylation may be associated with tumor resistance and progression in many solid and hematologic cancers including MDS.<sup>110</sup> In MDS, frequent hypermethylation of p15<sup>INK4b</sup> has been reported.<sup>56,57,111</sup> Agents shown to induce general and selective hypomethylation include 5-azacitidine, decitabine, and the newer methyl transferase antisense inhibitors.

Following pilot studies of continuous intravenous and subcutaneous 5-azacitidine in MDS, Silverman et al. conducted a large-scale randomized trial of subcutaneous 5-azacitidine, 75 mg/m<sup>2</sup> daily × 7 every 4 weeks (*n* = 99), versus observation (*n* = 92) in 191 patients with high-risk MDS.<sup>112,113</sup> Cross-over to 5-azacitidine was allowed if there was progression on the observation arm. Responses occurred in 61% of 5-azacitidine-treated MDS patients (9% complete response, 15% partial response, 35% hematologic improvement) versus 5% in the observation arm (*P* < .01). The median time to leukemia transformation (21 vs. 13 months; *P* < .01) and the median survival (24 vs. 14 months; *P* = .10) were longer among 5-azacitidine-treated patients.<sup>112</sup> Quality of life was also improved.<sup>113</sup> Thus, 5-azacitidine therapy effectively modified the natural history of MDS.

Wijermans et al. treated elderly patients with high-risk MDS with decitabine, 40 to 50 mg/m<sup>2</sup> over 24 hours daily × 3 every 6 weeks (120 to 150 mg/m<sup>2</sup>/course), and later at 15 mg/m<sup>2</sup> over 4 hours every 8 hours for 3 days (135 mg/m<sup>2</sup>/course) every 6 weeks.<sup>114</sup> In an update of 125 patients in three studies (median age, 70 years; IPSS risk intermediate-1 in 35, intermediate-2 in 38, and high-risk in 52) 49% responded: complete response in 24 (20%), partial response in 12 (10%), and hematologic improvement in 23 (19%).<sup>114</sup> Response rates were 58% in IPSS high-risk and 39% and 45% in IPSS intermediate-1 and -2 risk groups, respectively. Ten patients (8%) died during therapy. In 15 patients with chromosomal abnormalities who obtained complete response, disappearance of the cytogenetic abnormalities was noted. The median response duration was 9 months. The median survival was 15 months: 19 months in intermediate -1, 13 months in intermediate -2, and 14 months in high-risk patients. Hypermethylation at three cytosine residues in the 5' region of the p15 gene was detected in 59% of patients. Efficient reduction of methylation with decitabine therapy either accompanied or preceded suppression of bone marrow blasts and improvement of cytopenias. However, responses to decitabine also occurred in the absence of p15 hypermethylation, suggesting that p15 is one but not the only molecular target of pharmacologic demethylation in MDS, or that decitabine may induce anti-MDS activity through mechanisms other than hypomethylation.<sup>111</sup>

### Other Chemotherapeutic Agents

Homoharringtonine, a semisynthetic plant alkaloid, showed activity in chronic myelogenous leukemia and AML.<sup>115</sup> Feldman et al. treated 15 patients with MDS with homoharringtonine, 5 mg/m<sup>2</sup> by continuous infusion daily for 9 days every month, and observed four responses (27%).<sup>116</sup> Significant myelosuppression and high induction mortality discouraged further studies. Lower dose schedules of homoharringtonine, 2.5 mg/m<sup>2</sup> daily × 7, alone or in combinations, may prove effective and less toxic.<sup>115</sup>

### Amifostine

Amifostine, an organic thiophosphonate, increases normal hematopoiesis *in vitro*, suppresses apoptosis, and inhibits production of TNF-α and other inflammatory cytokines. In a multiinstitutional study, patients with MDS received amifostine, 200 or 400 mg/m<sup>2</sup> intravenously 3 times weekly for 3 weeks every 5 weeks. Among 75 evaluable patients, single or multilineage hematologic response was observed in 27 (36%). A 50% decrease in blasts was noted in ten patients (13%) and a 50% decrease in ringed sideroblasts in nine patients (total 16 patients). Ten of the 16 also had peripheral blood responses.<sup>117</sup> Other studies reported lower response rates.<sup>118</sup>

### Immunotherapy

Immunosuppression may be pathophysiologic in some MDS cases, and immune therapy may be beneficial.<sup>119</sup> Patients with hypoplastic MDS have had complete and durable remissions with therapies similar to those used in aplastic anemia. ATG resulted in responses in 44% of patients.<sup>120</sup> Cyclosporin A resulted in clinical improvements in 14 of 17 patients treated for low-risk MDS.<sup>121</sup> Studies of combinations of ATG, cyclosporine A, growth factors, and corticosteroids are in progress.

### Other Strategies

Monoclonal antibodies targeted against surface antigens expressed in MDS (e.g., CD33 and CD45) may be useful.<sup>122</sup> Anti-TNF strategies using pentoxifylline-based combinations were not beneficial.<sup>123</sup> Other anti-TNF strategies may incorporate amifostine and pentoxifylline or use soluble TNF receptors alone or in combination with amifostine, pentoxifylline, and anti-Fas ligand. Antiangiogenesis therapy with thalidomide, 200 to 800 mg orally daily, produced complete response in only one of nine patients in one study<sup>124</sup>; another study reported clinical benefits in 10 of 20 evaluable patients (50%).<sup>125</sup> Based on the association of p53 mutations with

MDS,<sup>53,126</sup> Bishop et al. investigated whether inactivation of p53 RNA by antisense and rebound in p53 expression through the use of OL(1)p53 would be effective. Only one of ten high-risk MDS patients treated had a transient response.<sup>127</sup> Approaches attempting to enhance immunologic response in MDS, using linomide or IL-2, have not been successful.<sup>128,129</sup> Investigations of the new RAS inhibitors and antitelomeric strategies will be of interest in MDS.<sup>130,131</sup>

Agents with interesting differentiation properties include hexamethylene bisacetamid and sodium phenylbutyrate. In two studies in MDS, hexamethylene bisacetamid given by continuous infusion induced complete response in three patients and partial response in six patients among a total of 57 patients treated (objective response rate, 17%).<sup>74,132</sup> Sodium phenylbutyrate, a histone deacetylase inhibitor, was given to 27 patients at doses up to 440 mg/kg daily × 7 every 4 weeks: 17 had improvements in granulocyte counts and 3 had improvements in platelet counts.<sup>71</sup>

### Correlative Studies and Mechanism of Actions

While each of these new approaches has provided encouraging results, little is known about how they influence specifically the pathophysiology of MDS. Understanding how these agents affect methylation, cytokines, and genes involved in apoptosis or proliferation cascades may refine treatments to be more selective and less toxic and help combine them in more appropriate simultaneous and sequential schedules.

### SUMMARY

While several strategies were initially thought to be hopeful in MDS (e.g., low-dose Ara-C, growth factors), progress has been modest. Better understanding of the pathophysiology of MDS (e.g., apoptosis, clonality, cytokines) may produce tailored strategies. The improved classification of MDS may allow more appropriate therapies for low- versus high-risk groups. Growth factors and immunosuppressive strategies may improve results in low-risk MDS, while the combination of more selective anti-MDS agents (topoisomerase I inhibitors, hypomethylating agents) may improve outcome in high-risk MDS. Progress in SCT (graft-versus-MDS, mini-SCT, preparative regimens) could result in its broader applications. Finally, it is hoped that new targets and targeted therapies will emerge that will add to our knowledge and better treatment of MDS.

### INTRODUCTION

Tumors may produce signs and symptoms at sites distant from the primary tumor or its metastases and these are referred to as *paraneoplastic syndromes*. The syndromes may be due to (1) tumor production of substances that directly or indirectly cause distant symptoms, (2) depletion of normal substances that leads to a paraneoplastic manifestation, or (3) host response to the tumor that results in the syndrome. The evidence for the existence of a paraneoplastic syndrome may range from the mere association of the syndrome with the presence of an actively growing tumor to the cloning of the gene responsible for the syndrome. Among the best characterized of the paraneoplastic syndromes are those producing polypeptide hormones, such as adrenocorticotropin (ACTH) or parathyroid hormone, that affect organ function at remote sites. In such situations, the paraneoplastic syndrome parallels the underlying malignancy, and treatment of the underlying tumor leads to disappearance of the hormone. Additional tumor-derived proteins responsible for paraneoplastic syndromes have been identified, including various growth factors and cytokines such as interleukin-1 (IL-1) and tumor necrosis factor (TNF). Antibodies produced by certain malignancies may lead to neurologic paraneoplastic syndromes such as the Eaton-Lambert syndrome. Many paraneoplastic syndromes, especially those of an immune etiology, do not respond to treatment of the underlying malignancy.

The paraneoplastic syndrome may be the first sign of a malignancy, and its recognition may be critical for early cancer detection. Certain paraneoplastic syndromes that secrete proteins can be used as tumor markers in monitoring patients before and after therapy. In some situations, the underlying disease cannot be treated, but the symptoms and complications of the paraneoplastic syndrome must be treated. This chapter reviews the wide range of paraneoplastic syndromes including the endocrinologic, hematologic, gastrointestinal (GI), renal, cutaneous, and neurologic paraneoplastic syndromes.

### ENDOCRINOLOGIC MANIFESTATIONS OF CANCER

Endocrine syndromes of cancer are caused by the tumor's direct production of hormones, hormone-precursors, or cytokines, as well as cancer metabolism of steroids to active forms.<sup>1</sup>

### ECTOPIC ADRENOCORTICOTROPIC HORMONE SYNDROME

In 1928, Brown first described the syndrome of ectopic ACTH overproduction, when he reported a patient with small cell lung carcinoma and associated hirsutism, diabetes mellitus, hypertension, and adrenal hyperplasia.<sup>2</sup> The syndrome was further characterized in 1965 when 88 patients with Cushing's syndrome and cancer were described.<sup>3</sup> This report was the first to suggest that tumors produced ACTH or an ACTH-like substance, which led to adrenal hyperplasia and hypercortisolism, coining the term <sup>ectopic ACTH production</sup>. Subsequently, proopiomelanocortin (POMC), the precursor hormone of ACTH, was described, containing not only ACTH, but melanocyte stimulating hormone, b-lipotropin, endorphins, and enkephalins.<sup>4,5 and 6</sup>

Many normal tissues produce minute amounts of POMC, while carcinomas produce higher quantities, and in some instances can convert these to active ACTH, producing the Cushing's syndrome. Patients with ectopic ACTH syndrome have a much higher ratio of ACTH precursors to endogenous ACTH, when compared with

patients with Cushing's disease (hypercortisolism secondary to a pituitary adenoma).<sup>7</sup> The molecular control of this process lies in the fact that three promoter regions control transcription of the POMC gene. In normal pituitary glands the P<sub>2</sub> promoter is active, while in cancer-associated ACTH production, the P<sub>1</sub> promoter predominates.<sup>8</sup> It is postulated that loss of tumor suppressor genes leads to overproduction of the C-fos oncogene, which leads to increased POMC gene expression, along with many other proteins in the oncogenic cascade.<sup>9</sup> Some neoplasms then convert pro-ACTH to active ACTH, resulting in the ectopic ACTH syndrome.<sup>1</sup>

Ectopic ACTH is commonly associated with small cell carcinoma of the lung, but can also be found in a variety of neoplasms (Table 47-1). While 3% to 7% of patients with small cell carcinoma of the lung develop Cushing's syndrome, many patients with small cell carcinoma of the lung secrete ACTH precursors without the development of the syndrome.<sup>10</sup>

TABLE 47-1. Tumors Associated with Ectopic Adrenocorticotrophic Hormone

### Clinical Presentation

Cushing's initial description of the peripheral effects of a hyperfunctioning pituitary adenoma included truncal obesity, purple striae, hypertension, fatigue, moon facies, buffalo hump, weakness, depression, amenorrhea, hirsutism, and edema. The differential diagnosis of a patient with hypercortisolism includes Cushing's disease, adrenal dysfunction, ectopic ACTH production, and corticotropin-releasing hormone (CRH) overproduction. Pituitary overproduction (Cushing's disease) is the most common etiology, occurring in 55% to 82% of patients, while adrenal dysfunction occurs in 5% to 32%, ectopic ACTH production in 11% to 25%, and CRH overproduction in less than 1% to 2%.<sup>11,12,13</sup> and <sup>14</sup> Although signs and symptoms of hypercortisolism are not specific, several features of ectopic ACTH production are distinguishing: Myopathy with weakness, muscle wasting, hyperpigmentation, and hypokalemia are more common in ectopic ACTH production. Cushing's disease is more common in young women (3 to 1), whereas older men (at higher risk for lung cancer) typically have ectopic ACTH production.<sup>10</sup> Commonly, hirsutism, severe hypertension, and hyperpigmentation are noted on physical evaluation, while glucose intolerance, hypokalemia, and metabolic alkalosis make up the usual biochemical profile. The hypokalemia can be severe and life threatening.

### Diagnosis

Distinguishing between pituitary adenoma, ectopic ACTH production, and primary adrenal disorders is the primary focus of the diagnostic workup (Fig. 47-1). The two most common screening tests for cortisol overproduction are the 24-hour urinary free cortisol and the low-dose dexamethasone suppression test. In normal subjects cortisol production should be suppressed by a relatively low dose of dexamethasone, whereas patients with Cushing's disease or ectopic ACTH production are not affected.

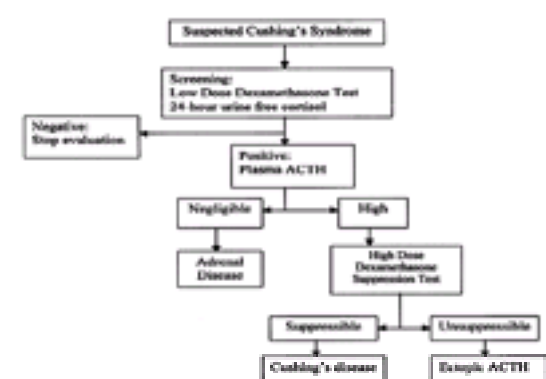

FIGURE 47-1. Diagnostic algorithm for the evaluation of patients with suspected Cushing's syndrome. See text for details of various tests. ACTH, adrenocorticotrophic hormone.

With reliable radioassays of ACTH, plasma levels can be determined early in the diagnostic workup. In primary adrenal disease, ACTH levels are low, while in ACTH-dependent Cushing's syndrome the ACTH level is elevated.<sup>14</sup> Classically, plasma ACTH and ACTH precursor levels in ectopic ACTH production are much higher than in Cushing's disease (pituitary adenoma); however, there is a great deal of overlap, particularly in the case of slow-growing malignancies such as bronchial carcinoids. Once primary adrenal disease is eliminated, with normal or elevated ACTH levels, a high-dose dexamethasone suppression test is indicated. High-dose dexamethasone suppresses cortisol production (and thus the urinary study results) in patients with Cushing's disease but not ectopic ACTH production or primary adrenal disorders.<sup>10</sup> False-positive dexamethasone suppression test results are seen when dexamethasone is metabolized more rapidly than normal. Drugs such as diphenylhydantoin, phenobarbital, and primidone, as well as disease states such as thyrotoxicosis cause rapid dexamethasone metabolism. Furthermore, bronchial carcinoids can have ACTH and cortisol suppression with high-dose dexamethasone testing in 40% to 50% of cases.<sup>15</sup>

While the reliability of the dexamethasone suppression test is good, the test is cumbersome and its performance characteristics (sensitivity and specificity) are not perfect. For these reasons, the metyrapone and CRH stimulation tests have been developed. In both tests the sensitivity of pituitary adenoma to stimulation by either cortisol deprivation (metyrapone) or directly (CRH) is exploited. Metyrapone blocks the production of cortisol in the adrenal by inhibiting the conversion of 11-deoxycortisol to cortisol, leading to an increased ACTH secretion in normal patients, thus testing the integrity of the adrenal-cortisol-pituitary feedback loop. Patients with Cushing's disease show stimulated ACTH production, whereas ectopic ACTH production is unaffected. In the largest reported study, the metyrapone test correctly predicted Cushing's in 71% of patients with ACTH-dependent Cushing's syndrome. The combination of the dexamethasone suppression test and the metyrapone test predicted 82% of the cases (significantly better than either test alone).<sup>16</sup> Similarly, pituitary adenomas are generally responsive to ovine CRH stimulation, while ectopic ACTH-producing tumors are not. In one report of 41 patients with ACTH-dependent hypercortisolism, 29 of 33 patients with pituitary adenoma were stimulated with ovine CRH, whereas none of the 8 patients with ectopic ACTH production were stimulated.<sup>17</sup> This led to a sensitivity of 88%, a specificity of 100%, and a diagnostic accuracy of 90%, which compared favorably with the standard dexamethasone suppression test. Again, the combination of CRH stimulation and dexamethasone suppression led to a superior diagnostic accuracy of 98%.

Other evaluations that are more invasive or less well established in diagnosing Cushing's syndrome include inferior petrosal blood sampling with or without CRH stimulation,<sup>18</sup> continuous dexamethasone infusion,<sup>19</sup> and serum chromogranin A.<sup>20</sup> Inferior petrosal venous samples show a marked gradient with peripheral samples in pituitary adenoma. The diagnostic accuracy is high, but the test is expensive and invasive. One hundred twenty-one patients were evaluated with 7-hour continuous infusion dexamethasone at 1 mg/h. The sensitivity for pituitary disease was 100%, the specificity was 90%, and the diagnostic accuracy was 98%. This evaluation was thought to be more convenient and accurate, but these results have not been confirmed. Serum chromogranin A has been shown to be a potential marker of ectopic

production. The results, at this point, are preliminary, however.

### Treatment

Localization is the most important aspect of therapy. Since a major portion of patients with ectopic ACTH have lung cancer, chest evaluation is initially in order. Plain radiographs followed by computed tomography (CT) detect more than 90% of the lung tumors associated with ACTH production.<sup>11,21,22</sup> The exception is bronchial carcinoid tumors, which are visualized on 36% of initial radiographs, but are localized by CT scan in approximately 85% of cases.<sup>23</sup> Octreotide receptor scintigraphy has been promoted for localizing ACTH-producing tumors, because many such tumors have octreotide receptors.<sup>24</sup> An additional advantage of localizing tumors with octreotide receptor scintigraphy is the suggestion of possible therapy with either somatostatin analogues or radiolabeled octreotide.

Surgery is the treatment of choice in patients with early-stage tumors producing Cushing's syndrome because it can completely alleviate symptoms. In one series of 41 patients with ectopic ACTH and absence of small cell cancer of the lung, 16 of 21 (76%) patients with localized tumors were cured of Cushing's syndrome with surgery. Specifically, 81% of bronchial carcinoid tumors were cured with resection, and 9 of 12 (75%) patients with occult ACTH production were palliated with bilateral adrenalectomy.<sup>25</sup> While bilateral adrenal removal is effective in treating Cushing's syndrome, the patient must have lifelong glucocorticoid and mineralocorticoid replacement. Patients with severe muscle weakness and uncontrolled hypertension are candidates for this approach. The use of laparoscopic adrenalectomy has been reported to effectively palliate patients with Cushing's with minimal morbidity and no mortality reported.<sup>26</sup>

The majority of patients do not have surgically resectable disease and may have ongoing symptoms related to Cushing's syndrome. Medical therapy for ectopic ACTH production centers on inhibiting cortisol production with mitotane, aminoglutethimide, metyrapone, or ketoconazole (Table 47-2).<sup>27,28</sup> and<sup>29</sup> Mitotane is effective in lowering cortisol levels; however, it is rarely used because of its severe toxicity and slow onset of action. Aminoglutethimide is used in only limited situations, because of incomplete responses. Metyrapone is an effective treatment, particularly in combination with aminoglutethimide. Because of its rapid onset of action and favorable toxicity profile, ketoconazole has evolved as the therapy of choice for ectopic ACTH. In one small study, 66% of patients with ectopic ACTH production had a hormonal response and symptomatic improvement with ketoconazole at a dose of 400 to 1200 mg/d. A minority developed symptomatic hypoadrenalism.

Drug	Dose
Ketoconazole	400-1200 mg/d
Metyrapone	500-4000 mg/d
Aminoglutethimide	500-2000 mg/d
Mitotane	4-12 g/d
Sandostatin	300-1500 µg/d

**TABLE 47-2.** Drugs Used for Treating Ectopic Adrenocorticotrophic Hormone Production

Suppression of primary ACTH production can be accomplished by two means: cytotoxic chemotherapy, for the primary problem, and octreotide suppression of ACTH release. In general, chemotherapy alone is not associated with control of Cushing's syndrome, but is combined with adrenal suppression in most cases. As well, if patients show significant localization with octreotide receptor scintigraphy, a trial of octreotide may be in order. In one small study of ten patients treated with octreotide, four had significant rapid responses.<sup>30</sup> The combination of ketoconazole and octreotide has also been reported.<sup>31</sup>

### SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

The syndrome of inappropriate antidiuretic hormone production (SIADH) was first reported in two patients with lung cancer and hyponatremia.<sup>32</sup> The proposed etiology was an abnormal production of ADH or an ADH-like substance by the cancer. In 1968, arginine vasopressin (ADH) was extracted from cancers associated with this syndrome, confirming the original hypothesis.<sup>33</sup> While the majority of small cell lung tumors positively stain for arginine vasopressin by radioimmune assay,<sup>34,35</sup> and<sup>36</sup> only 3% to 15% of patients with small cell lung carcinoma have this syndrome.<sup>37,38</sup> Clearly, as with ectopic ACTH production, the vast majority of tumors that contain these substances does not produce the clinical syndrome.

The pathophysiology of SIADH is well described. After vasopressin is released, it binds to specific receptors in the renal collecting ducts and ascending limb of the loop of Henle. Excess water is reabsorbed and increased sodium is delivered to the distal nephron. This increases intravascular volume, which in turn increases renal perfusion and decreases proximal tubular resorption of sodium. ADH secretion continues in SIADH despite the decrease in plasma osmolality, causing eventual hyponatremia.<sup>39,40</sup>

### Clinical Features and Diagnosis

The cardinal features of SIADH are water intoxication and hyponatremia, including the following principal findings: decreased serum osmolarity, inappropriate elevation of urine osmolarity with urine sodium levels greater than 20 mEq/L, euvolemia (absence of hypovolemia), normal renal function, normal adrenal function, and normal thyroid function. Most patients are asymptomatic, but when symptoms develop they generally reflect central nervous system toxicity. In its early stages, patients complain of fatigue, anorexia, headaches, and mild altered mental status. As the syndrome progresses, patients may experience continued delirium, confusion, fatigue, and seizures. Ultimately, patients develop refractory seizures, coma, and rarely death. Most patients, however, experience minimal symptoms and are discovered on routine laboratory evaluation when they have hyponatremia.

In evaluating a patient with hyponatremia and cancer, other causes of hyponatremia need to be considered. In general, the first step in evaluating patients with hyponatremia is to assess volume status. SIADH is one of the so-called euvolemic hyponatremic states. Therefore, it is necessary to eliminate states associated with volume overload such as congestive heart failure, nephrotic syndrome, malignant ascites, and significant liver disease. It is also essential to exclude extrarenal volume depletion and renal sodium wasting. Once the patient is determined to be euvolemic, other causes of euvolemic hyponatremia must be ruled out, including hypothyroidism, renal dysfunction, and Addison's disease. A careful review of medications is also essential.

Once the diagnosis of SIADH is made, a wide variety of etiologies must be considered, including central nervous system diseases, pulmonary diseases, and drugs. Tumor-associated SIADH is a diagnosis of exclusion. For the purposes of treatment, however, differentiating tumor-related SIADH from other causes of SIADH is not necessary. Of note, it is rarely necessary to perform a water-loading test in order to make the diagnosis of SIADH. Because these patients are often unable to excrete free water, they can develop significant water intoxication, leading to serious morbidity in this setting.

The principal malignancy associated with SIADH is small cell lung carcinoma, although others have been described (non-small cell lung cancer, head and neck cancers, and others). Seventy-five percent of all SIADH associated with malignancy is secondary to small cell lung carcinoma. Previously it was proposed that SIADH was a marker of tumor burden as well as a negative prognostic factor.<sup>41</sup> However, more recent reports have indicated that SIADH is neither an indicator of poor outcome nor disease burden.<sup>42</sup> Indeed, many patients with small cell lung carcinoma only develop SIADH after treatment.<sup>43</sup> Of interest, several chemotherapeutic agents commonly used in oncology cause transient SIADH including vincristine, vinblastine, vinorelbine, ifosfamide, cyclophosphamide, and cisplatin.<sup>44,45</sup> and<sup>46</sup>

### Treatment

As with any syndrome associated with ectopic hormone production, treating the underlying disease is the most effective means of controlling SIADH. Chemotherapy treatment of the associated small cell lung cancer is generally associated with improvement in the syndrome. SIADH has not been shown to be a negative prognostic

factor in terms of response to chemotherapy. In situations in which brain metastases are present, the addition of radiation therapy is important. Because surgery is not generally thought to be an effective modality in patients with small cell lung cancer, surgery is rarely undertaken in patients with malignancy-associated SIADH. In chemotherapy-related SIADH, the offending drug should be stopped.

Supportive measures such as fluid restriction and pharmacologic therapy can be undertaken to treat SIADH. Patients with sodium levels under 130 mmol/L are placed on a free water restriction (500 mL/d), in addition to treatment of the primary malignancy.<sup>47</sup> In the event that this measure does not bring the serum sodium above 130 mmol/L, pharmacologic agents such as demeclocycline can be instituted. Demeclocycline inhibits the effect of arginine vasopressin on the kidneys.<sup>48</sup> The recommended dose of demeclocycline is 600 to 1200 mg/d in divided doses. Other less common medications that have reported efficacy include fludrocortisone, urea, and lithium. Finally, in severe cases in which patients have life-threatening convulsions or coma, patients can be treated with hypertonic saline solution with intravenous furosemide. It is important not to raise the serum sodium too rapidly (the recommendation is 1 mEq/L/h) due to the risk of central pontine myelinolysis.<sup>49</sup> It is generally thought that hypertonic saline and Lasix treatment should be carried out in the intensive care unit setting.

## HYPOCALCEMIA

Although most of the discussion regarding disturbance of calcium balance and malignancy revolves around hypercalcemia, hypocalcemia is actually more common in patients with bone metastases.<sup>50,51</sup> Tumors associated with lytic bone metastases such as breast, prostate, and lung cancers, can lead to hypocalcemia.<sup>52,53</sup> Also, rarely, hypocalcemia can occur in patients whose tumors secrete calcitonin (i.e., medullary carcinoma of the thyroid). More common than hypercalcemia, hypocalcemia is rarely symptomatic. Patients occasionally develop the features of hypocalcemia such as tetany and neuromuscular irritability, but can show mild neuromuscular dysfunction by electromyography. Therapy, consisting of calcium infusion, is reserved for those patients with findings of neuromuscular irritability or symptoms such as tetany and seizures. Signs of neuromuscular irritability including Chvostek's sign and Trousseau's sign (carpal spasm with decreased blood flow) indicate the need for calcium infusion. For a discussion of hypercalcemia, please refer to the chapter on [Metabolic Emergencies](#) (see Chapter 51.3).

## ONCOGENOUS OSTEOMALACIA

Rickets is a well-recognized inborn error of metabolism, while the adult counterpart, osteomalacia, is usually secondary to intestinal malabsorption syndrome, renal tubular acidosis, and chronic renal insufficiency. Oncogenous osteomalacia is a rare syndrome characterized by osteomalacia, hypophosphatemia, hyperphosphaturia, and decreased vitamin D levels. Mean age at diagnosis is approximately 35 years. Patients typically present with bone pain, phosphaturia, renal glycosuria, hypophosphatemia, normocalcemia with normal parathyroid hormone function, low 1,25-(OH)<sub>2</sub>-D<sub>3</sub>, and increased alkaline phosphatase. The proposed mechanisms include inhibition of the conversion of 1,25-dihydroxyvitamin D and a tumor-secreted *phosphaturic substance*. It is usually associated with benign mesenchymal tumors including hemangiomas and hemangiopericytomas, but rarely is seen with multiple myeloma and prostate cancer.<sup>54,55,56,57</sup> and <sup>58</sup> The typical tumor involves prominent giant cells, spindle cells, and a high degree of vascularity. Approximately one-half of the tumors are in the lower extremities, and the remaining tumors are divided between the head and upper extremities with some patients having tumors at multiple sites. The definitive therapy is removal of the tumor, if possible. Otherwise, treatment requires large doses of vitamin D and phosphate.

## CALCITONIN PRODUCTION BY TUMORS

Calcitonin is a polypeptide hormone that is produced by C cells of the thyroid. Calcitonin prevents calcium release from bone and causes increased renal excretion of calcium, sodium, and phosphate.<sup>59</sup> Because medullary thyroid carcinoma produces calcitonin, calcitonin serum levels are a sensitive tumor marker to monitor this disease. They are also useful in identifying patients with multiple endocrine neoplasia type 2, a familial disorder involving an association of medullary carcinoma of the thyroid, pheochromocytoma, and parathyroid adenomas.

A variety of tumors, including small cell lung cancer, carcinoids, breast cancer, and GI cancer also may secrete calcitonin.<sup>60,61</sup> and <sup>62</sup> While calcitonin levels may reflect clinical tumor status in these diseases, they are not used as tumor markers. Furthermore, there is no known paraneoplastic syndrome associated with calcitonin.

## CHROMOGRANIN A

Chromogranin A is a 68-kD glycoprotein found in the neurosecretory granules of normal and malignant amine precursor uptake and decarboxylation cells.<sup>63,64</sup> Chromogranin A is released into the circulation via exocytosis from neuroendocrine storage vesicles. It may act in neuroendocrine secretion by binding intravesicular calcium. Its sequence is nearly identical to pancreastatin, which inhibits insulin and somatostatin secretion from the pancreas.<sup>65</sup> As with calcitonin, it is unknown whether chromogranin A is associated with a paraneoplastic syndrome. Chromogranin A secretion is most commonly associated with small cell lung cancer and neuroendocrine tumors.<sup>66,67</sup> and <sup>68</sup>

## GONADOTROPINS

The human hormones with gonadotropic properties are follicle-stimulating hormone (FSH), luteinizing hormone (LH), and human chorionic gonadotropin (HCG).<sup>69</sup> These three hormones are composed of two polypeptide chains; *a* and *b* subunits. The *a* subunit is common to all of the hormones and the *b* subunit determines biologic and immunologic specificity. Both subunits are required for bioactivity. In normal individuals, the pituitary produces FSH and LH. Biologically active HCG is produced by the placenta and is therefore normally found only in pregnant women. Because the levels of FSH and LH vary under normal physiologic conditions, the *b*-HCG hormone is typically used for following paraneoplastic syndromes.

Gonadotropin secretion may occur in pituitary tumors, gestational trophoblastic tumors, germ cell tumors, hepatoblastomas in children, bronchogenic carcinomas, and GI cancers.<sup>70,71,72</sup> and <sup>73</sup> Gonadotropins measured in tumors arising in gestational tissue, testes, ovaries, and endocrine organs are valuable tumor markers and are discussed in the following chapters: Cancers of the Endocrine System, Gynecologic Tumors, Cancer of the Ovary, and Cancer of the Testes.

Although many studies have suggested elevations in HCG in a number of common tumors, it may also be elevated in nonmalignant chronic diseases. Values for the *a* and *b* subunits of HCG are significantly higher in cancer patients than in patients with nonmalignant disease.<sup>69,74</sup> Elevations of *b*-FSH, thyroid-stimulating hormone-*b*, and *b*-LH have not been observed. With rare exceptions, however, these markers are not routinely used to follow common cancers.

The frequency of symptoms associated with tumor-produced gonadotropin is unknown. The most common problem is a male patient presenting with unexplained gynecomastia. In this situation, a *b*-HCG determination should be performed as well as a careful examination of the testes and radiographic examination of the chest and mediastinum. Germ cell tumors of the testes or extragonadal sites and lung cancers are the most frequent causes of the combination of gynecomastia and HCG elevation.<sup>75</sup> Other extragonadal tumors that produce HCG include lung cancer, adrenal carcinoma, hepatoma, GI tract tumors, and tumors of the genitourinary tract.<sup>76,77,78,79,80,81</sup> and <sup>82</sup> Histologic specimens have revealed that all of these tumors contain syncytial giant cells or choriocarcinomatous elements similar to trophoblastic germ cell tumors. Conversely, 40% of patients with extragonadal germ cell tumors *masquerading* as poorly differentiated carcinomas had immunohistochemical staining for *b*-HCG and  $\alpha$ -fetoprotein without serum elevation of these markers.<sup>83</sup> Many of these patients responded to chemotherapy, as would be expected of germ cell tumors.

## TUMOR-PRODUCED HUMAN PLACENTAL LACTOGEN, GROWTH HORMONE-RELEASING HORMONE, PROLACTIN, AND THYROTROPIC SUBSTANCE

Human placental lactogen (hPL) has been detected in a small percentage of patients with nontrophoblastic nongonadal tumors.<sup>84,85</sup> This may be associated with elevated levels of estrogen, HCG, and gynecomastia. hPL in nonpregnant women is diagnostic of malignancy.<sup>85</sup>

Elevated growth hormone levels have been reported in rare patients with gastric and lung cancer.<sup>86</sup> Whether this is due to ectopic production or overproduction by cells that retain the ability to secrete growth hormone from primordial origin remains controversial.

Growth hormone-releasing hormone production has been reported in nonpituitary tumors and, like pituitary tumors, results in acromegaly.<sup>87,88</sup> and <sup>89</sup> This 44 amino acid peptide has been isolated from pancreatic tumors as well as bronchial and foregut carcinoids. Secretion of growth hormone-releasing hormone can be controlled by

administration of long-acting somatostatin analogues. The definitive therapy is removal of the tumor, whenever possible.

Patients with cancers of the lung, colon, breast, ovary, and cervix, as well as hypernephroma have been reported with elevated prolactin levels, and one case was associated with galactorrhea.<sup>90,91</sup> and <sup>92</sup> Symptoms can be subtle; male subjects may only exhibit decreased libido, whereas postmenopausal women may have no symptoms. Treatment of the tumor decreases prolactin levels. Because these cases are extremely rare, it is important to exclude the presence of a pituitary lesion in patients with elevated prolactin levels.

Tumor-associated thyroid-stimulating hormone production without thyrotoxicosis has been reported.<sup>93</sup> An association has been reported between hyperthyroidism and gestational trophoblastic disease with biochemical hyperthyroidism.<sup>94</sup> This may also be seen in testicular tumors. In some cases, the excess HCG produced by trophoblastic tumors appears to be the thyroid-stimulating substance.<sup>95</sup>

## HYPOGLYCEMIA

Insulinomas frequently produce hypoglycemia; however, hypoglycemia associated with non-islet cell tumors is an unusual paraneoplastic syndrome. Mesenchymal tumors including a variety of sarcomas and mesotheliomas are the most common cause of non-islet cell-induced hypoglycemia. Rarely, adrenal carcinomas, GI cancers, and varied other tumors have been associated.<sup>96,97</sup> These tumors are typically large, often invade the liver, and have a protracted course. The patient may present with typical signs and symptoms of hypoglycemia, including generalized neurologic abnormalities.

These tumors may cause hypoglycemia by a variety of mechanisms including production of nonsuppressible insulin-like growth factors-1 and -2 (IGF-1 and -2), hypermetabolism of glucose, production of substances stimulating ectopic insulin release, massive liver infiltration, production of hepatic glucose inhibitor, insulin binding by an M protein in myeloma, insulin receptor proliferation, or rarely ectopic insulin production.<sup>97,98,99,100,101</sup> and <sup>102</sup> The most likely mechanism is tumor production of IGFs (also called *somatomedins*), a family of peptide hormones normally produced by the liver under growth hormone regulation.<sup>103,104,105</sup> and <sup>106</sup> Several reports have specifically identified excess production of PRO-IGF-2, which binds to insulin and IGF receptors in malignancy. This in turn down-regulates growth hormone secretion and decreases hepatic production of IGF-binding proteins with eventual hypoglycemia.<sup>107,108</sup>

The treatment of paraneoplastic hypoglycemia initially involves glucose infusion. Following this, tumor debulking should be carried out, although the long-term effect of debulking is poorly understood. If treatment of the tumor is not possible, then the use of subcutaneous and long-acting intramuscular glucagon or high-dose corticosteroids might be considered.

## HEMATOLOGIC MANIFESTATIONS OF CANCER

Paraneoplastic syndromes that involve hematopoietic cells and clotting factors are extremely common. While the etiologies of most of these paraneoplastic abnormalities remain unexplained, advances in the understanding of hormones and growth factors that regulate hematopoiesis has led to a better understanding of some of these disorders.<sup>109,110</sup>

### ERYTHROCYTOSIS

Erythrocytosis secondary to a wide variety of tumors is well described in the literature. The most common solid tumor leading to erythrocytosis is renal cell carcinoma, which is often associated with elevated serum erythropoietin levels. Benign renal lesions such as cystic kidneys may also cause erythrocytosis, and other tumors of the kidneys such as Wilms' tumor and hemangiomas rarely cause erythrocytosis. The next most common malignancy leading to erythrocytosis is hepatoma, also likely secondary to erythropoietin production. Cerebellar hemangioblastomas are also known to produce erythrocytosis. Other tumors leading to erythrocytosis include uterine fibroids, adrenal tumors, and pheochromocytomas.<sup>111,112</sup> Adrenal cortical tumors and virilizing ovarian tumors can produce androgenic hormones that may lead to erythrocytosis.<sup>113</sup> Prostaglandins produced from tumors can enhance the effect of erythropoietin and lead to erythrocytosis.

It is still important to rule out other causes of erythrocytosis even in the presence of a tumor. Polycythemia rubra vera is typically associated with elevated white count and platelets as well as splenomegaly. There are obvious causes of polycythemia secondary to arterial desaturation associated with hemoglobinopathies, carboxyhemoglobin, and so forth. Erythropoietin can be measured from the blood when it is suspected that it is overproduced secondary to a tumor. Erythrocytosis secondary to tumors is usually not high enough to require treatment, but if the hematocrit is extremely high (i.e., greater than 55% for a man or greater than 50% for a woman) phlebotomy can be used. Control of the tumor usually controls the erythrocytosis, as well.

### ANEMIA

The most common anemias in cancer patients are the normocytic normochromic anemia of chronic disease, anemia secondary to bone marrow invasion, which may be associated with leukoerythroblastosis, and anemia secondary to chemotherapy and radiation therapy. Normochromic, normocytic anemia, or anemia of cancer, is a common paraneoplastic syndrome, characterized by low serum iron, normal or increased ferritin, normal iron stores, and a low serum erythropoietin level. It is thought that IL-1, TNF, and transforming growth factor- $\beta$  are produced by tumors and effect a decreased erythropoietin response.<sup>114</sup>

A rare cause of anemia in cancer patients is pure red cell aplasia. The relationship of thymoma and pure red cell aplasia often associated with hypogammaglobulinemia is well described in the literature.<sup>115,116</sup> Pure red cell aplasia may also be associated with a variety of lymphoid malignancies including chronic lymphocytic leukemia (CLL) and large granular lymphocytic lymphoma and leukemia.<sup>117</sup> Rarely, pure red cell aplasia is associated with solid tumor malignancies.

Autoimmune hemolytic anemias are typically associated with B-cell malignancies including CLL and lymphomas,<sup>118,119</sup> and arise secondary to immunoregulatory abnormalities in these diseases, rather than a direct secretion of tumor-derived substances. Hallmarks of the disease are a positive direct antiglobulin test result, elevated reticulocyte count, decreased haptoglobin, and elevated lactate dehydrogenase. Warm antibody hemolytic anemia is most commonly associated with lymphomas, CLL, and mucin-producing adenocarcinomas. Cold agglutinin disease is most common in Waldenström's macroglobulinemia and lymphomas.<sup>120</sup> Autoimmune hemolytic anemia is rarely associated with solid tumor malignancies; however, an association with ovarian, GI, lung, breast, and renal cell cancers has been reported.<sup>121</sup> Corticosteroid treatment appears to be less effective in autoimmune hemolytic anemia associated with carcinomas than in those that are idiopathic or associated with lymphoid malignancies. The Coombs' test result may revert to negative with control of the tumor.

Microangiopathic hemolytic anemia is characterized by fragmentation of red cells and is observed in diseases associated with lesions in small blood vessels such as thrombotic thrombocytopenic purpura, congenital vascular abnormalities, and the hemolytic uremic syndrome. Microangiopathic hemolytic anemia has also been reported in association with malignancy.<sup>122,123</sup> Such patients may have intimal proliferation of arterioles, intravascular tumor growth, or intravascular fibrin precipitation. Thrombocytopenias may also be associated. Disseminated intravascular coagulation (DIC) may contribute to microangiopathic hemolytic anemia in metastatic carcinomas by inducing the red cell fragmentation from fibrin strands. Patients typically have pronounced schistocytosis with *microspherocytes*, which are spherocyte-shaped erythrocytes less than 5  $\mu$ m in diameter. The reticulocyte count is typically increased and a leukoerythroblastic blood picture may predominate. The mechanism remains unknown. The microangiopathic hemolytic anemia syndrome may respond to effective anticancer therapy. It is typically associated with adenocarcinoma of the GI tract, heart, lung, and prostate, as well as after mitomycin C chemotherapy.

### GRANULOCYTOSIS

Granulocytosis with elevation of the white blood cell count above  $15 \times 10^9/l$  without infection or leukemia is common in neoplasms.<sup>124,125,126</sup> and <sup>127</sup> Isolated or associated monocytosis is also described.<sup>128</sup> Neoplasms most commonly associated with granulocytosis include Hodgkin's disease, lymphoma, and a variety of solid tumors including gastric, lung, pancreatic, and brain, as well as malignant melanoma. The granulocytosis associated with a paraneoplastic leukemoid reaction consists of mature neutrophils with some band forms seen. This differs significantly from chronic myelogenous leukemia in which there are many more immature cells, basophils, and eosinophils; a decreased leukocyte alkaline phosphatase; elevated vitamin B<sub>12</sub> and vitamin B<sub>12</sub>-binding capacity; and the presence of the Philadelphia chromosome. The common mechanism associated with tumor-associated granulocytosis is tumor production of growth factors including granulocyte

colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, IL-3, IL-1, and a variety of others. <sup>129,130</sup>

## GRANULOCYTOPENIA

Granulocytopenia is typically secondary to chemotherapy, radiation therapy, or tumor infiltration of bone marrow. It is possible in some cases that the tumors may produce a factor that suppresses granulopoiesis by interfering with any number of growth factors. As well, there are rare reports of antibodies against granulocytes in patients with Hodgkin's disease and nonchemotherapy-induced neutropenia. <sup>131</sup> Neutropenia associated with large granular lymphocytic leukemia and lymphoma may be caused by immune dysregulation of T cells. The preferred therapy for severe granulocytopenia is direct stimulation with growth factors including granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, or both.

## EOSINOPHILIA AND BASOPHILIA

Eosinophilia is commonly associated with Hodgkin's disease and mycosis fungoides and is rarely associated with other lymphomas and solid tumors. <sup>132</sup> The tumor cells may be producing a factor that specifically stimulates eosinophil production. In one study, a tumor-associated eosinophil-stimulating factor was found to be a glycoprotein of 45 kD. <sup>133</sup> Other candidate cytokines include granulocyte-macrophage colony-stimulating factor, IL-3, and IL-5, which are involved in the development and differentiation of eosinophils. <sup>134</sup> Eosinophilia is rarely of sufficiently high counts to lead to symptoms of Löffler's-like syndrome, which is associated with nodular pulmonary infiltrates with cough and fever. Basophilia is associated with chronic myelogenous leukemia and a variety of other myeloproliferative disorders, but is not typically associated with symptoms. <sup>135</sup>

## THROMBOCYTOSIS

Thrombocytosis is quite common in cancer patients and may be associated with Hodgkin's disease, lymphomas, and a variety of carcinomas and leukemias. <sup>136</sup> Thrombocytosis is expected early in the course of a variety of myeloproliferative diseases including polycythemia rubra vera and chronic myelogenous leukemia. It is, of course, the hallmark of primary thrombocytosis. Thrombocytosis may also be associated with inflammatory disorders, hemorrhage, iron deficiency, hemolytic anemia, and postsplenectomy. The thrombocytosis secondary to malignancies may be secondary to overproduction of thrombopoietin. <sup>137</sup> Thrombosis and hemorrhage are rarely associated with this paraneoplastic syndrome and treatment is not generally indicated.

## THROMBOCYTOPENIA

Thrombocytopenia in cancer patients is typically secondary to chemotherapy, radiation therapy, DIC, or tumor infiltration of bone marrow. A syndrome similar to idiopathic thrombocytopenia purpura is commonly seen in lymphoid malignancies including CLL and lymphomas, as well as Hodgkin's disease. Rarely, solid tumors such as lung, breast, and GI cancers have been associated with a similar syndrome. <sup>138,139,140,141,142</sup> and <sup>143</sup> These patients may have bleeding, petechia, and purpura and may respond to high-dose prednisone, splenectomy, or both. Other common causes of thrombocytopenia, such as heparin-induced thrombocytopenia, thiazide diuretics, and a variety of other drugs, should be ruled out. Typical of any other idiopathic thrombocytopenia purpura, the patients have adequate or increased megakaryocytes in the bone marrow associated with the thrombocytopenia and do not respond to transfused platelets.

## THROMBOPHLEBITIS

The association of cancer and thrombophlebitis was first observed by Trousseau and this association still bears his name. <sup>144</sup> The incidence of thrombophlebitis in cancer patients is quite common and migratory thrombophlebitis is well documented. Recurrent deep venous thrombosis, warfarin resistance, and thrombosis at unusual sites should increase suspicion of occult malignancy in a patient without a known diagnosis of cancer. The greatest risk of migratory thrombophlebitis is with pancreatic cancer; however, it may be seen in a variety of adenocarcinomas, including breast, ovarian, and prostate cancer. <sup>123</sup> The activation of coagulation by tissue factor is clearly implicated in the patients with solid tumors when compared with normal controls. <sup>145</sup> As well, mucinous adenocarcinomas produce a sialic acid moiety that can activate factor X, causing a hypercoagulable state. <sup>146</sup> It is likely that cancer-related thrombosis represents a complex imbalance of coagulation and fibrinolysis: increased fibrinogen and platelet catabolism; decreased protein C, S, and antithrombin; direct generation of thrombin; and thrombocytosis all represent abnormalities associated with malignancy. <sup>147</sup>

The treatment, although difficult, must be initiated with heparin; however, it is often unsuccessful and long-term therapy with either warfarin or heparin is typically not satisfactory. Initial reports of the beneficial effects of low-molecular-weight heparin in cancer patients with thrombosis <sup>148</sup> are supported by a retrospective metaanalysis. In this study, a significant reduction in mortality was reported in cancer patients treated with low-molecular-weight heparin compared with those treated with unfractionated heparin for deep venous thrombosis. The cause of reduced mortality appeared to be an indirect effect that persisted well beyond discontinuation of the drug. <sup>149</sup> Treatment of the underlying malignancy is the most definitive therapy, but usually in these particular diseases is also unsuccessful.

## COAGULOPATHIES AND DISSEMINATED INTRAVASCULAR COAGULATION

The most common coagulation abnormalities in cancer patients are elevated levels of fibrin or fibrinogen degradation products, thrombocytosis, and hyperfibrinogenemia, representing overcompensated DIC with fibrinolysis. This may be accompanied by an increased synthesis of fibrinogen and various clotting factors and platelets. Overt DIC with consumption of platelets and clotting factors and bleeding is rare and is most commonly associated with acute promyelocytic leukemia and adenocarcinomas. <sup>150</sup> DIC is detected by a combination of abnormal prothrombin time, thrombocytopenia, and hypofibrinogenemia. <sup>151,152</sup> The platelet count is abnormal in more than 90% of cases of DIC. The most useful confirmation test for DIC is the measurement of fibrin degradation products. Identification and treatment of precipitating factors is critical in the management of DIC. Some investigators have advocated replacement of coagulation factors and platelets in combination with heparin. The use of heparin alone is controversial and is more commonly used with thromboembolic or necrotizing complications typically seen in the chronic DIC of malignancy. A variety of other therapies including antiplatelet drugs and fibrinolytic inhibitors and activators have been suggested, but have no proven efficacy. Epsilon amino caproic acid is contraindicated. Treatment of the underlying malignancy is essential.

## NONBACTERIAL THROMBOTIC ENDOCARDITIS

Nonbacterial thrombotic endocarditis may lead to thrombotic or hemorrhagic complications and may occur with or without DIC. <sup>153,154</sup> and <sup>155</sup> It is characterized by sterile verrucous fibrin platelet lesions in the left-sided heart valves. A typical presentation is emboli to the brain and other organs associated with focal or diffuse neurologic abnormalities. Typical diffuse abnormalities include confusion, seizures, and disorientation. The definitive diagnostic test is cerebral angiography showing multiple arterial occlusions. While some patients may have heart murmurs, the majority do not. Echocardiography picks up vegetations larger than 2 mm. The association of nonbacterial thrombotic endocarditis is most common with adenocarcinoma of the lung. Other adenocarcinomas are less frequently associated, and rarely nonadenocarcinomas, lymphomas, and leukemias are associated. <sup>156</sup> Bleeding may be found in the skin, central nervous system, genitourinary tract, upper respiratory tract, GI tract, and lower respiratory tract. Treatment of the underlying malignancy is the primary therapy. Anticoagulants are not indicated.

## GASTROINTESTINAL MANIFESTATIONS OF CANCER

### PROTEIN-LOSING ENTEROPATHY

Protein-losing enteropathy is a disorder defined by an excessive loss of serum proteins into the GI tract, which generally leads to hypoproteinemia. It was postulated that the hypoproteinemia associated with protein-losing enteropathy was due to impaired protein synthesis. However, it has been shown that synthesis of proteins in these patients is normal or slightly increased, while the serum half-life of protein such as albumin is dramatically decreased. <sup>157</sup> It has also been shown that enteric loss of proteins contributes to, but is not the sole etiology of, the hypoproteinemia seen in patients with this disorder. <sup>158</sup>

Normally, the GI tract plays a small role in the catabolism of serum proteins. <sup>159</sup> Approximately 10% of all normal protein loss of albumin and globulin loss is through the GI tract. <sup>160</sup> It is thought that malignancy-related protein-losing enteropathy results from the increased mucosal permeability to serum proteins due to abnormal cellular structure, mucosal erosion or ulceration or lymphatic obstruction. <sup>161</sup> Hypoalbuminemia can be seen in virtually any cancer of the GI tract including esophageal, gastric, colonic, and carcinoid syndrome. <sup>162</sup> It has also been described in acquired immunodeficiency syndrome (AIDS) patients with Kaposi's sarcoma. <sup>163</sup> Intestinal

involvement of lymphoma including Waldenström's macroglobulinemia, Hodgkin's disease, and non-Hodgkin's lymphoma can lead to protein-losing enteropathy. <sup>164,165</sup>

In contrast to renal protein loss, the protein loss in GI disorders is independent of the size of the protein. Therefore, proteins of various sizes such as albumin, immunoglobulins, and ceruloplasmin all are lost equivalently in contrast to patients with nephrotic syndrome. Once the protein loss becomes greater than the body's ability to synthesize proteins, decreased protein levels in the serum result. Usually, this decline in serum proteins progresses until a new set point is reached. At that point, the protein level stabilizes and a new homeostasis is achieved. Also, of note, in both GI as well as non-GI sources of hypoproteinemia, proteins of long serum half-life (i.e., albumin) tend to be more affected than proteins of shorter serum half-life (i.e., retinol-binding protein). Other serum constituents associated with these proteins may be affected by the hypoproteinemia. Specifically, constituents that depend on carrier proteins, such as iron, copper, and calcium, may be depressed when patients develop hypoproteinemic states.

Clinically, patients with protein-losing enteropathy develop hypoproteinemia. This may or may not be associated with peripheral edema, but is rarely associated with severe edema or anasarca. Despite the fact that globulin levels are depressed, the patients rarely develop opportunistic infections and rarely develop coagulopathy even though clotting factors are also lost. Patients may or may not have other GI symptoms, such as diarrhea.

The diagnosis of protein-losing enteropathy is generally not difficult. Patients are noted to be hypoproteinemic on routine chemistry evaluation. Other sources of hypoproteinemia such as malnutrition and liver disease must be excluded. In the past, cumbersome nuclear studies were performed looking for protein loss in the stool. These have largely been replaced by new techniques using a  $\alpha_1$ -antitrypsin, a protein, which is not degraded in the lower GI tract. Therefore, if it is lost in excessive amounts it is excreted unchanged in the stool. Clearance of this protein is used to confirm the diagnosis of protein-losing enteropathy. <sup>166</sup> It should be noted that the presence of diarrhea could abnormally influence the interpretation of this study. <sup>166</sup> Also, fecal occult blood can falsely elevate this study result.

Once the diagnosis of protein-losing enteropathy has been made in association with cancer, the treatment consists of treatment of the primary malignancy. In situations with lymphatic obstruction, a low-fat diet should be instituted. Patients frequently require the use of medium-chain triglycerides, which do not require intestinal lymphatic transport. With appropriate treatment of the cancer and dietary therapy, approximately 50% of the patients improve with treatment. <sup>157</sup>

## ANOREXIA AND CACHEXIA IN THE CANCER PATIENT

Cancer anorexia-cachexia syndromes (CACS), as it is now referred, is the most common paraneoplastic syndrome, consisting of anorexia, nausea, and weight loss. While it afflicts patients with solid tumors most commonly, more than 50% of all cancer patients have some demonstrable weight loss, and 15% experience loss of greater than 10% of their normal body weight. <sup>167</sup> Survival is negatively affected if a patient has greater than 10% weight loss, <sup>167</sup> in part due to problems with infection and wound healing. <sup>168</sup> Problems associated with weight loss may be exacerbated by treatment with surgery, chemotherapy, or radiation. As well, cancer therapy can lead to new difficulties with food intake such as postoperative ileus, esophagitis, and stomatitis.

Multifactorial derangements in biochemical pathways lead to cancer-related decreased food intake. <sup>162</sup> Tumors produce factors that change the patient's perception of food, particularly taste and smell, which leads to a lack of enjoyment. The central nervous system's control of appetite can be altered by tumor factors, <sup>163</sup> such as serotonin. Local obstruction and abnormal swallowing interfere with food intake when tumors involve these portions of the alimentary tract. Maldigestion and malabsorption may result from obstruction of biliary or pancreatic secretions. When patients become nauseated due to either anatomic factors related to their tumor or as a result of chemotherapy or radiation treatment, they may develop a psychological aversion for food, which is difficult to control.

Cancer patients possess abnormally high serum levels of IL-1b, TNF-a, IL-6, IFN-g, and serotonin, <sup>169,170</sup> produced as a response to the tumor, rather than by the tumor itself. Administration of these cytokines is capable of reproducing CACS, thus further supporting their role in its etiology. <sup>171</sup> The physiologic changes induced by the tumor through these cytokines are numerous and result in progressive weight loss through a variety of mechanisms (i.e., serotonin changing the taste and smell of food). As well, in cancer patients, there is an increased basal energy expenditure with alterations in carbohydrate, protein, and lipid metabolism. In cases of starvation, weight loss arises primarily from fat stores, whereas in cancer patients there is equal loss of fat and skeletal muscle. <sup>172</sup> Skeletal proteins are frequently sacrificed in accelerated gluconeogenesis with the loss of amino acids and subsequent loss of lean body mass. <sup>173</sup> However, CACS is not solely a state of starvation; the tumor continues to grow while the host is depleted with an increase in total body protein conversion and destruction of peripheral muscle stores. <sup>173</sup> Even when sufficient calories are supplied to patients through various means, the patients are unable to incorporate amino acids into lean body proteins. <sup>173</sup> A cancer-driven inflammatory response can divert resources used for production of normal serum proteins to other organ sites (i.e., liver). <sup>174</sup> Malnourished cancer patients also lose a great deal of their lipid reserve; a decrease in lipoprotein lipase, responsible for moving triglycerides into fat cells, results in weight loss. <sup>175</sup> Treatment with individual anticytokine antibodies reverses specific features of CACS, but no single antibody eradicates all aspects of the syndrome. <sup>176</sup>

When clinically evaluating a cancer patient for CACS, appetite, intake over prior weeks, weight, and weight loss are all critical. In one study, a weight less than 90% of ideal body weight, 10% weight loss over the last 6 months, or both were associated with a poor prognosis. <sup>177</sup> Plasma proteins such as albumin have limited value in evaluating CACS, because they are affected by factors other than nutrient status. Immune responsiveness assessed by delayed type hypersensitivity skin tests, as well as total lymphocyte count, correlate not only with the patient's nutrient status, but also the ability to fight off various infections. In summary, the best means of determining a patient's nutrient status is a history and physical examination by an experienced clinician.

Treating patients with malnutrition and cancer is similar to treating other forms of severe stress such as burns, trauma, and sepsis; the primary objective is adequate caloric intake excluding calories from protein sources. Often the most difficult decision facing the clinician is choosing the route of administration. The widespread availability of total parenteral nutrition has made this an attractive option, particularly when patients are severely anorexic. However, numerous studies have found no survival benefit using total parenteral nutrition in cancer patients, with an increase in infectious and mechanical complications. <sup>178</sup> It has become axiomatic to use the GI tract for nutritional support whenever possible, because it has the benefit of being less expensive and more physiologic, and it maintains gut barrier function. The Harris-Benedict equation is useful for determining basal caloric needs. Generally, stress factors of cancer (estimated at 20% to 30% of the basal metabolic rate) are added to the patient's caloric needs. If other forms of stress are present, such as infection, these factors should be added. In addition to the caloric needs, 1.0 to 1.5 g of protein per kilogram of body weight is also given, and 25% to 40% of nonprotein calories should be in the form of lipid. The enteral formulations have been developed to balance these factors. When total parenteral nutrition is necessary, these same formulas are used for determining calorie protein and lipid intake. Once nutritional support is initiated, a 24-hour urine collection for nitrogen loss should be undertaken. If the patient has no diarrhea, 2 g of nitrogen should be added for insensible losses of nitrogen in the stool. Using these values, a nitrogen balance can be calculated; this balance should be positive, meaning that the patient receives more nitrogen than he or she excretes. This is critical in determining whether the patient is receiving adequate caloric intake.

Pharmacologic approaches to improving nutritional status in the cancer patient include appetite stimulants, corticosteroids and progestational agents, anabolic steroids, antidepressants, analgesics, and antiemetics. Unfortunately, most of these medications are of marginal benefit. Several studies have examined the utility of corticosteroids and found that in the short-term, they can increase appetite and elevate mood, but are limited because of progressive muscle weakness. Progestational agents including megestrol acetate and medroxyprogesterone acetate are appetite stimulants. Eight prospective randomized studies have now revealed that although these agents do stimulate appetite and weight gain, no survival benefit is associated with their use. One study found that 12 weeks of megestrol acetate (480 mg daily) produced an average weight gain of 5.41 kg, but no gain in performance status or quality of life. <sup>179,180</sup> The major risk of progestational agents is an increased risk of thromboembolic events. Cannabinoids such as dronabinol have been used, but most of these studies related to their use are in patients with AIDS-related anorexia, and definitive data in cancer patients are pending.

Unfortunately, the current therapy for CACS remains largely ineffective. Nutritional support, counseling, and the use of progestational agents continue to play the predominant role in management. Novel agents such as cytokine inhibitors have yet to be tested in randomized controlled trials.

## RENAL MANIFESTATIONS OF NONRENAL CANCER

Patients with nonrenal carcinoma develop many important renal complications. Treatment-related nephropathies, tubular interstitial defects, glomerular abnormalities, and fluid and electrolyte disorders are seen in many patients with cancer. Radiation nephritis and drug-induced toxicities from antineoplastic drugs (e.g., cisplatin), antibiotics, analgesics, and radiographic contrast agents all induce various forms of renal failure. Infiltrative disorders from leukemias and lymphomas, tubular precipitation abnormalities such as protein cast nephropathy, uric acid nephropathy, hypercalcemic nephropathy, and obstructive nephropathy lead to tubular interstitial diseases. Membranous glomerulopathy, minimal change disease, amyloidosis, and consumptive coagulopathy all lead to glomerular abnormalities. Finally, hypercalcemia, hypocalcemia, hyponatremia, and tumor lysis syndrome, covered in other areas of this book, lead to fluid and electrolyte disorders. While renal

manifestations of systemic cancer and its therapy are common, several classes of renal insult are specifically paraneoplastic in nature.

## GLOMERULAR DISORDERS

Most cases of membranous nephropathy are idiopathic, but a reasonable number have been associated with cancers, especially in the elderly. In an early report of 101 patients with idiopathic nephrotic syndrome, 11% had cancer with 8% having membranous nephropathy.<sup>181</sup> In 80% of cases the diagnosis of nephrotic syndrome is made concurrently or after the malignant disease, lending credence to the idea that it is a paraneoplastic process. Nephrotic range proteinuria, hypertension, and microscopic hematuria characterize the syndrome. Sixty percent of cancers of the stomach, lung, and colon have membranous nephropathy,<sup>182</sup> while other cancers such as rectal, pancreas, head and neck, ovary, bile duct, prostate, breast, kidney, and skin rarely produce glomerulonephritis.<sup>183,184</sup> Immunofluorescence studies reveal granular deposits of immunoglobulin and complement, whereas electron microscopy shows evidence of subepithelial deposits, which are the pathologic hallmarks of this process. Immune complexes are thought to play a role in malignancy-associated glomerular disease.<sup>182</sup> The responsible antigens include fetal antigens, autologous nontumor antigens, tumor-associated antigens, and viral antigens.<sup>185</sup>

Nephrotic syndrome has been reported to resolve with successful treatment of the underlying malignancy.<sup>186</sup> Other standard therapies include loop diuretics to symptomatically treat the peripheral edema associated with the syndrome. As well, careful monitoring for the development of thrombosis is warranted in severe protein wasting, especially renal vein thrombosis.

Other glomerular diseases include membranoproliferative glomerulonephritis<sup>187</sup> and minimal change disease.<sup>183</sup> Hodgkin's disease is the cause of most cases of minimal change disease, while other lymphoproliferative disorders, pancreatic carcinoma, and mesothelioma are also seen.<sup>188,189</sup> There is a parallel relationship between the activity of the lymphoma and the degree of proteinuria. Other cancer-associated glomerulopathies include focal and segmental glomerulosclerosis with CLL, T-cell lymphomas, and acute myelogenous leukemia; IgA nephropathy with lung, head and neck, and pancreatic cancers, mycosis fungoides, and liposarcoma; and membranoproliferative glomerulonephritis with CLL, Burkitt's, and other lymphomas, hairy cell leukemia, and malignant melanoma. Rarely rapidly progressive glomerulonephritis has been associated with lymphoma and monoclonal gammopathies.<sup>190</sup>

## MICROVASCULAR LESIONS

Hemolytic uremic syndrome is most often seen after chemotherapeutic agents such as mitomycin C, but has also been reported in malignancy. Giant hemangiomas and hemangioendotheliomas<sup>191</sup> and specific malignancies such as acute promyelocytic leukemia, prostate, gastric, and pancreatic cancers are the most common culprits. A renal vasculitis secondary to Henoch-Schönlein purpura has also been reported in a patient with lung cancer, but this is an extremely rare complication of malignancy. More frequent is the association of renal vasculitis secondary to a process such as cryoglobulinemia, a known complication of hepatocellular carcinoma and concomitant hepatitis C disease.<sup>190</sup>

## TUMOR INFILTRATION

Autopsy series show the kidney is commonly affected by infiltrative and metastatic processes<sup>192</sup>; 40% to 60% of patients with leukemia have tumor infiltration of the kidney. Non-Hodgkin's lymphoma more commonly invades the kidney than Hodgkin's disease,<sup>193</sup> although not all series support this distinction.<sup>194</sup> There is a strong association between bone marrow involvement by tumor and renal infiltration. In both non-Hodgkin's lymphoma as well as Hodgkin's disease the involvement tends to be nodular and bilateral, whereas in leukemia the involvement is infiltrative.<sup>195</sup> Treatment of the underlying malignancy often results in resolution of the renal lesions. Other tubular abnormalities, such as protein cast precipitation syndrome, paraprotein disease, uric acid nephropathy, hypercalcemia, and obstructive uropathy, are discussed in [Metabolic Emergencies](#), Chapter 51.3, and [Plasma Cell Neoplasms](#), Chapter 46.4.

## CUTANEOUS PARANEOPLASTIC SYNDROMES

A wide variety of cutaneous syndromes are associated with malignancies and may precede, be concurrent with, or follow the discovery of the underlying malignancy. It is critical that once a potential cutaneous paraneoplastic syndrome has been diagnosed, an appropriate systemic evaluation for a neoplasm is undertaken. The initial workup includes detailed medical history, complete physical examination, and routine screening laboratory tests. This is followed by studies directed by the abnormalities discovered during the preliminary evaluation, emphasizing those malignancies most strongly associated with the particular skin lesion. Some cutaneous syndromes are uncommon and usually are associated with cancer, whereas other cutaneous lesions are extremely common and associated with benign disorders or cancers. Certain cutaneous lesions are always associated with a particular tumor, whereas others are associated with a variety of malignancies. In general, the cause of the cutaneous lesions is typically unknown.

## PIGMENTED LESIONS AND KERATOSES

Acanthosis nigricans ([Table 47-3](#)) is characterized by a gray-brown hyperpigmented, symmetric, velvety plaque that often affects the neck, axilla, and flexor areas and anogenital region. There are four groups: the malignant, inherited, endocrine, and idiopathic. The malignant form appears the same as the benign form, but may progress rapidly; pruritus is common. The malignant variety may precede the tumor, occur simultaneously, or even follow the appearance of the tumor. It affects men and women equally and is typically associated with adenocarcinomas of the GI tract, predominantly gastric cancer, but has also been associated with a variety of other adenocarcinomas including lung, breast, ovarian, and even hematologic malignancies.<sup>196,197</sup> and <sup>198</sup> The pathogenesis remains uncertain.

Lesion	Description	Malignancy	Cause	Comments
Acanthosis nigricans	Gray-brown hyperpigmented, symmetric, velvety plaque that often affects the neck, axilla, and flexor areas and anogenital region.	Adenocarcinomas of the GI tract, predominantly gastric cancer, but also lung, breast, ovarian, and hematologic malignancies.	Idiopathic, inherited, endocrine.	May be associated with malignancy.
Tripe palms	Thickened palms characterized by exaggerated ridges with a velvety texture and brown hyperpigmentation.	Lung and gastric cancer.	Idiopathic.	Usually associated with lung and gastric cancer.
Cherry angiomas	Small, red, dome-shaped papules.	None.	Idiopathic.	May be associated with malignancy.
Spitzoid melanoma	Reddish-brown papules or nodules.	Idiopathic.	Idiopathic.	May be associated with malignancy.
Amelanotic melanoma	Reddish-brown papules or nodules.	Idiopathic.	Idiopathic.	May be associated with malignancy.
Page's disease	Reddish-brown papules or nodules.	Idiopathic.	Idiopathic.	May be associated with malignancy.
Seborrheic keratosis	Warty, brown papules or nodules.	Idiopathic.	Idiopathic.	May be associated with malignancy.
Basaloid melanoma	Reddish-brown papules or nodules.	Idiopathic.	Idiopathic.	May be associated with malignancy.
Basaloid melanoma	Reddish-brown papules or nodules.	Idiopathic.	Idiopathic.	May be associated with malignancy.

TABLE 47-3. Pigmented Lesions and Keratoses

Tripe palms is associated with thickened palms and characterized by exaggerated ridges with a velvety texture and brown hyperpigmentation.<sup>199,200</sup> Virtually, all of these cases are associated with cancer, and, in most patients, occur in association with acanthosis nigricans. The condition is usually associated with lung and gastric cancer.

Melanosis is caused by abnormal deposition of melanin, causing diffuse gray-brown pigmentation in the skin.<sup>201,202</sup> and <sup>203</sup> Melanosis may appear before or after the primary melanoma is detected, and it is often accentuated in light-exposed areas of the upper body. Histopathology demonstrates melanin granules in perivascular or interstitial melanophages; free granules may be seen in the dermis. Melanosis can also be caused by ACTH-producing tumors.<sup>204</sup> Hemochromatosis from iron deposition may appear similar to melanosis.

The sign of Leser-Trélat is characterized by the sudden appearance of seborrheic keratoses. Such keratoses may occur in elderly patients, and one could argue reports of cutaneous lesions regressing after the cancer is treated are only coincidental.<sup>205,206</sup> Adenocarcinoma of the stomach is the most common malignancy; lymphoma, breast cancer, and squamous cell carcinoma are also reported.<sup>207</sup>

Acrokeratosis paraneoplastica or Bazex's syndrome is characterized by symmetric psoriasiform acral hyperkeratosis. It is almost always associated with cancer, typically squamous cell carcinoma of the esophagus, head and neck, or lungs.<sup>208,209</sup> The skin lesions may precede the detection of the tumor or parallel the growth of the malignancy. Antigenic cross-reaction of basement membrane and tumor antigens, as well as secretion of growth factors such as insulin-like growth factor-1 (IGF-1) or transforming growth factor- $\alpha$  are postulated to cause this syndrome.<sup>210</sup>

Paget's disease of the breast is characterized by erythematous keratotic patches over the areola, nipple, or accessory breast tissue and is associated with breast cancer.<sup>211</sup> Extramammary Paget's disease is an erythematous exudative dermatitis located on the vulva in women, the genitals in men, and the perianal area in both sexes. Histopathologically, Paget's disease demonstrates large pale cells within the epidermis, and often in the cutaneous appendages. Extramammary Paget's disease is associated with an internal malignancy in 50% of cases. Most of these cancers are usually related to the site of the dermatosis. The most common sites of Paget's disease are in decreasing order: breast, uterus, rectum, bladder, vagina, and prostate gland.

## NEUTROPHILIC DERMATOSES

Sweet's syndrome is associated with fever, neutrophilia, and the appearance of erythematous painful raised cutaneous plaques. The distribution is typically on the face, neck, and upper extremities. Histopathology demonstrates a dermal infiltration of well-differentiated neutrophils, as opposed to leukemia cutis, which contains immature myeloid blasts. This syndrome may be associated with an underlying malignancy (approximately 20%), most frequently, acute myelogenous leukemia. Some cases have been associated with myeloproliferative and lymphoproliferative disorders, myelodysplastic syndromes, and carcinomas.<sup>212,213</sup> and <sup>214</sup> Sweet's syndrome may precede the detection of malignancy by many years or occur concomitantly. The etiology is thought to be hypersensitivity, and response to corticosteroids is usually prompt.

The lesions of pyoderma gangrenosum appear as painful papules that subsequently ulcerate with violaceous irregular borders and a purulent, hemorrhagic exudate with a necrotic base. Histopathology demonstrates a lymphocytic vasculitis or neutrophilic infiltrate. It is associated with basal and squamous cell carcinomas as well as cutaneous T-cell lymphomas.<sup>215</sup>

## ERYTHEMAS

Erythema gyratum repens (Table 47-4) is an unusual progressive scaling erythema with prorates and a wood grain appearance.<sup>216,217</sup> and <sup>218</sup> It is almost always associated with internal malignancies, most commonly lung, breast, uterus, and GI tract.

Disease	Description	Malignancy	Color	Comments
Erythema gyratum repens <sup>216</sup>	Progressive scaling erythema with pruritic appearance	Lung, breast, cervix, gastrointestinal	Colored	More often associated with malignancy
Symmetric erythema nodosum <sup>217</sup>	Circular and gray to white erythema on face, abdomen, limbs	Changomycin	Orange or reddish-purple	
Pruritus <sup>218</sup>	Spontaneous redness of face and neck	Carcinoma, leukemia, thymal carcinoma	Normal	Serum or other vascular proteins
Erythema annulare centrifugum <sup>219</sup>	Slowly migrating annular and configurate erythematous lesions	Prostate, leukemia, other	Colored	Often also with leukocytosis and other disorders
Exfoliative dermatitis <sup>220</sup>	Progressive erythema followed by scaling	Cutaneous T-cell and other lymphomas, Hodgkin's disease	Colored	Occurs in 3% to 3% of all cutaneous disorders

<sup>219</sup> The paraneoplastic syndrome.

TABLE 47-4. Erythemas

Necrolytic migratory erythema is a rare disorder characterized by circinate and gyrate areas of blistering and erosive erythema on the face, abdomen, and limbs.<sup>219,220</sup> It is the hallmark of a glucagonoma. The eruption clears following resection of the tumor.

Flushing is an episodic reddening of the face and neck, lasting a few minutes, typically associated with the carcinoid syndrome but also seen with leukemia, medullary carcinoma of the thyroid, renal cell carcinoma, and other forms.<sup>221,222</sup> and <sup>223</sup> Vasoactive peptides such as serotonin are thought to mediate this syndrome.<sup>224,225</sup>

Erythema annulare centrifugum is characterized by slowly migrating annular and configurate erythematous lesions; rarely, it is associated with cancer, but this association remains unproven.<sup>226,227</sup>

Exfoliative dermatitis is a progressive erythema followed by scaling, which is classically associated with cutaneous T-cell lymphoma but may be seen in other lymphomas.<sup>228,229</sup>

## ENDOCRINE AND METABOLIC LESIONS

Systemic nodular panniculitis or subcutaneous fat necrosis (Table 47-5) is characterized by violaceous nodules associated with adenocarcinoma of the pancreas and may be accompanied by polyarthralgia, fever, and eosinophilia.<sup>230</sup> Similar lesions are seen with pancreatitis, due to the release of pancreatic enzymes such as lipase, amylase, and trypsin into the serum.<sup>231</sup>

Disease	Description	Malignancy	Color	Comments
Systemic nodular panniculitis <sup>230</sup>	Violaceous nodules of subcutaneous fat, often accompanied by arthralgia, fever, and eosinophilia	Adenocarcinoma of pancreas	Blue to white of pain	Not to be associated with pancreatitis
Cushing's syndrome <sup>231</sup>	Broad purple striae, atrophy, hyperpigmentation, moon face, hypertension, osteoporosis, hirsutism	Small cell lung cancer, adrenal cortex, neuroendocrine, paraneoplastic, pituitary, testicular	Increased	Increased glucose, triglyceride, lipase
Addison's syndrome <sup>232</sup>	Hyperpigmentation, especially in scars, pressure points, points of friction, increased growth of hair	Adrenal gland carcinoma, lymphoma or carcinoma	Decreased	Usually related to non-malignant disease
Shinshu <sup>233</sup>	Increased hair in male distribution	Adrenal cortex, testicular tumor	Increased	Associated with insulin

<sup>232</sup> The paraneoplastic syndrome.

TABLE 47-5. Endocrine and Metabolic Lesions

Cushing's syndrome is associated with broad purple striae, hyperpigmentation, telangiectasia, atrophy of the skin, and mild hirsutism. Cushing's syndrome is caused by increased ACTH, typically from small cell lung cancer, thyroid cancer, testicular cancer, ovarian cancer, adrenal tumors, and a variety of other tumors.<sup>6,11</sup>

Addison's syndrome is characterized by generalized hyperpigmentation, especially in scars, pressure points, and points of friction. This syndrome is caused by decreased glucocorticoids and may be seen with malignant replacement of the adrenal gland.

Hirsutism is associated with virilism and is caused by increased glucocorticoids and testosterone, typically from adrenal and ovarian tumors.

## BULLOUS AND URTICARIAL LESIONS

Paraneoplastic pemphigus is most frequently seen in B-cell lymphoproliferative disorders including lymphomas and CLL, as well as Castleman's disease, thymoma, Waldenström's macroglobulinemia, and spindle cell neoplasms.<sup>232,233 and 234</sup> Patients develop painful bullous ulcers and intraepidermal and lichenoid skin lesions. Internal organ involvement is common and respiratory failure causes death in 30% of patients with this disorder.<sup>235</sup> Patients with paraneoplastic pemphigus demonstrate autoantibodies to desmogleins 1 and 3, which cause acantholytic blistering.<sup>236</sup> Antibodies to other cytoskeletal elements such as plakins have also been described.<sup>235</sup> The course of the disease is progressive and independent of the underlying malignancy. Corticosteroids and cyclosporin have been advocated and high-dose cyclophosphamide without stem cell rescue has been successful in one patient.<sup>237</sup> [Table 47-6](#) describes the bullous and urticarial lesions.

Disease	Description	Malignancy	Cause	Comments
Paraneoplastic pemphigus <sup>237</sup>	Blisters of the skin and blisters	Lymphoma, Kaposi's sarcoma, breast cancer	Autoantibodies react to desmoglein 1 and 3 and other epidermal elements	
Mulder pemphigoid	Large tense bullae with leukoplakic skin and blisters	B-cell lymphoma, myelodysplasia	Unknown	Questionable association with malignancy
Demasse lymphoma	Paraneoplastic pemphigus with leukoplakic skin and blisters	Lymphoma, myelodysplasia	Related to autoantibodies	
Muir-Torre syndrome	Sebaceous gland neoplasm	Colorectal lymphoma	Unknown	

<sup>237</sup>Paraneoplastic pemphigus

**TABLE 47-6.** Bullous and Urticarial Lesions

Bullous pemphigoid is characterized by large tense bullae. Histopathology demonstrates absent acantholysis. It is reported to be associated with lymphomas, but this remains controversial.

Muir-Torre syndrome is a sebaceous gland neoplasm that may precede, follow, or coexist with visceral cancers.<sup>238,239 and 240</sup> It is most often associated with GI tract adenocarcinoma of the colon, genitourinary tract, or lymphoma.

## MISCELLANEOUS LESIONS

Acquired ichthyosis ([Table 47-7](#)) is characterized by generalized dry, crackling skin, hyperkeratotic palms and soles, and rhomboidal scales. It is most commonly associated with Hodgkin's disease, but may be seen with lymphomas, multiple myeloma, and other malignancies.<sup>241,242</sup> It has also been associated with Kaposi's sarcoma and AIDS-related Kaposi's sarcoma.<sup>243,244</sup> Remission of the cancers may be accompanied by disappearance of the ichthyosis.

Disease	Description	Malignancy	Cause	Comments
Acquired ichthyosis <sup>245</sup>	Generalized dry, crackling skin; hyperkeratotic palms and soles; rhomboidal scales	Hodgkin's disease, other lymphomas, multiple myeloma, other	Unknown	Should be differentiated from hereditary ichthyosis (onset before age 30)
Bromhidrosis <sup>246</sup>	Excessive or abnormal odor of the body; often generalized	None	Unknown	Malignancy disease reported to up to 20%; possible association to skin cancer
Pachydermoperiostosis <sup>247</sup>	Thickening of the skin and creation of new folds; thickened lips, ears, and lids; macroglossia; clubbing; thickening of the forehead and scalp; and excessive sweating	Lung	Unknown	May be seen in lung disease and benign tumor
Hypertrichosis lanuginosa (malignant down) <sup>248</sup>	Excessive development of long, silky hair on the ears, forehead, and possibly the entire body	Lung, colon, bladder, sarcoma, glioblastoma	Unknown	High association with cancer
Pruritus <sup>249</sup>	Itchy skin	Lymphomas, leukemias, multiple myeloma, solid tumor, systemic lupus erythematosus, rheumatoid arthritis	Unknown	Related to distribution and concentration of generalized pruritus; sometimes an indicator for an underlying systemic disease

<sup>245</sup>Paraneoplastic pemphigus

**TABLE 47-7.** Miscellaneous Lesions

Dermatomyositis is a rare severe inflammatory myelopathy with erythema or telangiectasias of the knuckles, upper chest, or periorbital regions.<sup>245,246,247 and 248</sup> Dermatomyositis has been linked to malignancies, especially in adults after the age of 40. Frequency of cancer in adults is reported to vary from 10% to 50%, increasing with age. Malignancy can precede, follow, or occur with dermatomyositis; the most frequent pattern is onset of cancer within 1 year of the diagnosis of dermatomyositis.

Pachydermoperiostosis is characterized by thickening of the skin and creation of new folds; thickened lips, ears, and lids; macroglossia; clubbing; thickening of the forehead and scalp; and excessive sweating.<sup>249</sup> The cause of this syndrome is unknown, but it is most often associated with bronchogenic carcinoma.

Hypertrichosis lanuginosa (malignant down) is the development of long, silky hair on the ears, forehead, and possibly the entire body, associated with lung, colon, bladder, and a variety of other cancers.<sup>250,251</sup>

Pruritus may be the initial feature of an occult malignancy or the clinical manifestations of a previously diagnosed tumor. It is most frequently associated with Hodgkin's disease, but may be seen with polycythemia vera, cutaneous T-cell lymphomas, and a variety of other diseases.<sup>252,253 and 254</sup> Severe pruritus localized in the nostrils has been reported in some patients with advanced brain tumors.

Amyloid deposits, which may manifest as macroglossia, superficial waxy yellow and pink elevated nodules on the skin, may be associated with multiple myeloma or Waldenström's macroglobulinemia. They may also be associated with benign disorders such as primary systemic amyloid.

Herpes zoster is a vesicular eruption in a dermatomal pattern typically associated with the immunosuppression associated with Hodgkin's disease, lymphomas, and leukemias.<sup>255,256 and 257</sup>

## HEREDITARY DISORDERS

Cowden's disease ([Table 47-8](#)) is characterized by multiple hamartomas and is a rare autosomal dominant condition characterized by both benign and malignant tumors.<sup>258,259,260 and 261</sup> The main features are fibromas of the oral mucosa characterized by *cobblestoning* of the tongue and acral palmoplantar keratoses. Multiple facial trichilemmomas appear to be pathognomonic. There is an increased prevalence of malignancy, most often in women, typically breast and thyroid cancer.

Disorder	Gene	Prevalence	Age of Onset	Sex Ratio	Penetrance	Prognosis
Neurofibromatosis type 1	<i>NF1</i>	1:3,000	Childhood	1:1	100%	Variable
Neurofibromatosis type 2	<i>NF2</i>	1:25,000	Adolescence	1:1	100%	Variable
Tuberous sclerosis	<i>TSC1</i> , <i>TSC2</i>	1:10,000	Childhood	1:1	100%	Variable
Peutz-Jeghers syndrome	<i>STK11</i>	1:25,000	Childhood	1:1	100%	Variable
Klippel-Trénaunay syndrome	<i>MAP3K4</i>	1:100,000	Childhood	1:1	100%	Variable
McCune-Albright syndrome	<i>GNAS1</i>	1:10,000	Childhood	1:1	100%	Variable
Multiple endocrine neoplasia type 1	<i>MEN1</i>	1:30,000	Adolescence	1:1	100%	Variable
Multiple endocrine neoplasia type 2	<i>RET</i>	1:16,000	Adolescence	1:1	100%	Variable
Paraneoplastic syndromes	Various	Variable	Adult	Variable	Variable	Variable

**TABLE 47-8.** Hereditary Disorders

Gardner's syndrome is an autosomal dominant condition with a high malignant transformation rate. The syndrome includes multiple osteomas, fibromas, lipomas, desmoid tumors, fibrosarcomas, epidermoid cysts, and leiomyoma, as well as dental abnormalities.<sup>262,263</sup> The hallmark is intestinal polyposis of the colon and rectum, with development of colon carcinoma before the age of 30 in at least one-half of the patients. If untreated, death occurs before the age of 50; therefore, total colectomy is recommended for prevention.

Peutz-Jeghers syndrome is autosomal dominant characterized by hamartomatous polyps of the GI tract and mucocutaneous pigmentation of the lips, face, and oral mucosa and is commonly associated with both benign and malignant neoplasms.<sup>264,265,266,267</sup> and <sup>268</sup> There is a risk of approximately 2% to 3% of adenocarcinomas of the GI tract, and the carcinomas may arise in the hamartomatous polyps. Non-GI carcinomas affect mainly the breast, genitals, and pancreas. Cancers develop more frequently at younger ages.

Keratosis palmaris et plantaris or tylosis is an autosomal dominant disease associated with esophageal carcinoma. The disease consists of discrete hyperkeratotic papules on the palms and soles.<sup>269,270</sup> and <sup>271</sup>

Neurofibromatosis or von Recklinghausen is an autosomal dominant syndrome and is characterized by neurofibromas and café au lait spots. Malignancies develop in a minority of patients and are most often pheochromocytoma.<sup>272</sup>

The nevoid basal cell carcinoma syndrome is an autosomal dominant syndrome with early onset of multiple basal cell carcinomas, multiple jaw cysts, and anomalies of the skeletal system, specifically rib abnormalities such as ectopic calcification in the pits of the hands and feet.<sup>273,274</sup> and <sup>275</sup> The pits are pathognomonic of the syndrome, occurring in approximately two-thirds of adults with the syndrome. Medulloblastoma is the most common tumor. Leiomyomas and fibromas of the ovary can also occur. Central nervous system tumors have also been reported in early childhood. There are numerous additional hereditary disorders associated with malignancy described in [Table 47-8](#).<sup>276,277,278,279,280</sup> and <sup>281</sup>

## NEUROLOGIC MANIFESTATIONS OF CANCER

Remote effects of cancer on the central nervous system are neurologic disorders of unknown cause that occur exclusively, or with increased frequency, in patients with cancer.<sup>282</sup> Technically, the phrase *neurologic paraneoplastic syndrome* is a more general description that refers to any neurologic dysfunction that occurs in cancer patients that is not caused by metastasis or direct invasion of the nervous system by cancer. However, both phrases (*neurologic paraneoplastic syndromes* and *remote effects of cancer on the nervous system*) are often used interchangeably in the more restrictive sense and are used that way in this review.

The neurologic paraneoplastic disorders can logically be separated into anatomic categories, although there is often overlap. This is particularly true of the dementias, which are often lumped together with brain stem, cerebellar, and spinal cord lesions under the rubric of *carcinomatous encephalomyelitis*. The older term *carcinomatous neuromyopathy* has been used to describe all the remote effects of cancer on the nervous system as well as the disorders of peripheral nerves and muscle associated with cancer.

## FREQUENCY

Even though most patients with cancer can be demonstrated to have some mild degree of neuromuscular dysfunction (usually in the form of myopathy or peripheral neuropathy), the frequency of clearly defined, symptomatic neurologic paraneoplastic syndromes is extremely low. Recognized neurologic paraneoplastic syndromes occur in less than 1% of patients with cancer.<sup>282</sup>

However, the situation is complicated by the fact that not all patients with neurologic syndromes that appear to be paraneoplastic actually have an underlying cancer. In approximately 50% of patients with known cancer, the nervous system symptoms precede the discovery of the underlying malignancy.<sup>282,283</sup> The probability that a given paraneoplastic syndrome is associated with an underlying cancer in patients who have not had a tumor identified varies with the specific type of paraneoplastic syndrome ([Table 47-9](#)).

Syndrome	Percent Paraneoplastic
Lambert-Eaton myasthenic syndrome	60
Subacute cerebellar degeneration	50
Subacute sensory neuropathy	20
Opsoclonus-myoclonus (children)	50
Opsoclonus-myoclonus (adults)	20
Sensory motor peripheral neuropathy	10
Encephalomyelitis	10
Dermatomyositis	10

(From ref. 283, with permission.)

**TABLE 47-9.** Estimated Incidence of Neurologic Disorders That Are Paraneoplastic Syndromes

## PATHOGENESIS

The cause and pathogenesis of the neurologic paraneoplastic syndromes are not known. However, a variety of causative mechanisms have been proposed to explain the individual syndromes.<sup>282</sup> In 1888, Oppenheim was the first to suggest that the tumors themselves released substances that were directly neurotoxic.<sup>284</sup> No known paraneoplastic syndromes have been shown to be caused by this mechanism, although the nervous system can be secondarily affected when tumors release hormones [e.g., adrenocorticotropic hormone (ACTH) and parathyroid hormone related peptide (PTHrP)] and cytokines [e.g., tumor necrosis factors (TNF) and the interleukins (ILs)].

Opportunistic infections have also been invoked as a possible cause of paraneoplastic syndromes. Progressive multifocal encephalitis, formerly classified as a paraneoplastic syndrome, has been shown to arise from the JC virus<sup>285</sup>; it is possible that other infections may be responsible for other paraneoplastic syndromes. Detection of 14-3-3 protein, commonly found in the CSF of patients with Creutzfeldt-Jakob disease, has also been found in the CSF of 12.5% of patients with

paraneoplastic neurologic syndromes (including paraneoplastic cerebellar degeneration and limbic encephalitis). Although this etiologic link to slow viruses is intriguing, it is not clear how the 14-3-3 protein is involved in the development of paraneoplastic syndromes,<sup>286</sup> and further research in this area is warranted.

Another possible mechanism involves competition by the tumor for a biochemical nutrient or substrate. In this way, large metastatic carcinoid tumors produce an encephalopathy by depletion of tryptophan and niacin.<sup>287</sup> However, no evidence has been found of competition for a vital nutrient in any of the known paraneoplastic syndromes. Furthermore, it is unlikely that the small tumors frequently associated with paraneoplastic syndromes could consume enough of any substrate to produce a deficiency syndrome, and paraneoplastic syndromes usually run a course independent of that of the tumor.

There is increasing evidence that many of these syndromes are mediated by a T-lymphocyte mechanism. Pathologic study of the central nervous system of patients with paraneoplastic syndromes shows an intense inflammatory infiltrate (including T cells),<sup>288,289</sup> while T-cell receptor studies show that tumor-infiltrating T lymphocytes are specifically targeted to neuronal antigens.<sup>290</sup> Peripheral blood lymphocytes show an increase in memory helper T cells in seropositive patients with paraneoplastic syndromes versus seronegative controls.<sup>291</sup> Further, a report of cytotoxic T-cell activity in a patient with paraneoplastic sensory neuronopathy and anti-Hu antibodies provides provocative data regarding the relationship of T cells to the paraneoplastic process.<sup>292</sup> Further study in this area is ongoing.

The most widely accepted cause of many neurologic paraneoplastic syndromes appears to involve an autoimmune reaction. It is likely that certain antigenic molecules normally produced only in the central nervous system are produced ectopically by specific tumors. When the immune system reacts to these antigens, the neural tissues that share the same or similar antigens are also attacked. Subacute cerebellar degeneration, optic neuritis, opsoclonus-myoclonus, subacute sensory neuropathy, myasthenia gravis, and the Lambert-Eaton myasthenic syndrome (LEMS) have all been associated with the production of autoantibodies.<sup>293</sup> The most compelling evidence resides in the well-described LEMS in which autoantibodies against voltage-gated calcium channels are expressed by small cell lung cancer,<sup>294</sup> although no paraneoplastic syndrome has yet been proven conclusively to be caused by an autoimmune reaction.

## DIAGNOSIS

Because most neurologic paraneoplastic syndromes occur in patients who do not have cancer or have not had a diagnosis of cancer made before the neurologic syndrome develops, diagnosis is often difficult. The clinical problem is twofold: (1) Either the patient is known to have cancer, and the question is whether the neurologic symptoms are due to a remote effect or to metastatic disease, or (2) the patient is not known to have cancer and the questions are whether there is a paraneoplastic syndrome present and does the patient need to be carefully evaluated for an occult cancer.

In the first instance, remote effects are so rare and metastatic disease so common that in the patients with known cancer the physician is obligated to consider and rule out all of the other neurologic complications of systemic cancer before diagnosing a paraneoplastic syndrome. Neurologic symptoms that may cause diagnostic difficulty include dementia, cerebellar dysfunction, and weakness of the extremities. Dementia is one of the well-described remote effects of cancer on the nervous system. However, similar symptoms may occur in patients with multiple cerebral metastases, leptomeningeal involvement, or in older patients with low brain reserve and systemic metabolic alterations or early neurodegenerative disorders such as Alzheimer's disease. Cerebral metastases are usually visible on MRI and CT scans, while with neurodegenerative disorders, one usually sees hydrocephalus on neuroimaging and CSF abnormalities. Also, if the patient has become acutely demented, metabolic brain disease is a possible diagnosis, as are the late effects of radiation therapy to the brain for previous metastasis. In patients with lymphoma, infections of the central nervous system including progressive multifocal leukoencephalopathy, toxoplasmosis, and fungal meningitis must also be considered.

If cerebellar dysfunction develops in a patient with a known cancer, it is much more likely that the patient is suffering from a metastasis in the cerebellum than from a remote effect. Clinically, subacute cerebellar degeneration as a remote effect is characterized by bilateral appendicular signs (point to point test difficulties in both upper and lower extremities) and by dysarthria, usually without nystagmus. Dementia is common as well. Metastatic disease of the cerebellum usually causes difficulties with gait without involvement of the upper extremities or speech (midline lesion), or it causes unilateral ataxia without gross dysarthria (hemispherical lesion). An MRI or CT scan usually clarifies the diagnosis.

The most serious diagnostic problems arise in patients developing weakness of the lower extremities with absent reflexes and with or without bladder or bowel dysfunction. The physician may suspect a paraneoplastic peripheral neuropathy, but invasion of the cauda equina by leptomeningeal tumor is more likely. The diagnosis can usually be established by careful examination of the CSF and spinal imaging studies.

Most paraneoplastic neurologic diseases, such as sensomotor peripheral neuropathy, dementia, and acute transverse myelopathy, occur only slightly more commonly in patients with cancer than in the general population. In such patients, a careful search for an underlying neoplasm is unlikely to be fruitful and is probably not warranted. However, several neurologic syndromes occur exclusively or with a much higher frequency in patients with cancer. These syndromes include dermatomyositis in middle-aged and elderly men, subacute cerebellar degeneration, subacute sensory neuropathy, and a subacute motor neuropathy. Any patient presenting with one of the previously mentioned neurologic syndromes deserves a careful search for an occult cancer. If the initial search result is negative, a tumor should still be suspected until a definitive diagnosis is established.

## AUTOANTIBODIES

Some patients with paraneoplastic syndromes develop detectable autoantibodies and these are outlined in [Table 47-10](#). When found in the patient without a history of cancer, a search for an underlying malignancy should be undertaken. While several of these are most commonly associated with one specific syndrome (as in antivoltage-gated calcium channel and LEMS), they are not absolutely specific to a particular syndrome. For example, anti-Hu autoantibodies are seen in paraneoplastic encephalomyelitis, sensory neuronopathy, cerebellar degeneration, and opsoclonus-myoclonus.<sup>295</sup> Specific cancers are often associated with various paraneoplastic syndromes: 90% of anti-Yo autoantibodies indicates an underlying breast or gynecologic cancer.<sup>293</sup> However, autoantibodies are not required for the diagnosis of a paraneoplastic disorder to be made. Conversely, the presence of an autoantibody does not always herald the development of a paraneoplastic syndrome. Individual autoantibodies are discussed under the specific paraneoplastic syndromes with which they are associated.

Antibody	Site of Antigen	Gene	Cellular Function	Clinical Syndrome	Cancers
anti-Hu (HuN1)	Paraneoplastic	Hu1, Hu2, Hu3, Hu4, Hu5	RNA binding	Paraneoplastic encephalomyelitis, cerebellar degeneration, sensory neuronopathy, opsoclonus-myoclonus	N.S.C. sarcoma, seminoma
anti-P/Q (P/QN1)	Cerebellar cortex	P/Q1	RNA binding	Subacute cerebellar degeneration	None
anti-CR2 (CR2N1)	Cerebellar cortex	CR2	Complement binding	Subacute cerebellar degeneration	None
anti-CR3 (CR3N1)	Cerebellar cortex	CR3	Complement binding	Subacute cerebellar degeneration	None
anti-CR4 (CR4N1)	Cerebellar cortex	CR4	Complement binding	Subacute cerebellar degeneration	None

**TABLE 47-10.** Antineuronal Antibodies and Associated Paraneoplastic Syndromes and Cancers

## TREATMENT

Treatment for most neurologic paraneoplastic syndromes is generally ineffective. The major exceptions are LEMS in which plasmapheresis and 3,4-diaminopyridine therapy are effective, and opsoclonus-myoclonus, which often responds to corticosteroid therapy. As well, treatment of the underlying malignancy has been successful in LEMS and opsoclonus-myoclonus.<sup>296</sup> A report of the successful use of protein A immunoadsorption in a wide variety of neurologic paraneoplastic syndromes is encouraging,<sup>297</sup> but waits confirmation in larger randomized studies before it can be recommended as a standard of care. A possible reason for the general failure of treatment in these disorders is that most of the syndromes have a rapid onset, and there is usually insufficient time to make a diagnosis and start treatment before irreversible damage is done. It is also postulated that immunosuppression may promote tumor growth, thus resulting in more rapid cancer-related

deaths in these patients.

## SPECIFIC SYNDROMES

### ***Encephalomyelitis***

*Encephalomyelitis* is a global term for paraneoplastic syndromes with an intense inflammatory response, perivascular lymphocyte cuffing, and lymphocyte accumulation in brain or spinal cord.<sup>298</sup> The manifestation of the paraneoplastic inflammatory process can be quite varied, depending on the affected area of the central nervous system. For example, spinal cord involvement can lead to transverse myelitis or motor neuropathy, while sympathetic autonomic effects can lead to orthostatic hypotension.<sup>293</sup> It is unclear why specific areas of the central nervous system are affected in individual patients. There is no known treatment and the disorder runs a subacute course ending in severe debilitation.

### ***Paraneoplastic Cerebellar Degeneration***

Paraneoplastic cerebellar degeneration is a disorder that is characterized clinically by cerebellar signs and symptoms (ataxia, dysarthria, dysphagia) and pathologically by the diffuse loss of Purkinje cells in the cerebellum.<sup>299</sup> It is the most common paraneoplastic syndrome that affects the central nervous system, yet affects less than 1% of patients with cancer. Although the syndrome is sometimes present in patients without cancer, it is most often associated with cancers of the lung (especially small cell carcinoma), ovary, breast, and lymphomas (especially Hodgkin's disease).<sup>300,301 and 302</sup>

Evidence of diffuse cerebellar dysfunction is the most common clinical presentation of the disorder. In the majority of cases, the neurologic signs and symptoms antedate the discovery of underlying cancer by months to years.<sup>282</sup> The onset of symptoms is usually abrupt, with symmetric ataxia of the arms and legs progressing over weeks to months, usually associated with dysarthria and sometimes nystagmus. The seropositive patients appear to progress more rapidly.<sup>303</sup> In addition, a mild to moderate degree of dementia is often present. MRI and CT initially show no abnormalities; however, as the disease progresses, some degree of cerebellar atrophy is usually found on imaging studies. CSF may be normal, but there is usually a mild pleocytosis and increased protein.<sup>304</sup> There is frequently an increase in the CSF IgG, and oligoclonal bands may also be present.<sup>282,283,302</sup> The clinical course is one of subacute worsening and then stabilization at a severe level of neurologic dysfunction, with improvement highly unlikely.

Several autoantibodies have been found in association with paraneoplastic cerebellar degeneration.<sup>303,304 and 305</sup> When present, the titers of these antibodies are usually much higher in the CSF than in the serum, suggesting synthesis within the central nervous system. The most commonly found autoantibodies are high-titer polyclonal IgG anti-Purkinje cell antibodies (anti-Yo antibodies). These antibodies are found almost exclusively in female patients with paraneoplastic cerebellar degeneration and underlying cancers of the breast, ovary, or female genital tract.<sup>306</sup>

Other patients do not have anti-Yo antibodies but instead have other, less specific, autoantibodies including type 1 antineuronal nuclear autoantibodies (anti-Hu antibodies)<sup>295</sup> and anti-Ri antibodies.<sup>304</sup> Anti-Hu antibodies are more commonly associated with paraneoplastic encephalomyelitis and sensory neuronopathy; however, some patients with small cell lung carcinoma may develop a cerebellar syndrome that is clinically indistinguishable from the anti-Yo associated form, even though these patients lack anti-Yo and have only anti-Hu antibodies. A separate group of patients have been identified who have breast cancer, anti-Ri antibodies, and cerebellar degeneration (often with opsoclonus-myoclonus) in the absence of either anti-Yo or anti-Hu antibodies. In addition, some patients with Hodgkin's disease and a number of other neoplasms may have paraneoplastic cerebellar degeneration in the complete absence of any antineuronal antibodies.

In most instances, patients with paraneoplastic cerebellar degeneration have similar clinical presentations and clinical courses.<sup>292</sup> However, spontaneous remissions do occur, predominantly in patients with Hodgkin's disease and without anti-Purkinje cell autoantibodies.<sup>300</sup>

### ***Limbic Encephalitis***

Paraneoplastic limbic encephalitis is a rare complication of testicular neoplasms, small cell lung carcinoma, and other cancers; it can also occur in the absence of cancer.<sup>282</sup> Pathologically, the syndrome is characterized by loss of neurons in the amygdala, hippocampus, and insular cortex, occasionally with additional involvement of other deep gray matter structures.<sup>302,307</sup> There is usually gliosis, lymphocyte cuffing of blood vessels, and microglial nodules. The clinical manifestations include subacute development of personality changes and loss of short-term memory occurring over days to weeks. Less commonly there can be seizures, hallucinations, and disorientation. Autoantibodies have been described in patients with limbic encephalitis and testicular cancer. These anti-Ta antibodies recognize proteins (Ma1 and Ma2) present in the nucleus and cytoplasm of neurons. The function of these proteins is unknown.<sup>308</sup> There is no proven treatment, although there have been anecdotal reports of improvement when the underlying primary tumor responded to treatment.

### ***Paraneoplastic Opsoclonus-Myoclonus***

Opsoclonus is a problem of saccadic instability and consists of high-amplitude, involuntary, chaotic, conjugate, saccadic eye movements. These are often associated with focal myoclonus and ataxia. Opsoclonus is seen in two settings. In children, opsoclonus can be a self-limited condition that is probably due to a viral infection that involves the brain stem and is not related to cancer. More rarely, opsoclonus (with or without myoclonus) can also be a paraneoplastic syndrome. In children, the paraneoplastic syndrome is most often associated with neuroblastoma and occurs in approximately 2% of patients with neuroblastoma.<sup>309</sup> Approximately 50% of children who present with opsoclonus have an underlying neuroblastoma.<sup>310</sup> In one-half the cases, the opsoclonus predates the diagnosis of cancer. Paraneoplastic opsoclonus-myoclonus in children responds to corticosteroids; however, in a review 69% of these patients had long-term residual neurologic damage.<sup>311</sup>

In adults, opsoclonus-myoclonus is much less common than in children and less likely to be associated with an underlying neoplasm. Only approximately 20% of adults who present with opsoclonus have tumors,<sup>282</sup> and unlike children, the most commonly associated tumor is lung cancer.<sup>312</sup> As with many paraneoplastic syndromes, the neurologic abnormalities usually precede the diagnosis of an underlying neoplasm. The clinical picture is one of progressive eye movement abnormalities and myoclonus. The CSF usually shows a mild pleocytosis with slightly increased protein. Neuroimaging study results are usually normal. Treatment is rarely effective, but spontaneous remissions and remissions after treatment of the primary tumor occur infrequently. Neuropathologic findings run the spectrum from normal to a picture similar to paraneoplastic cerebellar degeneration with loss of Purkinje cells. Anti-Hu and anti-Ri antibodies have been found in a small number of cases, but no consistent pattern or presence of antibodies has been identified.<sup>282</sup>

### ***Cancer-Associated Retinopathy***

Degeneration of the photoreceptors in the retina is a rare paraneoplastic syndrome. In more than 90% of the described cases, small cell carcinoma of the lung is the primary tumor; malignant melanoma is the second most common primary tumor associated with the condition. The major pathologic findings are widespread degeneration of the rods, cones, and ganglion cells of the retina.<sup>313</sup> There is also usually degeneration of the outer neuronal layer of the retina with lymphocytic infiltration. Clinical findings consist of photosensitivity, scotomatous visual loss, and attenuation of the caliber of retinal arterioles. Frequently, decreased color vision, night blindness, and decreased visual acuity are also present. The CSF is usually normal. Electroretinography is abnormal; however, visual-evoked responses are normal. Serum autoantibodies that react with retinal cells have been identified in some, but not all cases. Antineuronal antibodies recognizing the photoreceptor recoverin are the best described.<sup>314</sup> Corticosteroids have sometimes resulted in improved visual symptoms.

### ***Subacute Sensory Neuronopathy***

Subacute sensory neuronopathy is a rare paraneoplastic disorder that presents with sensory loss in the extremities. The disorder occurs in patients with cancer but more commonly is found in patients without cancer and in association with primary Sjögren's syndrome.<sup>302,315,316</sup> In most patients, the sensory symptoms precede the diagnosis of cancer, and only approximately 20% of patients with the syndrome are ever demonstrated to have an underlying neoplasm.<sup>282</sup> When present, the most common underlying cancer is small cell carcinoma of the lung in 90% of cases.<sup>316</sup> Women are affected more often than men.

Pathologic findings consist of severe neuronal loss of primary sensory neurons in the dorsal root ganglia and gasserian ganglia. The cell loss is often patchy and sensory large fibers (e.g., proprioceptive nerves) are preferentially involved. There is often variable lymphocytic infiltration of the ganglia and secondary loss of white matter tracts in the posterior columns. The initial clinical symptoms are numbness, tingling, and dysesthetic pain in the distal extremities. The sensory loss progresses

over days to weeks to involve all four extremities and ascends to involve the trunk and face. Deep tendon reflexes are lost; however, motor power is usually normal. The disease tends to stabilize after several months at a severe level of disability; most patients are unable to walk. Treatment with corticosteroids and plasmapheresis has not been successful. Occasionally, the syndrome remits spontaneously or improves after the primary tumor is treated.

### **Subacute Motor Neuronopathy**

Subacute motor neuronopathy is a condition associated primarily with Hodgkin's disease and other lymphomas (although there have been rare occurrences with other tumors).<sup>317</sup> The syndrome is characterized by subacute, progressive lower extremity weakness without significant sensory loss. The weakness is of the lower motor neuron type. Nerve conduction velocities are normal, and electromyography shows evidence of denervation. There is usually a mild elevation of protein in the CSF without pleocytosis. Pathologic findings include anterior horn cell degeneration, demyelination of the anterior (motor) nerve roots, and variable demyelination of spinal cord white matter. A specific motor neuropathy, Guillain-Barré syndrome, is increased in frequency in patients with Hodgkin's disease and is therefore labeled a paraneoplastic syndrome.<sup>203</sup>

Unlike most other neurologic paraneoplastic syndromes, subacute motor neuronopathy usually develops *after* the diagnosis of the underlying neoplasm has been made, and the disorder frequently develops while the cancer is in remission (e.g., following *curative* mantle radiotherapy). The weakness usually does not produce profound debilitation and runs a course independent of the underlying malignancy. Typically, the weakness stabilizes or improves after several months. Presently, there is no effective treatment.

### **Paraneoplastic Sensomotor Peripheral Neuropathy**

Mixed motor and sensory peripheral neuropathies are extremely common in cancer patients. In most cases the neuropathies are caused by neurotoxic chemotherapy, malnutrition, or metabolic problems that are not per se paraneoplastic. However, a rare subacute or chronic sensomotor neuropathy has been described,<sup>315</sup> and is most frequently associated with lung cancer. The neuropathy involves the distal extremities in a characteristic glove and stocking distribution; bulbar structures are usually not involved. The CSF is usually normal or shows only a mild increase in protein. Nerve conduction study results are usually consistent with an axonal neuropathy, and electromyography demonstrates denervation. Pathologic study of nerves shows axonal degeneration, segmental demyelination, or a combination of the two. The neuropathy tends to stabilize and remain chronic. However, the condition can also remit and recur. No specific treatment is available.

### **Lambert-Eaton Myasthenic Syndrome**

LEMS is a disorder of the myoneural junction that results in proximal muscle weakness. Approximately 40% of patients do not have an underlying cancer; women make up the majority of patients in this group.<sup>318</sup> Of the 60% of patients with an underlying neoplasm, approximately two-thirds have small cell lung carcinoma.<sup>203</sup>

LEMS is caused by an antibody attack on the presynaptic nerve terminal, specifically on the voltage-dependent calcium channels.<sup>319</sup> The antibodies block the entry of calcium into the terminal in response to an action potential and this decreases acetylcholine release. LEMS has been induced in animals by passive transfer experiments in which animals were injected with IgG from patients with the disorder.<sup>294,320</sup>

The clinical findings include muscle weakness and fatigability that is usually worse in the proximal muscles. Unlike classic myasthenia gravis, the weakness usually does not involve the bulbar musculature, although approximately 30% of patients experience dysphagia. Approximately one-half of patients have symptoms of cholinergic dysautonomia (e.g., dry mouth and impotence).<sup>293</sup>

Nerve conduction velocities show a characteristic pattern with normal conduction velocities and initially low amplitude compound muscle action potential. After exercise, the CMAPs increase to near normal levels. Repetitive nerve stimulation studies show a decrement of the compound muscle action potentials at low stimulation rates and an increase in the compound muscle action potentials at high stimulation rates.

In contrast to most paraneoplastic syndromes, the LEMS has been reported to respond to plasmapheresis, intravenous immune globulin, and immunosuppression.<sup>282</sup> Drugs that increase transmitter release (e.g., 3,4-diaminopyridine) relieve symptoms and may be beneficial in maintenance therapy. Pyridostigmine propagates the effect of 3,4-diaminopyridine, but is usually ineffective when given alone.<sup>293</sup> Treatment of the underlying cancer also results in clinical improvement.

### **Dermatomyositis and Polymyositis**

Dermatomyositis and polymyositis are inflammatory myopathies characterized by the subacute development of proximal muscle weakness, with or without pain and muscle tenderness.<sup>321</sup> Dermatomyositis has the classic heliotrope rash over the face, elbows, knees, and knuckles, in addition to the muscle weakness. Both conditions are usually idiopathic and are associated with cancer in only approximately 10% of cases.<sup>322</sup> The muscle syndrome usually precedes the diagnosis of the underlying cancer. When the characteristic findings are present in men older than 40 years, there is a higher incidence of underlying cancer, especially carcinoma of the lung, and a search for cancer is warranted. The most commonly associated cancers are breast and lung tumors.

In addition to proximal symmetric muscle weakness and skin changes, there is usually an elevation in muscle creatinine kinase. Electromyography is consistent with a myopathic process, and muscle biopsy usually shows inflammatory infiltrates, necrotic fibers, and atrophic fibers, sometimes in a perifascicular pattern. Treatment with immunosuppressive agents, including corticosteroids, is the standard therapy. The syndrome follows an inconsistent course and often is independent of that of the tumor.

### **Miscellaneous Syndromes**

The following syndromes have been described that have less concrete supporting data and are so rare that an in-depth review is not warranted. Stiff-person syndrome has been reported rarely in women with breast cancer, often preceding the oncologic diagnosis. Symptoms include painful muscle cramps and stiffness. Antiampiphysin autoantibodies are associated with this syndrome.<sup>323</sup> Acute necrotizing myopathy has been described in several patients with rapid progression of symmetric, proximal muscle weakness, with pathologic evidence of muscle fiber necrosis without inflammation.<sup>324</sup> Paraneoplastic vasculitic neuropathy is a syndrome characterized by nonsystemic subacute vasculitic neuropathy, usually due to small cell lung and lymphoma. Neuropathy varies from mononeuropathy multiplex to polyneuropathy. Axonal neuropathy is the characteristic finding in electrophysiologic studies, while the microscopic evaluation reveals a vasculitis. Unlike most other paraneoplastic syndromes, treatment of the underlying cancer or immunotherapy for vasculitis is helpful.<sup>325</sup> Myasthenia gravis, a classic paraneoplastic syndrome associated with thymoma, is discussed in depth in [Neoplasms of the Mediastinum](#), Chapter 32, and is not discussed here.

## **MISCELLANEOUS PARANEOPLASTIC SYNDROMES**

### **HYPERTROPHIC OSTEOARTHROPATHY**

A clinical syndrome, presumably hypertrophic osteoarthropathy (HOA), has been in the medical literature since antiquity. Hippocrates described the syndrome, which was most certainly digital clubbing, 25 centuries ago, and this syndrome was called *hippocratic fingers*. In the past, the problem was termed *pulmonary HOA*,<sup>326</sup> but because other nonpulmonary diseases can cause the syndrome, the term was simplified to HOA. In 1992, an international workshop on HOA met in Florence, Italy, and established a consensus for the diagnosis classification and assessment of this syndrome.<sup>327</sup>

To fulfill diagnostic criteria of this disease, both digital clubbing and periostosis must be present. Digital clubbing can be defined as paronychia soft tissue expansion associated with the loss of the curved linear lucency normally present at the junction between the nail and the skin. This may progress to a prominent bulbous enlargement of the distal end of the digit, representing an underlying increase in vascular and connective tissues. Periostosis is represented by periosteal proliferation in tubular bones, particularly the tibia and femurs. Incomplete forms of HOA have been recognized including clubbing alone, isolated periostosis, and pachydermia associated with any of the minor manifestations of the syndrome (synovial effusions, seborrhea, folliculitis, hyperhidrosis, hypertrophic gastropathy, and acroosteolysis).<sup>328</sup> Some investigators have also used a response to nonsteroidal antiinflammatory agents to confirm the diagnosis of HOA.<sup>329</sup>

HOA can be characterized as either primary or secondary. The secondary forms are either generalized or localized. The localized forms are seen in patients with

hemiplegia, aneurism, infectious arthritis, and patent ductus arteriosus. The generalized syndromes are more common and are associated with six major disease categories including pulmonary diseases, cardiac diseases, liver disease, intestinal disease, mediastinal disease, and miscellaneous problems. By far the most common are the pulmonary syndromes including non-small cell lung cancer, metastatic malignancy, cystic fibrosis, pulmonary fibrosis, chronic infections such as abscess or bronchiectasis, and arteriovenous fistula. Cyanotic congenital heart disease is the most likely etiology of cardiac-associated HOA. Cirrhosis is the most common liver problem associated with HOA, but the syndrome can also be seen with hepatic carcinoma. Inflammatory bowel disease including Crohn's disease and ulcerative colitis, as well as other chronic infections and bowel malignancies, are rarely associated with HOA. The mediastinal diseases associated with HOA are esophageal carcinoma, thymoma, and achalasia, while the miscellaneous category is headed by Grave's disease and thalassemia.

The treatment of HOA is somewhat disappointing. As with virtually all paraneoplastic syndromes, successful treatment of the underlying disease is associated with a rapid resolution of the problem. However, in most cases of lung cancer the disease is generally in an advanced state and, therefore, successful treatment is difficult. Patients with severe pain have been successfully treated with nonsteroidal antiinflammatory drugs.<sup>330</sup> Surgery and other arthritic treatments such as colchicine have been less successful.<sup>331</sup> Liver transplantation in patients with liver diseases associated with HOA has been related to dramatic improvement in symptoms,<sup>332</sup> as has lung transplantation in patients with underlying lung disease.<sup>333</sup> Many times, however, the symptoms can be quite debilitating and do not respond to therapy.

## FEVER

Fever occurs in many patients with cancer. The causes of fever in cancer patients include infection, tumor, drug fever, reaction to blood products, and autoimmune diseases. Thirty percent of patients with cancer develop fever at some point during the course of their malignancy,<sup>334</sup> with the majority having an underlying infection.<sup>335</sup> The major differential point in determining whether the fever is due to infection is the presence or absence of neutropenia. In patients with low white blood cell count, infection causes more than two-thirds of all fevers,<sup>336</sup> while patients with normal white blood cell counts are infected far less frequently. Twenty percent of fevers in nonneutropenic patients are secondary to infection, whereas 45% remain unexplained after complete evaluation.<sup>337</sup>

In the absence of infection, it is thought that cancer cells can produce cytokines, which cause fever. Renal cell carcinoma is the most common cancer associated with fever in up to one-half of patients,<sup>338</sup> while hepatoma patients develop fever one-third of the time.<sup>339</sup> Pel-Ebstein fever is seen in patients with Hodgkin's disease and is an important prognostic feature of this disease. Fever is also seen in patients with non-Hodgkin's lymphoma.<sup>340</sup> Acute leukemia, osteosarcoma, atrial myxoma, adrenal carcinoma, pheochromocytoma, and hypothalamic tumors are also rarely associated with the development of fever.<sup>341</sup>

The endogenous pyrogens have been well described over the past 20 years. IL-1 replaces the term *endogenous pyrogen*, which was initially used to describe this cytokine associated with Hodgkin's disease.<sup>342</sup> Subsequently, IL-1 has been shown to increase circulating neutrophils and cortisol and be intimately involved in the acute phase response. TNF (a and b subtypes) has also been shown to cause fever, although it does not use the same receptors as IL-1 and appears to induce IL-1.<sup>343</sup> As well, interferon and IL-6 have been shown to produce fever, and it is expected that several more cytokines will eventually be added to the class of endogenous pyrogens.<sup>344</sup>

The most important point in the management of fever in patients with cancer is evaluating for infection. In patients with neutropenia this could be life threatening, but it is also important in nonneutropenic patients. If infection is excluded, nonsteroidal antiinflammatory drugs are a reasonable means to manage patients with fever. Nonsteroidal drugs effect a decrease in fever by inhibiting cyclooxygenase, reducing prostaglandin E<sub>2</sub> synthesis. Some investigators use the response to nonsteroidal antiinflammatory drugs to differentiate fever caused by infection from that caused by a tumor. In two separate studies, response to indomethacin and naproxen was associated with a high incidence of tumor-related fever compared with infectious etiologies.<sup>345,346</sup> Corticosteroids are also effective antipyretics, both through inhibition of prostaglandin E<sub>2</sub> and blocking transcription of mRNA for pyrogenic cytokines.<sup>344</sup>

### INTRODUCTION

Cancers of unknown primary site are common. Their exact incidence is unknown, because many of such patients are "assigned" other diagnoses (an issue discussed later in [Carcinoma of Unknown Primary Site As a Distinct Clinicopathologic Entity](#)) and are, therefore, not represented accurately in tumor registries. Nonetheless, unknown primary cancers accounted for 2% of all cancer diagnoses reported by Surveillance, Epidemiology and End Results registries between 1973 and 1987. <sup>1</sup> We believe that a more realistic estimate of the incidence of these patients is 6% of all invasive cancers in the United States per year (approximately 80,000 to 90,000 patients). Within this heterogeneous patient group are found several clinical presentations and histologic tumor types. The largest group of patients has metastatic carcinoma of unknown primary site. Others have equivocal histologic diagnoses and tumors that create difficulty in classification using the time-honored method of light-microscopical examination. Specialized pathologic studies are essential in delineating the type of neoplasm present in many of these patients and, at times, may suggest the site of origin. Extreme heterogeneity in clinical presentations, histologic appearances, and natural histories has rendered systematic evaluation of such patients difficult, and an established base of knowledge has developed slowly. Only a few investigators have been interested in detailed studies of these patients. Therefore, past information suffers from many generalizations and is not representative of the entire patient population. These data are derived from grouping all patients and deal primarily with results of various chemotherapeutic regimens.

Over the last few decades, several important oncologic issues have changed. Combination chemotherapy, often used with surgery or radiation therapy, has proved to be potentially curative for selected patients with several metastatic tumors. In addition, palliation and prolongation of survival have been demonstrated after systemic therapy for patients with many other tumor types. Furthermore, treatment continues to evolve and improve. Such therapeutic improvements have relevance for patients with cancers of unknown primary site, because some have these responsive neoplasms (i.e., with occult primaries or atypical histologies).

Diagnostic pathology has improved remarkably. More routine use of electron microscopy and the emerging fields of immunohistochemistry and molecular genetics are contributing to more precise diagnosis of neoplasms. Now possible is defining more reliably the histology and, at least in selected patients, the origin and biology of neoplasms. In concert with evolving diagnostic techniques, several clinical syndromes and features are being recognized and are helping physicians to understand and better manage patients with unknown primary cancer. Oncologists are rethinking issues involving patients with cancers of unknown primary site.

Appropriate patient management requires an understanding of several clinicopathologic features that help to identify patients with more responsive tumors. Typically, patients with cancer of unknown primary site develop symptoms or signs at a metastatic site, and the diagnosis is made by biopsy of a metastatic lesion. History, physical examination, and other appropriate evaluation of such patients fail to identify the primary site. The initial biopsy should be generous, because many studies may be required. Routine light-microscopical histology establishes the neoplastic process and provides a practical classification system by which the patient subsequently can be evaluated and managed. The broad category of cancers of unknown primary site offers four major light-microscopical diagnoses: (1) poorly differentiated neoplasm, (2) well-differentiated and moderately well-differentiated adenocarcinoma, (3) squamous cell carcinoma, and (4) poorly differentiated carcinoma (with or without features of adenocarcinoma). These diagnoses vary with respect to clinical characteristics, recommended diagnostic evaluation, treatment, and prognosis. The approximate size of the various groups and subsets of patients are illustrated according to clinicopathologic evaluation in [Figure 48-1](#).

**FIGURE 48-1.** Relative size of various clinical and histologic subgroups of patients as determined by optimal clinical and pathologic evaluation. PDA, poorly differentiated adenocarcinoma; PDC, poorly differentiated carcinoma; PDMN, poorly differentiated malignant neoplasm. (From Hainsworth JD, Greco FA. Treatment of

patients with cancer of an unknown primary site. *N Engl J Med* 1995;329:257, with permission.)

## POORLY DIFFERENTIATED NEOPLASMS OF UNKNOWN PRIMARY SITE

If pathologists are confident of a cancer but cannot differentiate a general category of neoplasm (e.g., carcinoma, lymphoma, melanoma, sarcoma), it is designated as a poorly differentiated neoplasm of unknown primary site. A more precise diagnosis is essential in patients having this type of cancer, because many have responsive tumors. Approximately 5% of all patients with cancers of unknown primary site (nearly 4000 U.S. patients annually) present with this diagnosis on initial light-microscopical appearance, but few remain without a defined lineage after specialized pathologic study. The most frequent tumor for which effective therapy is available is non-Hodgkin's lymphoma. In reported series, 35% to 65% of poorly differentiated neoplasms were found to be lymphomas after further pathologic study.<sup>2,3,4</sup> and <sup>5</sup> Most of the remaining tumors in this group are carcinomas. Melanoma and sarcoma together account for fewer than 15% of all tumors in such patients.

The evaluation of poorly differentiated tumors requires specialized pathologic studies. Immunoperoxidase tumor staining, electron microscopy, and genetic analysis can be helpful in the differential diagnosis. The most common cause of a nonspecific light-microscopical diagnosis is an inadequate or poorly handled biopsy specimen. If possible, fine-needle aspiration biopsy should not be performed in affected patients as an *initia* diagnostic procedure, because the histologic pattern is not preserved and the ability to perform special studies is limited. We have documented several instances in which a fine-needle aspiration has suggested a specific diagnosis, which was proved later to be incorrect by an incisional biopsy. Frequently, a more definitive diagnosis can be made by obtaining a larger biopsy. Communication with pathologists is important, as special tissue processing may be necessary for some pathologic studies. In addition, all clinical information also may help pathologists to narrow down, or become more certain of, diagnoses. Some neoplasms remain unclassifiable by light microscopy, even with an adequate biopsy specimen. Additional pathologic study always is indicated in such cases.

## IMMUNOPEROXIDASE TUMOR STAINING

Immunoperoxidase staining is the specialized technique most widely available for the classification of neoplasms. Often, immunoperoxidase staining can be done on formalin-fixed, paraffin-embedded tissue, which broadens its applicability, rendering repeat biopsy unnecessary in some patients. Immunoperoxidase antibodies are either monoclonal or polyclonal and are directed at cell components or products, which can include enzymes [e.g., prostatic acid phosphate, neuron-specific enolase (NSE)]; normal tissue components [e.g., keratin, desmin, vimentin, neurofilaments, common leukocyte antigen (CLA)]; hormones and hormone receptors (e.g., estrogen receptor); oncofetal antigens [e.g., a-fetoprotein (AFP)]; carcinoembryonic antigen (CEA); and other substances (e.g., S-100 protein, chromogranin). Many new antibodies are being developed, and this area of diagnostic pathology is a dynamic and evolving field. Usually, specific diagnoses cannot be made on the basis of immunoperoxidase staining alone, because none of these reagents is directed at tumor-specific antigens. Staining also can be extremely variable, and a particular stain may be negative; yet, other data may nonetheless support a particular tumor type. For example, a neuroendocrine carcinoma does not stain invariably with all neuroendocrine reagents. Therefore, results must be interpreted in conjunction with the light-microscopical appearance and the clinical picture. Some immunoperoxidase staining patterns that are useful in the differential diagnosis of neoplasms are outlined in [Table 48-1](#).

Tumor Type	Immunoperoxidase Staining
Carcinoma	Epithelial marker (e.g., cytokeratin, EMA) (+)
Lymphoma	CD45, CD20, CD30, CD45 (+)
Melanoma	S-100, HMB-45, Melan-A (+)
Neuroendocrine carcinoma	Chromogranin, Synaptophysin, NSE (+)
Prostate carcinoma	Prostate-specific antigen (PSA) (+)
Testicular carcinoma	AFP, HCG, PLAP (+)
Sarcoma	Desmin, Vimentin (+)
Transitional cell carcinoma	Cytokeratin, EMA (+)
Adenocarcinoma	Cytokeratin, EMA (+)
Embryonal carcinoma	AFP, HCG, PLAP (+)
Choriocarcinoma	HCG (+)
Teratoma	AFP, HCG, PLAP (+)
Embryonal carcinoma	AFP, HCG, PLAP (+)
Choriocarcinoma	HCG (+)
Teratoma	AFP, HCG, PLAP (+)

**TABLE 48-1.** Immunoperoxidase Tumor-Staining Patterns Useful in the Differential Diagnosis of Poorly Differentiated Neoplasms

Usually, several important questions can be answered by immunoperoxidase staining. The CLA stain usually can be used to make the important distinction between lymphoma and carcinoma.<sup>6,7</sup> Staining for NSE, chromogranin, and synaptophysin can suggest a neuroendocrine carcinoma (e.g., small cell lung cancer, carcinoid, islet cell tumor, etc.).<sup>8,9</sup> and <sup>10</sup> Staining for prostate-specific antigen (PSA) strongly suggests prostate carcinoma in a man with metastatic adenocarcinoma.<sup>10,11</sup> Certain staining characteristics can suggest breast carcinoma (e.g., estrogen or progesterone receptors, gross cystic fluid protein 15), amelanotic melanoma (e.g., positive staining for S-100 protein, vimentin, HMB-45), or sarcoma (e.g., positive staining for desmin, vimentin, factor VIII antigen).<sup>12,13,14,15</sup> and <sup>16</sup> Staining for human chorionic gonadotropin (HCG) or AFP can suggest the diagnosis of a germ cell tumor in an appropriate clinical situation.<sup>17,18</sup>

Several problems are associated with immunoperoxidase stains. Technical expertise is required to perform these tests accurately and reproducibly, and proper interpretation requires an experienced pathologist. Appropriate control slides are stained and examined concurrently, because nonspecific staining occasionally is a problem. Care must be taken to avoid overinterpretation, because no staining pattern is entirely specific. Certain stains, particularly CLA and PSA, are relatively specific; however, false-positive and false-negative results can occur with any of these stains. For example, some carcinomas stain with vimentin, some sarcomas stain with keratin, and a wide variety of carcinomas (other than neuroendocrine and germ cell tumors) stain with NSE and HCG, respectively.

In some circumstances, diagnoses based on immunoperoxidase staining in patients with poorly differentiated neoplasms of unknown primary site can be used to plan therapy and to predict outcome. Undifferentiated neoplasms identified as lymphoma on the basis of positive CLA staining respond well to the combination chemotherapy used for non-Hodgkin's lymphoma.<sup>2</sup> In 35 patients with equivocal routine light-microscopical histology and positive CLA staining, treatment with a variety of standard lymphoma regimens results in an actuarial disease-free survival of 45% at 30 months. These patients' outcome was similar to that of a group of concurrently treated patients who had non-Hodgkin's lymphomas with typical light-microscopical histology. In patients whose diagnoses were based on immunoperoxidase staining with tumors other than lymphoma, only limited data exist concerning treatment outcome.

## ELECTRON MICROSCOPY

A diagnosis can be made by electron microscopy in some poorly differentiated neoplasms. Electron microscopy is not widely available, requires special tissue fixation, is relatively expensive, and should be reserved for the study of neoplasms with unclear lineage after routine light microscopy and immunoperoxidase staining. Like immunoperoxidase staining, electron microscopy is reliable in differentiating lymphoma from carcinoma. It may be superior to immunoperoxidase staining for the identification of poorly differentiated sarcoma. Other structures, such as neurosecretory granules (neuroendocrine tumors) or premelanosomes (melanoma), can suggest a particular tumor. Often, undifferentiated tumors have nonspecific ultrastructural features; therefore, the absence of a particular ultrastructural finding cannot be used to rule out a specific diagnosis. Some neoplasms defy further classification despite specialized pathologic study.

In some instances, electron microscopy provides evidence for adenocarcinoma or squamous cell carcinoma. Features of adenocarcinoma include intercellular and intracellular lumina and surface microvilli. Squamous carcinomas are characterized by frequent and prominent desmosomes and by prominent bundles of prekeratin filaments in the adjacent cytoplasm. Usually, determining the origin of poorly differentiated adenocarcinoma or squamous carcinoma is not possible by electron-microscopical features. Treatment implications are unclear for adenocarcinoma and squamous carcinoma recognized only by ultrastructural features.

## GENETIC ANALYSIS

The identification of chromosomal abnormalities and genetic changes associated with neoplasms is becoming increasingly important. The use of tumor-specific

chromosomal abnormalities in diagnosis still is limited, but future research likely will identify many additional specific genetic abnormalities.

The biology of the primary tumor in patients with unknown primary neoplasms remains an enigma. Certainly, these tumors possess a metastatic phenotype. Some of these primary tumors may regress or involute or grow very slowly. Possibly some arise from embryonic epithelial "rest cells" that did not complete their appropriate migration. Often, karyotypic analysis of metastatic carcinomas demonstrates diverse multiple complex abnormalities, and is not yet helpful (in most instances) for diagnosis or classification, but is more representative of advanced neoplasms of many types (e.g., various chromosome 1p abnormalities).<sup>19</sup> Overexpression of p53, bcl-2, C-myc, Ras, and Her-2-neu has been observed in unknown primary carcinomas<sup>20,21 and 22</sup>; however, controversy continues regarding the frequency of expression and the clinical relevance. Tumors that strongly express p53 and bcl-2 may be more responsive to platinum-based chemotherapy.<sup>21</sup> Recently, we showed that 10% of the poorly differentiated carcinomas are strongly positive for Her-2-neu staining (F. A. Greco and J. D. Hainsworth, unpublished data). Patients affected by these tumors will be reasonable candidates for an anti-Her-2-neu antibody therapeutic trial. Recently, DNA microarrays have been studied in acute leukemias,<sup>23</sup> and this technique holds promise as a method of classifying neoplasms on the basis of gene expression monitoring, perhaps identifying specific genetic patterns or fingerprints independent of previous histologic and biologic knowledge. In the future, this and other techniques may identify more specific tumor lineages or primary tumor types subject to specific therapies in patients with unknown primary cancers. On the other hand, the pathogenesis of some carcinomas of unknown primary site may arise from specific genetic lesions. Possibly, many such tumors have similar gene expression distinct from specific carcinomas of recognized primary sites. This possibility is suggested by the unusual occurrence of metastatic adenocarcinoma of unknown primary site in monozygotic twin brothers with a primary immunodeficiency disorder (X-linked hyper-IgM syndrome).<sup>24</sup> The technology is now available to classify unknown primary carcinoma by gene expression, a technique that also has the potential to identify their primary origin and to provide more specific therapy by pharmacogenomic evaluation. As more precise and specific genetic lesions are identified in primary neoplasms and their metastases (e.g., lung, breast, ovary, germ cell), we can expect these data to provide more useful diagnostic and therapeutic information for unknown primary cancers. The identification of germ cell tumors already has met this expectation.

Chromosomal abnormalities have been well characterized in several hematopoietic neoplasms. Most B-cell non-Hodgkin's lymphomas are associated with tumor-specific immunoglobulin gene rearrangements, and typical chromosomal changes have been identified in some B-cell and T-cell lymphomas and in Hodgkin's disease.<sup>25,26</sup> In the rare instance when the diagnosis of lymphoma cannot be established definitively with either immunoperoxidase staining or electron microscopy, detection of chromosomal translocations t(14:18); t(8:14); or t(11:14) or the presence of an immunoglobulin gene rearrangement provides definitive diagnostic information.

A few other nonrandom chromosomal rearrangements associated with nonlymphoid tumors have been identified. A chromosomal translocation, t(11:22), has been found in peripheral neuroepitheliomas and frequently in Ewing's tumor.<sup>27,28</sup> An isochromosome of the short arm of chromosome 12 (i12p) and other chromosome 12 abnormalities are found in a large percentage of germ cell tumors.<sup>29,30</sup> A recently developed genomic hybridization technique can detect extra 12p material in paraffin-embedded tissue specimens.<sup>31</sup> This technique likely will improve the applicability of testing, as tissue culture is not necessary. Several other nonrandom cytogenetic abnormalities found in other tumors include t(2:13) in alveolar rhabdomyosarcoma; 3p deletion in small cell lung cancer; 1p deletion in neuroblastoma; t(X:18) in synovial sarcoma; and 11p deletion in Wilms' tumor. Polymerase chain reaction has been used to identify Epstein-Barr viral genomes in the tumor cells of patients with cervical lymph node metastases of unknown primary site, suggesting nasopharyngeal primaries.<sup>32</sup> Among head and neck tumors, Epstein-Barr virus has been associated only with nasopharyngeal carcinoma. Because some of these tumor types discussed are poorly differentiated and often are metastatic at the time of diagnosis, identification of these genetic changes may provide a specific diagnosis. Genetic diagnosis has been applied successfully to a subset of patients with carcinoma of unknown primary site (see [Poorly Differentiated Carcinoma](#), later in this chapter).

## ADENOCARCINOMA OF UNKNOWN PRIMARY SITE

### CLINICAL CHARACTERISTICS

Well-differentiated and moderately well-differentiated adenocarcinoma are the most frequent light-microscopical diagnoses in patients with carcinoma of unknown primary site, accounting for approximately 60% of patients (some 50,000 U.S. patients annually). Typically, patients with this diagnosis are elderly and have metastatic tumors at multiple sites. Frequently, the sites of tumor involvement determine the clinical presentation; common metastatic sites include lymph nodes, liver, lung, and bone.

Often, the clinical course is dominated by symptoms and signs related to the metastases. The primary site becomes obvious in only 15% to 20% of patients during life.<sup>33</sup> At autopsy, however, a primary site is detected in 70% to 80% of patients. The most common primary sites identified at autopsy are the lung and pancreas, accounting for approximately 40%.<sup>34</sup> Other gastrointestinal sites (e.g., stomach, colon, liver) are frequent, although adenocarcinomas from a wide variety of other primary sites occasionally are encountered. Adenocarcinomas of the breast, prostate, and ovary are rare in patients in this group.<sup>34</sup> Also, an unexpected metastatic pattern seems to be observed; for example, occult pancreatic primaries more frequently involve bone rather than liver.

Historically, as a group, patients with metastatic adenocarcinoma of unknown primary site have a very poor prognosis, with inexorable progression and a median survival of only 3 to 4 months. This finding is not surprising, considering the fact that many such patients harbor lung or gastrointestinal neoplasms. Many patients in this group have widespread metastases and poor performance status at the time of diagnosis. However, stereotyping *all* patients with adenocarcinoma of unknown primary site would be an error, because within this large group are subsets of patients with more favorable prognoses. In addition, chemotherapy has improved considerably in the last 5 years, and many patients now candidates for chemotherapy have a reasonable expectation of clinical benefit and improved survival.

### PATHOLOGY

The diagnosis of well-differentiated or moderately well-differentiated adenocarcinoma is based on light-microscopical features, particularly the formation of glandular structures by neoplastic cells. We have considered patients with well-differentiated or moderately well-differentiated adenocarcinoma as one group. These histologic features are shared by adenocarcinomas, and the site of the primary tumor usually cannot be determined by histologic examination. Typically, certain histologic features are associated with a particular tumor type (e.g., papillary features with ovarian cancer and signet-ring cells with gastric cancer). However, these characteristics are not specific enough to be used as definitive evidence of the primary site. Immunoperoxidase stains and electron microscopy are of limited value in identifying the site of origin of most well-differentiated or moderately well-differentiated adenocarcinomas. The stain for PSA is an exception because it is relatively specific for prostate cancer, and it should be used in men with suggestive clinical findings. Positive immunoperoxidase staining for estrogen or progesterone receptors and gross cystic fluid protein 15 suggests metastatic breast cancer in women with metastatic adenocarcinoma. Occasionally, neuroendocrine stains (e.g., NSE, chromogranin, synaptophysin) can identify an unsuspected neuroendocrine neoplasm. Several other stains or batteries of stains have been evaluated,<sup>35,36,37 and 38</sup> but none are truly tumor-specific and, if used, should be used in connection with all other clinical data.

The diagnosis of poorly differentiated adenocarcinoma should be viewed differently, because some affected patients are distinctive in tumor biology and responsiveness to systemic therapy (see [Poorly Differentiated Carcinoma](#), later in this chapter). Usually, this diagnosis is made when only minimal or questionable glandular formation is seen on histologic examination or, on occasion, when tumors exhibit positive staining for mucin but have no "glandular features." Well-differentiated adenocarcinoma, poorly differentiated adenocarcinoma, and poorly differentiated carcinoma are diagnoses that probably represent parts of a spectrum of tumor differentiation rather than specific, sharply demarcated entities. These histologies represent a heterogeneous group of tumors with various biologic and clinical properties. Different pathologists may use slightly different criteria for making each of these three diagnoses. Therefore, an appropriate approach is to perform additional study with immunoperoxidase staining or electron microscopy in all poorly differentiated adenocarcinomas.

### DIAGNOSTIC EVALUATION

An exhaustive search for the primary site is not indicated because it rarely can be found. Therefore, the clinical evaluation should be performed to evaluate any suspicious clinical symptoms or signs and to determine the extent of metastatic disease. Initial evaluation should include a thorough history and physical examination, standard laboratory screening tests (i.e., complete blood cell count, liver function tests, serum creatinine, urinalysis), and chest radiography. All men should have a serum PSA determination, and all women should undergo mammography. Computed tomography (CT) scans of the abdomen can identify a primary site in 10% to 35% of affected patients and frequently are useful in identifying additional sites of metastatic disease.<sup>39,40</sup> Additional symptoms, signs, or abnormal physical and laboratory findings should be evaluated with appropriate diagnostic studies. Extensive imaging evaluation of asymptomatic areas rarely is useful in identifying a primary site, is expensive, and often results in confusing or false-positive results.

Positron emission tomography (PET) may be an important addition for the evaluation of potential primary sites. These data are very limited now, but one small series

identified likely primary sites in 7 of 29 patients (24%).<sup>41</sup> The availability of various tumor markers (CEA; CA-15-3; CA-19-9; CA-125, B-HCG, a-fetoprotein) has not proved, in general, to be useful for diagnosis or prognosis but can be used to follow the response to therapy.<sup>42,43</sup>

## TREATMENT

The group of patients with adenocarcinoma of unknown primary site contains several clinically defined subgroups for which useful, rather specific therapy can be given. Therapy can be useful also for some patients who are not a part of one of these subgroups, as empiric chemotherapy recently has improved.

### Peritoneal Carcinomatosis in Women

Adenocarcinoma causing diffuse peritoneal involvement is typical of ovarian carcinoma, although carcinomas from the gastrointestinal tract, lung, or breast occasionally can produce this clinical picture. In several women described with diffuse peritoneal carcinomatosis, no primary site was found in the ovaries or elsewhere in the abdomen at the time of laparotomy.<sup>44,45,46,47,48</sup> and <sup>49</sup> These patients frequently had histologic features typical of ovarian carcinoma, such as papillary configuration or psammoma bodies. This syndrome has been termed *multifocal extraovarian serous carcinoma* or *peritoneal papillary serous carcinoma*. These patients have a primary peritoneal carcinoma. In the early 1980s, several anecdotal case reports documented excellent responses to cisplatin-based chemotherapy in women with this syndrome.<sup>44,45,46</sup> and <sup>47</sup> This tumor is more common in women with a family history of ovarian cancer, and preventive oophorectomy, as expected, does not protect them from this disease.<sup>48</sup> As for ovarian carcinoma, the incidence of primary peritoneal carcinoma is increased in women with *BRCA1* mutations.<sup>49</sup>

**Table 48-2** summarizes the results of seven series including a total of 258 women with this syndrome.<sup>50,51,52,53,54,55</sup> and <sup>56</sup> The clinical features are similar to ovarian carcinoma or abdominal carcinomatosis. Many patients have elevated serum levels of CA-125 antigen. An occasional patient will present with pleural effusion only. Metastases outside the peritoneal cavity are unusual, and their histologic features are similar to those of ovarian carcinoma (usually papillary configurations but also other histologies, including poorly differentiated carcinoma). The initial treatment plan for most patients included laparotomy with surgical cytoreduction, and the majority of these patients was treated with cisplatin-based combination chemotherapy. A few patients received cisplatin, chlorambucil, or melphalan alone. Recent series have documented the activity of paclitaxel.<sup>56</sup> A summary of the results in 258 women are as follows: Twenty-two percent (range, 10% to 40%) of all patients had a complete response to chemotherapy, median survival was 18 months (range, 11 to 24 months), and long-term survival (more than 2 years) was 16% (range, 6% to 26%).

Study	Number of Patients	Therapy	Complete Response Rate (%)	Long-Term Survival (%)	Median Survival (mo)
Lee et al., 1987 <sup>50</sup>	25	Surgical cytoreduction and cisplatin-based chemotherapy	22	26	20
Isaacs et al., 1987 <sup>51</sup>	38	Surgical cytoreduction and cisplatin-based chemotherapy	26	17	20
Dattaguru et al., 1987 <sup>52</sup>	76	Surgical cytoreduction and cisplatin-based or carboplatin-based chemotherapy	31	9	11
Reasen et al., 1987 <sup>53</sup>	23	Surgical cytoreduction and cisplatin-based chemotherapy	13	9	17
Travis et al., 1987 <sup>54</sup>	74	Surgical cytoreduction, cisplatin alone or in combination with melphalan alone	20	20	20
Wheeler et al., 1987 <sup>55</sup>	33	Surgical cytoreduction, cisplatin-based chemotherapy	30	11	20
Beer et al., 1987 <sup>56</sup>	46	Surgical cytoreduction, cisplatin-based chemotherapy plus paclitaxel	40	26 weeks	20
Total	258		22	16	18

**TABLE 48-2.** Therapy for Women with Peritoneal Adenocarcinomatosis of Unknown Primary Site

Frequently, women with metastatic adenocarcinoma involving the peritoneal surface and no obvious primary site have biologically distinct tumors and often are responsive to chemotherapy. The site of origin of these carcinomas likely is the peritoneal surface (primary peritoneal carcinoma). Because ovarian epithelium is in part an extension of the mesothelial surface, some carcinomas arising from the peritoneal (mesothelial) surface may share a similar lineage (Müllerian derivation) and biology with ovarian carcinoma. Certainly, this possibility should be considered and would not be surprising (e.g., papillary mesothelioma). Optimal management of these patients includes aggressive surgical cytoreduction followed by postoperative chemotherapy. Cisplatin or carboplatin plus paclitaxel considered optimal for the treatment of advanced ovarian cancer would seem a reasonable choice for initial chemotherapy, and the results are likely to be similar to ovarian carcinoma.<sup>57,58</sup> Approximately 20% of the patients in this group have complete responses to therapy, and some 16% have prolonged disease-free survival.

We have encountered a few men with this syndrome (papillary adenocarcinoma), but confirming the precise biology is difficult, and the lesions may be metastatic from an occult primary tumor arising elsewhere. A trial of chemotherapy also should be considered.

### Women with Axillary Lymph Node Metastases

Breast cancer should be suspected in women who have axillary lymph node involvement with adenocarcinoma. Occasionally, the histologic finding is poorly differentiated carcinoma. Men with occult breast cancer can present in this fashion but are rare. The initial lymph node biopsy should include measurement of estrogen and progesterone receptors. Elevated levels provide strong evidence for the diagnosis of breast cancer.<sup>59</sup> If no other metastases are identified, these patients may have stage II breast cancer with an occult primary, which is potentially curable with appropriate therapy. A few reports using PET and magnetic resonance imaging scans have identified occult breast cancer even with normal mammography results.<sup>60,61</sup> Additional study is necessary before these procedures are recommended routinely in this setting. Modified radical mastectomy has been recommended in affected patients, even when physical examination and mammography results are normal. An occult breast primary has been identified after mastectomy in 44% to 80% of patients.<sup>62,63</sup> and <sup>64</sup> Usually, primary tumors are less than 2 cm in diameter; in occasional patients, only noninvasive tumor is identified in the breast.<sup>65</sup> Prognosis after primary therapy is similar to that of other patients with stage II breast cancer.<sup>62,63,64,65</sup> and <sup>66</sup> Radiation therapy to the breast after axillary lymph node dissection is an effective alternative primary therapy. Adjuvant systemic chemotherapy is indicated in this setting and is similar to standard therapy for stage II breast cancer.

Women with metastatic sites in addition to the axillary lymph nodes may have metastatic breast cancer with an occult primary tumor. Such women should be managed as if they have metastatic breast cancer. Elevated serum levels of CA-15-3 or CA-27-29 suggest the possibility of breast cancer. Estrogen and progesterone receptor status is of particular importance because those with positive hormone receptors may derive major palliative benefit from hormonal therapy, chemotherapy, or both.

### Men with Possible Prostate Carcinoma

PSA concentrations should be measured in men with adenocarcinoma of unknown primary site. These tumors also can be stained for PSA. Even when clinical features (i.e., metastatic patterns) do not suggest prostate cancer, a positive PSA (serum or tumor stain) is reason for a trial of hormonal therapy.<sup>67,68</sup> Osteoblastic bone metastases also are an indication for an empiric hormone trial, regardless of the PSA findings.

### Chemotherapy for Metastatic Adenocarcinoma of Unknown Primary Site

Approximately 90% of patients with well-differentiated or moderately differentiated adenocarcinoma of unknown primary site are not listed in one of the several foregoing clinical subgroups. In the past, chemotherapy of various types has produced low response rates, very few complete responses, and no long-term survivals.<sup>69</sup>

The results of chemotherapy in reported series of 10 or more patients from 1964 to 1991 have been reviewed. A total of 1102 patients were reported in 33 trials.<sup>33,70,71,72,73,74,75,76,77,78,79,80,81,82,83,84,85,86,87,88,89,90,91,92</sup> and <sup>93</sup> The only single agent studied adequately was 5-fluorouracil (5-FU), with response rates ranging from 0% to 16%.<sup>33,70,71</sup> Cisplatin has been reported as a single drug in only one series,<sup>72</sup> with a response rate of 19%. Other single agents (including methotrexate, doxorubicin, mitomycin C, vincristine, and semustine) that have been reported produced response rates from 6% to 16%.<sup>73</sup> The FAM regimen (5-FU, doxorubicin, and mitomycin C) and various modifications have been used often, their use based on the demonstrated activity of these combination regimens in some gastrointestinal

cancers.<sup>74,75,76,77,78,79,80,81,82,83,84</sup> and <sup>85</sup> Response rates varied from 8% to 39% (mean, 20%); complete responders registered fewer than 1%; median survival was 4 to 15 months (mean, 6 months); survival beyond 2 years was rare; and disease-free survival beyond 3 years was nonexistent.

These data should be viewed with several factors in mind. Some of the series are small, and large randomized comparisons are lacking. In addition to those with adenocarcinomas, some patients with poorly differentiated carcinoma of unknown primary site were included in many of these series. The patients did not undergo standard evaluation or comparison in regard to sites of metastasis (nodal vs. visceral), performance status, gender, or age.

Cisplatin-based combination chemotherapy has not been evaluated adequately. However, two small randomized comparisons of doxorubicin with or without cisplatin<sup>74,77</sup> (subject to the many confounding factors previously mentioned) demonstrated no difference in median survival but more toxicity in the cisplatin-containing arm. A third, more recent, small randomized trial<sup>94</sup> did show the superiority of cisplatin, epirubicin, and mitomycin C as compared to mitomycin C alone (median survival, 9.4 months vs. 5.4 months). We also have seen some useful clinical responses to cisplatin or carboplatin-based chemotherapy and to 5-FU plus leucovorin. The combination of 5-FU and leucovorin has not been evaluated adequately but does not appear active in patients with liver metastasis arising from an unknown primary site,<sup>95</sup> a group most likely to have gastrointestinal primaries.

Several retrospective analyses have identified clinical and pathologic features associated with a more favorable response to empiric chemotherapy.<sup>96,97,98</sup> and <sup>99</sup> Some of these features include tumor location in lymph nodes, female gender, and poorly differentiated histology. Patients with liver or bone involvement have a relatively poor prognosis.<sup>96</sup>

Recent chemotherapy has improved considerably for patients who have adenocarcinoma and poorly differentiated carcinoma but do not fit into a specific "treatable" subset. The introduction of several new drugs with rather broad-spectrum antineoplastic activity is changing the standard treatment for patients having any of several common epithelial cancers. These drugs include the taxanes, gemcitabine, vinorelbine, and the topoisomerase I inhibitors. We have completed several phase II trials incorporating paclitaxel and docetaxel into first-line therapy for patients with carcinoma of unknown primary site. The initial trial included 71 patients, and the preliminary results of the first 55 patients were published.<sup>100</sup> The chemotherapy regimen, patients' characteristics, and treatment results are summarized in [Table 48-3](#), and the survival curve is shown in [Figure 48-2](#) for all 71 patients (F. A. Greco and J. D. Hainsworth, unpublished data). With a minimum follow-up of 34 months, the median survival was 11 months, and the 1-, 2-, and 3-year survivals were 48%, 20%, and 14%, respectively. This paclitaxel-based regimen delivered in a multicenter community-based setting (Minnie Pearl Research Network) was well tolerated and easily administered in the outpatient area. Only patients who had carcinoma of unknown primary site (any histology) and were not in a previously defined treatable subset, with the exception of poorly differentiated neuroendocrine carcinoma, were eligible for this trial. The response rate of 66 evaluable patients was 48%, with ten complete responses (15%). The toxicity was moderate, primarily myelosuppression, but with only 12 hospitalizations for fever-neutropenia and no treatment-related deaths. Long-term follow-up for these 71 patients (minimum follow-up, 34 months) is of interest; the median survival was 11 months, and the median 1-, 2-, and 3-year actual survivals of patients with complete response (20 months, 80%, 40%, 20%, respectively) was significantly longer ( $P = .025$ ) than those with partial response or stable disease (11 months, 50%, 15%, 10%, respectively). This latter group survived significantly longer ( $P = .033$ ) than did patients who progressed on therapy ([Fig. 48-3](#)).

REGIMEN	
Regimen for unknown primary site	
Paclitaxel 100 mg/m <sup>2</sup> , Day 1; Carboplatin, Day 1	
Etoposide 100 mg/m <sup>2</sup> , Day 1	
Etoposide 100 mg/m <sup>2</sup> , Day 2	
PATIENT CHARACTERISTICS	
Characteristics (N = 71)	
Age (yr)	71
Sex	34 M, 37 F
Primary site	40 Unknown
Histology	40 Adenocarcinoma, 10 Poorly differentiated carcinoma, 21 Unknown
Site of metastasis	30 Lung, 10 Liver, 10 Bone, 10 Lymph nodes, 10 Other
ECOG performance	0 10 (14%), 1 30 (42%), 2 20 (28%), 3 11 (16%)
Response rate	48%
Complete response	15%
Partial response	33%
Stable disease	14%
Progression	38%
RESULTS	
Survival	Median 11 months
1-year survival	48%
2-year survival	20%
3-year survival	14%
CR	15%
PR	33%

Progression	38%

**TABLE 48-3.** Summary of Phase II Trial of Paclitaxel, Carboplatin, and Extended-Schedule Oral Etoposide

**FIGURE 48-2.** Survival curve for 71 patients with adenocarcinomas or poorly differentiated carcinoma. Patients with poor prognostic features were selected. The minimum follow-up is 34 months; median survival is 11 months; 1-, 2-, and 3-year survivals are 48%, 20%, and 14%, respectively.

**FIGURE 48-3.** Survival curve for patients with complete response (CR) was significantly better (0.025) than for those with partial response (PR) or stable tumor, which in turn was better (0.033) than for those with progressive tumor.

Subsequently, we turned our attention to docetaxel and have performed two sequential phase II trials in the same patient population with either docetaxel (75 mg/m<sup>2</sup>) and cisplatin (75 mg/m<sup>2</sup>) given every 3 weeks in 26 patients or docetaxel (65 mg/m<sup>2</sup>) and carboplatin [area under the curve (AUC) = 5] every 3 weeks in 47 patients (F. A. Greco and J. D. Hainsworth, unpublished data January 1999). These combinations also were active, but the docetaxel-plus-cisplatin regimen was associated with substantial gastrointestinal toxicity, and the carboplatin regimen was associated with more myelosuppression. More than 20% of all patients responded to these regimens, with no differences for those with well-differentiated adenocarcinoma or poorly differentiated carcinoma. Although the follow-up is shorter than that of the paclitaxel-based trial, the 1 and 2 year survivals are similar. By combining these taxane-based chemotherapy trials, a total of 144 patients (71 on paclitaxel regimen, 73 on docetaxel regimens) have been treated and followed up ([Fig. 48-4](#)). Some preliminary analysis of these patients is of interest. The median follow-up is 25

months, and median survival is 10 months, with actuarial survival at 1, 2, 3, and 4 years of 42%, 22%, 17%, and 17%, respectively. Complete responders, partial responders, and stable disease patients survive significantly longer than do those with progressive disease, and the study revealed a major trend for improvement in survival for poorly differentiated neuroendocrine carcinomas (too few in number to reach statistical significance). No difference was seen in survival for adenocarcinoma versus the poorly differentiated carcinomas. However, patients with known favorable subsets were not included in these trials. Women survived significantly longer than did men, and those with performance status 0, 1 (Eastern Cooperative Oncology Group scale) lived longer than did those with performance status 2. The progression-free survival of these 144 patients reveals that a small number of patients remain alive without progressive cancer: 1 year, 16%; 2 years, 9%; and 3 years, 9%. A subsequent, recently reported trial by others of 72 patients confirmed the activity of paclitaxel and carboplatin with a 41% response rate.<sup>101</sup> The median survival had not been reached but was greater than 8 months.

**FIGURE 48-4.** Survival curve for 144 patients who received taxane-based combination chemotherapy. With a median follow-up of 25 months, the median survival is 10 months, and the 1-, 2-, 3-, and 4-year survivals are 42%, 22%, 17%, and 17%, respectively.

These data are encouraging. The patients who have more common unknown primary adenocarcinoma or poorly differentiated carcinoma but do not fit into any previously defined “treatable” subset now can attain substantial clinical benefits from taxane-based combination chemotherapy. Despite the fact that randomized trials still are lacking, both the median survival and 1-, 2-, and 3-year survival results are superior to the results seen in the past and are now comparable to the survivals of several other groups of advanced carcinoma patients receiving various types of chemotherapy (e.g., extensive-stage small cell lung cancer and advanced non-small cell lung cancer). Certainly, vast room for improvement exists, and basic and clinical research remain a priority for further enhancing the therapy for such patients.

We have continued to study empiric chemotherapy. Recently, gemcitabine was tested as secondary therapy in previously treated patients, and a response rate of only approximately 10% was observed, but several other patients had minor response or subjective improvement (or both). Topotecan given orally is being evaluated in previously treated patients. For previously untreated patients, the combination of paclitaxel, carboplatin, gemcitabine (followed by weekly paclitaxel consolidation) is ongoing.

## SQUAMOUS CARCINOMA OF UNKNOWN PRIMARY SITE

Squamous carcinoma at a metastatic site represents approximately 5% of all patients with unknown primary carcinomas (nearly 4000 U.S. patients annually). Effective treatment is available for patients with certain clinical syndromes, and appropriate evaluation of these patients is important.

### SQUAMOUS CARCINOMA INVOLVING CERVICAL AND SUPRACLAVICULAR LYMPH NODES

The cervical lymph nodes are the most common metastatic site. Usually, patients are middle-aged or elderly, and frequently they have abused tobacco or alcohol. When the upper or middle cervical lymph nodes are involved, a primary tumor in the head and neck region should be suspected. Clinical evaluation should include an examination of the oropharynx, hypopharynx, nasopharynx, larynx, and upper esophagus by direct endoscopy, with biopsy of any suspicious areas. CT of the neck better defines the disease in the neck and occasionally identifies a primary site. PET scanning also may identify primary sites but remains controversial.<sup>102,103</sup> Detection of Epstein-Barr virus genome in the tumor tissue is highly suggestive of a nasopharyngeal primary site<sup>31</sup> (see [Genetic Analysis](#), earlier in this chapter), particularly in poorly differentiated carcinomas. Other genetic studies of squamous cell carcinoma of the head and neck region have shown genetic alterations in “normal tissue” as a precursor of invasive carcinoma.<sup>104</sup> Further study is indicated, as these findings do not yet have a practical application. When the lower cervical or supraclavicular lymph nodes are involved, a primary lung cancer should be suspected. Fiber-optic bronchoscopy should be performed if the chest radiograph and head and neck examination results are normal, as this has a high yield, frequently identifying a lung primary.<sup>105</sup>

When no primary site is identified, local treatment should be given to the involved neck. The reported results in more than 1400 patients are primarily retrospective, single-institution experiences, often using a variety of treatment modalities.<sup>106,107,108,109,110,111,112,113,114,115,116,117,118,119,120,121,122,123,124,125,126,127,128</sup> and <sup>129</sup> In many of these series, a large minority of patients had poorly differentiated carcinoma and adenocarcinoma (see [Special Issues, Single Site of Neoplasm](#), later in this chapter). A substantial percentage (usually 30% to 40%) of patients achieved long-term disease-free survival after local treatment modalities. The results obtained using radical neck dissection, high-dose radiation therapy, or a combination of these modalities have been similar. The volume of tumor in the involved neck influences outcome, with N1 or N2 disease having a significantly higher cure rate than N3 disease or massive neck involvement.<sup>126,128</sup> Poorly differentiated carcinoma also represents a poor prognostic factor in such patients. When resection alone is used as the primary treatment modality, a primary tumor in the head and neck subsequently becomes apparent in 20% to 40% of patients. Primary tumors surface less commonly when radiation therapy is used, presumably owing to the eradication of occult head and neck primary sites within the irradiation field. Radiation therapy dosages and techniques should be similar to those used in patients with primary head and neck cancer,<sup>117</sup> and the nasopharynx, oropharynx, and hypopharynx may be included in the irradiated field.

Patients with low cervical and supraclavicular nodes do not do as well, because lung cancer is a frequent site of occult primary tumors. Patients with no detectable disease below the clavicle should be treated with aggressive local therapy, because 10% to 15% of these patients will have long-term disease-free survival. Chemotherapy also should be considered for such patients.

The role of chemotherapy for metastatic squamous carcinoma in cervical lymph nodes is controversial. One small nonrandomized comparison of patients treated with local modalities alone or with local modalities combined with chemotherapy (cisplatin and 5-FU) showed a higher complete response rate (81% vs. 60%) and longer median survival time (>37 months vs. 24 months) in patients also receiving chemotherapy.<sup>120</sup> Paclitaxel-based chemotherapy may be more effective. Neoadjuvant chemotherapy and radiation therapy in locally advanced head and neck carcinoma is gaining acceptance, and consideration of chemotherapy for these unknown primary tumor patients now would also seem reasonable. In those who receive local therapy first, adjuvant platinum-based or paclitaxel-based chemotherapy should be considered.

### SQUAMOUS CARCINOMA INVOLVING INGUINAL LYMPH NODES

Most patients with a tumor in inguinal lymph nodes have a detectable primary site in the genital or anorectal areas. Careful examination of vulva, vagina, cervix, penis, and scrotum is important and should include biopsy of any suspicious areas. Digital examination and anoscopy should be performed to exclude lesions in the anorectal area. Identification of a primary site in such patients is important, because curative therapy is available for carcinomas of the vulva, vagina, cervix, and anus, even after spread to regional lymph nodes. Nearly 50% of patients with inguinal presentations have poorly differentiated carcinoma. For patients in whom no primary site is identified, surgical resection with or without radiation therapy to the inguinal area sometimes results in long-term survival.<sup>73,124</sup> Such patients should be considered also for neoadjuvant or adjuvant chemotherapy.

### SQUAMOUS CARCINOMA METASTATIC TO OTHER SITES

Usually, metastatic tumor in areas other than the cervical or inguinal lymph nodes represents metastasis from an occult primary lung cancer. CT scans of the chest and fiber-optic bronchoscopy should be considered. Chemotherapy with regimens employed in the treatment of non-small cell lung cancer may be considered in

patients with good performance status. Other rare presentations include primary tumors from the head and neck, esophagus, anus, and skin.

Patients with the diagnosis of poorly differentiated squamous carcinoma should be evaluated carefully, particularly if other clinical features are atypical for lung cancer (i.e., young patients, nonsmokers, unusual metastatic sites). Occasionally, adenocarcinomas, particularly in the breast, undergo squamous differentiation at metastatic sites. As with the diagnosis of poorly differentiated adenocarcinoma, this histologic diagnosis (squamous cell) sometimes is based on minimal histologic findings. Additional pathologic evaluation with immunoperoxidase stains or electron microscopy should be considered. When the diagnosis remains unclear, such patients should be considered for a trial of therapy for poorly differentiated carcinoma.

## POORLY DIFFERENTIATED CARCINOMA (WITH OR WITHOUT FEATURES OF ADENOCARCINOMA) OF UNKNOWN PRIMARY SITE

Patients with poorly differentiated carcinoma or adenocarcinoma of unknown primary site appear to represent distinctive subgroups with specific therapeutic implications. They account for approximately 30% of all patients with carcinoma of unknown primary site (nearly 25,000 U.S. patients annually); approximately two-thirds have poorly differentiated carcinoma, and one-third has poorly differentiated adenocarcinoma. Often, chemotherapy trials in the past included such patients and the more common patients with well-differentiated adenocarcinoma of unknown primary. All such patients were assumed to be similar, and they experienced both a poor response to 5-FU-based chemotherapy and a short survival. These chemotherapy trials included drugs likely to be useful in a palliative sense for a minority of patients with gastrointestinal, lung, and breast carcinomas. Some patients with poorly differentiated carcinomas have responsive neoplasms, and some are curable with cisplatin-based combination chemotherapy.<sup>99,130,131,132,133,134,135,136,137</sup> and <sup>138</sup> Clinical and pathologic evaluation is, therefore, crucial in patients with poorly differentiated carcinoma.

### CLINICAL CHARACTERISTICS

The clinical characteristics in this diverse group of patients appear to differ—albeit with considerable overlap—from the characteristics of patients with well-differentiated adenocarcinoma. The median age of this patient group is younger, although both groups have a wide age range. Often, patients with poorly differentiated carcinoma reveal a history of rapid progression of symptoms (often <30 days) and have objective evidence of rapid tumor growth.<sup>34,99,130</sup> Most important, the location of metastases often differs, and the predominant sites of involvement frequently are lymph nodes, mediastinum, and retroperitoneum, occurring much more commonly than in well-differentiated adenocarcinoma. Some of these relatively distinctive clinical features are useful in identifying chemotherapy-responsive subsets of patients (see following [Pathologic Evaluation](#) section).

### PATHOLOGIC EVALUATION

Light-microscopical features that can differentiate chemotherapy-responsive tumors from nonresponsive tumors have not been identified.<sup>131</sup> Even with careful retrospective review of these tumors, responsive tumors of well-defined types (e.g., germ cell tumor, lymphoma) only rarely are identified.

These tumors should undergo routine additional pathologic study with immunoperoxidase staining; in selected tumors, electron microscopy and genetic analysis also are appropriate. The use of routine light microscopy alone is not adequate to assess such tumors. The information provided by these additional pathologic studies has been summarized previously (see [Poorly Differentiated Neoplasms](#), earlier in this chapter). The frequency of more specific diagnoses, particularly lymphoma, is much lower in the carcinoma group than in the group initially diagnosed by routine light microscopy as poorly differentiated neoplasm. This is not surprising, because carcinoma is a more specific diagnosis. Other diagnoses still may be suggested.

To assess the clinical utility of immunoperoxidase tumor cell staining in patients with poorly differentiated carcinoma of unknown primary site, we retrospectively performed a battery of stains on archival tumors from patients treated prospectively.<sup>132</sup> Poorly differentiated carcinoma or poorly differentiated adenocarcinoma was diagnosed on the basis of routine light-microscopical examination, and all patients were treated before the technology of immunoperoxidase staining was used routinely (1978 to 1983). Therefore, results of immunoperoxidase staining could be correlated with clinical outcome in this group of similarly treated patients with a long median follow-up. Immunoperoxidase staining confirmed the diagnoses of poorly differentiated carcinoma in 49 patients (56%) and yielded other diagnoses in 16 patients (18%): melanoma in eight patients, lymphoma in four, prostatic carcinoma in one, and neuroendocrine tumor in three (see [Neuroendocrine Carcinoma of Unknown Primary Site](#), later in this chapter). In 24 patients (28%), the immunoperoxidase staining pattern was inconclusive; electron microscopy occasionally was helpful in clarifying the diagnosis in affected patients. Seventy-five patients (86%) received combination chemotherapy with a cisplatin-based regimen, and 24 patients (28%) had a complete response. Nine of these patients later were given specific diagnoses by immunoperoxidase staining; lymphoma was diagnosed in four patients, melanoma in four patients, and yolk sac tumor in one patient. All patients with an immunoperoxidase diagnosis of lymphoma had clinical features compatible with lymphoma and are long-term survivors. Patients with immunoperoxidase features suggesting melanoma were surprisingly responsive to chemotherapy, with three of seven complete responses and two long-term survivors. Patients with melanoma diagnosed by immunoperoxidase staining alone should not be excluded from a trial of cisplatin-based therapy. Immunoperoxidase staining is useful in the routine evaluation of metastatic poorly differentiated carcinoma of unknown primary site, as occasionally it can suggest the lineage of the tumor and can have specific therapeutic implications. Others have reported similar findings in patients treated with cisplatin-containing chemotherapy.<sup>139</sup>

Immunoperoxidase staining should be used in the evaluation of poorly differentiated carcinomas to do the following: (1) confirm the diagnosis of carcinoma; (2) identify a primary site of a recognized carcinoma (e.g., prostate); (3) identify patients who may have other neoplasms, such as lymphoma or melanoma (although therapeutic recommendations for neoplasms other than lymphoma identified in this manner remain to be established); and (4) identify a group of patients in whom electron microscopy may provide important additional information.

Electron microscopy can be useful for a small minority of these carcinomas. In general, electron microscopy should be reserved for those tumors not diagnosed by immunoperoxidase stains. Lymphoma can be diagnosed reliably (in most instances) in those tumors mistakenly believed to be carcinoma. In addition, sarcoma, melanoma, mesothelioma, and neuroendocrine tumors occasionally are defined by subcellular features. Neuroendocrine differentiation is particularly important.

Chromosomal or genetic analysis is becoming an increasingly important method of diagnosis. Specific abnormalities have been identified in several neoplasms. Evaluation for these abnormalities may be useful in patients with poorly differentiated carcinoma of unknown primary site. In reference to germ cell tumors, Motzer et al.<sup>140</sup> performed genetic analysis on tumors in 40 patients with primarily midline carcinomas of uncertain histology. In 12 of the 40 patients with poorly differentiated carcinoma, abnormalities of chromosome 12 (e.g., i[12p]; del[12p]; multiple copies of 12p) were diagnostic of germ cell tumor. Other specific abnormalities were diagnostic of melanoma (two patients), lymphoma (one patient), peripheral neuroepithelioma (one patient), and desmoplastic small cell tumor (one patient). Of the germ cell tumors diagnosed on the basis of genetic analysis, five achieved a complete response to cisplatin-based chemotherapy. This outcome confirms our previously formulated hypothesis that some of these patients have histologically atypical germ cell tumors.<sup>130,134</sup> These genetic findings can be diagnostic in these patients. Additional specific genetic abnormalities or gene expression monitoring in solid tumors likely will improve our ability further to establish tumor lineage or biology and, it is hoped, also will improve therapy. Preliminary results using polymerase chain reaction to identify Epstein-Barr viral genomes in neck nodes have established an occult nasopharyngeal primary in some patients.

Autopsy data looking specifically at patients with poorly differentiated carcinoma of unknown primary site are limited. Additionally, the number of postmortem examinations in medicine in general is declining. On the basis of limited necropsy data we have accumulated, primary sites appear to be found in only a minority of such patients (40%). These findings are contrary to those for well-differentiated adenocarcinoma of unknown primary site, in which the primary site is found in most patients (>75%) at autopsy.<sup>34</sup>

### DIAGNOSTIC EVALUATION

The clinical evaluation of patients with poorly differentiated carcinoma of unknown primary site is similar to that described for patients with well-differentiated adenocarcinoma of unknown primary site. A medical history, physical examination, routine laboratory testing, and chest radiograph should be obtained for each patient. Any clues are followed with appropriate diagnostic testing. CT scans of the chest and abdomen should be performed in all patients in this group, owing to the frequency of mediastinal and retroperitoneal involvement. Serum levels of HCG and AFP should be measured because substantial elevations of these markers suggest the diagnosis of germ cell tumor. Serum tumor markers, such as CEA, CA-125, CA-19-9, and CA-15-3, can be helpful in monitoring response to chemotherapy. PET scanning may have a role in diagnosis and after therapy, but further data are necessary before recommending PET scanning as standard.

## TREATMENT

When additional pathologic studies identify a specific neoplasm (e.g., lymphoma, sarcoma), appropriate therapy can be administered. Patients with elevated serum levels of HCG or AFP and clinical features suggestive of extragonadal germ cell tumor (e.g., mediastinal or retroperitoneal mass) should be treated with chemotherapy that is effective for germ cell tumors, even when pathologic examination results are not diagnostic.

Most affected patients have multiple metastases and only the nonspecific diagnoses of poorly differentiated carcinoma or poorly differentiated adenocarcinoma despite additional pathologic study. The first reports showing that some of these patients (a small subset) have highly responsive tumors appeared in the late 1970s.<sup>133,134,135</sup> and <sup>136</sup> Most such patients were young men with mediastinal tumors; serum levels of HCG or AFP frequently were elevated. Most of these patients were thought to have histologically atypical extragonadal germ cell tumors. Although several other tumor lineages subsequently have been identified in these patients (i.e., thymoma, neuroendocrine tumors, sarcomas, lymphomas), most still defy precise classification.

Further evidence for the responsiveness of many other tumors in patients with poorly differentiated carcinoma of unknown primary site has accumulated during the last 20 years. On the basis of encouraging results in a few patients treated from 1976 to 1978, we prospectively studied the role of cisplatin-based therapy for patients with poorly differentiated carcinoma of unknown primary site. In a series of reports, we have documented a high overall response rate and long-term disease-free survival in a minority of such patients.<sup>130,131,132,133,134,135,136,137</sup> and <sup>138</sup> Our experience in the treatment of 220 such patients, accumulated between 1978 and 1989, is summarized in [Table 48-4](#). Most of the patients in this group did not have clinical characteristics strongly suggestive of extragonadal germ cell tumor. However, involvement of the mediastinum, retroperitoneum, and peripheral lymph node groups was relatively common. In the early years of this study, most patients received treatment with cisplatin, vinblastine, and bleomycin (PVB) with or without doxorubicin, then the most commonly used regimen for the treatment of advanced testicular cancer. Later, as etoposide replaced vinblastine, these patients received cisplatin and etoposide with or without bleomycin. All patients received an initial treatment trial of two courses of therapy, and responding patients received a total of four treatment courses. Major tumor responses were seen in 138 of 220 patients (62%), and 58 patients (26%) had complete response to treatment.

**TABLE 48-4.** Clinical Characteristics of 220 Patients with Poorly Differentiated Carcinoma of Unknown Primary Site

Our most recent update of this initial group of patients shows the following: 12% (26 patients) of the entire group has remained alive and free of tumor at a minimum follow-up of 6 years, with a range of 6 to 17 years (median, 11 years). Fourteen patients who were relapse-free at a minimum of 11 months at the time of our original report<sup>141</sup> cannot be documented now as alive and free of the original tumor. Six patients are lost to follow-up, though each was known to be alive and relapse-free at 1, 2.5, 3, 3.5, 4, and 7 years, respectively. Four patients died with progressive carcinoma of unknown primary site (two at 1 year and two at 7 years after initial chemotherapy). Three patients developed new cancers: one brain tumor, one pancreatic carcinoma, one lymphoma (two at 9 years and one at 17 years, respectively, after the initial therapy). One patient died of an unrelated cause 4 years after therapy.

The survival curves for the entire group of 220 patients and for the subset of 58 (26%) who had a complete response to chemotherapy are shown in [Figure 48-5](#) and [Figure 48-6](#). The median survival of complete responders was approximately 3 years. Median survival for all patients was 20 months. Of the 58 complete responders, 22 patients remain alive and relapse-free (38%), representing 10% of the entire group of 220. Four additional patients were treated in an “adjuvant setting” after resection of all gross tumor and all remain alive, bringing the total to 12% of all patients relapse-free. These long-term survival statistics are not censored. Patients who are lost to follow-up (six), died of second unrelated cancers (three), or died of other causes (one) are included as deaths on the curves. It is of note that 50 of the 220 patients were treated by oncologists outside our center, and their long-term results are equivalent. These results in a large series of patients support the notion that these poorly differentiated histologic types, as a whole, represent more sensitive tumors than well-differentiated adenocarcinoma, and substantial prolongation of life is possible for some of these patients, with the expectation of cure for a small minority.

**FIGURE 48-5.** Survival curve for all 220 patients with poorly differentiated carcinoma (12% at 17 years).

**FIGURE 48-6.** Survival curve of complete responders (38% at 17 years).

In only 32 of the 220 patients (14%) was the primary site or specific tumor type eventually identified ([Table 48-5](#)). In 19 of these 32 patients, the definitive diagnosis

Therefore, selection of patients with *clinical features* highly suggestive of extragonadal germ cell tumor, despite the nondiagnostic histology, defines a subgroup with a complete-response rate and long-term survival higher than those of the group as a whole. As discussed, Motzer et al.<sup>140</sup> provided strong support for the hypothesis that some of these patients have extragonadal germ cell tumors. Those researchers demonstrated chromosome 12 abnormalities diagnostic of germ cell tumors in several young men with poorly differentiated midline carcinomas of unknown primary site. The excellent response to treatment and survival (50% complete responders, 20% disease-free survival) for patients in our initial series with clinical features highly suggestive of extragonadal germ cell tumor suggests that these tumors are germ cell tumors, albeit histologically atypical. These treatment results do not differ greatly from those in patients with known extragonadal germ cell tumors treated with standard cisplatin-based therapy.<sup>146,147</sup> If feasible, genetic analysis on tumor tissue should be performed as a diagnostic test for selected patients with carcinoma of unknown primary site.

Responsive tumors are heterogeneous in their origin, and only a small subset of patients have histologically atypical germ cell tumors. A few of the patients have non-Hodgkin's lymphoma. Certain lymphomas may be confused with anaplastic carcinomas; some lymphomas, notably the Ki-1 lymphomas, also can stain positively with epithelial membrane antigen, further complicating their differentiation from carcinoma.<sup>148</sup> It is hoped that this confusion will be minimized or eliminated with the routine use of immunoperoxidase staining for CLA. A second group of highly responsive tumors are poorly differentiated neuroendocrine carcinomas. The origin of such tumors remains speculative, but they may be an anaplastic variant of occult primary carcinoma.

The nature of the other responsive tumors in this heterogeneous group of patients remains even more speculative. Malignant thymoma is a tumor recently recognized to be responsive to cisplatin-based therapy, with some patients experiencing long-term complete remissions.<sup>149</sup> Some patients with poorly differentiated carcinoma located predominantly in the mediastinum may have thymoma. In our original series, a few patients who were long-term survivors were identified as having "melanoma" on the basis of immunoperoxidase stains. This diagnosis seems unusual because melanoma is a tumor that normally is unresponsive to chemotherapy. Possibly, melanomas identifiable only by immunoperoxidase staining or electron microscopy represent a uniquely chemotherapy-sensitive subset. Finally, some responsive tumors possibly represent a heretofore undefined tumor type. Alternatively, some may represent highly undifferentiated—and therefore perhaps chemotherapy-sensitive—epithelial tumors from occult primary sites, which usually are much less responsive to systemic therapy. Future knowledge and refinements in genetic diagnosis may establish the identity of many of these tumors.

Table 48-7 shows the relation of response and long-term survival (>6 years) to the site of dominant tumor involvement. Regardless of other factors, dominant tumor in the retroperitoneum, peripheral lymph nodes, or mediastinum is fairly favorable. Forty-five of 105 patients in these categories had a complete response, and 20 patients remain alive and relapse-free (19%).

Dominant Tumor Site	Number of Patients	Overall Response Rate (CR/PR) (%)	Number of Complete Responses (%)	Number of Patients Alive >6 Years (%)
Mediastinum	42	55 (33)	21 (50)	10 (24)
Regional lymph nodes* (cervical, axillary, inguinal)	28	34 (21)	11 (39)	6 (21)
Retroperitoneum	45	29 (64)	15 (33)	4 (9)
Bone	3	3 (100)	1 (33)	1 (33)
Other sites	4	1 (25)	1 (25)	1 (25)
Lung	29	20 (69)	8 (27)	1 (3)
Liver	11	3 (27)	1 (9)	1 (9)
Paraneoplastic	4	2 (50)	1 (25)	0
Multiple sites (no dominant site)	30	20 (67)	3 (10)	1 (3)
Other sites†	18	4 (22)	2 (11)	1 (6)
Total	220	140 (64)	58 (26)	38 (17)

CR, complete response; PR, partial response.  
 \*Includes four patients treated in adjuvant setting.  
 †Sites include pancreas (three patients), brain (one), neuroendocrine tumor (one), stomach (one), parotid (one), and sarcoma (one).

TABLE 48-7. Chemotherapy Response, Survival, and Predominant Site of Tumor

Prognostic factors also have been evaluated in a large series of patients reported from the M. D. Anderson Hospital. This large group was heterogeneous, containing patients with all histologic subtypes. Those with clinical features of extragonadal germ cell tumors were excluded, and only a minority of patients with poorly differentiated carcinoma received cisplatin-based treatment as used in the treatment of germ cell tumors. Some of the same clinical features that we identified were found to be important prognostic features, including limited number of organ sites involved, tumor location in lymph nodes (including mediastinum and retroperitoneum) other than the supraclavicular lymph nodes, and female gender (seen also in our recent series). In addition, the relatively poor outcome of patients with adenocarcinoma as compared to other histologies was confirmed. However, they could not identify a subset of patients with poorly differentiated carcinoma and long-term survival after chemotherapy.<sup>96,150,150</sup> Although these prognostic features are useful, occasional excellent responses are seen even in patient groups with "unfavorable" clinical features. At present, even these patients should be considered for a trial of chemotherapy.

## NEUROENDOCRINE CARCINOMA OF UNKNOWN PRIMARY SITE

Improved pathologic methods for diagnosing neuroendocrine tumors has resulted in the recent recognition of a wider spectrum of these neoplasms. The incidence of unknown primary neuroendocrine tumors is not known, but an estimate suggests approximately 4000 U.S. patients annually. Most of the well-described adult neuroendocrine tumors have distinctive histology and a known primary site of origin (Table 48-8). The well-differentiated or low-grade neuroendocrine tumors (typical carcinoid, islet cell tumors, and others) occasionally present without a recognizable primary site and usually possess an indolent biologic behavior. Carcinoid tumors of unknown primary site appear to be increasing.<sup>1</sup> A second group of neuroendocrine tumors are poorly differentiated by light microscopy but have "neuroendocrine features (typical small cell, atypical carcinoid, or poorly differentiated neuroendocrine carcinoma) and act aggressively. A third group of neuroendocrine tumors, recently recognized, has high-grade biology and no distinctive neuroendocrine features by light microscopy. The initial diagnosis in this group usually is poorly differentiated carcinoma, and neuroendocrine features are recognized only when immunoperoxidase staining (or, more definitively, if electron microscopy) is performed. Neuroendocrine carcinomas of unknown primary site occur in each of these three categories.

Indolent Biology	Aggressive Biology
Carcinoid tumor (many primary sites)	Small cell lung cancer, atypical or poorly differentiated carcinoids (many primary sites)
Islet cell tumor, pancreas	Extrapulmonary small cell carcinoma (many primary sites)
Pheochromocytoma, adrenal	Peripheral neuroepithelioma (usually in adolescents)
Medullary carcinoma, thyroid	Merkel cell tumor, skin
Paraganglioma-neurons	Neuroblastoma, adrenal

TABLE 48-8. Adult Neuroendocrine Tumors with Known Primary Sites

## LOW-GRADE NEUROENDOCRINE CARCINOMA

Occasionally, metastatic neuroendocrine tumors with histologic features typical of low-grade well-differentiated carcinoid or islet cell tumor are found without obvious primary site. In this situation, metastatic tumor usually involves the liver or bone (or both) and sometimes is associated with clinical syndromes produced by the secretion of bioactive substances (e.g., carcinoid syndrome, glucagonoma syndrome, vipomas, Zollinger-Ellison syndrome). In some affected patients, further evaluation reveals primary sites in the small intestine, rectum, pancreas, or bronchus.

As predicted by the histologic appearance, these neuroendocrine tumors usually exhibit an indolent biology, and slow progression over years is likely. Management should follow guidelines established for metastatic carcinoid or islet cell tumors from obvious primary sites. Often, these neoplasms are refractory to systemic chemotherapy, and cisplatin-based chemotherapy produces low response rates.<sup>151</sup> Depending on the clinical situation, appropriate management may include local therapy (resection of isolated metastasis, hepatic artery ligation-embolization), treatment of associated syndromes with somatostatin analogs, streptozocin, doxorubicin, 5-FU-based systemic therapy, or symptomatic management.

## SMALL CELL CARCINOMA

Patients with a history of cigarette smoking and small cell undifferentiated carcinoma at a metastatic site usually have a lung primary tumor. CT of the chest and fiber-optic bronchoscopy should be performed. Perhaps PET scanning may be useful in this setting, but data are limited. If a pulmonary lesion is identified, affected patients should be treated according to recommendations for small cell lung cancer. Small cell carcinoma can arise also from a variety of extrapulmonary primary sites. Patients with localizing symptoms should undergo appropriate diagnostic studies.

When no primary site is identified, patients with small cell carcinoma should be treated with combination chemotherapy as recommended for small cell lung cancer. We have found that paclitaxel, carboplatin, and oral etoposide is a very active therapy for these patients and have continued to evaluate this regimen. Initially, these tumors are chemotherapy-sensitive, and major palliative benefit can be derived from treatment. An occasional patient will enjoy long-term benefit. In the rare instance in which the tumor appears at a single metastatic site, the addition of radiation therapy or resection (or both) to combination chemotherapy should be considered.

## POORLY DIFFERENTIATED NEUROENDOCRINE CARCINOMA

In approximately 10% of poorly differentiated carcinomas, electron microscopy reveals neurosecretory granules, a finding diagnostic of neuroendocrine carcinoma. These tumors have been called *poorly differentiated neuroendocrine tumors*, *atypical carcinoids*, or *primitive neuroectodermal tumors*. In some of these tumors, neuroendocrine features are recognizable by light microscopy; in others, the light-microscopical diagnosis is “poorly differentiated carcinoma.” Though electron microscopy is the most accurate means of pathologic diagnosis, most of the tumors also have typical immunoperoxidase staining patterns with positive staining for neuron specific enolase, chromogranin, and synaptophysin.

Previously, we reported on a group of 29 patients with poorly differentiated neuroendocrine tumors<sup>137</sup> and later updated our experience to include 51 patients, 46 treated with combination chemotherapy (Table 48-9). Most of these patients had clinical evidence of high-grade tumor, and most had metastases in multiple sites. Thirty-three of 43 evaluable patients (77%) responded to chemotherapy with a cisplatin-based combination regimen. Thirteen patients (26%) had complete responses, and eight remain continuously disease-free more than 2 years after completion of therapy. Our more recent experience would favor the use of paclitaxel, carboplatin, and oral etoposide in such patients.

Feature	Number of Patients
<b>CLINICAL CHARACTERISTICS</b>	
Male	34
Female	17
Smoking (>10 pack-years)	35
<b>DOMINANT TUMOR SITE</b>	
Retropneumothorax	13
Perihilar lymph nodes	7
Mediastinum	6
Blow	6
Esoph	6
Colon	6
Multiple sites (no dominant site)	6
<b>TREATMENT</b>	
Cisplatin-based combinations	36
Cyclophosphamide, doxorubicin, vincristine with or without etoposide	8
Surgical resection only	3
Radiation therapy only	2
<b>RESPONSE TO CHEMOTHERAPY</b>	
Complete response	13 (26%)
Partial response	20
No response or unassessable	10
Continuously disease-free	8 (15%)

TABLE 48-9. Poorly Differentiated Neuroendocrine Tumors of Unknown Primary Site in 51 Patients

The origin of these poorly differentiated neuroendocrine carcinomas remains unclear. In four of our patients, specific diagnoses were made either subsequently in their clinical course or at autopsy. Two patients had carcinoid tumors with “undifferentiated” growth pattern (both presented with abdominal carcinomatosis); one had small cell lung cancer; and one had extragonadal germ cell tumor with predominant neuroendocrine differentiation. Likely some additional patients with small cell histology had small cell lung cancer with occult primary tumor, but more than one-half of these patients had no smoking history, and the absence of overt pulmonary involvement renders this diagnosis unlikely in most patients. Probably, some of these tumors are undifferentiated variants of well-recognized neuroendocrine tumors (e.g., carcinoid tumor), without a recognizable primary site. In the undifferentiated form, the clinical and pathologic characteristics no longer resemble the characteristics of the more differentiated counterpart. Anaplastic or atypical carcinoid tumors arising in the gastrointestinal tract are responsive to cisplatin-based chemotherapy, whereas carcinoid tumors with typical histology usually are resistant.<sup>151</sup> A few reports of patients with “extrapulmonary small cell carcinoma of unknown primary site” also have documented chemotherapy responsiveness and occasional long-term survival after systemic therapy.<sup>152,153</sup> However, the term *extrapulmonary small cell carcinoma* implies the existence of a known primary site (e.g., head and neck, salivary gland, prostate, cervix, esophagus, bladder, etc.); therefore, these tumors are more aptly described as *neuroendocrine carcinoma of unknown primary site*.

Although the origins of these poorly differentiated neuroendocrine tumors remain undefined, the presence of neurosecretory granules in the tumors of patients with poorly differentiated carcinoma identifies a highly treatable subgroup. Molecular genetic studies may be helpful if an 11:22 translocation (peripheral neuroepithelioma or soft tissue Ewing's sarcoma) or i(12p) abnormality (germ cell tumor) is identified. All patients with disease not otherwise specifically diagnosed should be treated with a trial of combination chemotherapy. As are small cell neuroendocrine carcinomas, these tumors are very sensitive to the combination of paclitaxel, carboplatin, and oral etoposide. Some patients with a single site of tumor involvement may be curable with local treatment modalities alone; however, a course of adjuvant chemotherapy also should be considered in such patients if clinically feasible.

## SPECIAL ISSUES

### CARCINOMA OF UNKNOWN PRIMARY SITE AS A DISTINCT CLINICOPATHOLOGIC ENTITY

We have been struck over the last two decades by the number of times patients and their referring physicians (often oncologists) are very frustrated by unknown primary cancer. Often, they are somewhat obsessed with finding the primary site or at least giving their patients a more specific diagnosis. Many reasons underlie these feelings. Some patients think that their oncologists are not clever enough as diagnosticians and seek the advice of others. Some oncologists feel relatively inadequate and wonder what other tests they might order; some have been relatively tentative, not feeling confident in recommending any therapy. Certainly, a reasonable clinical and pathologic evaluation of these patients and their tumors is indicated, with oncologists being aware of possible primary sites and the relevance in particular patients. However, once these considerations and evaluation are complete and no additional helpful information is forthcoming (as often is the case), physicians should stop, discuss the issue with their patients and their families, and accept the clinicopathologic diagnosis as an unknown primary tumor. Indeed, most patients at this point have unknown primary cancer; such tumors only occasionally surface during life and often cannot even be found at autopsy. Patients will be better served, and physicians will eventually feel more comfortable—and therefore manage these patients more effectively—once their patients accept and understand this diagnosis as a distinct clinicopathologic entity. They have a diagnosis.

A second very practical issue in the United States is the determination of Medicare reimbursement for chemotherapy for cancer diagnoses. Most typically, these reimbursements are determined by Medicare (and several other third-party insurers) by consulting two compendia: the *American Hospital Formulary Drug Information* (AHFS) and the *United States Pharmacopeia Drug Information* (USPDI). Their entries are listed by an indication index or by tumor types [ICD-9( *International Classification of Diseases-9*) codes] and a generic drug index. Tumor types and drugs used for a particular tumor type are listed. The list is based on published literature showing “effectiveness” or clinical benefit in a specific tumor type. This system is particularly arbitrary. The diagnosis code for unknown primary cancer is not listed at all in AHFS or USPDI. Therefore, no drugs are listed as “useful” for patients with unknown primary cancer. Usually, Medicare will not pay for any drug not

listed as an indication.

Many patients with unknown primary cancer are coded with another diagnosis by oncologists. At times, this is a “good guess” of the possible primary tumor (e.g., non–small cell lung cancer in patients with lung lesions or mediastinal node involvement; hepatoma, pancreatic, or colon cancer for patients with liver involvement, etc.). Furthermore, patients at times are assigned a diagnosis based on the pathology report alone (e.g., adenocarcinoma consistent with pancreatic or colon primary tumor). Certainly, this practice allows for reimbursement for some drug costs by a system that otherwise has not even recognized unknown primary cancer. This activity, in turn, causes the true incidence of unknown primary cancer to be underestimated. Recently, we and others provided the editors of AHFS and USPD with considerable data concerning unknown primary cancer, and we hope that the diagnosis code and specific drugs useful for this entity will appear in their pages soon.

Currently, more than enough clinical and pathologic data allow classification of patients confidently as having an unknown primary cancer, and the more global acceptance of this entity will help these patients to establish an identity, will stimulate more interest by physician investigators, and eventually will improve general understanding of such patients and their tumors.

### **EXTRAGONADAL GERM CELL CANCER SYNDROME**

Selected patients with poorly differentiated carcinoma almost certainly have germ cell tumors, although the histologic features are atypical even when generous pathologic specimens are available for study. Chromosomal analysis (as discussed) may provide a definitive diagnosis in some of these patients, particularly if their tumor cells contain specific chromosome 12 abnormalities. Even if they are not found or in the absence of a genetic study, young people who have mediastinal or retroperitoneal masses or multiple lung nodules (with or without elevated serum levels of HCG or AFP) should be suspected of harboring a germ cell tumor. Lymphomas should be ruled out by immunoperoxidase stains, electron microscopy, or (if necessary) cytogenetic studies. The “extragonadal germ cell cancer syndrome” was described in 1979.<sup>133,134</sup> The full syndrome displays the following features: (1) It occurs in young men (<50 years); (2) tumors are predominantly located in the midline (mediastinum, retroperitoneum) or multiple pulmonary nodules; (3) the symptom interval is short (<3 months) and history is of rapid tumor growth; (4) serum levels of HCG, AFP, or both are elevated; and (5) a good response to previously administered radiation therapy or chemotherapy is demonstrated.

Few patients have all elements of this syndrome. These clinical features are those of extragonadal germ cell tumors but, without definitive histology, the diagnosis is not unequivocal. In rare cases, women can develop these tumors, and the other features also are not absolute. Any one feature suggests the possibility of a germ cell tumor. Treatment with cisplatin-based therapy is prudent in affected patients who may have atypical germ cell tumors.

### **SINGLE SITE OF NEOPLASM**

In situations in which only one site of neoplasm is identified (e.g., one node group or one large mass), the possibility of an unusual primary tumor mimicking metastatic disease should be considered. Several unusual tumors could present in this fashion, including Merkel-cell tumors, skin adnexal tumors (e.g., apocrine, eccrine, and sebaceous carcinomas), and even sarcomas, melanomas, or lymphomas that are interpreted mistakenly as metastatic carcinoma (pathologically and clinically). Usually, patients with one site of involvement have metastatic carcinoma, and many other sites are present but are not detectable. In the absence of any other documented metastatic disease, such patients should be treated with aggressive local therapy (i.e., resection, radiation therapy, or both) because a minority will enjoy long-term disease-free survival. Patients who present with isolated cervical, supraclavicular, and inguinal adenopathy often have squamous cell carcinoma, but a minority harbor poorly differentiated carcinoma and adenocarcinoma. In addition to receiving definitive local therapy, these patients also should receive either neoadjuvant or adjuvant platinum-based or paclitaxel-based chemotherapy, but knowing whether this treatment is superior to local therapy alone is difficult.

On occasion, patients will present with apparent solitary metastasis of adenocarcinoma or poorly differentiated carcinoma in the brain, liver, subcutaneous tissue, intestine, or other areas. In most instances, other metastases will become clinically apparent with time. Certainly, some examples highlight resection or irradiation of these single areas and illustrate patients doing well with no evidence of recurrence. At times, the resection may be planned as palliative, particularly with a brain metastasis. The method of choice in managing these patients is to resect the single lesion. After resection, and depending on the other clinical circumstances, patients may be candidates for chemotherapy, particularly if their histology is poorly differentiated carcinoma. In those patients with single metastases (i.e., brain), radiation therapy is a prudent consideration after surgical resection. Often, isolated axillary carcinoma in women arises from an occult breast cancer and has important therapeutic implications (see [Adenocarcinoma of Unknown Primary Site](#), earlier in this chapter).

### **UNSUSPECTED GESTATIONAL CHORIOCARCINOMA**

In young women with poorly differentiated carcinoma or anaplastic neoplasms, particularly with lung nodules, oncologists must be aware of the possibility of metastatic gestational choriocarcinoma. The history of recent pregnancy, spontaneous abortion, or missed menstrual periods should suggest this possibility. In this group of patients, serum HCG levels invariably are elevated. On occasion, biopsy specimens do not show the classic appearance of choriocarcinoma but simply that of metastatic carcinoma, usually poorly differentiated. Ultrasonography or CT scan of the abdomen may show an enlarged uterus, and a dilation and curettage may be indicated in such patients. Most affected patients are curable with single-agent methotrexate.

### **ISOLATED PLEURAL EFFUSION**

Occasionally, an isolated pleural effusion containing carcinoma in women will represent metastatic disease from occult ovarian carcinoma or primary peritoneal carcinomatosis. Even when affected patients have no symptoms or signs and an abdominopelvic CT scan result is normal, the primary tumor may reside in the abdomen or pelvis. Such occult abdominal neoplasms may arise from the ovary or the peritoneal surface (see [Adenocarcinoma of Unknown Primary Site](#), [Peritoneal Carcinomatosis in Women](#), earlier in this chapter) and most characteristically cause a pleural effusion. In the absence of clues of neoplasm in the abdomen, an elevated plasma CA-125 level suggests the possibility of this phenomenon. In the absence of clinical findings in the abdomen, laparoscopy or exploratory laparotomy might be diagnostic, but these procedures are not therapeutic in this setting. Some of these tumors are particularly responsive to chemotherapy with paclitaxel and a platinum agent.

An isolated pleural effusion can be a manifestation of a peripheral lung carcinoma (usually adenocarcinoma), a mesothelioma or, rarely, a lesion from other sites. Diagnosis may be difficult; at times the primary tumor is not apparent even after thorocostomy and chest tube drainage. Usually, cytology shows adenocarcinoma. Electron microscopy may reveal ultrastructural features diagnostic of mesothelioma. The therapy for such patients is difficult. In those with poor performance status or advanced age, a trial of tamoxifen or megestrol acetate is reasonable. In fit patients, a trial of chemotherapy (as discussed) for unknown primary carcinoma should be considered.

### **GERM CELL TUMORS WITH METASTASES OF OTHER HISTOLOGIES**

On occasion, patients with germ cell tumors, particularly extragonadal primaries, may have a metastatic lesion that consists of only somatic tumor cells. This is particularly true for neuroendocrine or sarcomatous differentiation. Patients, therefore, may be diagnosed as having a neuroendocrine tumor or sarcoma. In these rare instances, a primary germ cell tumor (usually extragonadal) is present elsewhere and subsequently will be clinically apparent. Making the diagnosis initially is difficult. An elevated plasma AFP or HCG level is suggestive. The presence of a mediastinal, retroperitoneal, or testicular mass supports this possibility. Chromosomal analysis of tumor tissue may be diagnostic if a specific chromosome 12 abnormality is found. If affected patients have metastatic germ cell tumor with metastases of other histologies, the treatment of choice is cisplatin-based chemotherapy. Such patients appear to have a worse prognosis than do those with typical germ cell tumors, probably because the somatic cell tumors are less sensitive to chemotherapy.

### **MELANOMA AND “AMELANOTIC” MELANOMA**

Approximately 10% to 15% of all melanomas presenting with an unknown primary site are believed to be “amelanotic.” We have viewed this diagnosis with considerable skepticism. At times, the only reason for the pathologic diagnosis is the histologic pattern's similarity to melanoma, even though no pigment is demonstrated. In our experience, detailed pathologic and molecular study occasionally has revealed a group of other specific diagnoses, including lymphomas, neuroendocrine tumors, germ cell tumors, sarcomas, and poorly differentiated carcinoma (otherwise not specified).

Melanosomes or premelanosomes seen on electron micrographs have been considered diagnostic of melanoma but, on rare occasion, these structures are seen in other tumors. Some believe amelanotic melanomas do not always form premelanosomes, opening the question as to whether they really are melanomas. Immunoperoxidase panels also are useful in suggesting the diagnosis of melanoma (see [Table 48-1](#)). Of considerable interest is that in our original series of 220

#### INTRODUCTION

*Peritoneal carcinomatosis* is defined as the spread and implantation of tumor cells throughout the peritoneal cavity, and it is considered an incurable disease state leading to significant patient suffering. However, oncologists should recognize peritoneal carcinomatosis not as a terminal event for the patient but as a regional disease entity that requires special attention and as a therapeutic challenge for consideration of novel management strategies. Although the primary histology dictates the clinical course, important concepts of diagnosis and treatment are common among all forms. Also, the palliative management of complications, such as bowel obstruction and ascites, warrants special consideration. The purpose of this chapter is to provide a general overview of peritoneal carcinomatosis as a regional stage of metastatic disease. This includes a discussion of the biology of tumor spread and implantation and techniques for early recognition of peritoneal tumors. General concepts regarding regional treatment approaches are reviewed.

#### PATHOPHYSIOLOGY

The peritoneum is a serous lining of mesothelial cells with a rich vascular and lymphatic capillary network.<sup>1</sup> The flow of abdominal fluid provides clues to the development and pattern of peritoneal carcinomatosis. Gravity, diaphragmatic and intestinal movement, and diaphragmatic and omental absorption via lymphatics leads to a characteristic peritoneal fluid circulation (Fig. 49-1).<sup>2</sup> Lymphatic endothelial cells have been shown to form channels extending from the peritoneal cavity directly into lymphatics,<sup>3</sup> most notably in the diaphragm. Flessner et al.<sup>4</sup> demonstrated that the absorption of <sup>125</sup>I-labeled albumin from the peritoneal cavity concentrated in the diaphragm and abdominal wall peritoneum but not in the visceral peritoneum. The most dependent recess is the pouch between the rectum and uterus or bladder. Hagiwara et al.<sup>5</sup> demonstrated a site-specific correlation between the number of milky spots at specific peritoneal locations and the number of infiltrating tumor cells. Milky spots represent an immunologic filter similar to the lymphatic drainage of solid organs and seem to represent sites where peritoneal fluid drains into lymphatic channels. If fluid is actively absorbed into these spots, it is easy to hypothesize that free clumps of tumor cells could become trapped at these spots and develop into tumors. Milky-spot tissues are found in the hepatoduodenal ligament, base of mesentery, appendiceal epiploicae, gonadal fat (corresponding to the pouch of Douglas), and the greater omentum. The omentum contains the highest concentration of milky spots. The constant flux of fluid, the sites of absorption and filtration, and gravity all play a role in the pattern of peritoneal tumors. It has been proposed that more aggressive, invasive tumors have a “stickier” phenotype and are more likely not to follow the experimental observations of peritoneal spread but have a more random distribution close to the initial site of peritoneal contamination.<sup>6</sup> In addition, more aggressive, invasive tumors are better at forming tumors on moving surfaces, such as the serosal surface of the small bowel.

**FIGURE 49-1.** Circulation of fluid in the peritoneal cavity. Flow is generated by diaphragmatic movement, absorption of material from the diaphragmatic lymphatic channel, and gravity. 1, Lesser sac; 2, foramen of Winslow; 3, Morison's pouch; 4, right triangular ligament; 5, right subphrenic space; 6, falciform ligament; 7, left subphrenic space; 8, phrenocolic ligament; 9, bare area of the descending colon; 10, root of the small bowel mesentery; 11, bare area of ascending colon; 12, duodenum; 13, esophagus; 14, root of the transverse mesocolon; 15, bare area of the rectum; 16, bladder. (From ref. 2, with permission.)

Tumor cells reach the peritoneal cavity by direct invasion of aggressive gastrointestinal (GI) tumors through the serosal lining of the organ or through a pressure-burst effect of less invasive tumors that push through the serosal surface without tissue invasion. This is characteristic of appendiceal and ovarian tumors, in which even a benign tumor can grow large enough to break through the wall of the organ and contaminate the peritoneal cavity with neoplastic cells.<sup>7</sup> It is possible for hematogenous metastases from extraperitoneal tumors to invade secondarily or burst into the abdominal cavity, leading to peritoneal carcinomatosis. A final source for peritoneal contamination of tumor cells is iatrogenic spillage of neoplastic cells. A classic example is during cholecystectomy in the setting of unrecognized gallbladder cancer, in which the subserosal plane of tumor cell invasion is dissected during the resection, spilling tumor cells throughout the region.<sup>8</sup> It is also possible to contaminate the peritoneal cavity during a needle biopsy for diagnosis.

Seeding of the peritoneal cavity with tumor cells does not necessarily lead to implantation, proliferation, and formation of carcinomatosis.<sup>9</sup> Different tumors and heterogeneous cell populations within a single tumor will lead to different efficiencies with regard to tumor formation after peritoneal seeding.<sup>10</sup> The requirements for peritoneal tumor seeding are different from the requirements for hematogenous metastases. The tumor cells must make their way into the cavity, then stick to the peritoneal surface via adhesion molecules.<sup>11</sup> They must avoid immunologic destruction and, once implanted, be able to stimulate angiogenesis for continued growth. In general, this can be accomplished with a less aggressive tumor cell than that required for hematogenous spread. Also, it may be possible for tumors to grow to a limited extent within the peritoneal cavity without implantation and vascularization but relying on nutrients within peritoneal exudate for survival.

#### DIAGNOSIS

Although the follow-up and early detection of metastatic cancers in general is in debate in the absence of effective therapy,<sup>12</sup> the early diagnosis of peritoneal spread

of cancer would be preferable in the setting of experimental protocols for regional therapy. In other cases, the early detection of peritoneal spread might alter the management of the primary tumor or avoid surgical exploration for hepatic or pulmonary metastasectomy. However, peritoneal spread is diagnosed in most patients after surgical exploration for bowel complications or after clinical ascites develops. At this stage in the setting of invasive tumors, a regional therapy approach is probably beyond any chance of success.

Standard imaging tests, including ultrasonography and helical computed tomography (CT) scans, are notably insensitive for the detection of peritoneal tumor. The sensitivity of CT scan for peritoneal nodules measuring smaller than 1 cm is on the order of 15% to 30%.<sup>13</sup> Ultrasonography is similarly insensitive. It is important to consider findings other than solid-tumor detection that may suggest the presence of peritoneal carcinomatosis. These include the presence of ascites, fixing together of bowel loops, thickening of mesentery, and omental matting.

Advances in magnetic resonance imaging (MRI) have been demonstrated to improve significantly detection of peritoneal tumor nodules.<sup>14</sup> Low et al.<sup>15</sup> have demonstrated that abdominal MRI is superior to helical CT for the detection of peritoneal and bowel wall abnormalities. It may be that MRI of the peritoneal cavity is improved with dilute oral barium contrast materials. In general, CT scans are easier to interpret for the general oncologist and are cheaper to obtain and, therefore, are still more widely used than MRI. For patients on clinical protocol, however, improved imaging should be a goal for the oncologist, to aid in follow-up of peritoneal disease. Nelson et al.<sup>16</sup> studied intraperitoneal infusion of contrast material before CT scanning, but this did not significantly improve the sensitivity for detection of peritoneal metastases.

Positron emission tomography (PET) imaging for metastatic GI tumors is under investigation at numerous institutions and may improve the sensitivity for detecting small nodules. In general, PET has not been shown to be sensitive for lesions measuring smaller than 1 cm in the abdominal cavity. Extrahepatic peritoneal nodules of smaller than 1 cm were not detected by [<sup>18</sup>F]fluorodeoxyglucose (FDG) PET scanning as a preoperative screen for patients undergoing hepatic metastasectomy for colorectal cancer.<sup>17</sup>

Another mechanism for screening for peritoneal spread of tumor involves peritoneal lavage cytology. This can be performed as a percutaneous closed technique or at the time of laparoscopy or laparotomy for resection of primary disease. The sensitivity of this test depends on the ability to lavage completely all regions of the peritoneal cavity and the ability to detect cancer cells accurately. Sensitivity may be improved using polymerase chain reaction techniques or immunohistochemistry.<sup>18,19</sup> The sensitivity also depends on the number of cells being shed into the peritoneal cavity by the tumor. Even in cases with advanced, grossly evident peritoneal metastases, the ascites can be negative for tumor cells. A study by Fujiwara et al.<sup>20</sup> compared closed abdominal lavage cytology to second-look laparotomy. In this study, 14 patients who had positive cytology results also had positive disease on second-look laparotomy. Three patients with negative cytology had positive disease on second-look laparotomy. The other 23 patients had negative cytology and negative second-look laparotomy. This illustrates the fact that cytology can be helpful in predicting the presence of carcinomatosis, but it is not as sensitive as direct inspection and palpation of the peritoneal surfaces.

Much has been studied regarding the prognostic utility of lavage cytology for patients at high risk of peritoneal spread, as in the case of gastric cancer, colon cancer, and pancreatic cancer.<sup>21,22</sup> Positive cytology correlates with full-thickness invasion through the bowel wall, as would be expected.<sup>23</sup> Positive cytology also seems to correlate with a poor prognosis for peritoneal recurrence.<sup>24,25</sup> It is not clear, however, whether cytology has any added prognostic value over the stage of the primary tumor. It should be noted also that cells shed into the peritoneal cavity may not be viable or may not be able to establish new tumor sites; therefore, the presence of tumor cells may not predict the development of carcinomatosis.

By far the most sensitive modality for detecting the spread of tumor is direct visualization of the peritoneal surfaces along with palpation of the abdominal contents. Visualization of the peritoneal surfaces can be accomplished with a minimally invasive approach. Laparoscopy is now used routinely in most cancer centers as a staging modality for patients with resectable pancreatic and gastric cancers. Its greatest utility is in diagnosing small peritoneal metastases and small surface liver metastases that are not detected on imaging tests.<sup>26</sup> The minimally invasive laparoscopy allows for safe, directed peritoneal lavage for cytology as well. Laparoscopy should be considered for the detection of peritoneal surface tumors in patients in whom therapy would be altered or investigational therapy considered for tumor spread in this fashion. This includes patients who are considered for preoperative neoadjuvant regional therapy before surgical resection for resectable pancreatic and gastric cancer. Laparoscopy may also be of utility in patients with carcinomatosis who should be followed up for response to therapy to determine whether to change therapies or continue the current treatment strategy.<sup>27,28</sup> Repeat laparoscopy for following up disease status at intervals during therapy is feasible. The adhesions after multiple tumor debulkings and laparoscopies may ultimately limit the sensitivity of detection and increase the risk of laparoscopy. Open abdominal exploration and palpation of the peritoneal surfaces is extremely sensitive for even small 1- to 2-mm peritoneal surface nodules. Palpation of the areas at high risk should be performed during any cancer surgery for intraperitoneal malignancies. This includes the greater omentum, the deepest recess of the pelvic peritoneum, the base of the small bowel mesentery and transverse mesocolon, the falciform ligament, and the diaphragm.

## HISTOLOGIC SUBTYPES

### PSEUDOMYXOMA PERITONEI

Classically, the diagnosis of *Pseudomyxoma peritonei* includes any low-grade or benign tumor within the abdominal cavity that produces copious amounts of mucinous ascites. The term was first coined in 1884 by Werth<sup>29</sup> as a description of the gelatinous material filling the peritoneal cavity of a patient with a ruptured cystadenoma of the ovary. In 1901, Fraenkel<sup>30</sup> first associated *P peritonei* with a ruptured mucocele of the appendix. Because of the relative rarity of this clinical entity, it is generally poorly understood by oncologists. The spectrum of conditions that are considered to fall under the general diagnosis of *P peritonei* is quite large.<sup>7</sup> This leads to confusion in determining the expected clinical outcome and treatment approaches for this condition.

The condition of diffuse mucinous ascites can be caused by any tumor that has spread into the peritoneal cavity and produces significant amounts of mucin. This includes well-differentiated adenocarcinomas of the GI tract and benign mucin-secreting adenomas of the appendix.<sup>7</sup> A benign tumor of the appendix can grow to a size that ruptures the wall of the appendix and leads to spillage of benign cells into the peritoneal cavity. These cells can then continue to proliferate and produce copious amounts of mucin despite a completely benign histology, with the inability to invade into tissues and metastasize hematogenously or via lymphatics. The most important prognosticator for patients with mucinous ascites is, therefore, whether the primary tumor is benign or malignant.

Clinical evidence of malignancy includes the presence of lymph node metastases and gross evidence of an invasive phenotype. Histologically, malignant tumors will have moderate to abundant cellularity, show evidence of invasion, and demonstrate cellular atypia and nuclear pleomorphism consistent with malignancy. Benign tumors have scant cellularity with no evidence of invasion into tissues and no cellular atypia. In difficult cases, it is helpful to examine the primary tumor carefully to determine whether the primary tumor represents invasion of tumor cells through the wall of the organ or a benign process that has ruptured the wall without invasion.

The site of origin of cells producing mucinous ascites often is difficult to define. This is especially the case when, in women, both the appendix and the ovaries are obliterated by tumor. Although the ovary can be a site for mucinous borderline tumors of low malignant potential or mucinous carcinomas, these are almost never associated with diffuse copious mucinous ascites.<sup>7</sup> Therefore, all cases of *P peritonei* with benign-appearing mucinous epithelial cells emanate from an appendiceal mucinous adenoma. These tumors often involve the ovaries at early stages but should not be confused with a primary ovarian cancer. Ruptured ovarian follicles may allow for a rich soil and sticky surface on which benign tumor cells can stick and proliferate. In surgical debulking procedures, appendectomy and bilateral oophorectomy should be performed.

Ronett et al.<sup>31</sup> have extensive experience in *P peritonei*, and they have classified cases of *P peritonei* into three pathologically and prognostically distinct groups: (1) disseminated peritoneal adenomucinosis; (2) peritoneal mucinous carcinomatosis; and (3) peritoneal mucinous carcinomatosis with intermediate or discordant features (Table 49-1). They have shown distinct difference in survival and prognosis in patients with disseminated peritoneal adenomucinosis as compared to those with carcinomatosis or discordant features (Fig. 49-2). This work verifies the importance of differentiating a malignant from a benign diagnosis. In their study, the median survival for patients with disseminated peritoneal adenomucinosis had not been reached with a median follow-up of approximately 6 years, whereas the median survival for patients with a malignant tumor producing mucinous ascites was approximately 16 months.

Factor	DPAM	PMCA
Primary site	Appendix	Appendix, colon, endometrium
Primary diagnosis	Mucinous adenoma	Mucinous adenocarcinoma
Regional spread	Mucinous ascites with cellularity	Carcinomatous cell clusters in ascites
Cellular features	Scant	Moderate to abundant
Morphology	Abundant extracellular mucin containing epithelial or foamy proliferative mucinous epithelium	Moderate to abundant extracellular mucin containing mucinoid proliferative mucinous epithelium or mucin gland, chains of cells, or individual cells with or without carcinoma
Cytologic atypia	Minimal	Moderate to marked
Mitotic activity	Rare	Infrequent to frequent
Lymph node involvement	Rare	Frequent
Peritoneal implantation	Rare (except for ovary)	Frequent

DPAM, disseminated peritoneal adenomucinosis; PMCA, peritoneal mucinous carcinomatosis. (Reproduced from ref. 7, with permission.)

**TABLE 49-1.** Distinguishing Pathologic Features of Disseminated Peritoneal Adenomucinosis and Peritoneal Mucinous Carcinomatosis

**FIGURE 49-2.** Kaplan-Meier curves demonstrating survival rates for patients with disseminated peritoneal adenomucinosis (DPAM), peritoneal mucinous carcinomatosis (PMCA), and PMCA with intermediate or discordant features. There is a statistically significant difference in survival between the three groups ( $P < .0001$ ). (From ref. 7, with permission.)

Despite this dramatic difference in prognosis, most studies include all forms of *P peritonei* together, and this confuses outcome determinants for therapy in this condition. It would be best not to use the term *P peritonei* without further classification into mucinous adenocarcinoma or benign mucinous tumors. The treatment approach should be different for patients with benign mucin-producing tumors as compared to those with mucinous carcinomatosis. Patients with benign tumors should be treated with aggressive surgical debulking to limit the symptoms of compression and abdominal distention caused by extensive mucinous ascites within the abdominal cavity. It has been reported that long-term disease-free survival can be accomplished with repeated tumor debulking.<sup>32</sup> The extent of required surgery and the indication for chemotherapy are controversial.<sup>33</sup> The complication rate of the procedure should be seriously considered in recommending treatment for a condition with such an indolent course. It may be that aggressive regional chemotherapy approaches should not be offered until their efficacy has been better defined in carcinomas. In the case of low-grade mucinous carcinomatosis, the uniformly poor prognosis encourages innovative and aggressive approaches. This includes intensive regional chemotherapy in combination with cytoreduction (as discussed in the [Intraperitoneal Chemotherapy](#) section).

Because of inconsistencies in pathologic diagnosis as well as different philosophies with regard to aggressiveness of surgery, it is difficult to define the prognosis and the best treatment strategies. The largest series of mucinous appendiceal tumors with peritoneal spread has been reported by Sugarbaker and Chang.<sup>34</sup> A total of 385 patients were reviewed. Patients with benign adenomucinosis had a 5-year survival of 80%, as compared to those with low-grade mucinous carcinomas, who had a 5-year survival of approximately 25%. The 5-year survival for those patients undergoing a complete resection was approximately 80%, as compared to those undergoing an incomplete resection, in which it was approximately 25%. It is probably not a coincidence that characteristics of surgical debulking and pathology lead to similar survival rates: Complete resection is more likely in patients with benign mucinous neoplasms as compared to those with more infiltrative mucinous carcinomas. As discussed in the [Surgery](#) section, the fact that complete cytoreduction has an improved prognosis over incomplete cytoreduction does nothing to support aggressive surgery for this disease. Of note, the mortality rate for extensive cytoreduction and early postoperative intraperitoneal chemotherapy in the Sugarbaker and Chang<sup>34</sup> series is 2%, with major morbidity of 27%.

Gough et al.<sup>35</sup> (from the Mayo Clinic) reviewed 56 patients with the malignant form of *P peritonei*. Only 20% of their patients had complete cytoreduction, and they reported a 10-year survival rate of 32%. Smith et al.<sup>36</sup> (from the Memorial Sloan-Kettering Cancer Center) reviewed 17 patients undergoing surgical debulking for *P peritonei* without histologic classification. They reported a 10-year survival rate of 60%.

In summary, the entity of *P peritonei* is becoming better defined. Classification of the benign and malignant subtypes is essential and should be used to define and compare therapeutic approaches for this disease. The use of aggressive surgery and regional chemotherapy approaches remains experimental and requires investigation in a multiinstitutional randomized format to make standard treatment recommendations.

## PERITONEAL MESOTHELIOMA

Peritoneal mesothelioma is a primary tumor of the mesothelial lining of the peritoneum. It is a rare tumor of approximately two cases per million population per year, but the incidence appears to be increasing. Tumors can be classified into benign lesions, borderline malignant lesions, and malignant tumors.<sup>37</sup> Benign lesions include adenomatoid mesothelioma and localized fibrous mesothelioma, which are rare tumors treated by surgical excision alone, with a good prognosis. Borderline tumors include multicystic peritoneal mesothelioma and well-differentiated papillary mesothelioma of the peritoneum.<sup>38,39</sup> and <sup>40</sup> Both of these tumors carry an indolent course, which can be treated with surgical debulking. These borderline tumors are characterized by local recurrences that can ultimately lead to complications within the abdominal cavity. It is not clear whether the tumors themselves will ultimately lead to the death of the patient. In a review of 22 patients, none died directly because of their disease, but several died as a result of complications of therapy.<sup>41</sup> One patient who died 29 years after he received a diagnosis of well-differentiated papillary mesothelioma had residual disease but died of unrelated causes. Microscopically, well-differentiated papillary mesothelioma consists of mesothelial cells in a well-developed papillary pattern with bland mesothelial appearance and cuboidal epithelium. It can be difficult to differentiate histologically the well-differentiated papillary mesothelioma from diffuse malignant mesothelioma, so multiple sections of tumor should be examined.

The malignant peritoneal mesotheliomas are less common than pleural mesotheliomas and have been associated with asbestos exposure and abdominal therapeutic radiation.<sup>42</sup> The association of malignant peritoneal mesothelioma and asbestos exposure has been reported to be as high as 83%; however, in our experience, it is much lower. These tumors often present with nonspecific abdominal pain and increasing abdominal girth secondary either to tumor mass or to the development of ascites. The diagnosis can be suggested by cytologic examination of ascites and verified by percutaneous biopsy of the omentum. These tumors tend to present with diffuse involvement of the peritoneal cavity, including an omental "cake" and diaphragmatic and pelvic tumor deposits ([Fig. 49-3](#)).

**FIGURE 49-3.** Diffuse malignant peritoneal mesothelioma of the papillary form. A thick omental “cake” is evident here, as is disease involving the mesentery of the small bowel. Notice the general sparing of the mobile surfaces of the small intestine. This disease was successfully debulked and treated with continuous hyperthermic peritoneal perfusion.

The epithelial type of malignant peritoneal mesothelioma is the most common type and has the best prognosis. The sarcomatoid and mixed (elements of both epithelial and sarcomatoid) forms are more aggressive, leading to fixed abdominal contents and an inability to successfully debulk these tumors surgically. Even among the primary epithelial form, there may be a spectrum of phenotypic aggressiveness and a variable clinical course. Some patients primarily experience ascites with no significant invasiveness to the tumors themselves, allowing for easy debulking and management of ascites. Other patients have more aggressive forms that can invade through the diaphragm to involve the chest, through the wall of the intestine (leading to complications of intestinal obstruction and bleeding), and into lymph nodes. The more invasive forms are difficult to debulk and have a worse prognosis. The sarcomatoid and mixed forms are rapidly growing tumors leading to intraabdominal complications and death within a year.<sup>43</sup>

Death from malignant mesothelioma is usually caused by complications from intraperitoneal progression. Hematogenous metastases are extremely rare, and secondary involvement of the chest occurs at a late stage and is usually not a life-threatening feature of this disease. Lymphatic metastases can be identified within the abdominal cavity with the more aggressive forms of epithelial mesothelioma and the sarcomatoid mesothelioma.<sup>44</sup> Patients with peritoneal mesothelioma in general have a better prognosis than those with pleural mesothelioma. CA-125 levels may be increased in patients with diffuse mesothelioma and can be followed up for response to therapy.

The natural history of diffuse mesothelioma is difficult to define. Reported series are small, owing to the rarity of this disease. Original reports suggested that the median survival was less than 1 year from the time of diagnosis.<sup>45</sup> However, multiple varied treatment approaches, usually combining surgical debulking with chemotherapy or total abdominal radiation (or both), may result in long-term survival.<sup>46</sup> Langer et al.<sup>47</sup> demonstrated a median survival of 22 months using surgical debulking and intraperitoneal chemotherapy with cisplatin and etoposide. No control, untreated arm is included in these trials to prove that the natural history is not sometimes indolent. It is also difficult to know whether adjuvant therapies improve the results of surgical debulking alone, as no series exists of aggressive surgical debulking alone for this disease. It is suggested, however, that the package of treatment strategies that have been used can successfully alter the natural history of this disease. Lederman et al.<sup>48</sup> reported that six of ten patients remain free of disease up to 6 years after diagnosis after treatment with surgical debulking, combination chemotherapy, and whole abdomen radiation. Whole abdomen radiation is not well tolerated and has not gained widespread acceptance. Other investigators have used intraperitoneal chemotherapy alone (cisplatin or cisplatin plus mitomycin C) with modest clinical responses and improvement in ascites but have failed to demonstrate a survival benefit. Markman and Kelsen<sup>49</sup> reported 47% palliation of ascites and a median survival of 9 months in 19 patients who were treated with intraperitoneal cisplatin and mitomycin C.

We have explored the combination of extensive surgical debulking followed by intraoperative, intraperitoneal chemotherapy in the form of continuous hyperthermic peritoneal perfusion with cisplatin combined with early postoperative intraperitoneal dwell chemotherapy with 5-fluorouracil (5-FU) and paclitaxel.<sup>50</sup> Patients who presented with incapacitating ascites have complete resolution of their ascites and long-term disease-free survival. The median time to progression after treatment in 18 patients was approximately 27 months, with a median overall survival not being reached after a median potential follow-up of 19 months ( Fig. 49-4). Ninety percent of patients had complete resolution of their ascites after therapy. Three patients were treated after recurrence of ascites approximately 2 years after their primary treatment, and all had resolution of their ascites again after retreatment. Other investigators have demonstrated similar success using the hyperthermic peritoneal treatment with mitomycin C for mesothelioma.<sup>51</sup>

**FIGURE 49-4.** Kaplan-Meier survival curve for 18 patients treated with continuous hyperthermic peritoneal perfusion with cisplatin at the National Cancer Institute for peritoneal mesothelioma. \*The progressive free survival analysis includes three patients who have been treated twice. (Adapted from ref. 50.)

## PRIMARY PERITONEAL CARCINOMA

Primary peritoneal carcinoma has been called by many names, including *papillary carcinoma of the peritoneum*, *extraovarian papillary serous carcinoma*, *serous surface papillary carcinoma*, and *psammocarcinoma*.<sup>52,53</sup> and <sup>54</sup> The cell of origin for primary peritoneal carcinoma is not clear. Both the germinal epithelium of the ovary and the mesothelium of the peritoneum arise from the same embryologic origin; therefore, the peritoneum may retain the multipotentiality of the Müllerian system, allowing for the development of a primary carcinoma. Hereditary predisposition may play a role in this disease, as patients have an increased risk with the BRCA1 mutation.<sup>55</sup>

Primary peritoneal carcinoma diffusely involves the peritoneal surface while sparing or only minimally involving the ovaries. It is histologically indistinguishable from primary epithelial ovarian carcinoma, and its diagnosis requires differentiation from mesothelioma and ovarian cancer. Immunohistochemistry differentiates this from peritoneal mesothelioma.<sup>56</sup> Primary ovarian cancer is ruled out by the following criteria<sup>57</sup>: (1) Both ovaries must be normal in size; (2) the extraovarian involvement must be greater than the involvement on the surface of the ovary; (3) the ovarian component must be less than 5 × 5 mm within the ovary or confined to the ovarian surface; and (4) the cytologic characteristics must be of the serous type. This is a tumor described almost exclusively in women. Patients are older than those with epithelial ovarian cancers. The presentation of primary peritoneal carcinoma is abdominal distention and diffuse nonspecific abdominal pain secondary to ascites.

In general, these tumors are treated as ovarian cancers with cytoreduction and adjuvant therapy with platinum-based chemotherapeutic regimens. The median survival for women with primary peritoneal carcinoma has been reported to range from 12 to 25 months. This is similar or slightly worse than for epithelial ovarian cancer. Carboplatin or cisplatin in combination with paclitaxel leads to a high response rate and a reported median survival of 40 months.<sup>52,58</sup>

## DESMOPLASTIC SMALL ROUND CELL TUMORS

The rare desmoplastic small round cell tumors typically occur in adolescents and young men and present with extensive involvement of the peritoneal surfaces. Rapid multifocal growth and hematogenous metastases to the liver, lungs, and lymph nodes are common. Reported median survival is 17 months, and long-term survival is uncommon. A combination of aggressive surgical debulking and systemic chemotherapy with cyclophosphamide, doxorubicin, and vincristine interspersed with ifosfamide, etoposide, and mesna (P6 protocol) appears to lead to an improved outcome.<sup>59</sup> The genetics of this tumor are interesting in that a consistent chromosomal translocation has been identified, which results in fusion of the Ewing's sarcoma gene with the Wilms' tumor gene.<sup>60</sup> This tumor can sometimes be difficult to differentiate from malignant peritoneal mesothelioma.

## GASTROINTESTINAL PRIMARY TUMORS

GI primary tumors are the most common source of peritoneal carcinomatosis in male patients. This includes colon cancer, gastric cancer, pancreatic cancer, gallbladder cancer, and primary small bowel adenocarcinomas. The range of aggressiveness of these cancers is quite broad. However, as opposed to appendiceal tumors, the majority of other GI primary tumors are aggressive, invasive forms. The most important risk factor for developing peritoneal carcinomatosis is the depth of invasion of the primary tumor. If the tumor has invaded through the serosa (T3), the entire peritoneal surface is at risk for the development of carcinomatosis. These patients should be considered for adjuvant regional chemotherapy.

Patients with peritoneal carcinomatosis from these types of aggressive GI cancers usually present with symptoms of partial small bowel obstruction, as opposed to diffuse ascites, as is seen with the less invasive malignancies. Successful management of these patients with a regional approach is unlikely by the time they develop symptoms and complications of intraperitoneal spread. Because of their invasive nature, these tumors often invade the retroperitoneum and bowel wall and extensively involve lymphatics, where intraperitoneal chemotherapy may not reach. Adequate surgical debulking becomes less feasible for these aggressive GI malignancies. The treatment goal should be prophylaxis against the development of carcinomatosis or treatment of those patients who are incidentally found, at the time of primary resection, to have minimal peritoneal spread that can be managed with complete surgical excision. Because of the uniformly poor prognosis with peritoneal spread, an aggressive, prophylactic regional chemotherapy approach seems warranted.

## GYNECOLOGIC PRIMARY TUMORS

Ovarian, endometrial, and cervical cancer can all invade into the peritoneal cavity and have a clinical course dominated by intraperitoneal spread of the tumor. Ovarian tumors (similar to appendiceal primary tumors) can lead to peritoneal contamination even in the setting of relatively low-grade, minimally aggressive tumors.<sup>61</sup> As compared to GI tumors (other than appendiceal), the ovarian carcinomatosis is less aggressive and, therefore, more amenable to surgical cytoreduction and regional intraperitoneal chemotherapy. Because of the sensitivity of ovarian tumors to systemic chemotherapy, carcinomatosis from an ovarian primary tumor represents a rare instance in which systemic chemotherapy can provide a long-term disease-free interval and potential cure.<sup>62</sup> It has been demonstrated that surgical debulking can improve the response and results of systemic chemotherapy.<sup>63</sup> The systematic staging of the peritoneal surface in patients with primary ovarian cancer is required to document microscopic metastases to the peritoneum, which would alter the treatment paradigm. Ascites is a common complication of peritoneal carcinomatosis from ovarian cancer, and palliation of ascites can play a significant role in the management of this disease.

## OTHER FORMS

Other forms of peritoneal carcinomatosis are less common, and peritoneal spread does not normally dominate the clinical course of these tumors. Among these lesions are tumors from the genitourinary tract, such as testicular cancer, transitional cell cancer of the bladder, and renal cancer.<sup>64</sup> We have seen hemangiopericytoma, adrenal cancer, and pediatric solid tumors contaminate the peritoneal cavity. Peritoneal sarcomatosis is discussed in [Chapter 39](#). Breast cancer can also lead to peritoneal carcinomatosis and ascites, which can be the only site of progressive disease in some patients. Palliation of ascites in these patients may improve their overall prognosis.

## TREATMENT

### SURGERY

Surgical debulking for peritoneal carcinomatosis is standard for the management of benign and low-grade malignant processes, such as *P peritonei*, mesothelioma, and ovarian cancer. In these settings, the goal of debulking is to "reset the clock" for development of symptoms. The more tumor that is removed, the longer the interval until the tumor grows to a symptomatic stage. Investigational strategies combine surgical cytoreduction with regional therapy. The goal of cytoreduction in this case is to leave behind only tumors smaller than 5.0 mm in diameter so as to allow for topical chemotherapy to penetrate and treat all cells within the tumor.<sup>65</sup> The best scenario is complete cytoreduction, wherein only microscopic disease is left behind. This is similar to bathing cells with chemotherapy in a Petri dish, ensuring delivery of chemotherapy to the cells.

Common sites for tumor spread should be closely examined, and resection of tumors is indicated where possible. This includes complete resection of the greater omentum, lesser omentum, falciform ligament, and peritoneum overlying the diaphragm; the base of the small bowel and transverse colon mesentery; and the pelvis. The splenic hilum is often involved with tumor, necessitating a splenectomy. Appendices epiploicae commonly are involved and may require limited bowel resections. The most difficult sites in which to achieve complete clearance are the hepatoduodenal ligament and pelvis. Oophorectomy, hysterectomy, partial bladder resection, and sigmoid colon resection may be required in the pelvis. Care must be taken to preserve blood supply to the stomach when dissecting the lesser omentum. The extent of resection should be dictated by the realistic treatment goal. Complete removal of all microscopic disease in the peritoneal cavity is not realistic, so the goal is to remove macroscopic disease in the hopes that chemotherapy or other adjuvant therapy will be more effective. An extensive procedure to remove pelvic peritoneal drop metastases in the setting of unresectable hepatic hilar disease does not make sense. Incidental extensive stripping of the peritoneum to address microscopic disease is not generally accepted, as all surfaces and all microscopic disease cannot be addressed.

Except in ovarian cancer, extensive cytoreduction for peritoneal carcinomatosis has not been objectively studied. Numerous trials demonstrate improved prognosis in patients who undergo complete debulking as compared to those whose tumors cannot be debulked,<sup>52,66,67</sup> but this is only a mirror of the aggressiveness of the tumor or late presentation. The ability to debulk completely correlates with an improved prognosis, but this should not be accepted as an indication to perform the procedure. Nevertheless, well-controlled trials are extremely difficult to perform in this disease state, and many definitive answers will not be obtained for some time. It is generally accepted in the setting of indolent, benign, or low-grade tumors, in which survival is dictated by complications of regional growth, that tumor debulking can extend survival. It is also accepted that intraperitoneal approaches that require direct absorption of chemotherapy into tumors will be more successful in the setting of minimal to microscopic residual disease. Complications of the procedure and quality of life must be considered in the decision for aggressive surgery. Enterotomies can lead to fistulas, bowel anastomoses can dehiscence (leading to peritonitis), and a permanent colostomy may not be a reasonable outcome for a disease with an expected indolent course.

Sugarbaker<sup>68</sup> has been a proponent of aggressive peritoneal resection for carcinomatosis in selected circumstances. He has described "peritonectomy" procedures, which have been widely quoted in the literature, by which the peritoneum and associated expendable structures are removed. The six procedures are (1) omentectomy-splenectomy; (2) left upper quadrant stripping; (3) right upper quadrant stripping; (4) lesser omentectomy and cholecystectomy; (5) pelvic peritoneal stripping, including hysterectomy and sigmoid colectomy; and (6) antrectomy. The procedures were undertaken only where gross tumor was present. The morbidity of such procedures in the context of intraperitoneal chemotherapy has been reported by the same group for 200 patients undergoing aggressive cytoreductive surgery and hyperthermic, intraoperative, intraperitoneal chemotherapy. The mortality rate was 1.5%, and grade III and grade IV morbidity were seen in 27% of patients.<sup>69</sup>

### INTRAPERITONEAL CHEMOTHERAPY

Systemic chemotherapy has been notoriously poor for the treatment of peritoneal carcinomatosis. This is mostly due to the fact that most GI solid tumors are not sensitive to chemotherapy, but other theoretic concerns exist regarding the successful penetration of chemotherapy into the peritoneal cavity (and into solid tumors in general). It should be noted that ovarian cancer patients with peritoneal carcinomatosis can be cured with systemic chemotherapy in rare cases.<sup>63</sup> The concept of delivering chemotherapy directly into the peritoneal cavity is appealing, theoretically allowing higher concentrations to be delivered to the tumor while minimizing systemic side effects. The mesothelial lining acts as a barrier to absorption of chemotherapy agents. Casper et al.<sup>70</sup> demonstrated 30-fold higher peritoneal

concentration of cisplatin when delivered into the peritoneal cavity as compared to intravenous delivery. High concentrations of chemotherapy topically applied to tumor cells should be more effective than what can be achieved with intravascular delivery.

The pharmacokinetic rationale for intraperitoneal chemotherapy has been recognized for many years,<sup>71</sup> and intraperitoneal chemotherapy trials blossomed in the early 1980s.<sup>72,73,74</sup> and <sup>75</sup> Larger, water-soluble and ionized compounds exit the peritoneal compartment more slowly than smaller lipid-soluble and un-ionized molecules. Pharmacokinetic models of peritoneal delivery have been developed.<sup>76,77</sup> Patients with peritoneal carcinomatosis may have decreased clearance of all drugs from the peritoneal cavity due to obstruction of lymphatic channels. In addition, the majority of compounds delivered into the peritoneal cavity are cleared by the portal circulation and, therefore, may be metabolized by the liver. Compounds that have a delayed clearance from the peritoneal cavity may allow for prolonged exposure of slowly dividing cells to the chemotherapy agent. If the agent requires mitosis for efficacy, this improves the chance of it being effective, compared to the relatively brief exposure provided by systemic delivery. Finally, by confining the treatment to direct absorption, systemic binding agents can be delivered and bind and inactivate systemically absorbed drug to minimize systemic toxicity.<sup>78</sup>

The main pitfalls for intraperitoneal chemotherapy include the difficulty in obtaining even distribution throughout the peritoneal cavity and the limited absorption of agents into tumor nodules.<sup>79</sup> Prior abdominal surgery leads to numerous loculations within the peritoneal cavity and prevents even distribution of intraperitoneal agents. Prolonged intraperitoneal dwell chemotherapy can be hampered by scarring around the delivery catheter, allowing for escape of tumor cells within protected areas of the abdomen. Large treatment volumes (>2 liters) have been shown to improve distribution.<sup>80</sup> Intraoperative and early postoperative intraperitoneal chemotherapy may allow for treatment of all peritoneal surfaces before dense, loculated scarred areas develop, but this may increase the morbidity associated with the procedure.<sup>81</sup> A randomized trial of adjuvant intraperitoneal chemotherapy with carbon-absorbed mitomycin in gastric cancer was prematurely terminated due to a statistically significant increase in major postoperative morbidity in the patients receiving chemotherapy.<sup>82</sup>

The ideal setting for ensuring complete distribution of chemotherapy to the peritoneal cavity is intraoperative treatment at the time of surgical debulking. Recirculating circuits and physical manipulation of abdominal contents during therapy may enhance distribution. Studies suggest, and logic concludes, that the best means for ensuring complete distribution during intraperitoneal therapy is to manipulate the contents of the peritoneal cavity by hand during treatment. This can be accomplished by a variety of techniques with the patient under general anesthesia, allowing a hand to be inserted into the abdominal cavity without spilling the chemotherapy solution.

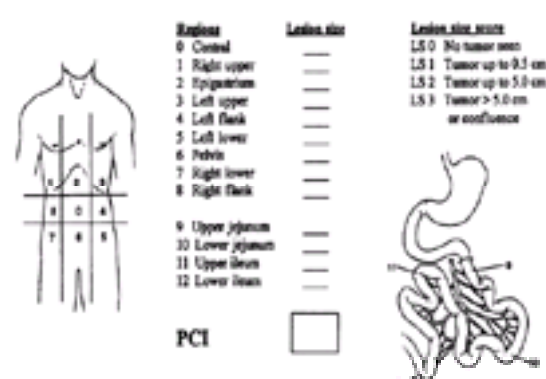

Tumor penetration of drugs delivered into the peritoneal cavity has been studied. Los et al.<sup>83</sup> demonstrated that the tumor concentration of cisplatin was significantly elevated after intraperitoneal delivery, as compared to systemic delivery, at a depth of 1.0 mm but not at 1.5 mm. Increasing pressure within the peritoneal cavity may improve penetration, and vasoactive agents that decrease capillary uptake of drugs in the tumor may allow for deeper penetration of drugs. Larger molecules may penetrate more deeply into some tissues than low-molecular-weight agents because of decreased capillary permeability and vascular washout of the compounds. On the other hand, if increased interstitial pressure occurs within tumors, as has been described, this may be an advantage to low-molecular-weight agents. Although it is easy to determine clearance from the peritoneal cavity and easy to assume that decreased clearance leads to increased exposure of intraperitoneal tumor to chemotherapy, it is not clear how decreased clearance correlates with absorption into tumor tissue. Decreased clearance may correlate with decreased tumor absorption, which may be counterproductive. On the other hand, for the treatment of microscopic cells that have not developed into tumor nodules, prolonged exposure in the peritoneal cavity should be advantageous.

A variety of agents have been delivered into the peritoneal cavity, and these are summarized in [Table 49-2](#). The mean peritoneal cavity peak concentrations over peak plasma concentrations range from 20 in the case of cisplatin to more than 600 for cytarabine and mitoxantrone and more than 1000 for paclitaxel. Regional toxicity has not been a major problem with most of these agents. Even mitomycin C, which is considered a very caustic agent to tissues when infiltrated, has been delivered into the peritoneal cavity safely. The most common agents that have been used in intraperitoneal trials include cisplatin, mitomycin C, 5-FU, and, recently, paclitaxel. Gemcitabine currently is being studied with intraperitoneal delivery.

Agent	Peak Peritoneal Cavity to Plasma Concentration Ratio
Carboplatin	18
Cisplatin	20
Mitomycin C	72
Methotrexate	92
5-Fluorouracil	258
Doxorubicin	474
Mitoxantrone	620
Paclitaxel	>1000

**TABLE 49-2.** Pharmacokinetic Advantages Associated with Intraperitoneal Antineoplastic Drug Delivery

In general, trials of intraperitoneal chemotherapy have been poorly controlled, with numerous treatment regimens for different histologies of varying prognosis at different stages of peritoneal involvement, making interpretation of results difficult.<sup>81,84</sup> In addition, the combination of aggressive surgical debulking and intraoperative or early postoperative chemotherapy make the interpretation of morbidity difficult. Sugarbaker<sup>85</sup> has used a complex scheme for assessing the extent of peritoneal disease and completeness of resection ([Fig. 49-5](#)). Adoption of this or similar standardized criteria should help in the standardization and interpretation of clinical trials. Histologic grade and clinical invasive phenotyping should also improve trial interpretation.

**FIGURE 49-5.** Proposed standardized scheme for assessing extensive peritoneal disease. The peritoneal cancer index (PCI) represents the sum of the lesion size scores for the different regions. (Reproduced from ref. 85, with permission.)

The utility and advantages of intraperitoneal chemotherapy have been demonstrated in randomized trials. Sugarbaker et al.<sup>86</sup> performed a small randomized trial comparing postoperative adjuvant 5-FU delivered intravenously (n = 30) to intraperitoneal delivery (n = 36) for patients with high-risk primary colorectal cancers. Although there was no difference in survival between the groups, the patients with intraperitoneal delivery had a significantly lower incidence of intraperitoneal recurrences and less hematologic and hepatic toxicity. More recently, the combined Southwest Oncology Group, Gynecologic Oncology Group, and Eastern Cooperative Oncology Group Intergroup Study examined intravenous versus intraperitoneal cisplatin with intravenous cyclophosphamide for stage III ovarian cancer.<sup>87</sup> This large, randomized, prospective, phase III trial demonstrated a significant survival advantage for patients receiving intraperitoneal cisplatin (49 vs. 41 months). In addition, this group experienced significantly less clinical hearing loss, neutropenia, and neuromuscular toxicity. Yu et al.<sup>88</sup> examined early postoperative

intraperitoneal chemotherapy as compared to no treatment after resection of gastric cancer (n = 248). This group demonstrated no overall survival benefit, but subset analysis suggested improved survival for stage III disease, as might be expected (49% 5-year survival vs. 18%). Follow-up trials should be focused on stage III disease. These results should stimulate continued interest in the peritoneal delivery of chemotherapy for peritoneal carcinomatosis and emphasize the need for randomized trials for GI malignancies to define better the advantages of intraperitoneal delivery.

One procedure that is becoming increasingly popular across the world for the treatment of peritoneal carcinomatosis is the intraoperative combination of hyperthermia and chemotherapy delivered as a recirculating perfusion.<sup>89,90,91,92,93,94</sup> and <sup>95</sup> Temperatures of 41C to 42C are maintained in the tissues over a period of 90 minutes by recirculating fluid that passes through a roller pump and heat exchanger delivering high concentrations of chemotherapy to the peritoneal cavity ( Fig. 49-6). The most common drugs used in this fashion have been cisplatin and mitomycin C.<sup>96</sup> The theoretic advantages of this technique include the improved mixing and surface exposure associated with the increased pressure and high flow rates of the perfusate along with intraoperative manipulation of the abdominal contents. The hyperthermia has been demonstrated to have selective cytotoxicity against cancer cells while the normal cells recover.<sup>97</sup> In addition, hyperthermia has been shown to enhance chemotherapy penetration into tumors,<sup>98</sup> improve intraperitoneal pharmacokinetics,<sup>99</sup> and work synergistically with chemotherapy to kill cancer cells.<sup>100</sup>

**FIGURE 49-6.** Peritoneal perfusion technique used at the National Cancer Institute. Chemotherapy solution is circulated through the roller pump, then through a heat exchanger and into the abdominal cavity. The outflow is collected from the pelvis and passes to a small reservoir and then back through the roller pump. Peritoneal temperatures are monitored via three probes inserted in different places in the peritoneal cavity, and intraabdominal pressures are monitored during the procedure.

This therapy has been demonstrated to be successful in randomized trials in Japan for completely resected advanced gastric cancer ( Table 49-3). These trials include mitomycin C as the active agent or mitomycin C and cisplatin in combination. Fujimoto et al.<sup>101</sup> reported an 8-year survival of 88% in patients receiving hyperthermic perfusion with mitomycin C for high-risk (serosal invasion) gastric cancers, as compared to 49% for surgery alone. Peritoneal recurrence was 23% in the control group, as compared to 1% in the treatment group.

Study	No. of Subjects	Peritoneal Agent	Agent and Dose	Duration (mo.)	Significance (P)	Follow-up (yr)	Survival (%)	P-value
Sega et al. <sup>102</sup>	26	CHPP	Mitomycin C, 8 mg/L	60	NS	2.5	45	NS
	26	Control	—	—	—	2.5	47	—

CHPP, continuous hyperthermic peritoneal perfusion; CHPP, continuous nonhyperthermic peritoneal perfusion; NS, not significant.

Statistical testing group: CHPP vs CHPP versus control.

[Adapted from Alexander HR, Borjesson M, Sakurai M, et al: Clinical trial of continuous hyperthermic peritoneal perfusion (CHPP) for the treatment of peritoneal carcinomatosis. In: DeVita V, Hellman S, Rosenberg S, eds: Principles and practice of oncology. Philadelphia, JB Lippincott, 1981, 1:111.]

**TABLE 49-3.** Clinical Results of Multiarm Studies Evaluating the Efficacy of Prophylactic or Therapeutic Continuous Hyperthermic Peritoneal Perfusion Immediately after Resection for Gastric Cancer

We have reported our results with continuous hyperthermic peritoneal perfusion in a phase I study with tumor necrosis factor and cisplatin against all forms of peritoneal carcinomatosis.<sup>102</sup> In that trial and subsequent trials, the response of patients with peritoneal mesothelioma stands out as being notable. We have demonstrated a median progression-free survival of 26 months and overall 2-year survival rate of 80% in patients with peritoneal mesothelioma treated with peritoneal perfusion with cisplatin.<sup>50</sup> This compares favorably to the natural history of peritoneal mesothelioma and the results of other therapeutic trials. Numerous centers are now reporting their results with heated peritoneal perfusion for different forms of peritoneal carcinomatosis. In an attempt to maximize chemotherapy delivery to these tumors, we (and others) have now combined postoperative intraperitoneal dwell chemotherapy with intraoperative heated peritoneal perfusion. Close scrutiny of the complication rates with these procedures is important, as their benefit at this point is only theoretic. A randomized trial comparing surgical debulking and systemic chemotherapy to surgical debulking plus intraoperative hyperthermic chemotherapy perfusion is necessary to demonstrate the true utility of these procedures.

## OTHER INTRAPERITONEAL THERAPIES

Other approaches for regional therapy for peritoneal carcinomatosis have been investigated. Total abdominal irradiation, in combination with surgical debulking and chemotherapy, has been shown to be effective in peritoneal mesothelioma and has been studied in other malignancies.<sup>103</sup> In general, the toxicity of total abdominal irradiation is unsatisfactory; therefore, this treatment approach has not become standard. Photodynamic therapy of the peritoneal cavity is under active investigation for all forms of peritoneal carcinomatosis. Patients receive an intravenous photosensitizing dose of dihematoporphyrin ethers followed by exposure of the peritoneal surfaces to laser light.<sup>104</sup> The approach has undergone phase I studies, but its efficacy has not been reported in phase II studies. Intraperitoneal immunotherapy approaches are under investigation, including the intraperitoneal delivery of adoptively transferred lymphocytes.<sup>105</sup> Gene therapy approaches are also being investigated, as intraperitoneal tumor cells may be ideally exposed to intraperitoneal delivered vectors, leading to a high transduction efficiency.<sup>106</sup>

## PALLIATION

Major complications of peritoneal carcinomatosis include partial and complete obstruction of the GI tract, leading to crampy abdominal pain, nausea, and vomiting. The other significant complication is the development of ascites, which can become incapacitating and the direct cause of death. The palliative management of these entities by the oncologist is required. Patients with crampy, abdominal pain suggesting partial small bowel obstruction should be worked up with a CT scan and upper GI series. A determination should be made about whether a simple bypass or resection of an obstructed region can be performed, in which case the appropriate operation is undertaken. In the setting of diffuse disease that cannot be bypassed, a percutaneous endoscopic gastrostomy tube should be inserted for palliation.<sup>107</sup> This is a simple procedure that can be performed with minimal complications, yet provides lasting palliation. Signs of peritonitis or systemic sepsis should raise concerns of a closed loop obstruction that may require emergent surgical resection. It is often helpful to ensure patency of the rectum in patients being explored for bypass of a small bowel obstruction in the setting of peritoneal carcinomatosis. A shelf of tumor in the pelvic peritoneal recess may lead to obstruction, placing a proximal bowel anastomosis at risk. Rarely, patients may require a colostomy or ileostomy for palliation. The nutritional management of patients who require a palliative gastrostomy in the setting of peritoneal carcinomatosis and bowel obstruction is controversial. In general, it is accepted that total parenteral nutrition does nothing to improve the quality of life or prolong survival in patients having peritoneal carcinomatosis secondary to aggressive GI malignancies. However, in the case of low-grade malignancies, these patients can survive for a very long time after palliative gastrostomy; therefore, parenteral nutrition should be considered. We have had the experience of managing a patient on total parenteral nutrition for more than a year with a good quality of life after palliative gastrostomy in the setting of a

low-grade, mucinous adenocarcinoma causing compressive bowel obstruction.

Management of malignant ascites is a challenge for the oncologist. In cases of malignant mesothelioma and ovarian cancer, the best therapy may involve aggressive surgical debulking and intraperitoneal chemotherapy. Numerous patients who have been considered terminal because of incapacitating ascites have been treated successfully in this manner. Schilsky et al.<sup>84</sup> demonstrated successful resolution of ascites with intraperitoneal dwell chemotherapy with 5-FU and cisplatin. Diuretics are ineffective in the management of malignant ascites, and intermittent paracentesis may be effective in the short term but invariably leads to electrolyte imbalance, hypoproteinemia, hypovolemia, and, ultimately, renal failure and death. Peritoneovenous shunts can be effective and should be considered. Straus et al.<sup>108</sup> reported that 89% of their shunts relieved symptoms of nausea, distention, loss of appetite, and dyspnea and that 79% of the shunts functioned for longer than 3 months or until death. Qazi and Savlov<sup>109</sup> reported 70% effective palliation with peritoneovenous shunt. As these shunts are rather easy to insert (under local anesthesia in most cases) with at least temporary palliation, they should be considered in patients with reasonable performance status and incapacitating ascites.

## INTRODUCTION

Individuals with human immunodeficiency virus (HIV) infection are at substantially increased risk of developing a number of neoplasms ( [Table 50.1-1](#)).<sup>1,2</sup> Three malignant conditions are now considered as defining acquired immunodeficiency syndrome (AIDS) when they occur in HIV-infected individuals: Kaposi's sarcoma (KS), certain aggressive non-Hodgkin's lymphomas (NHLs), and invasive cervical cancer.<sup>3</sup> The risk of KS among gay and bisexual men with AIDS is greater than 100,000-fold that of the background population.<sup>4</sup> Also, NHLs occur overall with approximately 60-fold greater frequency than expected based on rates of NHL in HIV-negative populations.<sup>5</sup> There are conflicting data regarding the excess frequency of cervical cancer in HIV-infected women,<sup>6,7</sup> but cervical intraepithelial neoplasia appears to be more difficult to control and invasive cancer appears to be more aggressive in HIV infection.<sup>8</sup>

Tumor	Relative Risk <sup>a</sup>	95% Confidence Interval
Kaposi's sarcoma	310.2	291.6–329.5
Non-Hodgkin's lymphoma	112.9	105.6–123.4
Invasive cervical cancer	2.9	0.7–18.6
Anal cancer	51.7	11.6–69.2
Non-acquired immunodeficiency syndrome cancers	1.9	1.5–2.3
Angiosarcoma	36.7	4.8–192.5
Soft tissue sarcoma	7.2	1.3–31.0
Hodgkin's disease	7.6	4.1–13.1
Leukemia	11.6	3.6–38.8
Multiple myeloma	4.5	0.6–13.2
Brain	3.5	1.4–7.2
Seminoma or germioma	2.9	1.1–6.3
Squamous cell carcinoma, oropharyngeal sites	6.8	1.4–19.8
Lung, adenocarcinoma	2.5	1.0–5.0

<sup>a</sup>Relative risk calculations based on comparisons of the cancer experience of people with acquired immunodeficiency syndrome and those of the general population under 70 years of age by matching population-based cancer and acquired immunodeficiency syndrome registries in the United States and Puerto Rico.  
(Data from ref. 1.)

**TABLE 50.1-1.** Post–Acquired Immunodeficiency Syndrome Relative Risks of Various Malignant Conditions in Patients with Acquired Immunodeficiency Syndrome

In addition, a number of other cancers that do not confer a diagnosis of AIDS occur with increased incidence among HIV-infected persons. In one study, a probabilistic matching algorithm comparing over 1 million people with AIDS, cancer, or both, the occurrence of several non–AIDS-defining cancers was found to be significantly increased in HIV infection (see [Table 50.1-1](#)); these include angiosarcoma (36.7-fold), Hodgkin's disease (7.6-fold), multiple myeloma (4.5-fold), brain cancer (3.5-fold), and seminoma (2.9-fold).<sup>1</sup> Age-, sex-, and period-adjusted standardized incidence ratios (SIR) in New South Wales, Australia, identified an increased incidence of Hodgkin's disease (SIR 18.3), multiple myeloma (SIR 12.1), leukemia (SIR 5.76), lip cancer (SIR 5.94), and lung cancer (SIR 3.80).<sup>2</sup> Thus, oncologists can expect to see a variety of malignant conditions with increased frequency in HIV-infected patients. One pattern that is emerging is that many tumors highly associated with HIV [such as KS or primary central nervous system lymphoma (PCNSL)] appear to be caused by oncogenic viruses. It will be important to understand the mechanisms by which HIV and these viruses interact, and this understanding should in turn lead to an increased appreciation for the pathogenesis of other tumors. On the other hand, certain tumor associations with HIV may have arisen because cohorts at risk for HIV may also have risk factors for other tumors (e.g., from increased exposure to other oncogenic viruses, increased cigarette smoking, and so forth) rather than because of HIV itself or HIV-induced alterations in immune function. Also, it should be pointed out that the relative risk of a large number of tumors is not increased in HIV disease, and this must be considered in evaluating the potential role of immunosurveillance in the pathogenesis of such tumors.

This chapter focuses primarily on those tumors that are considered as AIDS defining, but in general, certain principles common to the treatment of HIV-infected patients with cancer apply to various malignant conditions. The treatment of such patients can be quite complex and requires expertise in both the tumor and HIV infection. The goals of cancer therapy (i.e., curative versus palliative), and the relationship of these goals to the status of the underlying HIV infection should be evaluated in each case.

## KAPOSI'S SARCOMA

A cluster of cases of KS among young homosexual men in 1982 was one of the first epidemiologic signs of the AIDS epidemic.<sup>9</sup> One hundred sixty-two cases of KS were reported over an 11-month period that year, with most cases indexed to New York City. This was a striking epidemiologic finding given that only three cases had been reported in the period 1961 to 1979 for the same age group in New York City.<sup>9</sup> KS is now the most common tumor seen in HIV-infected patients.<sup>10,11 and 12</sup>

AIDS-associated KS well illustrates the interactions of basic, clinical, and applied sciences in unraveling the determinants of disease, resulting in both disease prevention and improved therapy. For many years, a relatively indolent form of KS had been sporadically reported in elderly men in Eastern Europe and countries bordering the Mediterranean (classic KS).<sup>13</sup> More recently, KS has been observed with increased frequency in Africa and in transplantation recipients. It was suggested from the initial pattern of the AIDS epidemic, even before the identification of HIV as the cause of AIDS, that sexual transmission of an infectious agent was likely to be involved in the etiology of KS. Specifically, those at highest risk for developing KS were those with evidence of cellular immune deficiency and whose

sexual partners had sex with other men.<sup>10,14,15</sup> After the 1984 joint discovery of HIV as the causative agent of AIDS by Gallo<sup>16</sup> and Montagnier,<sup>17</sup> studies showed that the epidemiologic pattern of KS was not satisfactorily explained by HIV epidemiology alone, and the search for a KS cofactor intensified. During this period, institution of educational and preventive strategies resulted in changes in sexual practices,<sup>18</sup> and lower rates of sexually transmitted diseases in groups at high risk for KS.<sup>19</sup> Since then, there has been a decreasing incidence and prevalence of HIV infection as well as of KS among homosexuals in the United States and other western industrialized countries.<sup>3,19</sup> Before 1985, KS was reported as the initial manifestation of AIDS in approximately 30% of cases,<sup>20</sup> but in the period 1992 through 1997, it was the initial manifestation in 12.5%.<sup>3</sup> The decrease in KS as the index disease for AIDS has occurred in part because the Centers for Disease Control (CDC) revised its definition of AIDS in 1992 to include a CD4 cell count under 200/ $\mu$ L,<sup>21</sup> and thus cases of KS that occur at lower CD4 cell counts are excluded from the index-case count. However, there has been a further decline in incident cases from 60 to 20 per 1000 person-years between 1992 and 1997,<sup>21</sup> invoking cause beyond a simple change in case definition. It should be noted, however, that KS is much more frequent in other areas of the world, particularly sub-Saharan Africa. In parts of Uganda, for example, KS represents almost one-half of all cases of cancers in male subjects and is the second most frequent tumor in female subjects.<sup>22,23</sup>

In 1994, Drs. Chang, Moore, and their colleagues discovered a new herpesvirus, called KS-associated herpesvirus (KSHV) or human herpesvirus-8 (HHV-8), and subsequent studies showed that this was an essential causative agent for all forms of KS.<sup>24,25</sup> This discovery has in turn enabled seroepidemiologic analyses of its pattern of infection indicating that populations with a high incidence of KS also had a high incidence of KSHV infection and that the epidemic of KSHV infection in gay men in the United States emerged almost simultaneously with that of HIV.<sup>26</sup> The seroincidence of KSHV then appeared to taper beginning after 1983, in concert with efforts to encourage safer sex practices among gay men at risk for HIV infection. Also, as discussed later (see [Treatment](#)), improved treatments for the underlying HIV infection may have contributed to the decline in KS incidence.<sup>27,28</sup>

KSHV transmission correlates with a history of sexually transmitted disease and the number of male sexual partners: Strictly heterosexual men appear to have a relatively lower risk.<sup>29,30</sup> Coinfection with both KSHV and HIV increases the risk of developing KS by as much as 10,000-fold as compared with KSHV infection alone, and disease manifestation occurs at a younger age. Individuals infected with KSHV but not HIV can develop KS, but it is rare and usually occurs after their fifth decade of life. The risk of developing AIDS-KS appears to be related to the CD4 cell count. The majority of cases occur when the CD4 cell count is below 200/ $\mu$ L, and the risk increases substantially as the CD4 cell count falls below 100/ $\mu$ L.<sup>4,31</sup> The 10-year probability of developing KS after coinfection with both HIV and KSHV approaches 50%.<sup>30</sup> Also, there is evidence that the risk of KS appears to be higher for those who acquire KSHV subsequent to HIV infection,<sup>32</sup> suggesting there is an important role for immune surveillance of KSHV and the risk of KS.

## **PATHOGENESIS**

KS is a multicentric tumor that arises simultaneously in multiple nonmetastatic sites ( [Fig. 50.1-1](#)). The lesions are highly vascular, accounting for their purplish hue. Microscopically, the tumors are characterized by a predominance of spindle-shaped cells.<sup>33</sup> There is heterogeneity of the cells that make up the lesions, but vascular endothelial cell histogenesis of both the vascular and spindle cell components of KS is suggested by the cellular expression of endothelial cell-associated antigens such as factor VIII-related antigen, HLA-DR antigens, E92, and OKM5.<sup>33</sup> However, there remains some uncertainty as to the cell of origin of this tumor. Cells in KS lesions also stain for coexpression of macrophage markers (PAM-1, CD68, and CD14).<sup>34,35</sup> Although advanced KS may involve monoclonal proliferation,<sup>36</sup> there is evidence that proangiogenic factor-driven hyperproliferation of endothelial-derived spindle cells is important at all stages of the disease.<sup>37,38</sup> Spindle cells produce and respond to proangiogenic factors such as basic fibroblast growth factor and vascular endothelial growth factor (VEGF).<sup>37,39</sup>

**FIGURE 50.1-1.** Cutaneous manifestation of Kaposi's sarcoma.

The angiogenic polypeptide cytokine oncostatin M, which is produced by activated lymphoid cells, shares functional similarity and structural homology to leukemia inhibitory factor and interleukin-6 (IL-6),<sup>40,41</sup> and has autocrine growth properties for cells derived from AIDS-KS.<sup>43,44</sup> Cells exposed to oncostatin M develop spindle morphology, increase proliferation in soft agar, and increase secretion of IL-6,<sup>44</sup> and induction of basic fibroblast growth factor.<sup>45</sup> The soluble form of IL-6 receptor- $\alpha$  (sIL-6 $\alpha$ ) makes cells expressing gp 130 (the oncostatin M receptor) responsive to IL-6.<sup>46</sup> Since AIDS-KS cells express high levels of IL-6, it is likely that, in the presence of soluble IL-6 receptor- $\alpha$ , cells with the oncostatin M receptor acquire an IL-6 autocrine growth loop.<sup>46,47</sup>

The discovery in 1994 of a novel herpesvirus called KSHV or HHV-8 has introduced some clarity regarding this complex array of cellular markers and cytokine pathways.<sup>25</sup> Essentially all patients with KS are infected with this virus and KSHV/HHV-8 appears to represent an essential factor in the pathogenesis of KS.<sup>48,49,50,51,52</sup> and<sup>53</sup> KSHV/HHV-8 is present in the flat endothelial cells lining vascular spaces of KS lesions as well as in typical KS spindle cells.<sup>50</sup> KSHV/HHV-8 can induce the production of a number of virally encoded mimics of human cytokines and other factors involved in KS pathogenesis.<sup>54,55</sup> KSHV encodes for viral homologues to human IL-6, macrophage inhibitory protein, and interferon regulatory factor. It alters other cellular angiogenic factors, which, also, with viral IL-6 and the viral macrophage inhibitory proteins, have the potential for stimulating spindle cells as well as angiogenesis.<sup>54,55</sup> Also, the constitutively active KSHV/HHV-8–encoded G-protein coupled receptor (KSHV GPCR), expressed on infected cells,<sup>56</sup> up-regulates production of VEGF and other angiogenic factors.<sup>57</sup> In addition, there is some evidence that the kinase domain region (KDR) receptor for VEGF is up-regulated in cells infected with KSHV, providing a basis for the paracrine effects of this angiogenic factor in KS.<sup>58</sup> The KSHV GPCR can also cause oncogenic transformation in transfected cells.<sup>59</sup> Moreover, chemokines, such as IL-8 and growth-related protein- $\alpha$  can activate KSHV GPCR over constitutive levels *in vitro*, suggesting that endogenous chemokines may be evolved in KS pathogenesis, in part through KSHV-related pathways.<sup>60</sup>

Although HIV can markedly increase the incidence of KS in KSHV/HHV-8–infected individuals, the precise role of HIV in KS pathogenesis is somewhat unclear. A number of observations invoke the role of HIV Tat protein as a coregulator of KS development. *In vitro*, HIV Tat protein can stimulate endothelial and KS-derived spindle cell growth and proliferation.<sup>61</sup> Normal vascular cells acquire spindle morphology and become responsive to the mitogenic effect of Tat after culture with inflammatory cytokines. Tat promotes adhesion of AIDS-KS and normal vascular cells through a specific interaction with the integrin receptors  $\alpha_5$ ,  $\beta_1$ , and  $\alpha_v\beta_3$ , whose expression is increased by inflammatory cytokines.<sup>62,63</sup> However, the degree of extracellular Tat released in HIV-infected patients is unclear. Other mechanisms by which HIV may potentiate the development of KS include increased levels of IL-6 and decreased cellular immunity (perhaps permitting increased KSHV/HHV-8 replication). These mechanisms may explain why in some cases, KS appears to improve with effective treatment of HIV.<sup>64,65</sup>

## **STAGING AND PROGNOSIS**

The unique clinical presentation of KS requires a departure from the standard oncologic staging approach. The widely used tumor, node, metastasis system (TNM), or other staging systems that incorporate histologic grade and biologic indices as the primary prognostic variables,<sup>66</sup> are not satisfactory in KS for a number of reasons. One is the multicentric nature of the disease. Lesions arise simultaneously at multiple sites without an obvious primary site (see [Fig. 50.1-1](#)). Almost all KS patients would be classified as having metastatic disease using the TNM system, but multiple areas of skin involvement may not necessarily imply a worse prognosis relative to more focal involvement. Indeed, it is not at all clear how to use the term *metastatic* in relation to KS. Also, assessment of tumor bulk is extremely difficult in KS. Consequently, staging has been relatively nonstandardized, relative to other cancers.

Uniform staging is central to response assessment and is necessary to help compare results among trials and with historic controls. The most widely used staging system for KS, devised by the AIDS Clinical Trials Group Oncology Committee, is the TIS staging system (Table 50.1-2). This system scores patients based on the extent of tumor involvement (T), the immune status of the patient (I), and other AIDS-related systemic illness (S) in an attempt to stratify risk of poor prognosis.<sup>67,68</sup> The TIS system stages patients as being overall good risk or poor risk, depending on the presence or absence of localized tumor versus more extensive tumor with associated edema, ulceration, visceral disease, or extensive oral KS; CD4 cells over or below 150/ $\mu$ L; and the presence or absence of antecedent opportunistic infections, thrush, constitutional symptoms, other HIV-related illness, and Karnofsky's performance status. Good risk is designated with a subscript 0, and poor risk by the subscript 1, the summary taking the form T<sub>0</sub> or <sub>1</sub>, I<sub>0</sub> or <sub>1</sub>, S<sub>0</sub> or <sub>1</sub>. A patient who is poor risk in any single category is considered poor risk overall.

	Good Risk (I: All of the Following)	Poor Risk (I: Any of the Following)
Tumor (T)	Confined to skin and/or lymph nodes and/or mucocutaneous disease confined to the palate	Tumor-associated edema or ulceration; extensive oral KS; gastrointestinal KS; KS in other mucocutaneous sites
Immune system (I)	CD4 cells $\geq 200$ / $\mu$ L	CD4 cells $< 200$ / $\mu$ L
Systemic illness (S)	No history of opportunistic infection or disease, no B symptoms (intermittent fever, night sweats, $>10\%$ involuntary weight loss, or diarrhea) persisting more than 2 wk; performance status $\geq 2$ (Karnofsky)	History of opportunistic infection, thrush, or both; B symptoms present; performance status $< 2$ ; other HIV-related illness (e.g., neurologic disease, lymphoma)

HIV, human immunodeficiency virus; KS, Kaposi's sarcoma.  
\*The revised CD4 count of 150 cells/ $\mu$ L is lower than the original proposal of 200 cells/ $\mu$ L. Example of staging: A patient with KS confined to the skin, CD4 count of 150 cells/ $\mu$ L, and a history of *Pneumocystis carinii* pneumonia would be T<sub>1</sub>I<sub>1</sub>S<sub>1</sub>.  
(Data from refs. 67 and 68.)

**TABLE 50.1-2.** Revised Acquired Immunodeficiency Syndrome Clinical Trials Group Staging Classification for Kaposi's Sarcoma<sup>a</sup>

Although this staging system is subject to observer bias, it is nevertheless predictive of survival. One of the most important prognostic factors is the CD4 count. A CD4 cell count greater than 150 to 200 cells/ $\mu$ L implies a better prognosis,<sup>68,69</sup> and <sup>70</sup> regardless of visceral involvement by KS.<sup>68</sup>

The extent of KS lesions as a prognostic factor has not uniformly been validated,<sup>69,70</sup> but the potentially confounding role of immunosuppression degree was not adequately controlled for in certain analyses. The degree of immunosuppression predicts life expectancy after the diagnosis of KS.<sup>71</sup> The clinical course of KS is quite variable, from remarkably indolent to rapidly fulminant, but there are no clear criteria on which to assess the risk of aggressive versus indolent disease. KS behavior can be affected by the degree of immunosuppression or alternatively by the degree of HIV replication.<sup>61,62</sup> and <sup>63,72</sup> There is evidence that KS may become more indolent with good control of HIV, but the long-term course of KS in patients with highly active antiretroviral regimens is not known. The role of other factors, such as the activity of KSHV/HHV-8, are not well understood at present, but could potentially contribute to risk assessment.

## TREATMENT

During the 1980s, KS was a frequent cause of death in AIDS patients.<sup>73,74</sup> In the late 1990s, however, a number of advances in the therapy of this disease have been seen. While KS is still a cause of considerable morbidity and mortality in HIV-infected individuals, better tumor control is now attainable in most patients than was possible several years ago. In addition, there is evidence that the development of highly effective antiretroviral regimens has contributed to a decline in the incidence of KS in HIV-infected individuals.<sup>75,76</sup> Finally, advances in understanding the pathogenesis of KS offer the possibility of developing new pathogenesis-based therapies that may be less toxic than the current agents.

In order to best understand the effect of more recent advances in the therapy of KS, it is useful to recount the standard therapy for this condition as of approximately 1993 to 1994. Overall, the initial therapies identified as being active against KS during the first few years of the AIDS epidemic can be divided into three groups: local measures, immunotherapy (interferon- $\alpha$ ), and cytotoxic chemotherapeutic agents.

### Local Therapy

Local therapies include surgical excision of the lesions, cryotherapy, photodynamic therapy, intralesional injections, radiation therapy, and topical application of various drugs and are most useful for patients with limited cutaneous disease that is cosmetically disturbing to the patient.<sup>77</sup> Intralesional injection or iontophoresis of low-dose vinblastine (0.1 mL of 0.1 mg/mL) or 3% sodium tetradecyl sulfate injection (0.1 to 0.3 mL) causes a nonspecific necrosis or sclerosis of mucocutaneous tissue with sometimes reasonable cosmetic outcome for small lesions.<sup>78,79,80</sup> and <sup>81</sup> Cryotherapy is easy to administer and unlike surgical excision, it can be accomplished without local anesthesia.<sup>82</sup> However, cryotherapy can cause permanent destruction of melanocytes, particularly in dark-skinned individuals. Topical 9-*cis* retinoic acid (Panretin Gel), approved by the U.S. Food and Drug Administration (FDA) for use in KS, may result in responses in over 45% of lesions but can cause local inflammation and lightening of the skin, yielding inadequate cosmesis in some cases.<sup>83,84</sup>

Radiotherapy is useful for localized disease, but as with other nonsystemic therapies, does not control disease outside of the treatment area. In addition, there are reports of a decreased tolerance to radiation among AIDS-KS patients, particularly on the mucosal surfaces where severe mucositis can occur.<sup>85,86</sup> Reappearance of KS in the area of previous irradiation can occur. Radiotherapy is useful as adjunctive therapy in severe disease to treat areas of painful involvement that may respond only slowly to systemic therapy. The use of carbon dioxide laser therapy to remove tumors of the mouth, oropharynx, and larynx has been reported to result in immediate improved oral intake and with less toxicity than is sometimes seen with radiation to the oral cavity.<sup>87</sup> Radiotherapy is also useful for cosmetic purposes, such as involvement of the eyelid or conjunctiva, when other local therapies are not practical. Applied doses vary between 800 rad given over one fraction to 3000 rad given over ten fractions, depending on the site of involvement, and disease status entering into the dosing algorithm. Complete responses can be seen in over 90% of lesions, but sometimes residual radiation-induced pigmentation or telangiectasia, which can at times be severe, limits the cosmetic outcome.<sup>85,88</sup> Doses of 1500 rad for oral lesions and doses of 2000 rad for lesions involving eyelids, conjunctiva, and genitals have been shown to be sufficient to produce shrinkage of the tumor and good palliation of the symptoms. Short-course radiotherapy may be useful and effective in some settings. Treatment comparisons of either 1600 rad over four fractions over 4 days or 800 rad as a single fraction yielded similar response rates of 78% to 81%. The toxicity was somewhat site dependent, and thus single-fraction therapy may not be appropriate in all cases.<sup>89</sup> Radiation therapy can be used for palliation of visceral disease, including pulmonary involvement, and may be reasonably well tolerated in some circumstances.<sup>90</sup>

Photodynamic therapy has been reported to be effective in KS, yielding high response rates, and has the advantage over other local therapies in that 40 to 50 lesions can be treated during a single session.<sup>91,92</sup> It is frequently associated with moderate pain and then photosensitivity for a number of weeks following the treatment.

### Immunotherapy

Immunotherapy with interferon- $\alpha$  was identified as being active in KS in the early 1980s, particularly in patients with over 200 CD4 cells/ $\mu$ L and disease limited to the skin.<sup>93,94</sup> Interferon- $\alpha$  appears to be more effective when used in combination with zidovudine monotherapy than when used alone,<sup>95</sup> and as will be discussed below, studies are underway to test this agent in combination with potent combination anti-HIV therapy (see Antiangiogenesis Approches, later in this chapter). The use of interferon- $\alpha$  is associated with a decreased white blood count, flu-like symptoms, and sometimes depression.

### Cytotoxic Chemotherapy

Early in the AIDS-KS epidemic, several cytotoxic chemotherapeutic agents were found to yield tumor responses with acceptable toxicity.<sup>96</sup> Vinca alkaloids (either vincristine, vinblastine, or an alternating regimen of the two) were among the first to be studied. Other active single-agent drugs included etoposide, bleomycin, and doxorubicin. Subsequently, several studies showed that the combination of doxorubicin, bleomycin, and vinca alkaloids (ABV) was effective, even in patients with extensive KS or disease that was refractory to other therapies.<sup>97,98</sup> The initial clinical studies of ABV in KS generally used relatively high doses of doxorubicin, either

40 mg/m<sup>2</sup> every 4 weeks or 20 mg/m<sup>2</sup> every 2 to 3 weeks.<sup>97,98</sup> Impressive response rates of 84% and 88%, respectively, were seen. However, the therapy was frequently limited by neutropenia and concomitant non-KS opportunistic infections. Also, although many patients derived benefit from such agents and regimens, as late as 1999 it was not infrequent to see patients die with severe, progressive KS in spite of optimal therapy.

This situation has improved somewhat with the development of two new chemotherapeutic approaches for KS: liposomal anthracyclines and paclitaxel.<sup>99</sup> Liposomal formulations of anthracyclines were considered in part because they were predicted to have a smaller volume of distribution than unencapsulated drug and thus remain in the circulation for longer periods of time.<sup>100,101</sup> Two such formulations, liposomal daunorubicin (DaunoXome) and pegylated liposomal doxorubicin (Doxil) have now been developed and found to be active in patients with KS and have prolonged half-lives as compared with unencapsulated forms. Moreover, there is some evidence that encapsulation of the drugs in liposomes helps target them to KS lesions, in part because of the sequestering of blood that occurs because of the leaky blood vessels in the lesions.<sup>102</sup> In early clinical studies, both preparations were found to induce major tumor responses, even in patients who had failed standard chemotherapy.<sup>100,103</sup>

With this background, liposomal anthracyclines as single agents were tested against active combination regimens in several randomized trials. In one study, liposomal daunorubicin (40 mg/m<sup>2</sup> every 2 weeks) was found to have a response rate comparable with ABV, although with somewhat less neutropenia.<sup>104</sup> It is noteworthy that the 28% major response rate of ABV in this study was substantially less than that found on previous studies. One likely reason for this is that the dose of doxorubicin used (10 mg/m<sup>2</sup> every 2 weeks) was less than that used in the earlier ABV studies. Another likely reason is that the patients in this randomized trial had advanced HIV disease with a median CD4 count of 29 cells/μL. The substantial difference in response rates to ABV in these two trials highlights the sensitivity of KS response rates to disease status and other parameters.

In two separate trials, pegylated liposomal doxorubicin was found to have better response rates against KS than either bleomycin plus vincristine (BV) or an ABV regimen with either less or roughly comparable toxicities.<sup>105,106</sup> In the study comparing it with BV, the major response rate to pegylated liposomal doxorubicin alone was 58%. Both of these liposomal preparations have now been approved by the FDA for the therapy of KS.

To address whether the liposomal anthracyclines were better used alone or in place of doxorubicin in combination regimens, a study of liposomal doxorubicin alone compared with liposomal doxorubicin, bleomycin, and vincristine (DBV) in patients with advanced KS was initiated.<sup>107</sup> At a protocol-mandated interim analysis on 126 evaluable patients (62 on liposomal doxorubicin and 64 on DBV), the major tumor responses (partial and complete responses) were similar in the two treatment arms (79% on liposomal doxorubicin vs. 80% on the combination regimen). However, more patients receiving DBV had toxicities requiring cessation of treatment than did patients receiving liposomal doxorubicin alone, and there was a trend toward better survival in favor of liposomal doxorubicin alone (11 vs. 18 deaths,  $P = .079$ ). The study concluded that single-agent liposomal doxorubicin had equivalent activity but lower toxicity than DBV, and all patients were switched to liposomal doxorubicin alone.

Paclitaxel was also developed for use in KS during this period based on observations that it targets cellular microtubules (such as vinca alkaloids shown to be active in KS, albeit causing the opposite effect) and its *in vitro* inhibition of a KS-derived spindle cell line.<sup>108</sup> An initial trial of paclitaxel at the National Cancer Institute (NCI) using a dose of 135 to 175 mg/m<sup>2</sup> administered over 3 hours every 3 weeks showed substantial activity in patients with advanced KS; 20 of 28 assessable patients had complete or partial responses for a major response rate of 71.4%.<sup>108,109</sup> It was noteworthy that five of six patients with pulmonary KS responded, as did four patients who had previously received anthracycline therapy.

Gill, Scadden, and their colleagues at the University of Southern California and Harvard University conducted a second trial of paclitaxel in 56 mostly previously treated patients with advanced KS.<sup>110</sup> This trial used a somewhat different regimen: 100 mg/m<sup>2</sup> of paclitaxel administered over 3 hours every 2 weeks. Overall, the major response rate in this trial was 59%. It was noteworthy that of the 32 patients who had received prior anthracycline therapy, 55% responded. In both trials, neutropenia was the dose-limiting toxicity, and a number of patients had improvement in KS-related symptoms. Largely based on the results of these two studies, the FDA approved paclitaxel as second-line therapy for KS in 1997. Also, it is important to emphasize that corticosteroids can result in dramatic acceleration of KS growth. Premedication with 10 mg of dexamethasone is adequate for premedication in taxane-based therapy, but corticosteroids should otherwise be avoided when possible.

The development of the liposomal anthracyclines and paclitaxel for KS appears to have enabled better palliation of symptoms with less toxicity than was possible with previous regimens, and at the present time, most oncologists treating KS patients consider these to be the two most valuable modalities for the treatment of advanced KS (Table 50.1-3). For most such patients, the liposomal anthracyclines (and especially liposomal doxorubicin) are generally considered the preferred first-line therapy. Paclitaxel is generally considered as a valuable second-line therapy, although for patients with particularly severe KS, some oncologists use it as initial therapy (this is a deviation from the current FDA labeling of the drug). Other therapies that are considered useful in some patients include ABV, weekly alternating vincristine and vinblastine, or BV.

Therapy	Response Rates
<b>COMMONLY USED STANDARD THERAPIES</b>	
Liposomal anthracyclines	
Doxorubicin	59% <sup>106</sup>
Daunorubicin	25% <sup>104</sup>
Paclitaxel	59–71% <sup>108,110</sup>
<b>ALTERNATIVE THERAPIES</b>	
Adriamycin/bleomycin/vinca alkaloids	24–88% (higher response rates with higher doxorubicin doses, but greater toxicity) <sup>97,98,100,102,106</sup>
Vincristine/vinblastine	45% <sup>101</sup>
Bleomycin/vinca alkaloids	25% <sup>106</sup>

**TABLE 50.1-3.** Therapies for Patients with Advanced Kaposi's Sarcoma

In an attempt to explore the relative merits of these agents as first-line therapy for KS, von Roenn and colleagues in the Eastern Cooperative Oncology Group and the AIDS Malignancy Consortium of the NCI have initiated a phase III trial comparing liposomal doxorubicin (Doxil), 20 mg/m<sup>2</sup> every 3 weeks, with paclitaxel, 100 mg/m<sup>2</sup> every 2 weeks in patients with advanced, untreated KS. This study should provide valuable guidance for therapy in advanced KS.

### Experimental Approaches to the Treatment of Kaposi's Sarcoma

Although the development of liposomal anthracyclines and paclitaxel has improved the therapeutic armamentarium for advanced KS, these agents have the potential for substantial toxicity. In particular, both cause bone marrow and immunologic suppression, although there is evidence that paclitaxel is relatively sparing of CD4 cells as compared with other cytotoxic agents.<sup>111</sup> Moreover, even in the absence of HIV infection, the regeneration of CD4 cells after cytotoxic therapy can take many months, especially in adults or older children.<sup>112</sup> For these reasons, there is a substantial interest in developing effective less toxic pathogenesis-based therapies.

**ANTIANGIOGENESIS APPROACHES.** One active area of research in this regard is the inhibition of new blood vessel growth, a field that has been pioneered by Folkman and colleagues.<sup>113,114</sup> and <sup>115</sup> KS is a highly vascular tumor, and for this reason, there is currently an interest in exploring the use of angiogenesis inhibitors in patients with KS. Compounds of interest that have been in phase I or II testing include pentosan polysulfate,<sup>116</sup> TNP-470 (an analogue of the fungal product fumagillin),<sup>117,118</sup> IL-12,<sup>119</sup> IM-862,<sup>120</sup> SU5416, and thalidomide.<sup>121,122</sup> Preliminary results from two initial phase II trials of thalidomide both showed that this agent had activity in a subset of patients with KS.<sup>121,122</sup>

IL-12 possesses a number of interesting immunologic and antiangiogenic characteristics that make it a potentially attractive agent for HIV-associated KS. There is evidence that HIV-infected patients have a specific defect in T-cell help for cellular response (Th1 cells), and that IL-12 selectively stimulates such responses.<sup>123,124</sup> In addition, IL-12 has been shown to be a potent inhibitor of angiogenesis,<sup>115,125</sup> possibly through induction of inducible protein 10, a potent inhibitor of

angiogenesis.<sup>125,126 and 127</sup> Interestingly, the constitutively active KSHV GPCR expressed on KS cells is inhibited by inducible protein 10,<sup>128</sup> leading to potentially decreased production of VEGF and other angiogenic factors by KSHV/HHV-8-infected cells.<sup>59,129</sup> A potential concern in the use of IL-12 is that it has been shown to slightly increase HIV replication *in vitro*.<sup>130</sup> However, this can easily be controlled by anti-HIV drugs.<sup>130</sup> Preliminary results from a phase I trial of IL-12 in patients with KS show that it has some activity.<sup>119</sup> In the future, it may also be of interest to explore the possible clinical utility of inducible protein 10 in this disease.

The results seen with thalidomide and IL-12, plus advances in angiogenesis research, have led to further interest in this approach to the treatment of KS. The AIDS Malignancy Consortium is conducting studies of novel antiangiogenic agents, including a phase I trial of the metalloproteinase inhibitor col-3 and of IM-862 versus placebo for evidence of therapeutic effect. There has been substantial interest in two biologic antiangiogenesis agents, endostatin and angiostatin,<sup>131,132</sup> and as development proceeds, they may be studied in KS.

Finally, it should be noted that interferon- $\alpha$  can inhibit angiogenesis,<sup>133</sup> and that this may be one mechanism for its anti-KS activity. Initial studies suggested that this agent was principally active in patients with disease limited to the skin and with over 200 CD4 cells/ $\mu$ L.<sup>93,94,134</sup> However, subsequent trials suggested that this agent also manifested anti-KS activity in patients with lower CD4 counts if given with nucleoside anti-HIV therapy.<sup>95</sup> To extend these observations, the AIDS Malignancy Consortium is now studying the effectiveness of interferon- $\alpha$  in combination with highly active antiretroviral therapy (AIDS Malignancy Consortium Trial 004) in patients with HIV-associated KS.

**RETINOIC ACIDS.** KS-derived spindle cells have been shown to proliferate in response to IL-6 and certain retinoids have been shown to down-regulate IL-6 receptors, at least on myeloma lines, and to have an antiproliferative effect on KS-derived cell lines.<sup>135,136 and 137</sup> Much of the initial interest in the retinoids centered on all-*trans*-retinoic acid. However, the results with this agent were inconclusive.<sup>138,139 and 140</sup> Also, a problem with the use of all-*trans*-retinoic acid is that it rapidly induces enzymes that significantly increase its metabolism, resulting in a substantially diminished area under the time concentration curve.<sup>141</sup> In part because of this and in part because it has a different pattern of receptor binding, more recent clinical work has focused on 9-*cis* retinoic acid. Preliminary reports from two clinical trials have provided evidence that this agent is active when administered orally to patients with KS.<sup>142,143</sup> The response rates in these studies were 46% and 37%. The most frequent side effects were headache and skin changes. Additional studies will be needed to further define the role of this agent in KS. As noted previously, topical 9-*cis* retinoic acid has been approved by the FDA for use in KS.

**HORMONAL APPROACHES.** One of the interesting epidemiologic features of AIDS-KS is that the vast majority of patients are male.<sup>10</sup> This male predominance is more than can be explained by patterns of KSHV/HHV-8 infection,<sup>51,144</sup> and it suggests that there may be some hormonal effect on the disease pathogenesis. Several years ago, Lundardi-Iskandar, Gallo, and coworkers found that a factor in the urine of pregnant women blocked the growth of a KS-derived cell line.<sup>145</sup> This factor was initially thought to be human chorionic gonadotropin, but subsequent investigation has suggested that it is a related urinary protein that is found in certain preparations of human chorionic gonadotropin.<sup>146</sup> Early clinical trials have shown that preparations of human chorionic gonadotropin containing this factor could induce regressions in KS.<sup>147,148</sup> Ongoing studies are now focused on better defining this active factor.

**KAPOSI'S SARCOMA-ASSOCIATED HERPESVIRUS, HUMAN HERPESVIRUS-8, AND HUMAN IMMUNODEFICIENCY VIRUS-RELATED APPROACHES.** The discovery of KSHV/HHV-8 has opened up many avenues of research in KS.<sup>24,25</sup> Most of the cells in KS lesions are infected with KSHV/HHV-8 in a latent state.<sup>52</sup> However, a small percentage of cells in KS lesions appear to contain KSHV/HHV-8 in a lytic state of replication, and if these few cells are important in ongoing tumor pathogenesis, then antiherpes drugs might have anti-KS activity. Although preliminary evidence suggests that antiherpes drugs such as acyclovir, foscarnet, or ganciclovir do not substantially decrease the population of KSHV/HHV-8-infected cells in the circulation, there is some anecdotal evidence of KS remissions being associated with the use of foscarnet.<sup>49,149,150</sup> Perhaps more noteworthy is the finding from a randomized clinical trial of oral ganciclovir that administration of this agent was associated with a lower rate of KS.<sup>151</sup> This result indicates that an antiherpes drug can reduce the incidence of KS, although it still remains unclear as to how it can affect established lesions.

While the role of ongoing KSHV/HHV-8 replication in the growth of KS lesions is still unclear, there is somewhat better evidence of a linkage between KS growth and HIV replication. The incidence of KS is much higher among patients coinfecting with HIV and KSHV/HHV-8 than in those with just KSHV/HHV-8 infection, and there are reports of KS regression during highly active anti-HIV therapy.<sup>152</sup> Also, there is evidence that the incidence of KS has declined in HIV-infected patients since the introduction of potent combination anti-HIV therapy.<sup>153</sup> Possible mechanisms for this association include interaction of HIV Tat protein with KS-derived spindle cells,<sup>154</sup> HIV-induced immunosuppression, HIV-related cytokine dysregulation, and the possible role of other HIV-encoded proteins. These epidemiologic findings provide a paradigm for the prevention of a tumor by antiviral control of the underlying viral and immunosuppressive disease.

## ACQUIRED IMMUNODEFICIENCY SYNDROME-ASSOCIATED LYMPHOMAS

### EPIDEMIOLOGY AND OVERVIEW

Beginning in 1973, before recognition of the AIDS epidemic, there was a clear increase in reported cases of lymphoma.<sup>176,177 and 178</sup> This trend overlapped with the early years of the epidemic, and from 1973 to 1988, there was a 50% increase in the incidence of NHL based on analysis of the NCI's Surveillance, Epidemiology, and End Results program data.<sup>155</sup> The incidence rates for primary brain lymphomas increased during the same period.<sup>156</sup> The increased incidence rates for large cell immunoblastic and small noncleaved cell NHL observed during the 1980s has been attributed largely, although not entirely, to the AIDS epidemic.<sup>155</sup>

Immune dysfunction had previously been associated with the development of lymphoproliferative disease and lymphomas, and with this background, investigators were alerted early in the AIDS epidemic to the possibility that this new disease might be associated with lymphomagenesis.<sup>157</sup> Indeed, as early as 1982, only 1 year after AIDS was recognized as a new epidemic disease, four cases of aggressive lymphoma in young men ranging in age from 24 to 35 years were reported within a 10-month period in the San Francisco area.<sup>158,159</sup> This was seen as remarkable because only one case of aggressive lymphoma had been reported in the age group 20 to 39 years for the period 1977 to 1980. It was thus recognized that the then-termed *KS and opportunistic infection syndrome* may predispose affected persons to more than one kind of tumor.<sup>14,15,158</sup>

Additional significance to the emerging problem of NHL was highlighted in 1985 with publication of the Surveillance, Epidemiology, and End Results program database, which suggested a ninefold increase of the morbidity odds ratio for aggressive lymphomas among *never-married men* (a term used to approximate homosexual men for epidemiologic purposes) in the San Francisco area 1981 to 1982 as compared with 1973 to 1980.<sup>160</sup> Ultimately, it was found that there was an overall 60-fold increase in the ratio of observed cases of NHL in HIV-infected persons compared with that expected in the HIV-negative population.<sup>5</sup> Because of these epidemiologic and immunologic considerations, NHL of high-grade pathologic type (diffuse, undifferentiated) and of B-cell or unknown immunologic phenotype, diagnosed by biopsy, was included in the case definition of AIDS in 1985.<sup>161</sup>

NHL is now the second most common AIDS-associated malignancy and is the AIDS-defining diagnosis in roughly 3% of HIV-positive patients.<sup>3,162</sup> It is not clear what percentage of HIV-infected patients ultimately develop NHL, since the occurrence of a second AIDS-defining event is not reportable. Estimates of incidence up to 10% per year with a prevalence of 4.5% to 25.0% have been documented in certain patient populations.<sup>163,164,165 and 166</sup> In addition to an increased risk of NHL in HIV-infected persons, the pattern of presentation differs from the HIV-negative population. Over 80% of lymphomas in HIV-infected patients are high-grade B-cell lymphomas,<sup>5,167,168</sup> whereas only 10% to 15% of lymphomas among HIV-negative patients are of this type.<sup>169</sup>

Data collected by the NCI suggest that between 8% and 27% of the approximately 40,000 annual cases of NHL are HIV-related.<sup>11</sup> In a long-term follow-up of patients participating in phase I trials of zidovudine, the predicted occurrence of NHL by Kaplan-Meier statistics was 8% after 24 months and 29% after 36 months of zidovudine.<sup>163</sup> A high risk of lymphoma development was also observed in patients followed for a long time on a phase I trial of didanosine.<sup>166</sup> Lymphoma risk appeared to be increased with the degree and duration of immunosuppression. These reports suggested that anti-HIV therapy might possibly increase the cumulative risk of HIV-infected individuals developing lymphoma by extending overall survival.<sup>163,166</sup> However, when these reports were published, concern arose that nucleoside reverse transcriptase inhibitors might directly contribute to development of lymphoma. The finding that that lifetime exposure in rodents was associated with vaginal tumors and the subsequent finding that administration of high-dose zidovudine to pregnant mice was associated with increased cancer rates among the offspring, further raised concern that these drugs were potentially carcinogenic in humans.<sup>170,171 and 172</sup> Clinical studies have not supported these concerns, however. First, some studies have reported relatively low overall rates of the development of lymphoma. In one study, only 24 (2.3%) of 1030 AIDS patients receiving zidovudine developed NHL.<sup>162</sup> With 1463 person-years of follow-up, the rate was 1.6 per 100 person-years of therapy. Also, data from a case-control study provided no evidence that the

use of zidovudine increased the risk of lymphoma in HIV infection.<sup>173</sup>

Another piece of evidence arguing against a role of zidovudine increasing the risk of B-cell lymphoma is that zidovudine is not implicated in lymphomagenesis or in inducing B-cell activation.<sup>174</sup> Also, it is worth remembering that an increased incidence of lymphoma in HIV-infected patients was found even before the introduction of zidovudine.<sup>161</sup>

The excess risk of developing AIDS-NHL appears to be independent of the particular risk group for HIV acquisition<sup>5,165,175</sup> or lifestyle factors such as drug use,<sup>175</sup> although one autopsy series suggested that patients with a prior history of KS had a 5.3-fold higher risk of NHL compared with HIV-infected patients with other AIDS-defining illnesses.<sup>164</sup> The risk, however, does vary with age. It has been reported that the excess risk of NHL in HIV is approximately 360-fold for the age group under 19 years, and 20-fold for the age group over 60 years of age.<sup>5</sup> However, NHL is a rare disease in western children (0.1 to 0.3 per 100,00),<sup>176</sup> such that a small number of excess cases translate into higher ratios of observed versus expected cases.<sup>5</sup> It has also been reported that male subjects and whites are at higher risk than other groups,<sup>177</sup> but this feature does not distinguish AIDS-NHL from the epidemiology of non-AIDS-NHL.<sup>178,179</sup> NHL is the most frequent AIDS-related malignancy among hemophiliacs,<sup>161</sup> primarily because KS appears so rarely in this group.

There may be innate biologic characteristics that predispose certain HIV-infected persons to develop NHL. In a study of 746 HIV-infected persons, the 3'A variant of stromal cell-derived factor-1 chemokine was associated with an approximate doubling of the NHL risk in heterozygotes and a fourfold increase in homozygotes.<sup>180</sup> The stromal cell-derived factor-1 3'A chemokine variant is carried by 37% of whites and 11% of blacks and may contribute to the lower risk of AIDS-NHL in blacks compared with whites.

A deletion in the CCR5 chemokine receptor gene has been reported to alter the risk for HIV infection and progression to AIDS.<sup>181</sup> In a matched case-control study, the CCR5 deletion variant CCR5- $\Delta$ 32 offered approximately a threefold protection against NHL.<sup>182</sup> By contrast, the AIDS-protective variant CCR2-64I had no significant effect on the risk of lymphoma. The CCR5 gene was not associated with a difference in risk for Kaposi's sarcoma, or development of opportunistic infections.<sup>183</sup> Costimulation of normal B cells with the CCR5 ligand RANTES (regulated on activation, normally T-cell expressed and secreted) induces a proliferative response, indicating that RANTES is a mitogen for B cells.<sup>184,185</sup> Perhaps the CCR5- $\Delta$ 32 mutation is protective through a mechanism involving a decreased response of B cells to the mitogenic activity of RANTES.<sup>183</sup> It is possible that such factors may provide a means of assessing the risk of NHL in HIV-infected persons and provide insights for preventive and treatment approaches for this disease.

It is conceivable that potent antiretroviral therapy (PAT) for HIV infection will have an effect on the incidence of AIDS-NHL. In the Australian AIDS registration data, NHL has decreased by 37.5% as an AIDS-defining diagnosis since 1994, coincident with the introduction of PAT as common anti-HIV therapy.<sup>186</sup> The French database has also suggested a decrease in NHL: Of 66,202 HIV-seropositive subjects, the incidence of lymphoma (peripheral and primary CNS) per 1000 patient-years in the first half of 1997 decreased 44% compared with the incidence in the first half of 1996.<sup>28</sup> The effect of PAT on PCNSL may be clearer. This effect is not surprising as PCNSL most commonly develops in patients with fewer than 50 CD4 cells/ $\mu$ L<sup>163,166,187</sup> and as PAT can profoundly increase the CD4 counts. In a prospective study, the probabilities of developing focal brain lesions were analyzed for linear trend comparing 1991 through 1996, a period before PAT, with 1997 through 1998, when PAT became commonly available. The odds ratio of developing PCNSL was 0.46 in the PAT era compared with pre-PAT.<sup>188</sup> Other studies have found less evidence of a substantial effect on the incidence of lymphoma. An analysis of data from the Multicenter AIDS Cohort Study showed that the incidence of NHL as the AIDS-defining condition has remained fairly constant over time.<sup>27</sup> Among a total of 6587 patients enrolled in AIDS Clinical Trials Group trials between November 1987 and February 1997, incidence rates of both KS and NHL per 100 person-years declined in concert with decreases in mortality, but the decreases in NHL were somewhat inconsistent, suggesting that current therapies have not appreciably ameliorated the incidence of NHL.<sup>76</sup> It is hard to predict the ultimate effect PAT will have on the development of NHL. On the one hand, it may reduce the immediate incidence through its beneficial effect on the viral load and CD4 count. On the other hand, as patients live longer with PAT, there may be a cumulative increase in the risk of patients developing NHL.

## PATHOLOGY AND CLASSIFICATION

Efforts to understand disease mechanisms for AIDS-NHL have involved consideration of NHL occurring in other conditions of disordered immunity. Immune-suppressive therapy in solid organ transplantation is associated with a 30- to 300-fold increase in the risk of lymphomas and has been used as a model of AIDS-associated lymphomagenesis.<sup>168,189</sup> These lymphoproliferations can sometimes respond to reduction in immunosuppressive therapy, but in other instances can also be aggressive and poorly responsive to treatment.<sup>190,191,192</sup> and <sup>193</sup> The congenital immunodeficiency syndromes also confer a predisposition to malignancy, providing yet another model in which to consider lymphomagenesis.<sup>194,195</sup> For example, in ataxia-telangiectasia, there are specific immune defects that have been identified and linked to chromosome breakpoints in genes involved in both the immune system and in certain malignancies such as Burkitt's lymphoma.<sup>196,197</sup> Further illustrating the role of immune dysfunction is the increased frequency of lymphoproliferative disease and lymphomas occurring in patients with autoimmune disease.<sup>198,199</sup> Autoimmune factors in HIV infection are suggested by the finding that antibodies to the HIV-1 gp41 protein cross-react with self-MHC class II antigens, triggering chronic antigenic stimulation of B cells.<sup>200</sup> Further, immunoglobulin somatic hypermutation with the preferential use of the V<sub>H</sub>4 family of immunoglobulin-variable genes (molecular events that are produced under chronic lymphoproliferative conditions) has been seen in AIDS-associated lymphomas.<sup>201,202</sup> and <sup>203</sup> Elevated serum IL-6 levels in HIV-infected patients have also been associated with a higher risk of certain forms of NHL.<sup>166,204</sup> Thus, chronic antigen stimulation from HIV, concomitant infections, or autoimmune phenomena can potentially lead to B-cell proliferation and oligoclonal expansion in a multistep process rapidly progressing from clinically undetectable hyperplastic adenopathy<sup>205,206</sup> to malignant monoclonal lymphoma in the setting of immunosuppression or other host factors such as deregulated cytokine production (i.e., IL-6, IL-10, tumor necrosis factor- $\beta$ ).<sup>166,204,207,208</sup>

## HISTOLOGY

AIDS-NHLs are histologically heterogeneous and are almost invariably derived from monoclonal B-cell populations,<sup>209,210,211</sup> and <sup>212</sup> although there are sporadic reports of T-cell lymphomas associated with HIV.<sup>213,214</sup> There are three major categories of HIV-associated B-cell lymphomas: (1) Burkitt's and Burkitt-like lymphomas; (2) B-cell immunoblastic lymphomas; and (3) the rarely occurring primary effusion lymphomas (PEL), also termed *body cavity lymphomas*.<sup>5,167,209,212,215,216,217,218,219</sup> and <sup>220</sup> The Revised European-American Classification of Lymphoid Neoplasms classifies all these lymphomas as either (1) Burkitt's and Burkitt-like, which includes small non-cleaved cell lymphomas (SNCL) and account for approximately 20% of the cases; and (2) diffuse large B-cell lymphoma, which include the large non-cleaved cell and large cell-immunoblastic plasmacytoid types and account for approximately 60% of cases.<sup>221,222</sup> HIV-associated PCNSLs are almost always of this latter morphologic type.<sup>223</sup> The World Health Organization proposes a unique classification for PEL.<sup>224</sup>

Occasional lymphomas arising in HIV-infected individuals have been reported to be polyclonal.<sup>225</sup> These tumors are most often Epstein-Barr virus (EBV)-negative tumors with no evidence of c-myc rearrangement. Less frequently, these polyclonal tumors are found to be EBV-positive with similarities to lymphoproliferations seen in transplant patients. Polyclonality is said to confer a favorable prognosis.<sup>226</sup> However, most authorities agree that the majority of AIDS-lymphomas are monoclonal.<sup>217</sup>

Other lymphomas that are seen in the setting of HIV but are not AIDS-defining conditions, include classical Hodgkin's disease,<sup>227,228</sup> polymorphic lymphoproliferative disorders resembling posttransplant-associated lymphoproliferative disease,<sup>229</sup> and lymphomatoid granulomatosis.<sup>230</sup> Multicentric Castleman's disease is sporadically reported in patients with AIDS-NHL and KS and is of interest because of its association with KSHV/HHV-8 and other similarities with lymphomagenesis.<sup>231</sup>

## SYSTEMIC LYMPHOMAS

As noted previously, the vast majority of systemic lymphomas developing in HIV-infected individuals are either diffuse large cell lymphomas or SNCL. The presence of distinct genetic pathways for AIDS-SNCL and AIDS-diffuse large cell lymphomas correlates with a number of clinical features that distinguish these two groups of tumors, including differences in the age of onset, CD4 counts at the time of presentation, time elapsed since HIV infection, and clinical presentation ( [Table 50.1-4](#)).<sup>209</sup> EBV expression patterns are distinct from posttransplant lymphoproliferative disorders related to iatrogenic immunosuppression and are heterogeneous among AIDS-NHLs.<sup>232</sup> These patterns appear to correlate with histiogenic origin of the malignant clone.<sup>233</sup>

Feature	Lymphoma Subtype			Primary Effusion Lymphoma
	Burkitt	Burkitt-like	Non-Burkitt	
Prevalence	~20% (sporadic) ~10% (AIDS)	~10% (sporadic) ~10% (AIDS)	~10% (sporadic) ~10% (AIDS)	~10%
EBV infection	~100%	~100%	~100%	~100%
CD4 count	Normal (decreased)	Decreased	Decreased	Decreased
Epstein-Barr virus	EBNA-2 EBNA-1 EBNA-2	EBNA-2 EBNA-1 EBNA-2	EBNA-2 EBNA-1 EBNA-2	EBNA-2 EBNA-1 EBNA-2
Immunophenotype	Negative	Negative	Negative	EBV
Gene	c-myc	c-myc	c-myc	Negative
BCL-6	Negative	Negative	EBV	Negative
BCL-2	Negative	Negative	Occasional	Negative
p53	EBV	EBV	Negative	Negative
BCL-2	EBV	EBV	EBV	Negative

**TABLE 50.1-4.** Comparison of Human Immunodeficiency Virus–Associated Lymphomas

Large B-cell lymphomas in HIV-infected patients are associated with EBV infection in 70% to 90% of cases and are more likely to occur later in the course of HIV infection in older patients with relatively low CD4 cell counts.<sup>209,234</sup> Cells tend to exhibit EBV-latency type 3 expression and in particular express Epstein-Barr nuclear antigen-2 (EBNA-2) and latent membrane protein-1 (LMP-1), which are EBV-specific antigenic targets.<sup>235,236</sup> and<sup>237</sup> It has been hypothesized that HIV-infected patients have a defect in these EBV-specific cytotoxic T-cell responses, thus allowing immune escape of the emerging lymphomatous clone. The viral oncogene LMP-1 may be involved in lymphomagenesis by increasing the threshold for cells to undergo programmed cell death<sup>238</sup> through up-regulation of the cellular antiapoptotic oncogene, bcl-2.<sup>239,240</sup> Unlike HIV-negative lymphomas of similar histology in which translocations of bcl-2 are often found,<sup>221,241,242</sup> rearrangements of bcl-2 are not generally found in peripheral AIDS-NHLs.<sup>212</sup> However, bcl-2 may be densely expressed in some cases.<sup>243</sup> EBNA-2 expression has been reported to be associated with extranodal disease,<sup>244</sup> which is a prominent feature of the large cell AIDS-NHLs.

SNCCCL is more likely to occur earlier in the course of HIV infection in younger patients with relatively preserved CD4 cell counts. Only a minority of cases (25% to 40%) express EBV.<sup>209,245</sup> If EBV is found in SNCCCL, EBNA-2 and LMP-1 are not typically expressed, as is also observed in EBV-positive cases of (sporadic) Burkitt's lymphoma in the general population. The lack of EBV protein expression could contribute to the ability of tumor cells to escape the relatively intact immune surveillance in these patients.

The different patterns of EBV expression found in these lymphomas may relate in part to the observation that the synthesis of various EBV transformation-associated proteins is regulated by different cellular factors depending on the differentiation stage of the host cell.<sup>233</sup> A number of these tumors express BCL-6, a protein selectively expressed by germinal center (GC) B cells, and it has been suggested that these lymphomas may originate from the GC.<sup>246</sup> Deregulated BCL-6 expression may contribute to lymphomagenesis by preventing post-GC differentiation.<sup>247,248</sup> Syndecan-1 (syn-1) is a proteoglycan that is not expressed in GC B cells, but it is expressed in specific subsets of post-GC B cells, including immunoblasts and plasma cells. It is absent on circulating and peripheral B lymphocytes, but is reexpressed on their differentiation into immobilized plasma cells.<sup>249</sup> BCL-6 and syn-1 appear to segregate into two major phenotypic subsets, suggesting that tumors displaying the BCL-6+/syn-1– phenotype originate from GC-related B cells, whereas tumors displaying the BCL-6–/syn-1+ phenotype derive from post-GC B cells. The differential expression of BCL-6 and syn-1 appears to be related to expression of LMP-1. Among EBV-infected AIDS-NHL, expression of the LMP-1 antigen can be found only in BCL-6–/syn-1+ tumors, suggesting that the GC stage is not permissive for LMP-1 expression, and that tumors expressing LMP-1 derive from more mature post-GC B cells. Cases with immunoblastic plasmacytoid features and LMP-1 expression thus appear to be BCL-6–/syn-1+ with post-GC histiogenic origin, whereas most SNCCCL and large non-cleaved cell lymphomas appear to originate from more immature GC B cells expressing BCL-6+/syn-1– and LMP-1–. Such considerations may provide insight into the complicated pattern of EBV expression in NHL.

Clustering of the protooncogenes c-myc, BCL-6, and the tumor suppressor gene product p53 is also predictable according to histologic subtype: C-myc activation is seen among 65% to 100% of SNCCCL cases, but rarely in large cell lymphomas.<sup>245</sup> Inappropriately regulated expression of c-myc, which can be independent of EBV infection in AIDS-NHL,<sup>245</sup> may contribute to lymphomagenesis by causing the down-regulation of lymphocyte function-associated antigen-1 adhesion molecules and loss of B-cell adhesion to cytotoxic T cells and natural killer cells.<sup>250</sup> This may provide another mechanism for malignant cells to escape immune surveillance. BCL-6 rearrangements occur in approximately 20% of large cell lymphomas, but are not found in SNCCCL. p53 overexpression is restricted to SNCCCL, possibly resulting in disruptions in programmed cell death.<sup>245</sup> A small number of cases of both large cell and SNCCCL have been observed to express activated RAS, potentially distinguishing these tumors from those found in the immunocompetent host.<sup>245</sup>

The Burkitt-like AIDS-NHL may be a distinct clinical entity from the HIV-negative morphologic counterpart. Most AIDS–Burkitt-like lymphomas appear to have a molecular pattern similar to that of typical Burkitt's lymphoma: The c-myc oncogene appears to be rearranged in the majority of cases but not the bcl-2 gene,<sup>216</sup> whereas in HIV-negative Burkitt-like lymphomas, rearrangement of c-myc is uncommon, and the bcl-2 gene is rearranged in 30% of cases.<sup>251</sup> However, some features clearly differentiate AIDS–Burkitt-like lymphomas from AIDS-Burkitt's lymphomas. The frequency of EBV infection in AIDS–Burkitt-like lymphomas (80%) is similar to that in diffuse large cell lymphoma, but the pattern of viral latency is similar to that seen in Burkitt's lymphoma (i.e., no LMP-1 or EBNA-2 expression) in approximately 60% of the cases. Also, patients with AIDS–Burkitt-like lymphomas usually have a relatively low CD4 count, similar to that seen in the diffuse large cell immunoblastic lymphomas. However, Burkitt-like lymphomas do not seem to share the predilection for CNS involvement associated with Burkitt's lymphoma. Burkitt-like lymphomas may be a morphologic variant in a continuum from Burkitt's lymphoma to diffuse large cell lymphomas in the context of the range of immunodepletion that occurs in HIV-infected patients.

## PRIMARY EFFUSION LYMPHOMA

PEL, also termed *body cavity lymphoma*, is a rare entity, and as the name implies, these tumors typically grow mainly in the pleural, pericardial, and abdominal cavities as lymphomatous effusions.<sup>217,252,253,254</sup> and<sup>255</sup> Sometimes, however, the initial presentation can be nodal, and in some cases the tumor can involve soft tissue or the gastrointestinal tract. PELs exhibit distinctive clinical and biologic features, including immunoblastic morphology and indeterminate immunophenotype. Monoclonality can be established by the finding of clonal immunoglobulin gene rearrangements indicating late B-cell genotype derivation that may have undergone antigenic selection.<sup>203,256</sup> These tumors are universally associated with KSHV/HHV-8 and appear to follow the same epidemiologic pattern as KS (i.e., the greatest frequency of occurrence is among those who acquire HIV infection from an individual who has sex with other men).<sup>253</sup> The majority of PELs are also EBV positive, although some PEL cell lines are EBV negative, and these usually lack rearrangements in c-myc.<sup>253,257,258,259</sup> and<sup>260</sup> There is evidence that VEGF is involved in the pathogenesis of this tumor.<sup>261</sup> KSHV/HHV-8 up-regulates production of VEGF, and SCID/beige mice inoculated intraperitoneally with BCBL-1 cells (an KSHV/HHV-8 infected PEL cell line) develop effusion lymphoma. Treatment with neutralizing anti-VEGF antibody inhibits formation of the lymphoma.<sup>262</sup> While the role of KSHV/HHV-8 is unclear, this virus may have a direct transforming role in PEL. In particular, viral BCL-2, IL-6, and cyclin D homologues may serve to delay apoptotic cell death or stimulate lymphomatous cell proliferation.<sup>54,59,259</sup> These observations may provide insights toward developing novel therapeutic strategies for this rare tumor. These tumors are often quite resistant to cytotoxic chemotherapy.

## CLINICAL PRESENTATION AND STAGING OF PERIPHERAL LYMPHOMAS

HIV-related NHLs frequently present as advanced stage 3 or 4 disease and behave aggressively with unusual patterns of organ involvement.<sup>163,167,263,264</sup> The majority of patients present with either a rapidly growing mass lesion or the development of systemic B symptoms (unexplained fever, drenching night sweats, or unexplained weight loss in excess of 10% of the normal body weight).<sup>265</sup> Extranodal involvement is common, including the bone marrow (25% to 40%), gastrointestinal tract (26%), and the CNS (17% to 32%).<sup>167,168,211</sup>

In addition to the standard NHL staging for HIV-negative patients, CD4 cell count, HIV viral load, and CNS assessment should be performed on all HIV-infected patients with lymphoma. Computed tomography of the brain with contrast is adequate to assess for parenchymal brain lesions, but magnetic resonance imaging with gadolinium has the potential advantage of revealing evidence of leptomeningeal involvement by lymphoma.<sup>266</sup> Cytologic examination of the cerebrospinal fluid should be performed in all cases.

NHL is significantly associated with a worse prognosis than many other complications of AIDS.<sup>267</sup> For systemic lymphomas, the factor most correlated with prognosis

is the CD4 cell count. With standard therapy, patients with fewer than 100 CD4 cells/ $\mu$ L have a median survival of approximately 4 months, whereas those with 100 or greater CD4 cells/ $\mu$ L have a median survival of 11 months.<sup>263,268</sup> Other factors associated with poor outcome are age over 35 to 40 years, high serum lactate dehydrogenase levels, presence of extranodal sites, intravenous drug use, and preexisting AIDS diagnosis.<sup>269,270</sup> The international prognostic index for lymphoma is thus of some utility in AIDS-lymphomas, although its use is not widely reported.<sup>271</sup> In a multivariate analysis of 192 patients, patients who had none or one of such factors had a median survival of 46 weeks, and 30% were alive at 144 weeks, suggesting longer term survival can be achieved in the subset of patients without unfavorable characteristics.<sup>272</sup> With the advent of PAT, it is quite possible that overall prognosis in AIDS-NHL will improve.

## TREATMENT OF PERIPHERAL ACQUIRED IMMUNODEFICIENCY SYNDROME LYMPHOMAS

Nearly two decades into the AIDS epidemic, optimal therapy for AIDS-NHL remains incompletely defined (Table 50.1-5). As noted previously, patients who develop AIDS-NHL continue to have a poor prognosis in spite of efforts to sort out the role of dose-intensive chemotherapy regimens for the immunocompromised host. The rapid improvements in therapy for the underlying HIV infection complicate the ability to compare clinical trials conducted at different times. To put this in perspective, it is instructive to consider some of the issues that have motivated the different treatment strategies for AIDS-NHL.

Regimen	Enrolled Patients	Median Survival (CD4 Cells/ $\mu$ L)	Complete Response Rate (%)	Median Overall Survival for Survival (%)	Author
Low-dose standard dose m-BACOD	175	88 (low)	41 (low)	5.5	Epstein et al. <sup>282</sup>
MACOP-B	141	227	61	5.16	Giordano et al. <sup>289</sup>
Low-dose standard dose CHOP plus HAART	11	175	35 (low)	Not available	Rosen et al. <sup>286</sup>
Intensive CDE	11	17	62	33 (not available)	Sprunt et al. <sup>287</sup>
Intensive EPOCH	11	201	71	25, 175, or 22 months (median, not yet reached)	Lillo et al. <sup>294</sup>

m-BACOD, doxorubicin, cyclophosphamide, bleomycin, and prednisone; CDE, cyclophosphamide, doxorubicin, and etoposide; CHOP, cyclophosphamide, doxorubicin, vincristine, and prednisone; EPOCH, etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin; HAART, highly active antiretroviral treatment; m-BACOD, methotrexate, bleomycin, doxorubicin, and cyclophosphamide; doxorubicin, cyclophosphamide, bleomycin, and prednisone.

**TABLE 50.1-5.** Selected Regimens and Outcomes for Acquired Immunodeficiency Syndrome–Associated Non-Hodgkin's Lymphoma

At the beginning of the AIDS epidemic, oncologists who treated AIDS-NHL recognized that patients frequently tolerated multiagent chemotherapy poorly, and that responses occurred in only a low percentage of patients and were often of short duration.<sup>211,273,274</sup> Importantly, in the early 1980s, prophylaxis against opportunistic infections had not yet been defined as standard practice,<sup>275</sup> and PAT was not available. At that point in time, second- and third-generation lymphoma regimens such as m-BACOD, ProMACE-CytaBOM, and MACOP-B were being explored in AIDS-NHL based on preliminary evidence that they may have been more efficacious in the treatment of lymphoma.<sup>276,277,278</sup> and <sup>279</sup> However, these regimens themselves were observed to sometimes cause opportunistic infections such as *Pneumocystis carinii* pneumonia in HIV-negative patients.<sup>279,280</sup> In 1993, an intergroup randomized trial failed to show that these regimens were more effective than cyclophosphamide, hydroxydaunorubicin (Adriamycin), Oncovin, and prednisone (CHOP) in HIV-negative patients and were perhaps associated with greater toxicity.<sup>281</sup> Before that report, based on early observations that these lymphoma regimens were toxic in AIDS patients, investigators began to consider lower dose modifications of the second- and third-generation lymphoma regimens in an attempt to reduce the toxicity and immunodeficiency caused by these regimens.<sup>282</sup> A large randomized trial comparing standard- with low-dose m-BACOD was completed in 1997, showing equivalent results in both groups, with complete responses ranging from 41% to 52%, but with a lower incidence of febrile neutropenia in the low-dose group.<sup>283</sup> However, the incidence of opportunistic infections was equivalent in both groups, and the low-dose arm was not shown to yield an improved survival outcome. Also, this study was not designed or adequately powered to determine if the subset of patients with more favorable HIV prognostic characteristics might have benefited from the higher dose intensity of the standard dose m-BACOD.<sup>284</sup> This issue is potentially important, as some studies of aggressive lymphomas in HIV-negative patients have suggested that chemotherapy dose intensity is associated with curative potential.<sup>285</sup> However, the strategy of low-dose chemotherapy clearly resulted in better quality of life with fewer treatment-related hospitalizations for a substantial proportion of the patients treated. In addition, several small studies using dose-reduced CHOP in AIDS-NHL have generally shown equivalent efficacy to standard dose CHOP, although the numbers are relatively small for assessment.<sup>286,287</sup> and <sup>288</sup>

At least one study suggests that more intensive chemotherapy may benefit the subset of patients with favorable prognostic factors. In a prospective multicenter study, 141 patients, with a median CD4 cell count of 227/ $\mu$ L, were treated with three cycles of doxorubicin, 75 mg/m<sup>2</sup>; cyclophosphamide, 1200 mg/m<sup>2</sup>; vindesine, 2 mg/m<sup>2</sup> for 2 days; bleomycin, 10 mg for 2 days; and prednisolone, 60 mg/m<sup>2</sup> for 5 days, followed by a consolidation phase of high-dose methotrexate plus leucovorin, ifosfamide, etoposide, asparaginase, and cytarabine (LNH84) and CNS prophylaxis with intrathecal methotrexate.<sup>289</sup> Zidovudine was started after chemotherapy. Eighty-nine patients (63%) achieved complete remission and 19 (13%) partial remission. With a median follow-up of 28 months, median survival and disease-free survival were 9 and 16 months, respectively. Twenty-three patients subsequently died of opportunistic infections while in complete remission. This study, conducted in the era before PAT, demonstrates that a subset of patients with AIDS-NHL were able to tolerate aggressive antilymphoma therapy and appeared to do reasonably well in terms of lymphoma-free survival. This study also highlights the potential importance of improved anti-HIV therapy in patients free of lymphoma.

A greater understanding of HIV disease has resulted in the standard prophylaxis against opportunistic infections and more effective treatment of the underlying HIV infection. These therapies have translated into improved survival and quality of life for patients with HIV disease. Prophylaxis for opportunistic infections clearly plays a major role during cytotoxic chemotherapy in such patients, but it is as yet unclear how advances in antiretroviral therapy will affect the treatment outcome of AIDS-NHL. To explore this issue, investigators have begun to administer newer antiretroviral regimens along with the chemotherapy regimens.<sup>204,290</sup> This is a complicated issue and as yet only scant data exist to guide best use of these drugs during chemotherapy. Preliminary results were recently reported from an NCI-sponsored trial conducted by the AIDS Malignancy Consortium. This trial involved 63 patients with a median CD4 cell count of 136/ $\mu$ L who received either modified or full-dose CHOP while receiving PAT with stavudine, lamivudine, and indinavir.<sup>288</sup> Sixty percent of patients had stage 3 or 4 lymphoma. HIV viral loads were stable, with many remaining below the level of detection for the test throughout the course of chemotherapy. The overall complete response rate for the trial was equivalent between the two dose groups: 33% for the modified and 32% for the full-dose group. These rates are similar to those previously reported without PAT,<sup>274,283,286</sup> although such comparisons may be of limited value. Pharmacokinetic data were collected and compared with historic controls. Elimination of cyclophosphamide was decreased from 70 mL/min/m<sup>2</sup> in historic controls to 39 mL/min/m<sup>2</sup> in the study patients, but without apparent effect on toxicity of the regimen. Doxorubicin elimination and the area under the time concentration curve of indinavir were similar to that in previous studies of these agents. These results highlight the feasibility of administering antineoplastic and antiretroviral drugs concomitantly, in spite of the potential complicated pharmacokinetics involved in this approach. At the same time, they show that there may be pharmacokinetic interactions and that there is room for improvement in the therapy of this disease.

In a study of 12 patients with AIDS-NHL treated with 96-hour continuous intravenous infusion of cyclophosphamide, doxorubicin, and etoposide (CDE) plus filgrastim, patients also received saquinavir and one or two nucleoside analogue anti-HIV drugs. Severe mucositis occurred in 8 of 12 patients (67%) treated with CDE plus saquinavir, which is more than the 3 in 25 (12%) rate of this toxicity in a previous trial of CDE without saquinavir.<sup>291</sup> This raises the possibility that pharmacokinetic interactions may have contributed to these different rates of toxicity. In addition, such approaches may affect the consistency of antiretroviral dosing.<sup>287,291</sup> In another trial of CDE, plasma etoposide levels were reported to be decreased by 11% to 38% on chemotherapy cycles given with didanosine compared with cycles without didanosine administration.<sup>292</sup> These results serve as a reminder that there may be complex and unexpected drug interactions when one attempts to combine complex chemotherapy regimens with complex anti-HIV regimens and that these interactions may affect the outcome of either therapy.

Preliminary results from a study at the NCI showed that 19 of 24 patients (79%) with HIV-associated NHL had a complete response using a modification of chemotherapy with etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin (EPOCH).<sup>293,294</sup> Cyclophosphamide was initially dosed according to CD4 count (187 mg/m<sup>2</sup> for CD4 cells less than 100/ $\mu$ L; 375 mg/m<sup>2</sup> if CD4 cells 100/ $\mu$ L or greater), and then adjusted up or down each cycle (by 187 mg/m<sup>2</sup> to a maximum of 750 mg/m<sup>2</sup>) depending on the neutrophil nadir. Antiretroviral therapy was suspended until completion of chemotherapy (maximum of six cycles), and then restarted. The median progression-free survival and overall survival had not been reached, but were 83% and 79%, respectively, at 22.5 months. Over 90% of the planned maximum dose intensity of doxorubicin [10 mg/m<sup>2</sup>/24 hours continuous intravenous infusion (CIV) for 4 days], etoposide (50 mg/m<sup>2</sup>/24 hours CIV  $\times$  4 days), and vincristine (0.4 mg/m<sup>2</sup>/24 hours CIV  $\times$  4 days), and 56% of the cyclophosphamide was administered with relatively little associated toxicity. Febrile neutropenia occurred in only 12% of the cycles administered. No new opportunistic infections developed in these patients despite the withdrawal of antiretroviral treatment on

initiation of chemotherapy (*Pneumocystis carini* pneumonia prophylaxis was administered to all patients, and *Mycobacterium avium-complex* prophylaxis to at-risk patients). All patients who had responded to antiretroviral therapy before development of AIDS-NHL responded again to PAT when it was subsequently started postchemotherapy. CD4 counts recovered to baseline within 12 months after PAT reinstatement.<sup>294</sup> While this strategy may have the advantage of optimizing dose intensity and protecting patients against development of resistant HIV, some physicians may feel uncomfortable withdrawing antiretroviral therapy (even for a relatively short period of time), and the results require further study.

A high percentage (15% to 20%) of HIV-associated lymphomas have involvement of the CNS at presentation.<sup>263</sup> CNS progression is a potentially important cause of mortality in this setting,<sup>274</sup> and as patients potentially live longer with better antiretroviral treatment after chemotherapy, CNS relapse may become a relatively more important issue. Therefore, in HIV-associated lymphomas, routine CNS prophylaxis with intrathecal methotrexate or cytosine arabinoside should be considered standard practice.<sup>187,295</sup>

Novel approaches to AIDS-NHL are clearly needed. Infusional chemotherapy regimens appear to have a favorable toxicity profile and may be useful in AIDS-NHL, but comparative trials with conventional intravenous bolus regimens have not been conducted. Until such data are available, it is unclear whether the encouraging data from small phase II trials of CDE and etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin truly represent an advance in the treatment of this condition. There is current interest in the potential role of the anti-CD20 monoclonal antibody, rituximab (Rituxan) in AIDS-NHL, and trials are currently planned to test this approach. Interest has also evolved in the use of stem cell transplantation in AIDS-NHL. Both autologous and allogeneic transplantation, with transfer of HIV-resistant genes into the marrow infusate are areas of interest being studied in clinical trials. In a collaborative trial being conducted by investigators at the National Institutes of Health, nonmyeloablative matched-sibling donor allogeneic transplantation is being studied with encouraging initial results.<sup>296</sup>

## PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA IN ACQUIRED IMMUNODEFICIENCY SYNDROME

### OVERVIEW AND PATHOLOGY

PCNSL makes up approximately 19% of AIDS-NHLs, which is substantially higher than that in non-AIDS-NHL (approximately 1%).<sup>165,222,297</sup> The frequency of PCNSL is more than 3000-fold higher in patients with AIDS than in the general population, occurring in up to 12% of HIV-infected individuals.<sup>298</sup> From 20% to 30% of CNS lesions in patients with AIDS are ultimately found to have PCNSL.<sup>5,299,300</sup> PCNSL is the second most common mass lesion found in patients with AIDS, and the most common brain tumor in this population.<sup>301,302</sup> The survival of patients with HIV-associated PCNSL is 2 to 5 months, which is substantially shorter than that in the non-HIV-infected population with PCNSL.<sup>298,303</sup> PCNSL occurs most frequently in patients with a CD4 cell count less than 50/ $\mu$ L and can occur in the setting of other CNS pathology such as toxoplasmosis.<sup>163,303,304</sup>

Definitive diagnosis of focal brain lesions in AIDS patients requires biopsy and yields a greater than 92% diagnostic rate.<sup>305</sup> However, there is often some reluctance to do this procedure. While stereotactic biopsy is generally safe, the location of some lesions poses technical challenge and can introduce potential morbidity to the patient as well as risk to the surgical team.<sup>306</sup> Therefore, in many medical centers it has become standard practice to treat AIDS patients who have focal brain lesions and antitoxoplasmosis antibodies empirically with antitoxoplasmosis therapy, reserving biopsy for those patients who are seronegative for antitoxoplasma antibodies or fail to respond to treatment.<sup>307</sup> However, delay in diagnosis can adversely affect survival in AIDS-PCNSL.<sup>308</sup> Such factors necessitate consideration of alternative, less invasive diagnostic modalities.

Computed tomography or magnetic resonance imaging scans usually demonstrate single or multiple contrast-enhancing masses that are not reliably distinguishable from toxoplasmosis or other CNS processes. Preliminary studies suggest that <sup>18</sup>F-fluoro-2-deoxyglucose and positron emission tomography may have some utility in distinguishing malignant and nonmalignant conditions, since high FDG uptake most likely represents a malignant process.<sup>309</sup> Also, there is some evidence that thallium 201 single photon emission computed tomography might be a useful, noninvasive method for differentiating intracranial lymphoma from nonneoplastic lesions in patients with AIDS.<sup>310,311</sup> However, these modalities have not been confirmed in large studies, and a high degree of intercenter variability in procedure may reduce the reliability of these techniques.

It has been shown that detection of CSF EBV DNA by polymerase chain reaction (PCR) in HIV-infected patients is reliably associated with PCNSLs,<sup>312</sup> lending support for the use of this assay as a diagnostic test for this condition. The basis for this approach is the observation that nearly all HIV-associated PCNSLs are associated with EBV infection.<sup>313</sup> In a series of 95 patients, including 40 patients with AIDS-PCNSL, the sensitivity and specificity of PCR for EBV DNA detection in lumbar CSF were 80% and 100%, respectively.<sup>312</sup> Lumbar puncture and subsequent assessment of EBV DNA would have allowed a correct diagnosis in 63.2% of patients with AIDS-PCNSL and excluded this diagnosis in 76.3% of patients without lymphoma (because EBV DNA was not detected).<sup>312</sup> Another group reported an even higher diagnostic confidence of AIDS-related focal brain lesions using minimally invasive procedures.<sup>314</sup> By combining CSF EBV DNA detection by PCR with <sup>201</sup>Tl single photon emission computed tomography, the presence of increased uptake, positive EBV DNA, or both had 100% sensitivity and 100% negative predictive value. Because PCNSL likelihood is extremely high in patients with hyperactive lesions and positive EBV DNA, brain biopsy may be avoided, and patients could promptly undergo definitive therapy.<sup>314</sup>

Most cases of PCNSL are of immunoblastic morphology with plasmacytic differentiation, large cell lymphomas with immunoblastic features, or are centroblastic polymorphic lymphomas.<sup>223</sup> SNCCCL are rare. EBV is consistently detected by PCR. The bcl-2 oncoprotein and LMP-1 of EBV are frequently strongly expressed. In a study of 11 AIDS-related primary brain lymphomas, LMP-1 and bcl-2 were expressed in all cases but one,<sup>315</sup> potentially implicating their involvement in CNS lymphomagenesis. Expression of mutated p53, or rearrangement of bcl-2 or the c-myc oncogene is not reported.<sup>316,317</sup> The precise histogenetic derivation and the molecular pathogenesis of PCNSL is poorly understood. Evidence suggests that these tumors may be segregated into two major biologic categories based on the expression pattern of BCL-6, LMP-1, and BCL-2.<sup>318</sup> In an analysis of 26 AIDS-related and 23 AIDS-unrelated PCNSL cases, expression of BCL-6 protein, which is restricted to GC B cells throughout physiologic B-cell maturation, was detected in all of the AIDS-unrelated PCNSL. However, only 56% of the AIDS-related cases expressed BCL-6. Expression of BCL-6 was mutually exclusive with expression of EBV-encoded LMP-1, and with few exceptions, of BCL-2. All but one PCNSL expressed hMSH2, which among mature B cells selectively stains GC B cells. Thus, a proportion of AIDS-PCNSLs may represent a divergent biologic spectrum from their non-AIDS counterparts.

### TREATMENT

Treatment modalities for immunocompetent patients are applied to patients with AIDS-PCNSL, but generally with substantially more toxicity and poorer results. PCNSL is highly responsive to whole brain irradiation, and a substantial proportion of patients can be expected to have complete tumor eradication; however, they have a high likelihood of subsequently succumbing to opportunistic infection<sup>319</sup> or recurrent lymphoma.<sup>320</sup> In a study of 55 AIDS patients with biopsy-proven primary CNS lymphomas, all tumors responded both clinically and radiologically to whole brain radiation therapy consisting of 4000 rad in 267-rad fractions over 3 weeks or an equivalent dose.<sup>319</sup> The mean duration of survival from the appearance of symptoms consistent with the mass lesion was significantly greater in patients who received radiation therapy than in those who did not (134 vs. 42 days). Autopsy findings showed that patients who did not receive radiation therapy generally died from tumor progression, whereas those who completed radiation therapy often died of opportunistic infections. Such observations emphasize the need for early diagnosis and treatment, and for treatment of opportunistic infections and the underlying HIV infection.<sup>319</sup> Relapse can occur remote from the primary site, but also within the radiation port.

Experience combining chemotherapy with radiotherapy suggests that a subgroup of patients can benefit from this approach, with survival reaching over 1 year.<sup>320,321</sup> However, this is still shorter than survival in non-AIDS patients, and still only a minority of patients so treated have survival greater than 1 year.<sup>322</sup>

Surgery has no therapeutic role in PCNSL since microscopic tumor infiltration into brain parenchyma extends from the site of primary involvement.<sup>323</sup>

### EFFECT OF ANTIRETROVIRAL THERAPY ON PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA INCIDENCE

Since AIDS-PCNSL appears to be an opportunistic illness associated with profound CD4 depletion (usually occurring in patients with less than 50 CD4 cells), it might be expected that better therapy for HIV would result in a decrease in the incidence of PCNSL. A large medical records analysis showed a decrease in the incidence of PCNSL from 8.5 cases per 1000 person-years in early 1994 to 0.9 cases per 1000 person-years in late 1996 ( $P = .04$ ). This change was coincident with changes in antiretroviral treatment patterns and an increase in the use of two or more drugs from 20% to 46% of patients.<sup>75</sup> Other data support these findings.<sup>28,188</sup> However,

many patients are now developing resistance to available therapies, and it is possible that the incidence may increase in the near future. Also, it is possible that the cumulative incidence of AIDS-related lymphomas may rise as patients live longer with HIV infection. <sup>163</sup>

## HODGKIN'S DISEASE

### EPIDEMIOLOGY

Although Hodgkin's disease is not an AIDS-defining condition, its association with HIV is apparent for several reasons: it presents in HIV-infected patients with distinct clinical and biologic characteristics that distinguish it from its HIV-negative counterpart ( *primary* Hodgkin's disease); and it occurs with somewhat increased frequency among HIV-infected patients. <sup>1,324,325</sup> By contrast, many registries have indicated a slight decrease in primary Hodgkin's disease incidence in recent decades. <sup>326</sup> An eightfold excess of Hodgkin's disease in HIV-infected patients has been found by linking AIDS and cancer registry data. <sup>12</sup> However, there is some controversy over the epidemiology, as some studies have not found an increased incidence of Hodgkin's disease in areas of high prevalence for HIV infection. <sup>327,328</sup>

Overall, Hodgkin's disease of the nodular sclerosis subtype (the most frequent subtype in HIV-negative patients) has increased over time, whereas Hodgkin's disease of mixed cellularity has declined. <sup>326</sup> However, among HIV-infected patients, the most common histologic subtype is mixed cellularity, followed by lymphocyte depleted. <sup>228,329,330,331,332,333</sup> and <sup>334</sup>

### PATHOGENESIS

EBV infection appears to be more predominant among cases of HIV-associated Hodgkin's disease than in cases of primary Hodgkin's disease. <sup>334</sup> Monoclonal expansions of EBV-infected cells have been found in from 78% to 100% of HIV-related Hodgkin's disease, but in only 15% to 48% of primary Hodgkin's disease cases. <sup>227,333,335</sup> EBV-encoded LMP-1 has been demonstrated in the tumor cells in from 25% to 50% of primary Hodgkin's disease cases, but in up to 100% of both the nodular sclerosing and mixed cellularity subtypes of Hodgkin's disease in HIV-positive patients. <sup>335</sup> The pattern of EBV gene expression may favor immune escape in HIV-related Hodgkin's disease. The EBV latency C promoter drives expression of the immunodominant EBNA3s that are targeted by cytotoxic T lymphocytes. In EBV-associated Hodgkin's disease, the C promoter is inactive and the immunodominant EBNA3s are thus not expressed. <sup>336</sup> This finding may be relevant to the frequent occurrence of Hodgkin's disease in relatively immunocompetent HIV-infected patients. <sup>228,331,333</sup>

### CLINICAL PRESENTATION, TREATMENT, AND PROGNOSIS

Patients with HIV-associated Hodgkin's disease generally present at a younger age, with higher stage disease, less frequent mediastinal involvement, more frequent involvement of extranodal sites of disease, and more frequent occurrence of B symptoms compared with their HIV-negative counterparts ( *Table 50.1-6*). <sup>333</sup> These differences are more than can be accounted for by the overrepresentation of the mixed cellularity histologic subtype in HIV-associated Hodgkin's disease, <sup>331</sup> a histologic subtype that involves the mediastinum less often compared with nodular sclerosing Hodgkin's disease. Compared with AIDS-associated NHL, in which the CD4 cell count is frequently less than 100/μL, the median CD4 cell count in HIV-associated Hodgkin's disease has been reported to be over 275 cells/μL in large patient series. <sup>228,331,333</sup>

Factor	HIV-10		HIV-20		HIV-30

**TABLE 50.1-6.** Comparison of Human Immunodeficiency Virus–Associated Hodgkin's Disease and Primary Hodgkin's Disease

Prognosis is generally poorer for HIV-Hodgkin's disease than for primary Hodgkin's disease. HIV-Hodgkin's disease patients frequently have a number of features that have been associated with poor prognosis in primary non-HIV-associated Hodgkin's disease, including male sex, large number of sites involved, and mixed cellularity or lymphocyte-depleted histology. <sup>337</sup> Because of this, the precise contribution of HIV infection per se to the poor prognosis is uncertain. In general, complete response rates are relatively high with systemic chemotherapy (50% to over 80%), <sup>333,338,339</sup> although rates as low as 14% have also been reported. <sup>340</sup> Relapse of Hodgkin's disease and progression of AIDS are common, contributing to poor overall survival. The CD4 cell count at the time of diagnosis is a prognostic factor. Patients with a CD4 cell count less than 250 to 200 CD4 cells/μL have a median survival of less than 11 months, <sup>331,333</sup> whereas higher CD4 cell counts are associated with somewhat better outcome. Although most patients do not have an AIDS diagnosis when they develop HIV-Hodgkin's disease, 48% to 71% develop AIDS within 3 years after treatment for HIV-Hodgkin's disease, <sup>331,333</sup> compared with development of AIDS in 22% for most other HIV-infected patients with similar CD4 cell counts. <sup>341</sup> These findings underscore the need for skilled management of the underlying HIV.

Most patients with HIV-Hodgkin's disease are treated with conventional chemotherapy regimens (i.e., radiotherapy, mechlorethamine, vincristine, procarbazine, and prednisone; doxorubicin, bleomycin, vinblastine, and dacarbazine; or alternating the two regimens; epirubicin, bleomycin, vinblastine, and prednisone; or combined modality therapy). <sup>329,338,342</sup> Because of the occurrence of multiple poor prognostic factors in HIV-Hodgkin's disease, most oncologists advocate use of systemic chemotherapy in all clinically staged patients. The CNS is rarely involved, so CNS prophylaxis is not commonly used. Strategies to improve outcome have included the use of antiretrovirals and colony-stimulating factors, but before the use of protease inhibitor anti-HIV therapy, outcomes were essentially equivalent among trials. <sup>338,339,343</sup> It is hoped that treatment outcomes with PAT may change these grim statistics.

## ANOGENITAL CANCERS IN HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Cervical cancer was added to the CDC list of AIDS-defining conditions in 1993. <sup>21</sup> Anal cancer, though not an AIDS-defining condition, is also relatively prevalent among HIV-infected women and homosexual and bisexual men with HIV infection. <sup>344</sup> These cancers are associated with human papilloma-virus (HPV) infection <sup>345</sup> and appear to be more aggressive in HIV-infected than in non-HIV-infected individuals. It is thus recommended that HIV-infected women undergo regular periodic cervical Papanicolaou (Pap) testing. The CDC has recommended cytologic screening as part of the initial evaluation when HIV seropositivity is diagnosed. The CDC recommends that if the initial Pap smear is normal, at least one additional evaluation should be repeated within 6 months. <sup>346</sup> If the repeat result is normal, then reevaluation should be done at least annually. If the initial or follow-up Pap smear shows severe inflammation with reactive squamous cellular changes, another Pap smear should be collected within 3 months. If the initial or follow-up Pap smear shows squamous intraepithelial lesions or atypical squamous cells of undetermined significance, the woman should be referred for a colposcopic examination of the lower genital tract and, if indicated, undergo colposcopically directed biopsies. HIV infection is not an indication for colposcopy among women with normal Pap smear results. Because of the common occurrence of HPV-associated cytologic abnormalities in the anal mucosa of both HIV-infected women and homosexual men, some experts have suggested that routine periodic cytologic examination of the anal mucosa should also be considered in high-risk individuals. <sup>6,347,348</sup> and <sup>349</sup> A model to estimate the clinical benefits and cost-effectiveness of screening HIV-positive homosexual and bisexual men for anal squamous intraepithelial lesions and anal squamous cell cancer indicates that Pap screening every 1 to 2 years beginning in early HIV disease would result in an incremental cost-effectiveness ratio of \$13,000 to \$16,000 per quality-adjusted life year saved, and thus offers quality-adjusted life expectancy benefits at a cost comparable with other accepted clinical preventive interventions. <sup>350</sup>

## CERVICAL CANCER

### Epidemiology

Squamous intraepithelial lesions, vulvovaginal condyloma acuminata, and anal intraepithelial neoplasia are seen with approximately fivefold increase in HIV-infected women compared with women not infected with HIV.<sup>6,351,352</sup> The prevalence of cervical intraepithelial neoplasia has been reported to range from 11% to 29% overall for HIV-infected women,<sup>6,353</sup> which may be higher than the 4% to 13% prevalence in HIV-negative women.<sup>354,355</sup> Among sexually active women, HIV-infected women have a substantially higher rate of persistent HPV infections of the types most strongly associated with intraepithelial lesions and invasive cervical cancer (i.e., HPV-16 or HPV-18).<sup>356,357</sup> HPV infection is associated with development of squamous intraepithelial lesions<sup>358</sup> and increased prevalence of HPV infection among HIV-infected women may explain the increased incidence of squamous intraepithelial lesions in this population.<sup>359</sup> Greater immune suppression is associated with increased incidence of high-grade cervical intraepithelial neoplasia in HIV-infected women, who may also present with invasive cervical cancer at a younger age and with more aggressive advanced stage disease compared with HIV-seronegative women.<sup>8,360</sup> This suggests that progression of HPV-associated dysplasia to frank invasive anogenital cancers may be more rapid in this population. Women with a CD4 cell count less than 500/ $\mu$ L appear to be at greater risk for poor outcome.<sup>360</sup> The incidence of invasive cervical cancer appears unchanged since the advent of PAT,<sup>75</sup> but it is unclear whether this is due to reduced usage of these medications among the women at highest risk for both HIV and HPV, or some other factor. Likewise, the effect of PAT on the incidence of anal squamous intraepithelial lesions is as yet unclear, but the data suggest that PAT may not result in regression of these lesions.<sup>361</sup>

Progressive immune deficiency may increase the risk of persistent oncogenic HPV infection,<sup>347,362</sup> but the association between HIV infection and HPV-associated anogenital disease could also be related to molecular mechanisms of HIV modulation of HPV expression.<sup>363</sup> For example, HIV Tat increases HPV-16 upstream regulatory region-directed chloramphenicol acetyltransferase expression driven by the native HPV-16 promoter (P97). Tat also reverses E2-mediated repression of P97-directed chloramphenicol acetyltransferase expression. Treatment of cells with HIV, Tat, or IL-6 modulates the expression of naturally integrated HPV-18 genes at the transcriptional level. However, in cell lines, the translation of HPV-18 proteins seems to occur only during HIV coinfection.<sup>364,365</sup> HIV Rev and Rev-responsive elements appear to modulate expression of the HPV type 16 L1 protein in epithelial cells.<sup>366,367</sup>

Among women infected with HPV-16 who have not developed cervical intraepithelial neoplasia, the amount of HPV-16 DNA in cervicovaginal lavage is significantly increased in those who are infected with HIV.<sup>368</sup> Consistent with this thesis is the observation that women with HIV viral loads over 10,000 copies per milliliter are at relatively higher risk of HPV infection-related abnormal PAP smear results.<sup>369</sup> Also, HPV appears to be more persistent in the anal mucosa of HIV-infected individuals.<sup>370</sup> Thus, it appears that HIV may be a cofactor for the oncogenic effects of HPV.

### Therapy

Standard therapy for preinvasive cervical neoplasia, including cryotherapy, laser therapy, cone biopsy, and loop excision, appears to be somewhat less effective in women with HIV infection due to the twofold higher frequency of recurrence even among those with high CD4 cell count.<sup>371</sup> The lower the CD4 count, the higher the risk for recurrence. Preliminary data suggest that early preinvasive lesions can regress with effective antiretroviral therapy,<sup>372</sup> and that PAT reduces recurrence and progression following standard excisional therapy.<sup>373</sup>

Invasive cervical cancer should be approached with the same principles of oncologic management that guide treatment of cervical cancer in HIV-negative patients. Patients with well-controlled HIV infection and relative immune preservation can be expected to have outcomes similar to that of HIV-negative women. Patients with advanced HIV disease may be more intolerant of the myelosuppressive effects of radiation therapy and combination chemotherapy. When such therapy is administered concomitantly with antiretroviral therapy, potential for overlapping toxicity of the various agents should be considered in the therapeutic plan. Following surgery, recurrence is common.<sup>374</sup>

## ANAL CANCER

Evidence of HPV infection of the anal canal and anal cancer and the immediate precursor lesions, high-grade anal intraepithelial neoplasia, are common among HIV-infected women<sup>6</sup> and among men who have sex with men, especially those with HIV or immunosuppression.<sup>347,375</sup> HPV infection of the anal epithelium has been reported to be double that of cervical and the prevalence of anal cytologic abnormalities in HIV-infected women have been reported to be 14% to 27%<sup>6,352</sup> compared with 7% in HIV-negative women.<sup>352</sup> Among men, a longitudinal study conducted of 287 HIV-seronegative and 322 HIV-seropositive men attending a community-based clinic revealed anal HPV DNA at entry among 91.6% of men with HIV and 65.9% of men without HIV.<sup>370</sup> History of recent anal warts predicted for HPV DNA in all men. Anal squamous intraepithelial lesions do not appear to regress in patients receiving PAT, but among those with high CD4 cell counts the effect appears to be variable.<sup>376</sup>

For invasive anal cancer, standard combined chemotherapy and radiation appears to effectively control disease in most patients.<sup>377,378</sup> Patients with CD4 counts less than 200/ $\mu$ L appear more likely to suffer treatment-related toxicity including cytopenias, intractable diarrhea, or moist desquamation requiring hospitalization or a colostomy either for a therapy-related complication or for salvage. Patients with CD4 of 200/ $\mu$ L or greater appear to have better disease control with acceptable morbidity.

## FUTURE DIRECTIONS

Most AIDS-associated cancers are virally mediated neoplastic processes. In this regard, HIV can play a varied role. It can induce an immunosuppressed host in which oncogenic viral infection and opportunistic neoplasia can develop relatively unchecked, and it can serve to stimulate the immune system to secrete cytokines that promote cellular proliferation and oligoclonal expansions of cells infected with a variety of known oncogenic viruses. Molecular interactions between HIV-related proteins (or factors induced by HIV) and genomic sequences in some of these viruses may modulate their oncogenic potential. Many AIDS-associated cancers thus appear to be preventable. However, as with other cancers, it is unlikely that behavioral prevention alone will eliminate these epidemic neoplasms. Great strides in the treatment of HIV infection have been made, although it is too soon to determine the ultimate effect of these advances on opportunistic neoplastic disease. The greater understanding of the virologic and molecular basis of these cancers may provide opportunities for advancement in prevention and treatment through antiangiogenesis approaches, antiviral-, vaccine-, and immune-based therapies. Research in AIDS malignancies has the potential to affect a number of other important fields in oncology, including general tumor angiogenesis, viral oncogenesis, immunologic control of tumors, and molecular pathogenesis of tumors. This should prove to be a fruitful area of research over the next decade.

#### INTRODUCTION

The transplantation of hematopoietic stem cells to restore bone marrow function after high-dose cytotoxic therapy for malignant and nonmalignant diseases and the surgical implantation of an allogeneic solid organ to restore organ function have become increasingly effective therapeutic modalities. The survival of patients undergoing hematopoietic stem cell and solid organ transplantation has improved as a result of more effective prophylaxis and treatment of infections in the early posttransplant period and the introduction of refined immunosuppressive regimens for preventing or treating graft-versus-host disease (GVHD) and graft rejection, respectively.<sup>1,2,3,4,5,6</sup> and <sup>7</sup> As larger numbers of patients are being cured of their underlying disease with transplantation, late complications, including the development of a malignancy, have assumed greater importance in the medical management of transplant patients.

The development of registries that collect data on large numbers of patients who have received hematopoietic stem cell or solid organ transplants has provided a mechanism to identify the late development of malignancies in transplant recipients.<sup>8,9</sup> The method most commonly used for analysis of the risk of a new malignancy is the standardized incidence ratio, which refers to the incidence of the malignancy observed in patients who have undergone transplantation compared with the expected incidence in the general population of the same age and gender. In the 1980s and 1990s, large numbers of patients undergoing hematopoietic stem cell transplantation (HSCT) and solid organ allografting have been followed, and several malignancies that occur with increased frequency compared with the general population have been identified.

#### IMMUNE SURVEILLANCE AND TUMOR DEVELOPMENT

It has been hypothesized that the host has a natural immunologic resistance against the development of cancer and that the prolonged or intense immunosuppression that is administered to transplant recipients would result in the frequent development of tumors. Class I and II major histocompatibility complex (MHC) molecules expressed on the surface of cells bind cellular peptides for presentation to CD8+ and CD4+ T cells, respectively, and this provides a mechanism whereby T cells, which are essential for protecting the host from virus infection, could also recognize and eliminate cells that have developed mutations that induce malignant transformation. Studies have shown that many common tumors in humans do present antigens to T cells, but there has been little direct evidence to support a role for immune surveillance in the development of these cancers.

Although immune surveillance does not appear to limit the development of common malignancies in normal hosts, the observation that many cancers that develop in chronically immunosuppressed transplant recipients are associated with oncogenic viruses such as Epstein-Barr virus (EBV) and human herpesvirus-8 (HHV-8), or with exposure to ultraviolet light suggests that immune surveillance mechanisms may function against these highly antigenic tumors. Virus-associated malignancies often undergo complete regression with withdrawal of immunosuppressive drugs or after restoration of functional T-cell responses to viral antigens by adoptive immunotherapy, and these observations provide direct evidence of a role for host immunity in containing the outgrowth of these tumors. Thus, immunodeficient transplant recipients provide a unique opportunity to reexamine the role of the immune system in tumor development and to determine the principles for effectively treating tumors in humans with immunotherapy.

#### HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS

Approximately 12,000 allogeneic and 18,000 autologous stem cell transplants are performed worldwide each year.<sup>10</sup> Several studies have demonstrated that patients who have received either an allogeneic or autologous HSCT are at an increased risk for the development of a new malignancy compared with the general population. Allogeneic HSCT recipients are at increased risk for the development of lymphoproliferative disorders and solid tumors, and autologous HSCT recipients are at increased risk for developing acute myeloid leukemia (AML) or myelodysplastic syndrome (MDS) and solid tumors. The peak time for the occurrence of these malignancies after transplant suggests distinct factors are involved in their pathogenesis. Solid tumors show a steady increase in incidence with time, lymphoproliferative disorders typically occur during the first year at the height of the immunodeficiency, and AML and MDS primarily occur in the first 3 years after transplant ([Fig. 50.2-1](#)).

#### SOLID TUMORS AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION

##### Epidemiology

Early studies in rhesus monkeys and in dogs given gamma irradiation and either autologous or allogeneic HSCT revealed a striking increase in the development of

solid tumors when compared with control unirradiated animals.<sup>11,12 and 13</sup> Tumors developed in these animal models a median of 8 years after transplantation, and it was anticipated that long-term follow-up of humans who received cytotoxic conditioning and HSCT might similarly reveal an increase in the incidence of solid tumors. The first large study to address the development of solid tumors in HSCT recipients evaluated 2145 patients who underwent allogeneic or syngeneic HSCT between 1970 and 1987 as treatment for leukemia or aplastic anemia. In this study, 13 solid tumors developed a median of 56 months (range, 2.5 to 163.0 months) after transplantation.<sup>14</sup> The histology of these malignancies was varied and included glioblastoma, melanoma, squamous cell carcinoma of the skin or oral cavity, basal cell carcinoma of the skin, adenocarcinoma of the gastrointestinal tract and lung, and hepatoma. Subsequent studies at other centers confirmed the late development of solid tumors in HSCT recipients.<sup>15,16 and 17</sup> These early studies validated the concern raised by animal models of stem cell transplantation and identified a need to evaluate larger numbers of patients to define the risk of individual tumors and to elucidate the pathogenesis of tumor development in these patients.

A multicenter study analyzed the occurrence of solid tumors in 19,220 patients who received allogeneic or syngeneic HSCT between 1964 and 1992.<sup>18</sup> Overall, the ratio of observed to expected (O/E) cases of new solid tumors was 2.7, with a cumulative incidence rate of 2.2% at 10 years and 6.7% at 15 years.<sup>18</sup> The rapid increase in the incidence of solid tumors between 10 and 15 years suggests that the risk will be even greater with longer follow-up. Cancers that occur with significantly increased frequency in HSCT recipients include melanoma (O/E = 5.0), cancers of the buccal cavity or oropharynx (O/E = 11.1), liver (O/E = 7.5), brain (O/E = 7.6), thyroid (O/E = 6.6), bone (O/E = 13.4), and connective tissues (O/E = 8.0) (Table 50.2-1). Breast, lung, gastrointestinal, and genitourinary tumors, which represent the most common malignancies in the general population, are not increased in HSCT recipients (Table 50.2-2).

Site of Tumor Development	Ratio of Observed to Expected Cases	95% Confidence Interval
Melanoma	5.0	2.5-8.9
Buccal cavity or oropharynx	11.1	6.5-17.8
Liver	7.5	1.5-22.0
Brain or other central nervous system	7.6	3.8-13.5
Thyroid	6.6	2.8-12.9
Connective tissue	8.0	2.2-20.5
Bone	13.4	4.3-31.3

\*The P value for the ratio of observed to expected cases for all tumors is <0.05.  
(Adapted from ref. 18.)

**TABLE 50.2-1.** Ratio of Observed to Expected Cases of Solid Tumors in Hematopoietic Stem Cell Transplant Recipients: Tumors That Occur with Increased Frequency Compared with the General Population<sup>a</sup>

Site of Tumor Development	Ratio of Observed to Expected Cases	95% Confidence Interval
Breast	1.1	0.4-2.2
Lung	0.7	0.1-2.6
Colon	0.7	0.0-3.8
Rectum	2.2	0.3-7.9
Cervix	0.7	0.0-3.9
Uterus	1.4	0.0-7.9

(Adapted from ref. 18.)

**TABLE 50.2-2.** Ratio of Observed to Expected Cases of Solid Tumors in Hematopoietic Stem Cell Transplant Recipients: Tumors That Occur with the Same Frequency as in the General Population

The factors associated with a significantly increased risk of solid tumor development in HSCT recipients are younger age at the time of transplant and the use of total body irradiation in the pretransplant conditioning regimen.<sup>18</sup> The risk of developing a tumor posttransplant is 36 times higher than expected for children who are younger than the age of 10 years at the time of transplant, 4.6 times higher for patients aged 10 to 29, and nearly normal for those patients who are aged 30 and older. The excess risk in children younger than age 10 years is primarily due to the development of brain and thyroid tumors in patients who have received pretransplant cranial irradiation. Total body irradiation in doses of greater than 10 Gy in a single dose or greater than 13 Gy in fractionated doses is associated with an increased risk for squamous cell carcinoma of the oral cavity (relative risk = 3.0), melanoma (relative risk = 8.2), thyroid (relative risk = 5.8), and central nervous system (CNS) tumors (relative risk = 4.3).<sup>18</sup>

The analysis of risk factors does not support a role for defective immune surveillance in the development of most solid tumors after HSCT because T-cell depletion of the stem cell graft; acute, chronic, or both acute and chronic GVHD; or transplantation from MHC-mismatched donors are not associated with an increased risk. However, there may be a potential role for immune deficiency or dysregulation in the development of melanoma and squamous cell carcinoma of the oral cavity in HSCT recipients. Transplantation of stem cells that are depleted of donor T cells to prevent GVHD confers an increased risk for melanoma (relative risk = 4.5).<sup>18</sup> Additionally, patients who develop chronic GVHD and require longer than 1 year of immunosuppressive therapy exhibit a significantly increased risk of squamous cell carcinoma of the buccal cavity (relative risk = 6.0) and skin (relative risk = 22.6).<sup>18</sup>

Solid tumors also develop with increased frequency in recipients of autologous HSCT, although the available data are derived from analysis of smaller numbers of patients and are not sufficient to accurately define the risk for specific tumors.<sup>15,19</sup> However, the types of solid tumors reported after autologous HSCT are similar to those seen in allogeneic HSCT recipients and include squamous and basal cell carcinoma of the skin, melanoma, CNS tumors, and thyroid carcinoma. The major risk factor for the development of solid tumors after autologous HSCT is the use of total body irradiation in the conditioning regimen. Studies assessing larger numbers of autologous HSCT recipients will be helpful in further defining the epidemiology of tumors in these patients. Because autologous HSCT recipients do not develop GVHD or receive immunosuppressive drug therapy, comparison of the incidence and types of malignancies that develop in these patients with allogeneic HSCT recipients may assist in elucidating the contributions of GVHD and immunosuppressive drug therapy to the pathogenesis of tumor development.

### Pathogenesis

The mechanisms operative in the genesis of solid tumors developing after HSCT have not been fully elucidated.<sup>20</sup> The use of total body irradiation is associated with a higher risk of solid tumor development, suggesting that DNA damage induced by ionizing radiation is an important contributor to tumorigenesis. Chronic GVHD is a risk factor for squamous cell cancer of the oral cavity, suggesting that chronic inflammation induced by alloreactivity at the local site, prolonged treatment with immunosuppressive drugs, decreased immune surveillance, or all of these factors may be involved in the development of tumors at this site.<sup>18,21</sup> DNA from viruses with known oncogenic potential, such as human papilloma virus and EBV, have occasionally been detected in squamous cell carcinomas developing in the skin or at mucosal sites in immunosuppressed patients, and additional studies are necessary to determine if these viruses contribute significantly to tumor development in HSCT recipients.<sup>22,23,24 and 25</sup>

The association of T-cell depleted transplantation with an increased risk of melanoma suggests a potential role for defective T-cell function in the pathogenesis of melanoma. T cells reactive with melanocyte differentiation antigens such as Melan A, gp100, and tyrosinase, which are expressed in both normal melanocytes and melanomas, have been identified in normal individuals.<sup>26</sup> A role in immune surveillance has not been proven, but such T cells are expanded in the blood and tumor infiltrates of some patients with melanoma, recognize and kill tumor cells *in vitro*, and can mediate tumor regression after *in vitro* expansion and adoptive transfer to tumor-bearing hosts.<sup>27,28</sup>

## Clinical Features, Diagnosis, and Management

The clinical features of solid tumors developing in HSCT recipients have not been distinguishable from tumors of the same histology developing in normal individuals, and diagnosis and management should be performed in accordance with standard practice for tumors of the same stage in nontransplant patients.

The increase in the incidence of second malignancies after HSCT does have an effect on long-term survival of these patients. A study that examined the causes of late deaths in patients free of their original disease 2 years after allogeneic HSCT found that new cancers accounted for 6% of the late deaths.<sup>29</sup> The median follow-up of patients in this study was only 80 months, and tumors that exhibit a longer latency may yet emerge. Thus, longer follow-up of HSCT recipients will be essential to fully evaluate the risk of solid tumor development and the effect on long-term survival. The current data would suggest that all HSCT recipients should be counseled pretransplant as to their risk of solid tumor development and that symptoms or signs that may be indicative of a malignancy be promptly evaluated to ensure early diagnosis and institution of therapy.

Newer approaches to allogeneic HSCT are being developed that use less intensive conditioning regimens either not containing total body irradiation or using lower doses of irradiation.<sup>30,31</sup> These approaches are not myeloablative and rely on the allogeneic graft-versus-tumor effect to eradicate the underlying malignancy. If such less intensive conditioning regimens prove to be equally efficacious as conventional myeloablative regimens and are widely adopted, the risk of secondary malignancies in allogeneic HSCT recipients may be reduced.

## LYMPHOPROLIFERATIVE DISORDERS ASSOCIATED WITH EPSTEIN-BARR VIRUS IN HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS

### Epidemiology

Posttransplant lymphoproliferative disorders (PTLDs), the overwhelming majority of which are of donor B cell origin and associated with EBV infection, are a life-threatening complication of allogeneic HSCT.<sup>32,33,34</sup> and<sup>35</sup> In contrast to solid tumors, which typically develop after an interval of several years, PTLDs most commonly develop during the first 6 months after HSCT and represent the most frequent new malignancy in the first 5 years after transplant.<sup>20,36</sup> In a large multicenter study of 18,014 patients who received allogeneic HSCT between 1969 and 1992, the cumulative incidence of PTLD was 1.0% at 10 years.<sup>36</sup> More than 80% of the cases occurred in the first year after transplant with the peak incidence in the third month posttransplant.

The risk of developing a PTLD differs dramatically in subsets of patients, depending on factors that interfere with the reconstitution of T-cell immunity. The use of MHC-mismatched donors, the administration of anti-T-cell antibodies in the preparative regimen or as GVHD prophylaxis or therapy, and depletion of T cells from the stem cell inoculum are all associated with an increased risk of PTLD.<sup>15,33,34,35</sup> and<sup>36</sup> Recipients of transplants from unrelated donors or donors mismatched at two or more MHC alleles with the recipient have a 3.7-fold greater risk of PTLD than recipients of transplants from matched related donors.<sup>36</sup> The use of antithymocyte globulin or anti-CD3 monoclonal antibodies as prophylaxis or therapy for GVHD is also associated with a markedly increased risk of PTLD.<sup>14,36</sup>

Patients who receive a stem cell transplant that is depleted of T cells to prevent GVHD are at higher risk (relative risk = 9.1) for developing PTLD than those who receive unmodified bone marrow or peripheral blood stem cells.<sup>36</sup> However, the method used to deplete T cells from the stem cell inoculum influences the risk of PTLD. A high risk of PTLD is seen when T-cell depletion is performed using monoclonal antibodies directed against surface markers expressed only by T cells or by both T cells and natural killer cells (relative risk = 12.8), or using sheep red blood cell E-rosetting techniques (relative risk = 15.6).<sup>36</sup> In contrast, depletion of T cells using techniques that eliminate both T and B cells, such as with the CAMPATH-1 antibody, which recognizes the CD52 surface molecule; elutriation, which removes lymphocytes based on size and density; or agglutination with soybean lectin, does not increase the risk of PTLD compared with unmodified HSCT.<sup>36,37,38,39</sup> and<sup>40</sup> The lower incidence of PTLD with these methods of T-cell depletion is presumably due to the removal of EBV-infected B cells from the stem cell inoculum.<sup>37,39,41</sup>

### Pathogenesis

EBV is a ubiquitous human gamma herpesvirus that establishes a persistent infection in more than 90% of adults, and the near universal association of this virus with PTLD implies a direct role in tumor development. During primary EBV infection in normal hosts, the virus enters B lymphocytes by an interaction between the viral envelope glycoprotein gp350/220 and the B-cell surface molecule CD21, which serves as the receptor for the C3d complement fragment.<sup>42</sup> Some infected B cells may express the entire array of viral genes and undergo lytic infection and cell death, but a characteristic of primary EBV infection is expression of a limited set of viral proteins that include EBNA-1, EBNA-2, EBNA-3A, EBNA-3B, EBNA-3C, EBNA-LP, LMP-1, LMP-2A, and LMP-2B.<sup>43</sup> This pattern of EBV gene expression, termed the *latency III program*, is responsible for the proliferation of B cells observed in the early stages of primary EBV infection and in PTLD developing in immunosuppressed patients.

How EBV induces B-cell proliferation continues to be the subject of intense investigation. The consensus is that immortalization of B cells requires the coordinated action of several EBV proteins. EBNA-1 is required for maintenance of the viral episome, and EBNA-2 functions as a transcriptional activator that induces the expression of viral and cellular genes that regulate cell growth.<sup>44,45</sup> and<sup>46</sup> LMP-1 acts as an analogue of a constitutively active form of the CD40 signaling molecule in B cells and activates NF- $\kappa$ B.<sup>47,48</sup> and<sup>49</sup> The expression of LMP-1 as a transgene in mice resulted in the development of oligoclonal or monoclonal B-cell lymphomas, suggesting that this molecule is critically involved in B-cell transformation.<sup>50</sup>

In response to primary infection with EBV, immunocompetent hosts mount both a humoral and cellular immune response that limits the spread of replicating virus and eliminates the proliferating EBV-infected B cells that express the latency III program of viral genes. The T-cell response is characterized by major expansions of CD3+ CD8+ cytotoxic T cells (CTLs) that recognize both EBV lytic phase viral antigens and, with the notable exception of EBNA-1, antigens that are expressed in the proliferating EBV-infected B cells.<sup>51,52</sup> and<sup>53</sup> The elimination of proliferating EBV-infected B cells by CTLs assists in terminating the acute infection. However, residual virus remains in resting memory B cells in which the viral DNA persists as an episome and EBNA-1 is the only viral gene that is expressed.<sup>44,54,55</sup> and<sup>56</sup> The presence of glycine/alanine repeat sequences in the EBNA-1 protein precludes its efficient processing and presentation to CTLs, thus latently infected B cells are able to evade immune elimination and serve as a reservoir for reactivation.<sup>57</sup> Reactivation of EBV in latently infected B cells may be characterized by expression of the lytic program of gene expression and production of new virions, or the latency III program that induces B-cell proliferation. Because of this persistent reservoir of virus, memory CTL responses to EBV must be maintained for the life of the host to prevent the outgrowth of EBV-infected B cells.

The balance that is established between host T-cell immunity and persistent EBV in immunocompetent hosts is acutely and dramatically perturbed in the setting of allogeneic HSCT. The administration of cytotoxic therapy before HSCT destroys the host T cells, which are required to maintain EBV in a latent state, and also eliminates the reservoir of host EBV-infected B cells. The infusion of unmanipulated allogeneic stem cells from an EBV-seropositive donor provides a new source of EBV-infected B cells and replaces the host EBV strain with the EBV strain of the donor.<sup>58</sup> Reconstitution of EBV-specific T-cell immunity is essential to reestablish control of EBV infection. However, a quantitative deficiency of EBV-specific CTLs is common in the first 6 months after allogeneic transplant.<sup>59,60</sup> T-cell depletion of the stem cell graft, which reduces the number of EBV-specific T cells administered to the recipient, or the use of monoclonal anti T-cell antibodies for GVHD prophylaxis or therapy, which eliminates EBV-specific T cells *in vivo*, further impairs T-cell recovery. In the setting of a severe deficiency of EBV-specific CTLs, EBV may reactivate, induce polyclonal proliferation of B cells, and result in the emergence of rapidly growing oligoclonal or monoclonal populations.

### Clinical Features and Diagnosis

PTLD in HSCT recipients commonly presents with fever and progressive lymphadenopathy. Involvement of pharyngeal lymphoid tissue with an exudative pharyngitis is observed in one-third of patients.<sup>38</sup> The lesions may be extranodal and involve the spleen, liver, lungs, gastrointestinal tract, kidneys, and CNS. Thus, PTLD should be included in the differential diagnosis of symptoms or signs related to these organs in a patient at high risk.

The diagnosis is usually established by biopsy and demonstration of the presence of EBV in involved tissue. Tumors developing after HSCT almost always consist of oligoclonal or monoclonal populations of donor B cells and most commonly exhibit a monomorphic diffuse large cell morphology, although plasmacytoid or polymorphic morphology are also seen.<sup>38,61</sup> The presence of EBV in the tumor is established by Southern blot of DNA extracted from tumor tissue or by analysis of EBV gene expression in tissue sections. Two EBV-encoded RNAs (EBERs) are abundantly expressed in PTLD and can be detected in tissue sections by *in situ* hybridization.<sup>62</sup> Immunohistochemical staining with antibodies against EBV proteins can also be used to confirm the presence of EBV in the tumor.<sup>63</sup> Analysis of Ig

gene rearrangements or characterization of repeat sequences at EBV DNA episomal joints is used to determine the clonality of tumor cells. Detection of high EBV DNA levels by polymerase chain reaction analysis of DNA in peripheral blood has been associated with PTLD and may be useful for early diagnosis and monitoring response to therapy.<sup>64</sup>

### **Therapy and Prophylaxis of Posttransplant Lymphoproliferative Disorders**

The development of PTLD in HSCT recipients is an ominous sign due to the propensity for these tumors to grow rapidly, and urgent therapy is usually necessary. Reduction in the intensity of immunosuppression is indicated, although this may not be possible in patients with severe GVHD. Surgical resection or irradiation may be appropriate as a temporary measure to control anatomically localized disease, but recurrences at other sites are common. Efforts to treat PTLD with chemotherapy regimens similar to those used to treat non-Hodgkin's lymphoma are only occasionally successful in HSCT recipients in part due to the toxicity of administering systemic chemotherapy to these patients.

Anecdotal reports and studies in small numbers of patients have examined systemic therapy with antiviral drugs and interferon- $\alpha$ . Although the administration of acyclovir or ganciclovir is often used as a component of therapy for PTLD, these drugs target the viral thymidine kinase, which is expressed in the replicative phase of EBV infection but not in proliferating EBV-infected B cells. These agents do not inhibit the growth of EBV-transformed B cells *in vitro* and would not be expected to be beneficial for PTLD. Pharmacologic induction of the viral thymidine kinase gene in EBV-infected cells by administration of arginine butyrate has been reported to render EBV-associated PTLD susceptible to ganciclovir and induce a complete regression in four of six patients.<sup>65</sup> The administration of interferon- $\alpha$  and immunoglobulin was reported to induce regression of PTLD in a small number of patients in an early study, but this approach has not been widely adopted.<sup>32</sup>

The infusion of anti-B-cell monoclonal antibodies directed at the CD21 and CD24 surface molecules has induced regression of PTLD in approximately 50% of patients. However, this approach is less effective in patients with oligoclonal or monoclonal disease and, at the present time, these antibodies are not commercially available.<sup>66,67</sup> and <sup>68</sup> The use of anti-CD20 monoclonal antibody (Rituxan) has been reported to induce remission of PTLD after HSCT in some patients, and the results of additional studies of this agent are eagerly awaited.<sup>69,70</sup>

The association of deficient EBV-specific T-cell immunity with the development of PTLD has led to efforts to restore T-cell responses to EBV by the adoptive transfer of T cells obtained from the stem cell donor. Support for this approach was provided by a study of five patients who developed PTLD after T-cell-depleted allogeneic HSCT and received infusions of unirradiated donor peripheral blood mononuclear cells containing  $1 \times 10^6$  CD3+ T cells per kilogram of recipient body weight.<sup>71</sup> Clinical and pathologic regression of the PTLD was observed in all five patients, and three of these patients became long-term survivors. Two patients with pulmonary involvement developed fatal respiratory failure after the lymphocyte infusions, and two of the three surviving patients developed chronic GVHD.<sup>71</sup> In a subsequent report, 19 patients with PTLD were treated with donor lymphocytes, and 16 achieved complete pathologic and clinical resolution of their disease.<sup>38</sup> Studies analyzing the frequency of EBV-specific CTLs in the blood before and after therapy demonstrated a rapid amplification of EBV-specific CTLs to levels equivalent to normal donors. However, due to the presence of alloreactive T cells in the donor cells used for therapy, GVHD developed in 50% of the patients treated with this approach.<sup>38</sup>

An approach to cellular therapy of PTLD that alleviates the problem of GVHD uses donor T cells that are enriched for EBV-specific reactivity and depleted of alloreactivity by *in vitro* culture. The infusion of such cultured EBV-specific T cell lines is effective in treatment of established PTLD in HSCT recipients. Transferred T cells can be identified in the regressing tumor and persist in the blood for longer than 18 months after infusion.<sup>72,73</sup> The prophylactic administration of EBV-specific T cell lines to patients who have received a T-cell-depleted HSCT has been effective in preventing PTLD in these high-risk patients.<sup>74</sup> At the present time, the major impediment to the broader application of cellular therapy for EBV-associated PTLD is the technical expertise and resources required to isolate EBV-reactive T cells.

## **HODGKIN'S DISEASE AND LATE-ONSET NON-HODGKIN'S LYMPHOMAS IN HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS**

### **Epidemiology**

Hodgkin's disease has been reported to occur with increased frequency in immunosuppressed patients, including solid organ transplant recipients and human immunodeficiency virus (HIV)-infected patients.<sup>75,76</sup> The incidence of Hodgkin's disease has been evaluated in 18,531 allogeneic HSCT recipients and compared with the incidence in the general population.<sup>77</sup> Eight cases of Hodgkin's disease were observed in the HSCT patients, which was significantly more than expected in the age- and sex-matched general population (O/E = 6.2). There was a trend toward a significantly increased risk in patients who developed grade 3 or 4 GVHD. The majority of cases were of mixed cellularity histology and contained the EBV genome; however, in contrast to EBV-associated PTLD, which typically occurs in the first 6 months after transplant, the onset of Hodgkin's disease occurred at a median of 4.2 years after transplant.<sup>77</sup> Cases of late-onset non-Hodgkin's lymphoma have also been reported in HSCT recipients, but the majority of these are T cell in origin and an association with lymphotropic viruses, such as EBV or human T-cell lymphotropic virus, has not been demonstrated.<sup>78</sup>

### **Clinical Manifestations and Management**

The cases of Hodgkin's disease reported in HSCT recipients were characterized by an aggressive histology, with 75% being mixed cellularity or lymphocyte depleted. Therapy with conventional chemotherapy or radiotherapy is usually effective, however, with six of the eight patients in the largest series alive 2.7 to 9.6 years after the diagnosis of Hodgkin's disease.<sup>77</sup>

## **ACUTE LEUKEMIA AND MYELODYSPLASTIC SYNDROME AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION**

### **Epidemiology**

AML and MDS are well-recognized complications of conventional chemotherapy and radiotherapy for Hodgkin's disease, non-Hodgkin's lymphoma, breast cancer, and other malignancies.<sup>79,80,81</sup> and <sup>82</sup> Patients who receive high-dose chemotherapy and autologous HSCT for non-Hodgkin's lymphoma and Hodgkin's disease have also been reported to have an increased risk of secondary AML or MDS compared with the general population. In three large series, the cumulative incidence of AML/MDS in recipients of autologous HSCT for non-Hodgkin's lymphoma or Hodgkin's disease was 5% at 5 years,<sup>83</sup> 18% at 6 years,<sup>84</sup> and 14.5% at 5 years,<sup>85</sup> respectively. Risk factors for the development of AML/MDS were age older than 40 years at the time of transplant, pretransplant irradiation, pretransplant therapy with alkylating agents, mobilization of stem cells with VP-16, and a low pretransplant platelet count.<sup>83,84,85</sup> and <sup>86</sup> In one study, the use of total body irradiation in the conditioning regimen was a risk factor for the development of AML/MDS after transplant.<sup>83</sup>

Rare cases of leukemia developing in donor cells after allogeneic HSCT have also been reported.<sup>87,88,89</sup> and <sup>90</sup> In these cases, the donor reportedly remained healthy and the mechanism of leukemogenesis in the recipient remained unexplained. Inadvertent transplantation of marrow from a donor with AML has also been reported.<sup>91</sup>

### **Pathogenesis**

The pathogenesis of secondary AML/MDS in patients who receive conventional chemotherapy or combined chemoradiotherapy is related to DNA damage in hematopoietic stem cells induced by alkylating agents, epiphyllotoxins, or ionizing radiation. It is unclear whether the risk of AML/MDS is entirely due to damage to stem cells from prior chemotherapy or if the conditioning regimen administered immediately before transplant further adds to the risk. A study of patients with multiple myeloma who underwent autologous HSCT found that the risk of developing AML/MDS correlated with the intensity and duration of pretransplant conventional chemotherapy.<sup>92</sup> However, the increased risk of AML/MDS when total body irradiation was a component of the conditioning regimen suggests that there may be additional contributions from regimen-related damage to residual stem cells in the patient or to the marrow stroma.<sup>83</sup>

Cytogenetic abnormalities are occasionally found in the marrow of patients being evaluated for autologous HSCT. In a few cases in which the marrow was morphologically normal and was used for transplant despite the presence of cytogenetic alterations, the patients developed MDS or AML in the first 12 months after transplant.<sup>93</sup> Thus, cytogenetic analysis of the bone marrow should be considered in patients with extensive prior therapy who are being evaluated for HSCT.

### **Clinical Features and Management**

The clinical features of AML/MDS after autologous HSCT are the same as those seen in cases of secondary AML/MDS that develop after conventional chemotherapy or low-dose radiation. These include frequent abnormalities of chromosomes 5 and 7 and a poor response to therapy. A small number of patients who have developed AML/MDS after autologous HSCT have subsequently been treated with a second high-dose cytotoxic regimen followed by allogeneic HSCT.<sup>94</sup> This approach is complicated by a high risk of regimen-related toxicity but can be curative.

## ORGAN TRANSPLANT RECIPIENTS

The transplantation of allogeneic solid organs has become a widely used and often life-saving therapy, with more than 20,000 procedures performed in 1997 in the United States.<sup>95</sup> However, recipients of organ allografts generally require life-long therapy with immunosuppressive drugs to prevent or treat episodes of graft rejection and are at increased risk for the development of a malignancy. The overwhelming majority of tumors arising in solid organ transplant recipients are *de novo* malignancies of recipient origin,<sup>9,96,97</sup> or recurrence of a malignancy existing in the recipient before transplant.<sup>98,99</sup> and <sup>100</sup> However, a malignancy of donor origin may occasionally arise in the transplanted organ *de novo* or be inadvertently transmitted to the recipient via the transplanted organ.<sup>101,102,103,104,105</sup> and <sup>106</sup> Polymorphic molecular markers that differ between donor and recipient can be used to determine the origin of the malignancy, and these studies should be considered in suspicious cases because withdrawal of immunosuppression can sometimes result in regression of donor-derived malignancies.<sup>102,103</sup>

Data from single institutions and large international registries have shown that the incidence of cancer in organ allograft recipients is increased three- to fourfold compared with the general population.<sup>9,97,107,108</sup> and <sup>109</sup> The incidence of tumor development increases with the length of observation after transplant. In two studies of renal allograft recipients, the risk of developing cancer at 20 years after transplant was 40% to 50% compared with a 6% cumulative risk in the general population of age-matched individuals.<sup>97,108</sup> Similar to the findings in HSCT recipients, malignancies that develop frequently in the general population, such as those occurring in breast, lung, prostate, colon, and cervix, are not increased in solid organ transplant recipients.<sup>110,111</sup> The incidence of cancers of the skin and lip, and B-cell lymphoproliferative diseases are increased in both solid organ transplant and HSCT recipients.<sup>9,97,108,112</sup> Kaposi's sarcoma (KS), which is rarely seen in HSCT recipients, is significantly increased in organ allograft recipients.<sup>113,114</sup>

## CANCER OF THE SKIN AND LIP

### Epidemiology

Cancer of the skin or lip is the most common neoplasm developing in organ allograft recipients, and the risk of a cutaneous neoplasm is increased 3.2- to 24.0-fold compared with the general population.<sup>115</sup> The most dramatic increase is in squamous cell carcinoma, but the risk of developing basal cell carcinoma, melanoma, and Merkel's cell carcinoma is also significantly increased. The cumulative incidence of skin cancer increases with time after transplantation (Table 50.2-3). The incidence of skin cancer in renal transplant recipients was 70% at 20 years in a study from Australia where sun exposure is high,<sup>116</sup> and 40% in a study from the Netherlands.<sup>115</sup> In two studies of heart transplant recipients, the incidence of skin cancer was 44% and 35% at 7 and 10 years, respectively.<sup>117,118</sup> In the general population, basal cell carcinoma of the skin occurs five times more frequently than squamous cell carcinoma, whereas in organ transplant recipients, squamous cell carcinoma occurs one to three times more frequently than basal cell carcinoma.<sup>114</sup>

Study	Transplant Type	Follow-Up (y)	Cumulative Incidence (%)		
			Squamous Cell Carcinoma	Basal Cell Carcinoma	Squamous Cell Carcinoma + Basal Cell Carcinoma
Bowen et al. <sup>115</sup>	Renal	11	5	12	6
		20	38	34	70
Berthel et al. <sup>116</sup>	Renal	10	1	1	10
		20	35	11	46
Langer et al. <sup>117</sup>	Heart	10	12	11	23
Epstein et al. <sup>118</sup>	Heart	7	20	11	31

TABLE 50.2-3. Cumulative Incidence of Skin Cancer in Organ Transplant Recipients

Cumulative sun exposure, the length of time after transplant, and mismatching between donor and recipient at the HLA-B locus or homozygosity at the HLA-DR locus have been identified as risk factors for the development of skin cancer in organ transplant recipients.<sup>117,119,120</sup> Features prevalent in patients with skin cancer in the general population, including light skin and blonde or red hair, are also prevalent in transplant recipients.

The length of time from transplant is an important risk factor and presumably reflects the contributions of immunosuppressive drug therapy to tumorigenesis. Insufficient data are available to conclude whether specific immunosuppressive drugs or the intensity of the regimen influences the risk of skin cancer. Patients who receive cyclosporine in addition to azathioprine and prednisolone<sup>121</sup> or who receive OKT3<sup>117</sup> have been reported to be at higher risk for the development of skin cancer. However, other studies have not found an association between the type of immunosuppressive drug regimen used and the risk of skin cancer.<sup>116</sup>

Sun exposure and cigarette smoking are risk factors for the development of cancer of the lip in organ transplant recipients. In addition to an increased incidence of malignant lesions, transplant recipients have a higher incidence of leukoplakia and dysplastic lesions of the lip when compared with age- and sex-matched controls.<sup>122</sup>

### Pathogenesis

Multiple factors may be involved in the pathogenesis of cancers of the skin and lip in organ allograft recipients, including underlying genetic predisposition, environmental factors, immunologic alterations induced by the transplant, immunosuppressive drugs, and viral infection. The mechanism by which transplantation and immunosuppressive drug therapy potentiates the development of skin cancer remains elusive. In murine models, tumors induced by ultraviolet light are often highly antigenic when transplanted into syngeneic mice, suggesting defects in the host immune response are required for tumor formation.<sup>123</sup> There is evidence that ultraviolet light induces local immunosuppressive effects that facilitate the establishment of tumors, and immunosuppressive drugs may potentiate this local impairment in host immunity.<sup>124,125</sup> Consistent with this hypothesis, the skin of renal allograft recipients exhibits a decrease in the density of CD4+ and CD8+ T lymphocytes, and CD1a+ dermal Langerhans' cells when compared with normal controls.<sup>126</sup> Moreover, melanomas that occur in solid organ transplant recipients lack the mononuclear cell infiltrates that are frequently seen in tumors in immunocompetent hosts and are associated with a good prognosis.<sup>127</sup> A potential role for cyclosporine in tumorigenesis that is distinct from its immunosuppressive properties has been identified. Exposure of tumor cells to cyclosporine increases the production of transforming growth factor- $\beta$ , which results in increased tumor cell motility and invasiveness *in vitro* and enhanced tumor growth and metastasis *in vivo*.<sup>128</sup>

The association of viral infections with the development of malignancies in immunosuppressed patients has prompted a search for viruses in skin cancers in organ allograft recipients. There have been reports of the detection of human papilloma-virus DNA in a significant fraction of skin cancers in organ transplant recipients.<sup>22,24,129,130,131,132</sup> and <sup>133</sup> However, other studies have failed to detect human papilloma-virus, and the role of this agent in the development of skin cancer in transplant recipients remains controversial.<sup>25,134</sup> EBV DNA and gene expression has been detected in tumors from 10 of 15 cardiac allograft recipients with squamous cell carcinoma, suggesting a potential role for EBV as a cofactor in tumor development.<sup>25</sup>

### Clinical Features, Management, and Prevention

Skin disorders that resemble malignancies, such as warts, hyperkeratoses, and keratoacanthomas, are frequently observed in transplant patients, and a biopsy

should be performed for suspicious lesions for accurate diagnosis. Premalignant lesions have been successfully treated with topical tretinoin <sup>135</sup> or a combination of low-dose etretinate and topical tretinoin. <sup>136</sup>

Skin cancers in organ transplant recipients are generally considered to be more aggressive than tumors that develop in the general population. Fifty percent to 80% of patients have multiple lesions, and individual lesions characteristically exhibit greater local invasiveness. <sup>108,137</sup> Squamous cell carcinomas in organ transplant patients are also more likely to metastasize to lymph nodes and distant sites. <sup>137</sup> Treatment of skin cancers in these patients is performed with the same modalities used for tumors in the general population, including surgical excision, cryosurgery, or radiotherapy.

Given the aggressive nature of skin cancers in organ allograft recipients, it is essential to educate patients about the hazards associated with sun exposure, provide strategies for protecting the skin from sunlight, and promote awareness of the importance of early detection and treatment. <sup>138,139</sup> Chemoprophylaxis of skin cancer with systemic retinoids may also be appropriate in high-risk patients. Acitretin has been suggested to reduce the number of new tumors in renal transplant recipients and to prevent keratotic skin lesions and skin cancer in a placebo-controlled trial. <sup>140,141</sup> The most effective preventive measure for skin cancer may come from the development of novel approaches to induce specific tolerance to the donor organ that do not require long-term administration of drugs that cause global immunosuppression. <sup>142</sup>

## EPSTEIN-BARR VIRUS–ASSOCIATED LYMPHOPROLIFERATIVE DISORDERS IN ORGAN TRANSPLANT RECIPIENTS

### Epidemiology

PTLDs associated with EBV infection are the second most frequent malignancy in solid organ transplant recipients. <sup>114</sup> In a study of 45,141 kidney transplant recipients and 7634 heart transplant recipients, the incidence of PTLD during the first year after transplant was 0.2% for kidney transplant recipients and 1.2% for heart transplant recipients. <sup>143</sup> These rates are 20 and 120 times higher, respectively, than the incidence of non-Hodgkin's lymphoma in the general population. <sup>143</sup> The incidence of PTLD is highest in the first year after transplant, but these tumors may develop with increased frequency for more than 6 years after transplant. PTLD in organ allograft recipients develop in host B cells, although the EBV strain may be derived from reactivation of latent virus in the host or virus transmitted with the donor organ. <sup>144,145</sup> Transplant recipients who are EBV seronegative and receive an organ from an EBV-seropositive donor are up to 76 times more likely to develop a PTLD than EBV-seropositive recipients. <sup>146,147 and 148</sup>

The drug regimen used to prevent or treat graft rejection influences the risk of PTLD, with the highest risk of PTLD observed in patients who receive cyclosporine, FK-506, or anti-CD3 monoclonal antibodies. <sup>143</sup> Heart, lung, or heart and lung transplants have a higher incidence of PTLD than patients receiving kidney or liver transplants because intensive immunosuppression must be maintained in these patients to prevent life-threatening graft rejection. <sup>143</sup> The administration of anti-CD3 monoclonal antibodies confers a particularly high risk of PTLD related both to the suppression of T-cell function and the release of T-cell cytokines that activate B cells. <sup>149</sup>

### Pathogenesis

The pathogenesis of PTLD occurring in solid organ transplant recipients is similar to that in HSCT recipients and reflects defective control of EBV by the host immune response. The immunosuppressive drugs administered to organ transplant patients potently suppress EBV-specific CTL activity *in vitro* and *in vivo*. <sup>150</sup> A study of 30 cardiothoracic transplant recipients who received cyclosporin A and azathioprine as rejection prophylaxis showed that EBV-specific CTL activity in the peripheral blood was suppressed or undetectable in all patients during the first 6 months after transplant. <sup>151</sup> Recovery of EBV-specific T-cell responses is further impaired in patients who require additional immunosuppressive therapy with prednisone or azathioprine to treat rejection episodes. <sup>151</sup> These studies support a deficiency of EBV-specific CTLs as the critical factor in pathogenesis, but the clinical presentation of PTLD in organ allograft recipients suggests that local factors at the tumor site also play a role. Tumors frequently involve the transplanted organ, the CNS, and the gastrointestinal tract, suggesting that immunoregulatory factors in the microenvironment may act in concert with a deficiency of EBV-specific CTLs to predispose to the development of PTLD. The organ allograft is a site of chronic antigenic stimulation, and local cytokines produced by alloreactive T cells have been suggested to promote the activation and growth of EBV-infected B cells. <sup>152</sup>

### Clinical Features, Diagnosis, and Management

Patients developing PTLD may present with an infectious mononucleosis syndrome, including fever, peripheral lymphadenopathy, and tonsillar enlargement. Occasionally, the disease presents with a fulminant course characterized by rapidly progressive diffuse multiorgan involvement and severe systemic symptoms. More commonly, PTLD presents with localized lesions in lymph nodes, extranodal sites, such as the gastrointestinal tract, CNS, lung, and the transplanted organ, or both nodes and extranodal sites. <sup>153,154 and 155</sup>

The diagnosis of PTLD is made by biopsy of involved tissue as described earlier for HSCT recipients. Three morphologic variants of PTLD are recognized in solid organ transplant recipients. These include plasmacytic hyperplasia, which is typically polyclonal, polymorphic B cell hyperplasia, which is typically monoclonal, and monomorphic lymphoma or multiple myeloma, which is monoclonal and contains alterations in oncogenes, tumor suppressor genes, or both, in addition to the EBV genome. <sup>61,156</sup> Studies suggest that patients with the monomorphic/myeloma morphology or with bcl-6 mutations have a poor response to therapy. <sup>157,158</sup>

A standard approach to the management of PTLD in organ allograft recipients has not been established. The therapeutic approach may depend on the site of tumor involvement, the rate of tumor growth, and the necessity to maintain intense immunosuppression. Initial therapy frequently consists of a reduction or withdrawal of immunosuppressive drug therapy, which can result in expansion of endogenous EBV-specific T cells and complete regression of the tumor. <sup>159,160</sup> However, this strategy may lead to rejection of the organ allograft, which, with the exception of renal transplant recipients who can return to dialysis therapy, can have disastrous consequences. Anatomically localized lesions may be amenable to surgical resection or limited field irradiation, but tumor recurrence is common.

Systemic therapy is usually necessary to control PTLD that fails to regress after a reduction in immunosuppressive therapy. The use of a combination of anti-B cell monoclonal antibodies targeting CD21 and CD24 for PTLD in organ transplant recipients resulted in a 55% survival at a median of 61 months, although the subset of patients with visceral disease, CNS involvement, or onset longer than 1 year after transplant responded poorly to therapy. <sup>68</sup> Early results with the anti-CD20 antibody (Rituxan) suggest a comparable response rate, although the follow-up on these patients is short. <sup>161</sup>

Chemotherapy has been used in patients who fail to respond to a reduction in immunosuppression or who have rapidly progressive disease. In small studies, standard regimens used for non-Hodgkin's lymphoma, such as cyclophosphamide, hydroxydaunorubicin (Adriamycin), Oncovin, and prednisone or ProMACE-CytaBOM have induced durable complete remissions in the majority of patients. <sup>162,163</sup> However, other studies have reported significantly less promising results due both to a high incidence of infectious complications related to neutropenia and refractory disease. <sup>155,164</sup>

Based on the encouraging results in allogeneic HSCT recipients, the use of cellular immunotherapy to restore EBV-specific T-cell immunity is being explored as therapy for PTLD occurring in solid organ transplant recipients. In contrast to the allogeneic HSCT recipients who have an immunocompetent stem cell donor that can be used as a source of T cells for therapy, EBV-specific T cells must be generated from the organ transplant recipient's blood before transplant and cryopreserved for later use. The feasibility of isolating and adoptively transferring EBV-reactive T cells from both EBV-seropositive and EBV-seronegative organ transplant recipients has been demonstrated. <sup>165,166</sup> The transfer of EBV-specific T cells resulted in an increase in the frequency of EBV-specific CTLs in the blood, and in a single patient with an established PTLD was associated with tumor regression. <sup>166</sup>

## LATE-ONSET LYMPHOMAS AND HODGKIN'S DISEASE IN ORGAN TRANSPLANT RECIPIENTS

The overwhelming majority of PTLD are EBV-associated and of B cell origin, but well-documented cases of T-cell lymphoproliferative disorders have been described in organ transplant recipients. The T-cell lymphoproliferations typically occur several years after transplant, involve the bone marrow and peripheral blood at presentation, and are not related to EBV, human T-cell lymphotropic virus, or HHV-8 infection. <sup>167</sup> The prognosis for these patients is poor despite the administration of chemotherapy and reduction of immunosuppression. <sup>167</sup>

Hodgkin's disease has also been reported in organ allograft recipients, and the tumors are usually EBV positive. <sup>76</sup> The clinical presentation is typical of Hodgkin's

disease in the general population, and these patients respond to conventional therapy.

## KAPOSII'S SARCOMA

### Epidemiology

The incidence of Kaposi's sarcoma is up to 500 times greater in organ transplant recipients than in the general population. <sup>168,169 and 170</sup> An analysis of patients reported to the Cincinnati Transplant Tumor Registry revealed that more transplant patients are diagnosed with KS than with colorectal, breast, or prostate cancer. <sup>114</sup> The major risk factors for the development of KS in organ transplant recipients include African or Middle Eastern origin and the use of antilymphocyte serum for immunosuppression. <sup>171</sup>

A human gamma herpesvirus termed *HHV-8* has been detected in KS lesions but not in uninvolved tissues from the same individual, leading to speculation that it plays either a direct causative role or is a critical cofactor in the pathogenesis of this tumor. <sup>172,173,174 and 175</sup> The role of HHV-8 in KS in organ transplant recipients has been examined by analysis of the serostatus of recipients and donors. The presence of HHV-8 antibodies before or after transplantation is highly predictive of the development of posttransplant KS, supporting a role for reactivation of endogenous HHV-8 or transmission of HHV-8 in the pathogenesis of KS. <sup>171</sup> The direct transmission of HHV-8 by the organ allograft has been demonstrated and, in conjunction with intensive immunosuppression, associated with the development of posttransplant KS. <sup>176,177</sup>

### Pathogenesis

The finding of HHV-8 DNA in KS lesions suggests that this herpes virus is central to the pathogenesis of the tumor. HHV-8 has been shown to reactivate soon after transplantation, and increasing levels of virus in the blood are associated with the development of KS. <sup>178</sup> Despite tantalizing leads from molecular studies of HHV-8 reviewed in the preceding chapter, the mechanisms by which HHV-8 induces tumor formation have not been elucidated. The role played by immunosuppressive drug therapy in the development of KS is also unresolved. *In vitro*, corticosteroids activate the lytic cycle of HHV-8 gene expression, suggesting that immunosuppression may increase viral load *in vivo*. <sup>179</sup> The spontaneous regression in KS lesions observed with withdrawal of immunosuppression in organ transplant recipients or with the resolution of immunodeficiency in HIV infection suggests that cellular immune responses have a crucial role in control of HHV-8 infection and preventing the development of KS. CD8+ CTLs specific for antigens expressed in latent and lytic infection have been identified in HHV-8 seropositive individuals, <sup>180</sup> and it anticipated that future studies will address the role of deficient T-cell responses to HHV-8 in the pathogenesis of KS.

### Clinical Features and Management

Sixty percent of organ allograft recipients with KS present with localized skin or mucosal lesions, and the remainder present with visceral disease involving the gastrointestinal tract, lungs, and lymph nodes. <sup>114,181</sup> The diagnosis of KS, which can be difficult in cases of visceral disease, is made by biopsy and histologic analysis. The mainstay of therapy for KS developing after solid organ transplant is reduction in immunosuppressive therapy. This intervention alone induces a complete response in approximately 25% of patients. <sup>114,181</sup> However, reintroduction of intensive immunosuppression to treat episodes of graft rejection has been associated with recurrence of the tumor. Due to the inability to maintain reduced levels of immunosuppression in many organ allograft recipients, chemotherapy using regimens described for KS in HIV infection is frequently required to control KS. <sup>181,182</sup> Novel less toxic approaches to treat KS are likely to emerge as the biology of these tumors is better understood. Cellular therapy with HHV-8-specific T cells may have a role in future therapeutic strategies. Additionally, KS cells have been shown to express the interleukin-4 receptor, and administration of interleukin-4 linked to a toxin molecule was highly effective in mediating tumor regression in a mouse xenograft model of established subcutaneous KS. <sup>183</sup>

## OTHER HUMAN HERPESVIRUS-8-ASSOCIATED MALIGNANCIES IN ORGAN TRANSPLANT RECIPIENTS

HHV-8 has also been associated with other malignancies, including primary effusion lymphoma in HIV-infected patients and multicentric Castleman's diseases in both HIV-positive and -negative patients. <sup>184,185</sup> Primary effusion lymphoma with integrated HHV-8 DNA has been reported to occur rarely in solid organ transplant recipients and can be distinguished from the more common PTLD by the presence of malignant pleural, peritoneal, or pericardial effusions without tumor mass, or adenopathy. <sup>186,187</sup>

#### INTRODUCTION

Superior vena cava syndrome (SVCS) is the clinical expression of obstruction of blood flow through the SVC. Characteristic symptoms and signs may develop quickly or gradually when this thin-walled vessel is compressed, invaded, or thrombosed by processes in the superior mediastinum. The first pathologic description of SVC obstruction, in a patient with syphilitic aortic aneurysm, appeared in 1757.<sup>1</sup> In 1954, Schechter<sup>2</sup> reviewed 274 well-documented cases of SVCS reported in the literature; 40% of them were due to syphilitic aneurysms or tuberculosis mediastinitis. These entities have since virtually disappeared, and cancer of the lung is now the underlying process in approximately 70% of patients with SVCS. It is estimated that, in the United States, 15,000 people develop SVCS each year.<sup>3</sup>

#### ANATOMY AND PATHOPHYSIOLOGY

The SVC is the major vessel for drainage of venous blood from the head, neck, upper extremities, and upper thorax. It is located in the middle mediastinum and is surrounded by relatively rigid structures, such as the sternum, trachea, right bronchus, aorta, pulmonary artery, and the perihilar and paratracheal lymph nodes. The SVC extends from the junction of the right and left innominate veins to the right atrium, for a distance of 6 to 8 cm. The distal 2 cm of the SVC is within the pericardial sac, with a point of relative fixation of the vena cava at the pericardial reflection. The azygos vein, the main auxiliary vessel, enters the SVC posteriorly, just above the pericardial reflection. The width of the SVC is 1.5 to 2.0 cm and it maintains blood at a low pressure. The SVC is thin-walled, compliant, and easily compressible, and is vulnerable to any space-occupying process in its vicinity. The SVC is completely encircled by chains of lymph nodes that drain all the structures of the right thoracic cavity and the lower part of the left thorax. The auxiliary azygos vein is also threatened by enlargement of paratracheal nodes. Other critical structures in the mediastinum, such as the main bronchi, esophagus, and the spinal cord, may be involved by the same process that led to obstruction of the SVC.<sup>4, 5 and 6</sup>

When the SVC is fully or partially obstructed, an extensive venous collateral circulation may develop. The azygos venous system is the most important alternative pathway. Carlson<sup>7</sup> found that dogs could not survive sudden ligation of the SVC below the level of the azygos vein, but they tolerated well ligation of the SVC above it. He could, however, successfully obstruct the SVC and the azygos vein in operations performed in two stages, presumably by allowing time for collaterals to form. Other collateral systems are the internal mammary veins, lateral thoracic veins, paraspinous veins, and the esophageal venous network. The subcutaneous veins are important pathways, and their engorgement in the neck and thorax is a typical physical finding in SVCS. Despite these collateral pathways, venous pressure is almost always elevated in the upper compartment if there is obstruction of the SVC. Venous pressures have been recorded as high as 200 to 500 cm H<sub>2</sub>O in severe SVCS.<sup>8</sup>

#### ETIOLOGY AND NATURAL HISTORY

SVCS usually has an insidious onset and progresses to typical symptoms and signs. Review of the data from three series ( [Table 51.1-1](#)) shows dyspnea to be the most common symptom.<sup>9, 10 and 11</sup> Dyspnea occurred in 63% of patients with SVCS. A sensation of fullness in the head and facial swelling was reported by 50% of the patients. Other complaints were cough (24%), arm swelling (18%), chest pain (15%), and dysphagia (9%). The characteristic physical findings were venous distention of the neck (66%) and chest wall (54%), facial edema (46%), plethora (19%), and cyanosis (19%). These symptoms and signs may be aggravated by bending forward, stooping, or by lying down.

Systems	Patients Affected (%)	Physical Findings	Patients Affected (%)
Dyspnea	63	Venous distention of neck	66
Facial swelling and head fullness	50	Venous distention of chest wall	54
Cough	24	Facial edema	46
Arm swelling	18	Cyanosis	19
Chest pain	15	Plethora of face	19
Dysphagia	9	Edema of arms	18

<sup>a</sup>Analysis based on data from 370 patients.<sup>9-11</sup>

**TABLE 51.1-1.** Common Symptoms and Physical Findings of Superior Vena Cava Syndrome

Malignant disease is the most common cause of SVCS. The percentage of patients in different series with a confirmed diagnosis of malignancy varies from 78% to 86% ([Table 51.1-2](#)). Lung cancer was diagnosed in 65% of 415 patients analyzed in these series.<sup>4, 10, 11 and 12</sup> Armstrong et al.<sup>9</sup> did a retrospective review of 4100 cases treated for bronchogenic carcinoma between 1965 and 1984, and they identified 99 patients (2.4%) with SVCS. Salsali and Clifton<sup>13</sup> observed SVCS in 4.2% of 4960 patients with lung cancer; 80% of the tumors inducing SVCS were of the right lung. Small cell lung cancer (SCLC) is the most common histologic subtype ([Table 51.1-3](#)), and it was found in 38% of the patients who had lung cancer and SVCS. In six large series of SCLC, 9% to 19% of patients demonstrated SVCS.<sup>14, 15, 16, 17, 18 and 19</sup> The second most common histologic subtype is squamous cell carcinoma, found in 26% of lung cancer patients with SVCS.

Histologic Diagnosis	Mil et al. <sup>1</sup> (59 Patients (%))	Strimling et al. <sup>1</sup> (17 Patients (%))	Perez et al. <sup>9</sup> (8 Patients (%))	Mil et al. <sup>2</sup> (63 Patients (%))	Total (147 Patients (%))
Lung cancer	19 (32)	6 (35)	6 (75)	8 (13)	39 (27)
Lymphoma	3 (5)	11 (65)	1 (12)	13 (21)	28 (19)

<b>Total</b>	<b>370</b>	<b>100</b>

**TABLE 51.1-3.** Lung Cancer Subtypes Associated with Superior Vena Cava Syndrome

Lymphoma involving the mediastinum was the cause of SVCS in 8% of patients reported in the series (see [Table 51.1-2](#)). Armstrong et al.<sup>9</sup> found SVCS in 1.9% of 952 lymphoma patients. Perez-Soler et al.<sup>20</sup> identified 36 cases (4%) of SVCS among 915 patients with non-Hodgkin's lymphoma (NHL) treated at the M. D. Anderson Cancer Center. Twenty-three patients (64%) had diffuse large cell lymphoma, 12 (33%) had lymphoblastic lymphoma, and one patient had follicular large cell lymphoma. Of their patients with diffuse large cell lymphoma and lymphoblastic lymphoma, 7% and 21% had SVCS, respectively. In a series of patients with primary mediastinal B-cell lymphoma with sclerosis, SVCS was present in 57% of patients.<sup>21</sup> Hodgkin's lymphoma commonly involves the mediastinum, but it rarely causes SVCS. Other primary mediastinal malignancies that cause SVCS are thymoma and germ cell tumors. Breast cancer is the most common metastatic disease that causes SVCS.<sup>4,10,12</sup> In one report, breast cancer was the cause of SVCS in 11% of cases.<sup>22</sup>

Nonmalignant conditions causing SVCS are not as rare as previously reported.<sup>9,23</sup> When the data were collected from general hospitals, as many as 22% of patients had noncancerous causes of SVCS.<sup>4,10,12</sup> Parish et al.<sup>10</sup> reported 19 patients with benign causes of SVCS, and Schraufnagel et al.<sup>4</sup> included 16 such patients in his series. Fifty percent of the patients in both reports had a diagnosis of mediastinal fibrosis, which was probably due to histoplasmosis. Parish et al.<sup>10</sup> reported six patients with thrombosis of SVC, and in five, the thrombosis developed in the presence of central vein catheters or pacemakers. Sculier and Field<sup>24</sup> reviewed 24 cases of central venous catheter-induced SVC. Of these, 18 were caused by pacemaker catheters. LeVeen peritoneovenous shunts, Swan-Ganz catheters, and hyperalimentation catheters were also involved. The increasing use of these devices for the delivery of chemotherapy agents or for hyperalimentation contributes to the development of SVCS in the cancer patient.<sup>25</sup>

Obstruction of SVC in the pediatric age group is rare and has a different etiologic spectrum. The causative factors are mainly iatrogenic<sup>26</sup> secondary to cardiovascular surgery for congenital heart disease, ventriculoatrial shunt for hydrocephalus, and SVC catheterization for parenteral nutrition. In a report of 175 children with SVCS, 70% were iatrogenic. Of the remaining 53 cases, 37 (70%) were caused by mediastinal tumors, eight (15%) were caused by benign granuloma, and four (7.5%) by congenital anomalies of the cardiovascular system. Two-thirds of the tumors causing SVCS in childhood are lymphomas.<sup>26,27</sup> Of 16 children reported from St. Jude Children's Research Hospital with SVCS at presentation, eight were diagnosed with NHL, four had acute lymphoblastic leukemia, two had Hodgkin's disease, one had neuroblastoma, and one had a yolk sac tumor.<sup>22</sup> Most children who developed SVCS late in the course of their malignancy had recurrent solid tumors.<sup>28</sup> Issa et al.<sup>27</sup> reported that mediastinal fibrosis secondary to histoplasmosis caused SVCS in 7 (5%) of the 150 patients reviewed.

## DIAGNOSTIC PROCEDURES

SVCS has long been considered to be a potentially life-threatening medical emergency.<sup>5,23,29</sup> It was common practice to immediately apply radiation therapy with initial high-dose fractions, sometimes even before the histologic diagnosis of the primary lesion was established.<sup>23,29,30</sup> Diagnostic procedures, such as bronchoscopy, mediastinoscopy, thoracotomy, or supraclavicular lymph node biopsy, were often avoided because they were considered to be hazardous in the presence of SVCS.<sup>5,23</sup> However, the safety of these invasive procedures in patients with SVCS has markedly improved, and the modern treatment of SVCS has become disease-specific from the outset.<sup>4,31,32</sup> Temporizing emergency mediastinal irradiation before biopsy is rarely used because it may preclude proper interpretation of the specimen in almost one-half of patients.<sup>33</sup>

The clinical identification of SVCS is simple because the symptoms and signs are typical and unmistakable. The chest film shows a mass in most patients. Only 16% of the patients studied by Parish had normal chest films.<sup>10</sup> The most common radiographic abnormalities are superior mediastinal widening and pleural effusion ([Table 51.1-4](#)). Computed tomography (CT) provides more detailed information about the SVC, its tributaries, and other critical structures, such as the bronchi and the cord.<sup>34</sup> The additional information is necessary because the involvement of these structures requires prompt action for relief of pressure. CT phlebography provides excellent imaging information on the site and extent of obstruction and the status of collaterals.<sup>35</sup> Helical CT phlebography replaced the combination of CT and digital phlebography that was advocated in the past.<sup>36</sup> The role of magnetic resonance imaging has been insufficiently investigated but appears promising, especially because this modality is noninvasive.<sup>37</sup>

Finding	Number of Patients	Percentage of Patients
Superior mediastinal widening	55	64
Pleural effusion	22	26
Right hilar mass	10	12
Bilateral diffuse infiltrates	6	7
Cardiomegaly	5	6
Calcified paratracheal nodes	4	5
Mediastinal (anterior) mass	3	3
Normal	14	16

(From ref. 10, with permission.)

**TABLE 51.1-4.** Chest Radiographic Findings for 86 Patients with Superior Vena Cava Syndrome

Contrast venography provides important information for determining if the vena cava is completely obstructed or remains patent and extrinsically compressed. <sup>31,38</sup> Dyet and Moghissi<sup>39</sup> demonstrated by venography that 41% of patients with SVCS have a patent SVC that is displaced or involved but not obstructed by a tumor. Another 19% have SVC obstruction below the azygos vein, for which collateral venous compression should be adequate. Venography is valuable if surgical bypass is considered for the obstructed vena cava. <sup>40</sup> Lokich and Goodman<sup>23</sup> stated that venograms are relatively contraindicated because the interruption of the integrity of the vessel wall, in the presence of increased intraluminal pressures, may result in excessive bleeding from the puncture site. However, no evidence of this complication has been reported. Although a venography can confirm the clinical diagnosis and outline the anatomy, priority should still be given to procedures that help establish the histologic diagnosis. Radionuclide technetium (Tc) 99m venography is an alternative, minimally invasive method of imaging the venous system. <sup>41,42</sup> and <sup>43</sup> Although images that are obtained by this method are not as well defined as those achieved with contrast venography, they demonstrate patency and flow patterns. Collateral circulation can be evaluated in a general manner and quantified to some degree by radionuclide venography. Gallium single photon emission CT may be of value in selected cases. <sup>44</sup>

In 58% of 107 patients reported by Schraufnagel et al., <sup>4</sup> the SVCS developed before the primary diagnosis was established. The diagnostic procedures used in different studies are summarized in [Table 51.1-5](#). Sputum cytology established the diagnosis for almost one-half of patients. Cytologic diagnosis is as accurate as tissue diagnosis in small cell carcinoma. <sup>45</sup> Bronchoscopy supplies the malignant cells for cytologic evaluation in most cases of small cell disease. <sup>46</sup> In the presence of pleural effusion, thoracentesis established the diagnosis of malignancy in 71% of patients. Biopsy of a supraclavicular node, especially if there was a suspicious palpatory finding, was rewarding in two-thirds of the reported attempts. SCLC and NHL often involve the bone marrow. A biopsy of the bone marrow may provide the diagnosis and stage for these patients. Mediastinoscopy has a very high success rate for providing a diagnosis, and a complication rate of approximately 5%. <sup>47</sup> Reports by Jahangiri and Goldstraw<sup>48</sup> (34 patients) and Mineo et al. <sup>47</sup> (80 patients), on using mediastinoscopy for patients with SVCS whose histologic diagnosis could not be established with less invasive techniques, confirmed the safety and high diagnostic yield of mediastinoscopy. No perioperative mortality was recorded and the diagnosis yield was excellent.

	Number of Procedures	Number Positive	Percentage Positive
Sputum cytology	59	29	49
Thoracentesis	14	10	71
Bone marrow biopsy	13	3	23
Lymph node biopsy	95	64	67
Bronchoscopy	124	65	52
Mediastinoscopy	105	95	90
Thoracotomy	49	48	98

**TABLE 51.1-5.** Positive Yield of Diagnostic Procedures for Patients with Superior Vena Cava Syndrome

Percutaneous transthoracic CT-guided fine-needle biopsy is emerging as an effective and safe alternative to an open biopsy or mediastinoscopy. <sup>49,50</sup> Successful diagnostic transluminal atherectomy also has been reported. <sup>51</sup> A thoracotomy is diagnostic if all other procedures have failed.

Ahmann<sup>31</sup> examined the traditional opinion that diagnostic procedures carry with them significant hazard, primarily excessive bleeding. <sup>23,29</sup> He reviewed 843 invasive and semiinvasive diagnostic procedures and found that only ten reported complications, none of them fatal. Ahmann <sup>31</sup> and others<sup>12,32</sup> found minimal evidence to suggest that diagnostic procedures such as venographies, thoracotomies, bronchoscopies, mediastinoscopies, and lymph node biopsies carry an excessive risk in patients with SVCS. In 163 patients treated at Memorial Sloan-Kettering Cancer Center for anterior mediastinal mass, 44 underwent general anesthesia. There were no deaths and only four patients had prolonged intubation, demonstrating the low risk of modern anesthesia in thoracic patients. <sup>52</sup>

## MANAGEMENT

The goals of treatment of SVCS are to relieve symptoms and to attempt the cure of the primary malignant process. SCLC, NHL, and germ cell tumors constitute almost one-half of the malignant causes of SVCS. These disorders are potentially curable, even in the presence of SVCS. The treatment of SVCS should be selected according to the histologic disorder and stage of the primary process. The prognosis of patients with SVCS strongly correlates with the prognosis of the underlying disease.

When the therapeutic goal is only palliation of SVCS, or when urgent treatment of the venous obstruction is required, direct opening of the occlusion should be considered. The newer techniques of endovascular stenting and angioplasty with possible thrombolysis should provide prompt relief of symptoms before more specific cancer therapy. <sup>3</sup>

## SMALL CELL LUNG CANCER

Chemotherapy alone or in combination with thoracic irradiation therapy is the standard treatment for SCLC. <sup>53</sup> Both chemotherapy and radiotherapy as initial treatments are effective in rapidly improving the symptoms of SVCS. <sup>15</sup> In an analysis of 50 patients with SCLC who presented with SVCS, investigators from Ontario, Canada recorded a response rate to chemotherapy of 93% and a similar response to mediastinal irradiation of 94%. <sup>19</sup> In this series, 70% of patients remained SVCS-free before death. It is of interest that, when the total treatment of SCLC included both chemotherapy and radiation, the risk of SVCS recurrence was significantly lower than when the treatment was chemotherapy alone. <sup>15</sup> A small randomized trial, however, could not show that the addition of mediastinal radiation after chemotherapy in patients with SCLC and SVCS increased the protection from local recurrence or improved the survival rate. <sup>16</sup>

Among 643 patients with SCLC, Sculier et al. <sup>15</sup> identified 55 patients (8.5%) with SVCS. One-half of patients developed the manifestations of SVCS before the histologic diagnosis was established. In the other patients, the syndrome developed after the pathologic diagnosis of SCLC was made, but before a specific treatment was started. Symptomatic relief of SVCS was obtained in 35 of 48 patients (73%) initially treated with chemotherapy and in three of seven patients (43%) who were initially treated with radiation. Relief of SVCS occurred within 7 to 10 days after initiation of therapy. In SCLC patients with recurrent or persistent SVCS after initial chemotherapy, the obstruction responded in five of seven patients (71%) who received additional chemotherapy and in 25 of 32 patients (78%) who received radiotherapy. <sup>19</sup> These data support retreatment of SVCS for palliation of symptoms.

In some series of SCLC, SVCS was a favorable prognostic sign, <sup>15,16,18</sup> whereas its presence did not affect survival in other reports. <sup>14,17</sup> A study of 408 patients with SCLC by Wurschmidt et al. <sup>18</sup> showed that the presence of SVCS independently predicted for better survival. Other independent predictors for better survival were stage and performance status. <sup>18</sup> The reason for the possible association of SVCS with better prognosis remains obscure. It is of interest to note that some researchers found a higher incidence of brain metastases at the time of diagnosis in SCLC patients with SVCS compared to patients without SVCS. <sup>17,18,53</sup>

Although randomized trials of the contribution of thoracic irradiation to chemotherapy have not consistently demonstrated an advantage to the combined modality approach, metaanalysis of these studies showed a small but significant improvement in local control and survival of patients with limited disease with the addition of radiotherapy. <sup>54,55</sup> The optimal sequence of the two modalities, and the dose and fractionation of radiotherapy, have not been fully established yet. <sup>56</sup> However, the use of combination chemotherapy as the initial modality, with subsequent rapid shrinkage of the tumor, may eliminate the necessity of irradiating a large volume of lung tissue. When chemotherapy is administered, the arm veins should be avoided. Veins of the lower extremities provide an alternative simple venous access.

## NON-HODGKIN'S LYMPHOMA

The most extensive experience in treating SVCS secondary to NHL is reported from the M. D. Anderson Cancer Center.<sup>20</sup> Twenty-two patients with diffuse large cell lymphoma and eight patients with lymphoblastic lymphoma were evaluated for results of treatment. The patients were treated with chemotherapy alone, chemotherapy combined with irradiation, or radiotherapy alone. All patients achieved complete relief of SVCS symptoms within 2 weeks of the onset of any type of treatment. No treatment modality appeared to be superior in achieving clinical improvement. The presence of dysphagia, hoarseness, or stridor was a major adverse prognostic factor for patients with lymphoma presenting with SVCS. Eighteen of 22 patients (81%) with large cell lymphoma achieved complete response. Relapse occurred in all six patients treated with irradiation alone, in four of seven patients treated with chemotherapy alone, and in five of nine patients treated with chemotherapy and radiotherapy. The median survival rate was 21 months. All eight patients with lymphoblastic lymphoma achieved complete response. Six relapses occurred in this group, and all were in sites not initially involved. Median survival was 19 months.

From these results, the researchers concluded that SVCS secondary to lymphoma is rarely an emergency that requires treatment before a histologic diagnosis is made. They recommended that the choice of treatment should be based on the histologic diagnosis and that the patients should undergo, if possible, a complete staging workup before therapy. However, lymphangiography should be avoided to prevent embolization of contrast material that could result in respiratory failure. They advocated chemotherapy as the treatment of choice, because it provides both local and systemic therapeutic activity. They suggested that local consolidation with radiation therapy may be beneficial in patients with large cell lymphoma with mediastinal masses larger than 10 cm.

A similarly favorable experience in children with T-cell lymphoma or leukemia (nine patients) and Hodgkin's disease (two patients) presenting with SVCS was reported from Israel.<sup>57</sup> Tissue diagnosis was obtained before specific therapy in all children; SVCS responded to chemotherapy within 2 to 10 days, and the overall 3-year disease-free survival rate was 78%.

## NONMALIGNANT CAUSES

Patients with nonmalignant causes of SVCS differ significantly from patients with malignant disease. If the cause is not malignant, the patients often have symptoms long before they seek medical advice; it takes more time to establish the diagnosis; and their survival is markedly longer.<sup>4</sup> Schraufnagel et al.<sup>4</sup> reported that the average survival rate was 9 years if the primary process was benign, compared with an average survival of 5 months for patients with lung cancer. Mahajan et al.<sup>58</sup> reviewed the literature of benign SVCS and reported 16 new cases. Twelve (75%) of these 16 patients had a mediastinal granuloma that was attributed to histoplasmosis. Most patients had an insidious onset of SVCS and were relatively young. Ten patients who were available for a follow-up of 1 to 11 years were all doing well at the time of the report. It was suggested that the good prognosis of patients with benign SVCS caused by fibrosing mediastinitis does not provide a role for SVC bypass surgery.<sup>58,59</sup> However, Nieto and Doty<sup>38</sup> advocated surgery for SVCS caused by benign disorders if the syndrome develops suddenly, progresses, or persists after 6 to 12 months of observation for possible collateral development.<sup>38</sup> In patients whose histoplasmosis complement fixation titers suggest active disease, ketoconazole treatment may prevent recurrent SVCS.<sup>60</sup>

## CATHETER-INDUCED OBSTRUCTION

In catheter-induced SVCS, the mechanism of obstruction is usually thrombosis. Streptokinase, urokinase, or recombinant tissue-type plasminogen activator may cause lysis of the thrombus early in its formation.<sup>24,61,62,63</sup> and <sup>64</sup> Heparin and oral anticoagulants may reduce the extent of the thrombus and prevent its progression. Removal of the catheter, if possible, is another option and should be combined with anticoagulation to avoid embolization. In patients for whom electrodes of a pacemaker must be changed, the broken wire should be removed to prevent the risk of developing SVCS.<sup>24,61,65</sup> Percutaneous transluminal angioplasty, with or without thrombolytic therapy, and stent insertion have been successfully used to open catheter-induced SVC obstructions.<sup>62,66,67,68</sup> and <sup>69</sup>

## TREATMENT

### RADIATION THERAPY

In patients with SVCS as a result of non-SCLC, radiotherapy has long been the primary treatment. The likelihood of relieving the symptoms and signs of SVCS is high,<sup>5,9</sup> but the overall prognosis for these patients is poor.<sup>4,5,9,25</sup> In the series of Armstrong et al.,<sup>9</sup> the 1-year survival for these patients was 17%, and the survival at 2 years declined to 2%. More recently, the use of percutaneous metal stent insertion to improve blood flow through the SVC has been introduced as an alternative to palliative radiation therapy in malignant SVCS.<sup>3,70</sup>

Radiotherapy is an optional treatment for most patients with SVCS.<sup>23,28,30</sup> It is also used as an effective initial treatment if a histologic diagnosis cannot be established and the clinical status of the patient is deteriorating. However, some reviews suggest that SVC obstruction alone rarely represents an absolute emergency that requires radiotherapy without a specific diagnosis, and endovascular stenting may be used as an alternative to radiotherapy for obtaining immediate relief of the obstruction.<sup>3,12,31,32,70</sup> Yet, SVCS may be the earliest manifestation of invasive involvement of additional critical structures in the thorax ( [Table 51.1-6](#) ), such as the bronchi. Under such circumstances, prompt treatment with irradiation may be required without any delay.

Complication	Number of Patients* (%)
<b>ESOPHAGUS</b>	
Symptoms of dysphagia or esophageal dysfunction	26 (24)
Anatomic evidence of esophageal invasion	6 (6)
<b>TRACHEA</b>	
Displaced on examination or esoradiogram	7 (7)
Compressed or invaded by lesion	14 (13)
<b>VOCAL CORD PARALYSIS</b>	
Unilateral	6 (6)
Bilateral	3 (3)
<b>PERICARDIUM</b>	
Tamponade	3 (3)
Neoplastic invasion at autopsy	6 (6)

\*Some patients may have had more than one complication. (From ref. 4, with permission.)

**TABLE 51.1-6.** Complications of Malignant Invasion Associated with Superior Vena Cava Syndrome

The fractionation schedule of radiation that has been recommended includes two to four large initial fractions of 3 to 4 cGy, followed by conventional fractionation to a total dose of 30 to 50 cGy.<sup>5,23,29</sup> However, no data clearly support a particular fractionation scheme.<sup>19</sup> In one study, patients treated with initial high-dose fractions showed a slightly faster symptomatic improvement than patients receiving conventional-dose radiation.<sup>9</sup> Improvement within 2 weeks or less was observed in 70% of those treated with initial high-dose fractions and in 56% of patients receiving conventional-dose therapy. This difference was not statistically significant.

A radiotherapy study evaluated the efficacy of treating patients with SVCS with a short course of hypofractionated irradiation.<sup>71</sup> The study compared a regimen of 8 Gy per fraction once a week to a total dose of 24 Gy to a program of delivering only two fractions of 8 Gy (total of 16 Gy) within 1 week. Transient dysphagia was the main side effect in almost one-half of patients in both programs. The 24-Gy regimen resulted in a complete resolution of symptoms in 56% of patients and a partial response in another 40%. The 16-Gy regimen yielded a complete response in only 28% of patients. The mean time for SVCS recurrence and the median overall survival rate were longer in the higher-dose regimen (6 months and 9 months, respectively) compared to the low-dose regimen (3 months and 3 months, respectively).

Serial venograms and autopsies<sup>31</sup> suggest that the symptomatic improvement achieved by radiotherapy is not always due to improvement of flow through the SVC, but it is probably also a result of the development of collaterals after the pressure in the mediastinum is eased.

The field of radiation for SVCS induced by lung cancer should encompass the gross tumors with appropriate margins, and mediastinal, hilar, and supraclavicular lymph nodes. In Armstrong et al.'s series,<sup>9</sup> supraclavicular failures occurred in 8 of 91 patients (9%) receiving radiation therapy to the supraclavicular fossae and in

two of six patients (33%) not receiving therapy to these lymph nodes.<sup>9</sup>

## ENDOVASCULAR STENTING AND ANGIOPLASTY

Percutaneous transluminal angioplasty using the balloon technique, insertion of expandable wire stents, or both, has been successfully used to open and maintain the patency of SVC obstruction resulting from malignant and benign causes.<sup>3,69,70,72</sup>

Thrombolysis is often an integral part of the endovascular management of SVCS because thrombosis is often a critical component of the obstruction and lysis is necessary to allow the passage of the wire. Balloon dilatation (angioplasty) may also be used before stenting. Most reports have emphasized the use of combination endovascular therapy—thrombolysis, angioplasty, and stent therapy.<sup>3</sup>

The experience with stenting has been growing rapidly. Most experience has been with three stents: the Gianturco Z-stent, the Wallstent, and the Palmaz stent. The Wallstent is the most commonly used device.<sup>3</sup> It is self-expanding and built of woven stainless steel wire. Its tight weave deters tumor ingrowth.

Total occlusion of the SVC is not a contraindication to stent therapy, and a success rate of 85% in total occlusion situations has been reported.<sup>73</sup> The largest experience in using stents to open malignant obstruction of the SVC was reported by Nicholson et al. in Great Britain.<sup>70</sup> The British team used Wallstents in 75 patients and obtained improvement of obstruction in all patients; 90% remained free of symptoms until death. This study retrospectively compared stent therapy with radiation therapy and found that only 12% of patients treated with radiation remained free of SVCS until death. However, long-term experience in maintaining patency after stent therapy in patients with SVCS from benign causes who are expected to have long survival, is still limited.<sup>69</sup>

Complication rates for endovascular therapy have ranged from 0% to 50% and include bleeding, stent migration, stent occlusion, and pulmonary embolus.<sup>3</sup> Most complications can be successfully treated with percutaneous methods.

## SURGERY

The experience with successful direct bypass graft for SVC obstruction is limited. It was recommended that autologous grafts of almost the same size as the SVC should be used.<sup>74</sup> Doty et al.<sup>75</sup> used a composite spiral graft, which was constructed from the patient's saphenous vein. They reported 23 years of experience with this procedure in 16 patients with benign obstruction of SVC; 14 patients maintained patency and 15 were relieved of symptoms of SVCS. Avasthi and Moghissi<sup>76</sup> reported successful bypasses of obstructed SVCs using Dacron prostheses. Magnan and associates<sup>77</sup> used an expanded polytetrafluoroethylene prosthesis to reconstruct the SVC in nine patients with malignancy-induced SVCS and in one patient with chronic mediastinitis. In all, patients' symptoms disappeared promptly after the operation, the grafts remained open, and survival rates at 1, 2, and 5 years were 70%, 25%, and 12.5%, respectively.<sup>77</sup>

The preferred bypass route is between an innominate or jugular vein on the left side and the right atrial appendage, using an end-to-end anastomosis.<sup>45</sup> Piccione et al.<sup>78</sup> used the autologous pericardium to reconstruct the SVC after resection for malignant obstruction. In patients with malignancy-induced SVCS, surgical intervention should be considered only after other therapeutic maneuvers with irradiation and chemotherapy have been exhausted. Most patients with SVCS of benign origin have long survivals without surgical intervention.<sup>58,59</sup> However, if the process progresses rapidly or if there is arterosternal goiter or aortic aneurysm, surgical intervention may relieve the obstruction.

## THROMBOLYTIC THERAPY

Thrombolysis is an important component of comprehensive endovascular therapy.<sup>3</sup> Successful experience with thrombolytic agents was also obtained in the treatment of catheter-induced SVCS.<sup>24,64,79</sup> A review of the response of SVCS to thrombolytic therapy from the Cleveland Clinic<sup>64,80</sup> showed that in 8 of 11 patients (73%) with a central venous catheter, lysed after thrombolytic therapy compared with only one of five patients who responded to thrombolytic therapy in the absence of a central catheter. The higher yield of thrombolytic therapy in patients with catheters is probably related to the mechanism of obstruction, the ability to deliver the agent directly to the thrombus, and to earlier recognition of SVCS in patients with malfunctioning catheters. In the Cleveland Clinic experience,<sup>64</sup> urokinase was more effective than streptokinase, and a delay administering therapy beyond 5 days of symptom onset was associated with a treatment failure. Favorable experience with recombinant tissue-type plasminogen activator as a thrombolytic agent for catheter-induced SVCS has been reported.<sup>62,63</sup>

## GENERAL MEASURES

Medical measures other than specific chemotherapy may be beneficial in temporarily relieving the symptoms of SVCS. Bed rest with the head elevated and oxygen administration can reduce the cardiac output and venous pressure. Diuretic therapy and a reduced-salt diet to reduce edema may have an immediate palliative effect, but the risk of thrombosis enhanced by dehydration should not be ignored. Steroids are commonly used, but their effectiveness has never been properly evaluated. They may improve obstruction by decreasing a possible inflammatory reaction associated with tumor or with irradiation. However, Green and colleagues<sup>81</sup> demonstrated the lack of inflammatory reaction and edema after radiotherapy for experimental SVCS, but documentation in a controlled fashion is lacking. Thrombolytic therapy with urokinase, streptokinase, and recombinant tissue-type plasminogen activator was effective in SVCS induced by indwelling catheters.<sup>62,64,79,80</sup>

## RECOMMENDATIONS

In patients without a clear cause of SVCS, an efficient diagnostic effort should be attempted before any oncologic treatment. However, percutaneous endovascular intervention should be considered, because it relieves symptoms without masking the diagnosis.

Three deep-cough sputum specimens should be obtained for cytologic analysis. A positive cytologic evaluation provides reliable pathologic information, particularly in the diagnosis of SCLC.<sup>45</sup> If there is pleural effusion, thoracentesis should be performed and the centrifuge-prepared specimen examined for the presence of malignant cells. If a suspicious lymph node is palpable, particularly in the supraclavicular area, a needle or open biopsy should be the next diagnostic step. In the absence of positive sputum results, pleural effusion, or accessible suspicious lymph node analysis, a bronchoscopy should be performed, and brushing, washing, and biopsy samples should be obtained for cytologic and histologic analysis. If these efforts do not provide the histologic diagnosis of the primary process, percutaneous transthoracic fine-needle biopsy under CT or fluoroscopic guidance is safe and highly effective.<sup>49,51</sup> In the rare patient for whom less-invasive procedures have failed to establish the diagnosis, the location of the suspicious lesion in the chest and the experience of the surgical team should determine whether mediastinoscopy or thoracotomy is performed.

During the diagnostic process, the patient can benefit from bed rest with the head elevated and with oxygen administration. Some clinicians advocate the use of diuretics and steroids (6 to 10 mg of dexamethasone given orally or intravenously every 6 hours) as a temporary palliative measure if the patient is uncomfortably symptomatic. Anticoagulation is of no proven benefit and may interfere with diagnostic procedures. After the cause of SVCS has been established, treatment of the primary process should promptly follow. Combination chemotherapy with an appropriate regimen is the treatment of choice for SCLC and NHL. Radiation therapy of the lesion and adjacent nodal areas may enhance control after initial response to chemotherapy. Non-SCLC causing SVCS is best treated with radiation therapy or endovascular stent insertion or both. The incorporation of CT scan information into a carefully designed treatment plan may enable the administration of a total radiation dose of more than 5000 cGy, which may provide long-term local control for some patients. Most patients with nonmalignant causes for SVCS have an indolent course and a good prognosis. Percutaneous transluminal angioplasty or stent insertion should be considered an effective alternative to surgery. However, the long-term maintenance of patency with stent insertion is still unknown. Surgery is indicated only when the process is rapidly progressing or caused by a retrosternal goiter or an aortic aneurysm. If SVCS is induced by a catheter, the catheter should be removed if possible. Heparin should be administered during the removal of the catheter to prevent embolization. In catheter-induced SVCS, urokinase, streptokinase, or recombinant tissue-type plasminogen activator are of value if used early in the thrombotic process.<sup>60, 61 and 62,80</sup>

The clinical course of SVCS rarely represents an absolute emergency. In these situations, the bronchus is likely to be obstructed by the same basic process, and irradiation may have to be started immediately, even before the histologic diagnosis is established.

#### INTRODUCTION

Spinal cord compression from metastatic cancer remains an important source of morbidity despite the fact that with early diagnosis, treatment is effective in 90% of patients.<sup>1</sup> Technical improvements in spinal imaging, radiation therapy, and surgery have allowed treatment of spinal cord compression to be dispensed with greater precision. However, the most important weapon against the devastation of paraplegia or sphincter dysfunction is a heightened awareness of possible spinal cord compression in the cancer patient and early intervention.

Despite its common occurrence, there have been few prospective studies<sup>1,2,3</sup> and 4 and randomized trials have been exceedingly rare.<sup>5,6</sup> and 7 At the dawn of the new millennium, treatment recommendations are based largely on empiric experiences described in retrospective reports. However, the pathophysiology of cord compression and the factors that predict treatment outcome are well known.

Malignant spinal cord compression is defined as the compressive indentation, displacement, or encasement of the spinal cord's thecal sac by metastatic or locally advanced cancer. Compression can occur via posterior extension of a vertebral body mass, resulting in compression of the anterior aspect of the spinal cord, or through anterior or anterolateral extension of a mass arising from the dorsal elements or invading the vertebral foramen, respectively. Intramedullary spinal cord metastases produce edema, distortion, and compression of the spinal cord parenchyma, resulting in symptoms and signs that are similar to epidural spinal cord compression. Virtually any neoplasm capable of metastasis or local invasion can produce malignant spinal cord compression. The response to nonsurgical therapy and the duration of survival following treatment can vary considerably among the different histologic tumor types. Therapy for the individual patient can be optimized once the tumor's histologic type is known and the extent, severity, and mechanism of spinal cord compression are established.

The degree of pretreatment neurologic dysfunction is the strongest predictor of treatment outcome. Ambulation can be preserved in greater than 80% of patients who are ambulatory at presentation.<sup>1,2,8,9</sup> and 10 Paraplegia, quadriplegia, and loss of bowel or bladder function are potential consequences of cord compression if it is diagnosed late or left untreated. Once lost, neurologic function cannot be regained in the majority of patients. The diagnosis of cord compression is easy to establish with contemporary diagnostic evaluations, and with early intervention the results of treatment are good to excellent. Therefore, the key to successful management is a heightened awareness of signs and symptoms, specifically newly developed back pain or motor dysfunction, leading to early diagnosis and treatment.

#### EPIDEMIOLOGY

In adults, metastatic spinal cord compression occurs in roughly 3.0% to 7.4% of patients with lung, prostate, and breast cancer,<sup>8</sup> and the overall frequency of malignant spinal cord compression has been reported to be approximately 5%.<sup>11,12</sup> Spinal cord compression is the second most frequent neurologic complication of metastatic cancer.<sup>13</sup> It can be identified at autopsy in 5% to 10% of patients dying of cancer.<sup>14,15</sup> Ten percent of adult patients with malignant spinal cord compression present without a known primary tumor or with cord compression as the initial presentation of a malignancy.<sup>13</sup> Cord compression at initial presentation is more commonly seen at general hospitals than at regional cancer centers.<sup>16</sup> Tertiary referral centers specializing in cancer may see 50 to 100 cases per annum, although the true incidence of malignant spinal cord compression is not known.<sup>17</sup> Intramedullary lesions make up only 0.8% to 3.8% of all cases of metastatic spinal cord compression.<sup>18</sup> Second episodes of malignant spinal cord compression occur in 7% to 16% of cases.<sup>19,20</sup>

In children, the frequency of metastatic spinal cord compression is approximately 4.0% to 5.5%.<sup>21,22</sup> and 23 In one report roughly 50% of cases presented with cord compression at the time of initial diagnosis, and 50% developed compression from secondary spinal metastases.<sup>23</sup> The most frequent tumor types producing pediatric cord compression are neuroblastoma (7.9% to 50%), Ewing's sarcoma (15% to 28.5%), rhabdomyosarcoma (15% to 28%), osteosarcoma (6% to 9%), lymphoma (6.0% to 7.5%), and leukemia (6%).<sup>21,22,23</sup> and 24 Cord compression has been reported to be more frequent in male than in female children, reflecting the epidemiology of childhood cancer.<sup>21,23,24</sup>

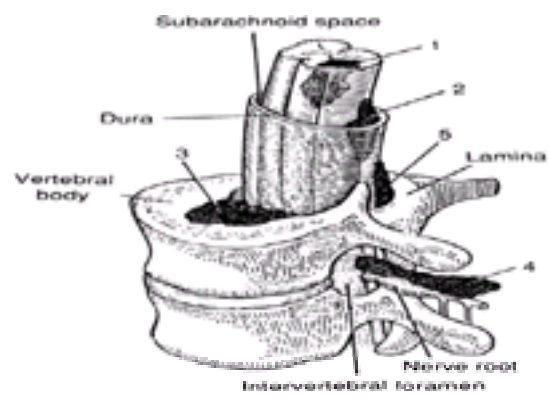

#### PATHOPHYSIOLOGY

In the majority of cases, vertebral body metastases result from the hematogenous dissemination of tumor clonogens that express tropism for the vertebral column bone marrow. More frequently growing in the well-vascularized marrow space of the posterior vertebral body, spinal metastases can produce cord compression in two ways. The first results from continued growth and obliteration of the marrow space with expansion into the epidural space, producing impingement on the anterior thecal sac and its surrounding venous plexus ( [Fig. 51.2-1](#)). Alternatively, destruction of cortical bone by tumor can result in vertebral body collapse with anterior angulation and posterior displacement of bony fragments into the epidural space against the thecal sac and epidural venous plexus. Compression of the cord, its blood vessels, and nerve roots can also occur from the posterolateral direction via invasion of tumor through the neural foramen. Paraspinal tumors or expanding paraaortic nodal metastases use this mechanism of compression. Posterior thecal sac compression from metastatic involvement of the neural arch does occur but with less frequency. Finally, intramedullary metastases that result from hematogenous dissemination produce internal compression of the spinal cord structures and parenchymal vasculature. The signs and symptoms of intramedullary cord compression are similar to those of external cord compression. However, myelography is less reliable for detection of intramedullary compression. Patterns of metastatic involvement of the spine are illustrated in [Figure 51.2-2](#) and displayed in [Figure 51.2-3](#), [Figure 51.2-4](#), [Figure 51.2-5](#), and [Figure 51.2-6](#).

**FIGURE 51.2-1.** An appreciation of the anatomic relationships within the spinal canal is important in understanding the pathophysiology of spinal cord compression. **A:** The normal spinal cord structures are shown. Note the relationship of the epidural venous plexus to the vertebral body and bony canal. **B:** The change in these relationships produced by a metastatic tumor arising from the vertebral body is illustrated. Note the obliteration of the epidural venous plexus and the compressive displacement of the spinal cord and its nerve roots. (Courtesy of Howard Bartner and Martha Blalock.)

**FIGURE 51.2-2.** Metastatic involvement of the spine. Intramedullary metastases reach the cord through hematogenous dissemination and grow within the cord parenchyma (1). Leptomeningeal metastases involve the meningeal membranes of the subarachnoid space, which are extramedullary and intradural (2). Epidural metastases usually arise from the highly vascular posterior aspect of the vertebral body and produce compression of the anterior aspect of the spinal cord (3). Epidural compression can also result from paravertebral tumors that invade the vertebral foramina (4) and, less often, from metastases arising in the epidural space itself (5). (Adapted from ref. 103.)

**FIGURE 51.2-3.** This sagittal view of a magnetic resonance image demonstrates an intramedullary metastasis in the lumbar spine from renal cell carcinoma.

**FIGURE 51.2-4.** This sagittal magnetic resonance image of the lumbar spine demonstrates anterior compression of the cauda equina below the conus medullaris. Note the pathologic fracture of the L-2 vertebral body and the retropulsed bone fragments compressing the thecal sac.

**FIGURE 51.2-5.** This axial view from a magnetic resonance image of the thoracic spine demonstrates posterolateral compression of the spinal cord resulting from invasion of the left neuroforamen.

**FIGURE 51.2-6.** A sagittal magnetic resonance image of the spine demonstrating posterior compression of the spinal cord from a metastasis arising in the spinous process.

process. Laminectomy is the most useful approach for tumors arising posterior to the cord.

In an early study of spinal cord compression employing Murphy-Sturm lymphoma in Sprague-Dawley rats, Rubin demonstrated the ability of radiation to produce neurologic recovery and the absence of significant radiation-induced edema in the treated spinal cord. <sup>25</sup> Usio et al., using a Walker 256 carcinoma cord compression model in rats, were able to document the early development of white matter necrosis and gliosis with preservation of large blood vessels. <sup>26</sup> Similar findings were reported by Ikeda et al. using a rabbit model of malignant epidural cord compression. Early pathologic changes included axonal swelling and white matter edema. Later changes consisted of white matter necrosis with relative sparing of gray matter. Microangiography of the compressed spinal cords revealed preservation of the anterior and posterior spinal arteries, while the central arteries were deformed and decreased in number. Stenosis and obstruction of the epidural venous plexus was observed in the earliest stages of neurologic dysfunction. <sup>27</sup>

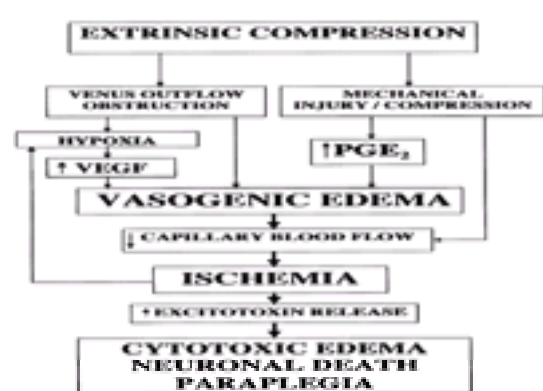

An analysis of spinal cord blood flow in rats with cord compression by Kato et al. revealed three distinct phases in the development of spinal cord compression: (1) initial circulatory disturbance resulting in white matter edema and neurologic dysfunction secondary to venous outflow obstruction; (2) decreased spinal cord blood flow resulting from vasogenic edema and mechanical compression of the cord; and (3) rapid loss of spinal cord blood flow in small arterioles and capillaries resulting in infarction with preservation of large extramedullary nutritional vessels. <sup>28</sup> The validity of this sequence of events was further confirmed by Arbit et al., who found loss of medullary centrifugal blood vessels at the level of compression, with preservation of radicular and subcommissural vessels. Spongy vacuolization and pallor of the white matter as well as spinal cord edema were also described. <sup>29</sup>

Within the spinal cord itself, existing evidence suggests that the pathophysiology of spinal cord compression is vascular in nature. <sup>26,28,29,30,31,32,33 and 34</sup> This has been shown repeatedly in animal models and has been corroborated by autopsy findings. <sup>35</sup> Initial extension of tumor into the epidural space results in compression of the epidural venous plexus, which normally drains blood from the spinal cord. Compression of the venous plexus leads to venous stasis. Relative hypoxia, increased vascular permeability, and interstitial edema appear to selectively involve the white matter, <sup>27,28 and 29</sup> although increased vascular permeability was observed involving gray matter in one model. <sup>26</sup> Edema in the spinal cord caused by increased vascular permeability impairs spinal cord function, resulting in weakness and sensory impairment. Interstitial edema increases the pressure within small arterioles early in the evolution of spinal cord compression and therefore retards blood flow. In the more advanced stages, pressure on small intramedullary arterioles produced by increasing interstitial edema combined with progressive direct physical pressure on the spinal cord by the expanding mass ultimately leads to arrest of capillary blood flow, resulting in ischemia of white matter. If left untreated, there is infarction of ischemic white matter and permanent neurologic loss.

Siegal and colleagues have evaluated the roles of cytokines, inflammatory mediators, and neurotransmitters in the pathophysiology of cord compression in a series of reports. <sup>45,46,47,48,49 and 50</sup> Spinal cord injury from compression was associated with increased water content, increased vascular permeability, and increased specific gravity in the compressed spinal cord as well as increased extravasation of blood cells into the cord parenchyma. <sup>45</sup> Treatment with dexamethasone phosphate was shown to reduce tissue-specific gravity in the compressed cord and to delay the onset of paralysis. <sup>46,47</sup> Similar results were obtained with indomethacin, which also decreased the elevated water content and reduced prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) levels in the compressed segments of the spinal cord. <sup>46,47</sup>

Later experiments demonstrated the ability of free dexamethasone to decrease free water content and PGE<sub>2</sub> levels in compressed segments of the spinal cord. <sup>48</sup> The potential role of glutamate in the production of cytotoxic edema was suggested when it was shown that N-methyl- D-aspartate receptor antagonists reduced the spinal cord free water. <sup>49</sup> This group also demonstrated that inhibitors of serotonin synthesis could reduce the elevated serotonin levels associated with spinal cord injury. Serotonin receptor antagonists reduced PGE<sub>2</sub> synthesis, reduced spinal cord vascular permeability, and delayed the onset of paraplegia. <sup>50</sup> These studies form the basis for development of new pharmacologic approaches to the treatment of cord compression.

The role of vascular endothelial growth factor (VEGF) in the pathophysiology of malignant spinal cord compression is being increasingly recognized. In the early stages of malignant spinal cord compression, venous stasis and relative hypoxia stimulate VEGF production. <sup>44</sup> VEGF increases vascular permeability and vasogenic edema in the spinal cord in response to transient ischemia <sup>36</sup> and trauma. <sup>37,38</sup> The progressive hypoxia, resulting from interstitial edema and decreased microcapillary perfusion, continues to drive VEGF production. Several observations suggest that the beneficial effects of dexamethasone are at least in part mediated by its effect on VEGF activity. Dexamethasone down-regulates VEGF gene expression, <sup>39,40 and 41</sup> inhibits VEGF activity, <sup>42</sup> and prevents the VEGF-induced cytoskeletal changes associated with vascular permeability (i.e., plasmalemmal ruffling and widening of intracellular spaces) in rat brain endothelial cells. <sup>43</sup> A model of the pathophysiology of malignant spinal cord compression is presented in [Figure 51.2-7](#).

**FIGURE 51.2-7.** A simplified schematic representation of the pathophysiologic changes leading to neuronal damage from cord compression. Several histologic studies suggest that the initial pathophysiologic changes resulting in vasogenic edema are confined principally to white matter. <sup>27,28 and 29</sup> PGE<sub>2</sub>, prostaglandin E<sub>2</sub>; VEGF, vascular endothelial growth factor.

The importance of the magnitude, rate, and duration of compression in regard to the neurologic outcome was studied in dogs with an epidural inflatable balloon by Tarlov et al. Paraparesis resulting from rapid compression of the cord could be reversed if decompression occurred within 9 hours. Paraparesis resulting from more gradual compression over 20 to 48 hours could be successfully reversed by decompression within the next 7 days, emphasizing that neurologic deficits are more likely to be reversed if compression occurs gradually rather than rapidly. <sup>30,31 and 32</sup> This has also been observed in humans. Rades et al. reported 96 patients treated with radiotherapy for spinal cord compression who were compared based on the duration of motor symptoms before treatment. Improvement of neurologic function 2 weeks after radiotherapy occurred in a higher percentage (89%) of patient with deficits that developed greater than 14 days before treatment, compared with patients who developed symptoms less than 14 days before treatment (12%). A separate cohort of patients with severe deterioration of motor function occurring within 48 hours before treatment experienced improvement in only 6% of cases. <sup>51</sup>

In summary, spinal cord damage and loss of neurologic function result from venous stasis, spinal cord edema, reduced capillary blood flow, ischemia, and mechanical compression culminating in infarction. Prostaglandins, cytokines, excitatory neurotransmitters, and inflammatory mediators regulate the sweeping pathophysiologic changes associated with hypoxia, edema, ischemia, and injury resulting from malignant compression. The rapidity of progression of neurologic symptoms indicates the severity of spinal cord injury and the likelihood of permanent neurologic loss. Dexamethasone and other antiinflammatory agents can delay the onset of paralysis and improve symptoms until decompressive measures intervene.

## CLINICAL PRESENTATION

The majority of patients who present with spinal cord compression have a known diagnosis of cancer. However, in 8% to 34% of cases it can represent the initial manifestation of cancer. <sup>52,53 and 54</sup> The frequency of tumor types for over 1000 patients with cord compression from the literature is listed in [Table 51.2-1](#). Spinal cord

compression develops within 3 months of the initial diagnosis of cancer in the majority of cases complicating lung carcinoma, whereas it can develop as long as 24 years after the initial diagnosis of breast cancer. <sup>3,9,52</sup>

**TABLE 51.2-1.** Frequency of Tumor Types Producing Cord Compression

The most frequently involved site is the thoracic spine (59% to 78%), followed by the lumbar spine (16% to 33%) and the cervical spine (4% to 15%) ( [Fig. 51.2-8](#)). Multiple epidural sites of compression can occur in 26% to 49%. <sup>55,56,57,58</sup> and <sup>59</sup> Intramedullary cord compression, accounting for only 1% to 4% of cases, is usually solitary and is often associated with parenchymal brain metastases. <sup>18,55,60,146</sup>

**FIGURE 51.2-8.** The frequency of involvement in the different regions of the spine is shown.

Pain accompanies malignant spinal cord compression in 70% to 96% of cases. <sup>7,52,53,61,62</sup> It usually precedes the diagnosis of spinal cord compression by days to months. <sup>52,63</sup> The pain may be local, radicular, or both. Local pain is present in the vast majority of cases and is caused by expansion, destruction, or fracture of the involved vertebral elements. The site of compression can usually be localized to the site of back or neck pain. Local back or neck pain is usually dull, aching, constant, and progressive. Back pain from vertebral destruction resulting in retropulsion of bone fragment is often worse in the supine position, a feature distinguishing cord compression from a herniated disc. Local back or neck pain can be exacerbated by movement, sneezing, straining, or neck flexion. The location of the involved vertebral body can usually be established by gentle spinal percussion. Radicular pain, which is usually, but not always, associated with local back or neck pain, is caused by compression of the nerve roots or cauda equina. Radicular pain is often shooting in quality and localizes to within one to two vertebral segments of the compression. Bilateral band-like girdle pain is characteristic of thoracic cord lesions, and unilateral radicular pain is more characteristic of lumbar or cervical lesions. Radicular pain from a cervical or lumbar lesion may involve the shoulder, hip, groin, perineum, or extremity.

Weakness, the second most common symptom at presentation, is usually what prompts the patient to seek medical intervention. Weakness, which usually follows the development of local or radicular pain, can develop gradually in association with progressive balance disturbance and numbness. Initial unilateral weakness is common when paresis develops gradually. Complete loss of motor and sensory function below the affected level (cord shock) can occur abruptly as vascular insufficiency progresses to frank ischemia. Neurologic examination of the patient with cord shock reveals absent motor, sensory, reflex, and autonomic function below the level of the lesion, and the affected extremities demonstrate flaccidity and absence of tone. Absence of perineal and anal reflexes and painless overflow incontinence complete the neurologic presentation. Flaccidity and areflexia are gradually replaced by paraplegia in flexion. Compression of the upper cervical spinal cord can produce paralysis of the upper extremities and respiratory failure, if acute. Chronic injuries of the cervical spine can produce wasting of the intrinsic muscles of the hand, forearm, or arm as well as progressive weakness of the intercostal muscles and diaphragm, leading ultimately to respiratory arrest. Lesions involving the conus medullaris or cauda equina produce flaccid paralysis of the lower extremities, absent or flexor plantar responses, saddle anesthesia, urinary retention leading to incontinence, and male impotence. The frequency of symptoms and signs of cord compression is presented in [Table 51.2-2](#).

## DIAGNOSTIC EVALUATION

The diagnostic evaluation of suspected cord compression should include a careful history, physical and neurologic examination, radiologic evaluation including a sagittal magnetic resonance imaging (MRI) survey of the spine, and, if indicated, urgent consultation by physicians in neurology, neurosurgery, radiation oncology, and medical oncology, when compression is caused by a chemosensitive neoplasm. Clear indications of epidural cord compression such as focal weakness, ataxia, and unexplained bowel or bladder dysfunction accompanied by back pain in the cancer patient demand urgent evaluation.

The medical history obtained from the cancer patient suspected of spinal cord compression should emphasize the onset, quality, location, and temporal pattern of back or neck pain. Back pain associated with spinal cord compression may be exacerbated by movement, lying flat, neck flexion, straight leg raising, straining, coughing, or sneezing. Symptoms of motor dysfunction are often described as stiffness or weakness that usually begins in one extremity and remains unilateral in nerve root compression but becomes bilateral with compression of the spinal cord or conus medullaris. Paresthesias due to involvement of the spinothalamic tract

begin distally, usually in the foot, and ascend to the level of involvement. Numbness and paresthesias are typically noticed later in the history than motor dysfunction.

Physical examination should emphasize localization of the level of suspected compression. This is often best initialized by asking the patient to point out the site of the back pain. Gentle percussion over the spine can confirm the site of involvement and help elucidate other sites of vertebral metastases. Flexor and extensor motor testing, deep tendon and plantar reflex assessment, sensory level identification via pin prick, and anal sphincter tone assessment are required components of any diagnostic evaluation for cord compression.

There are several radiologic and tumor imaging techniques that are potentially useful in the diagnosis and treatment of cord compression. Plain radiographic films continue to be quite useful in evaluation of cord compression associated with bony involvement of the spine or due to compression fracture. However, they are relatively insensitive for detecting bone involvement and soft tissue masses, and they cannot demonstrate the actual spinal cord itself.

Despite these limitations, plain films can be useful in diagnosing cord compression and in planning therapy. Plain radiographs detect bony abnormalities in 72% of patients with epidural cord compression.<sup>5</sup> Plain film radiographs detect the presence and location of epidural metastases in 83% of patients complaining of back pain. Vertebral body collapse, destruction of the pedicle, and blastic or sclerotic changes are characteristic findings observable with plain film radiography. However, paraspinous masses or vertebral body involvement resulting in less than 50% destruction of the cortex cannot be appreciated with plain film techniques. In addition, in up to 60% of patients with epidural compression by lymphoma and pediatric malignancies, plain films may be normal. Posterior or posterolateral compression resulting from a paraspinous mass invading the vertebral foramen is most common with these tumor types. Computed tomography (CT) and MRI are able to detect posterior or posterolateral cord compression secondary to neuroforamina invasion and are superior to plain films, bone scintigraphy, or myelography in that regard.

Myelography has the advantage over plain films of visualizing the level of the compression as indicated by a blockage of myelographic contrast. However, multiple sites of compression, which may be present in greater than 30% of cases, may require more than one subarachnoid puncture. For these reasons, CT, and to a much greater extent MRI, have emerged as the most useful techniques for imaging cord compression.

Bone scintigraphy is more sensitive than plain films in detecting metastatic involvement and provides information about the entire skeleton in a single examination. This facilitates screening the skeletal system for potential sources of referred pain, and it is useful in planning radiation therapy to multiple sites. However, bone scintigraphy is not as sensitive and specific in detecting spinal metastases as MRI<sup>64,65</sup> and is incapable of describing the soft tissue and spinal cord anatomy required for the proper diagnosis and treatment of cord compression. Furthermore, primarily osteolytic metastases produced by multiple myeloma, lymphoma, and other malignancies may not be detected by bone scan.<sup>67,68</sup>

In the pre-MRI era, myelography and CT were the imaging modalities of choice for the diagnosis of cord compression, and either or both of these tests are mandatory when MRI is not available or is nondiagnostic. When a complete myelographic block is detected following routine lumbar injection, an additional injection from above through a C-1 to C-2 puncture is required to evaluate possible additional sites of compression. CT following metrizamide myelography is an alternative to a C-1 to C-2 puncture in patients with a complete myelographic bloc. However, MRI is superior to both CT and myelography in convenience, anatomic detail, and cost.<sup>69</sup> Yet CT exceeds MRI in the evaluation of vertebral stability and bone destruction. Therefore, CT should be obtained before vertebral body resection or surgical stabilization of the vertebral column.

Positron emission tomography has been used to evaluate metabolic changes in the cervical spinal cord following mechanical spinal cord compression<sup>70,71</sup> and to identify intramedullary spinal cord metastases.<sup>72</sup> Although positron emission tomography is increasingly being studied in the setting of malignant spinal cord compression,<sup>61,72</sup> its current role is not completely defined.

MRI has replaced myelography and CT scanning as the diagnostic procedure of choice for evaluating cord compression.<sup>61,64,73,74,75,76,77,78,79</sup> and <sup>80</sup> MRI has a sensitivity of 93%, a specificity of 97%, and an overall diagnostic accuracy of 95% in detecting cord compression.<sup>75</sup> It is superior to bone scintigraphy in sensitivity and specificity for spinal metastases<sup>64,65</sup> and can distinguish between benign and metastatic causes of vertebral body collapse with a sensitivity of 97.6%, a specificity of 100%, and an overall accuracy of 98.2%.<sup>75</sup> The advantages of MRI over myelography for evaluating cord compression include its noninvasive ability to image soft tissue anatomy in great detail (tumors, spinal cord) and its ability to image multiple levels of cord impingement in one examination. Paraspinous and neuroforaminal tumors are not as easily identified with myelography as with MRI.<sup>80</sup> In addition, MRI allows avoidance of the 16% to 24% chance of neurologic deterioration following lumbar puncture for myelography.<sup>81</sup> MRI excels in demonstrating intramedullary metastases that can be missed completely by myelography.

The advantages of MRI over CT include its ability to distinguish the spinal cord proper from other soft tissue masses in the spinal canal, and its ability to assess thecal sac impingement in the presence of disrupted cortical bone as is frequently encountered with myeloma and blastic lesions from prostate cancer. MRI is safer, more convenient, better tolerated, more informative, and less expensive than other techniques used to diagnose cord compression. Jordan et al. compared the cost of evaluation of spinal cord compression with and without MRI. Establishing the diagnosis of cord compression was 65% more expensive when MRI was not used.<sup>69</sup>

Because of its diagnostic accuracy and ability to image multiple levels of involvement, MRI is extremely useful in planning local treatment. Identification of paravertebral tumor, neuroforamina invasion, and additional sites of vertebral metastases is important for designing radiotherapy portals and for planning surgical resection. Multiple sites of cord and nerve root impingement or compression are frequent. Myelography detects multiple sites of impingement in approximately 30% of cases, and MRI detects multiple sites in approximately 40% to 50% of cases<sup>55,56,57,58</sup> and <sup>59</sup> (Table 51.2-3). The frequency of multiple sites of impingement and compression decreases by approximately 50% when imaging is limited to only one spinal region (i.e., thoracic or lumbar).<sup>58</sup> It is therefore imperative that the entire spine be evaluated radiologically. A sagittal T1 nonenhanced survey of the entire spine quickly and easily identifies multiple sites of compression and should guide the acquisition of axial views through areas of involvement. Bone metastases appear as dark blotches relative to normal bone marrow in unenhanced T1 images. CSF and edematous tumor appear bright on T2 sequences. T2 sequences display CSF brightly, producing images that are similar to a myelogram. Axial T2 sequences can be useful in identifying small tumor nodules on nerve roots. Focal blastic lesions may produce decreased intensity on T2 images. In most cases of suspected epidural cord compression, MRI can be performed without contrast. However, gadolinium contrast images may complement noncontrast images in demonstrating paravertebral tumor and intramedullary metastases (see Fig. 51.2-3). Visualization of leptomeningeal involvement requires MRI contrast.<sup>82</sup> Myelography with or without CT is mandatory when MRI is nondiagnostic, when it is not available, or in cases of claustrophobia or severe scoliosis.

## TREATMENT

The diagnosis of cord compression requires emergent treatment. Delays in initiating treatment have been associated with deterioration in motor and autonomic function.<sup>54</sup> Animal models and clinical results have documented better functional outcome when pretreatment motor loss has been gradual and worse functional outcome when the onset of motor loss has been rapid.<sup>30,31</sup> and <sup>32,51</sup>

Rades et al. reported significantly better motor function and ambulation in patients with gradual rather than rapid onset of pretreatment paresis.<sup>51</sup> Despite these differences in expected outcome based on the rate of neurologic progression, there is no justification for delaying therapy once the diagnosis of cord compression has been made. Although untreated epidural cord compression is not fatal, the consequences of paralysis are devastating and loss of ambulation has been associated with shortened survival in a number of reports.<sup>1,2,9,10,83,84,85,86 and 87</sup>

Treatment of cord compression should be individualized, but started immediately. Ambulatory patients with radiographic evidence of early cord compression and no motor or sensory dysfunction can be treated safely without dexamethasone.<sup>1,8</sup> All other patients should be administered corticosteroids as soon as the diagnosis of cord compression is reached, regardless of whether diagnostic workup is complete. Surgical indications include spinal instability, retropulsion of bone fragments producing compression, previous radiotherapy at the site of compression, and lack of tissue diagnosis in the setting of rapid neurologic deterioration. Patients without an initial diagnosis of cancer can be biopsied using CT or MRI guidance if neurologic dysfunction is absent or is evolving slowly. Radiotherapy should follow surgical resection if the site has not been previously irradiated. All other patients should be considered for primary radiotherapy alone. Chemotherapy can be used as initial therapy for the highly chemosensitive adult or pediatric tumors in patients who are not candidates for surgery or radiation therapy.

The results of treatment of cord compression have improved in recent years as a result of earlier diagnosis with the greater availability of MRI and due to a heightened awareness of cord compression as a potential oncologic emergency.<sup>2,57,58,61,84,88,89 and 90</sup> The pretreatment degree of neurologic dysfunction is the strongest predictor of therapeutic outcome. Eighty percent to 100% of patients with minimal or no ambulatory dysfunction retain ambulation posttreatment.<sup>2,4,5,7,8,9 and 10,52,53,83,87,90,91,92 and 93</sup> Paraparesis improves with treatment in 34% to 63% of cases,<sup>2,8,10,88,92</sup> whereas paraplegia improves in up to 10% to 55% of cases.<sup>2,8,9,88,92</sup> The influence of pretreatment motor function is summarized in [Table 51.2-4](#).

Pretreatment Condition	Laminectomy and Radiation <sup>84</sup>		Radiation Alone <sup>7</sup>	
	No. Ambulatory/ No. Treated	Percentage Ambulatory	No. Ambulatory/ No. Treated	Percentage Ambulatory
Ambulatory	67/68	99	107/108	98
Paresis	41/50	82	48/92	50
Paraplegic	5/9	55	2/18	11

(Adapted from refs 2 and 88.)

**TABLE 51.2-4.** Effect of Motor Function on Treatment Outcome

Surgical techniques used to resect epidural tumors have become increasingly specialized. Laminectomy, the classic surgical approach for the treatment of cord compression is primarily reserved for resection of posterior or posterolateral tumors, despite the favorable results reported by Landmann et al.<sup>88</sup> When used for treatment of anterior epidural compression, the goal of laminectomy is to relieve pressure on the spinal cord via removal of the spinous processes and laminae from one vertebra above to one vertebra below the level of compression. While this approach does not readily allow debulking of tumor anterior to the spinal cord, it does allow relaxation of the spinal cord away from the impinging mass. However, the results of a laminectomy for tumors anterior to the spinal cord have been disappointing.<sup>7,14,94,95</sup> This is in part due to the inability to resect tumor anterior to the spinal cord, but more importantly due to the decreased spinal instability that can develop when posterior supporting elements are removed from an often eroded or collapsed vertebral body.

The development of alternatives to laminectomy, including techniques for anterior decompression<sup>34,96,97 and 98</sup> and newer techniques such as endoscopically assisted anterior decompression,<sup>98</sup> coupled with the limitations of laminectomy, have resulted in laminectomy being no longer regarded as the standard neurosurgical procedure for treatment of anterior epidural cord compression. As a general principle, the location of involvement within the vertebral column should determine the neurosurgical approach. Anterior decompression with spinal stabilization should be considered for tumors in the vertebral body producing anterior epidural compression, and laminectomy should be used for the minority of cases in which tumor involves the posterior vertebral elements or invades the neuroforamina.

Recommendations regarding the use of surgery or radiotherapy alone or in combination should be individualized. Despite the common occurrences of cord compression, there have been no randomized trials containing more than 30 patients in each arm.<sup>5,6 and 7</sup> Thus, the guidelines for treatment of cord compression are largely empiric. Appropriate treatment recommendation can only be made after assessing the patient's expected survival; the location, number, and mechanism of spinal cord compression(s); the tumor histology; the rapidity of neurologic progression; and any history of previous radiotherapy administered to the site under current consideration.

## CORTICOSTEROIDS

Corticosteroids (dexamethasone, methylprednisolone) are among the most effective treatments of neurologic dysfunction resulting from cord compression. Dexamethasone reduces edema, inhibits PGE<sub>2</sub> synthesis, and decreases the specific gravity of the compressed spinal cord.<sup>48</sup> It also was shown to delay the onset of paraplegia in experimental cord compression.<sup>45,48</sup> Although the mechanisms of dexamethasone action are not completely understood, dexamethasone has been shown to down-regulate VEGF expression in smooth muscle cells<sup>100,101</sup> and to prevent cytoskeletal changes associated with increased vascular permeability.<sup>43</sup> Despite the established role of dexamethasone in treatment of cord compression, the optimal dose and schedule have never been proven.<sup>8</sup>

There have been several prospective evaluations of dexamethasone in the treatment of cord compression, yet the superiority of high- versus low-dose dexamethasone has never been proven. Greenberg et al. reported the results of a prospective trial of high-dose dexamethasone and radiation for epidural cord compression. Eighty-three patients with epidural cord compression received 100 mg of intravenous dexamethasone at the time of diagnosis, followed by 96 mg for 3 days, and a subsequent taper of dexamethasone dose during the course of radiotherapy. Fifty-seven percent of patients were ambulatory following treatment. This result was no better than those previously reported for lower dose corticosteroid regimens. However, 64% of patients reported substantial pain reduction the first day of therapy.<sup>4</sup> Sørensen et al. conducted a prospective randomized trial of high-dose dexamethasone versus no corticosteroid therapy. In 57 patients treated with radiation for cord compression, 81% of the dexamethasone group and 65% of the radiation alone group were ambulatory at 3 months.<sup>5</sup> A prospective randomized study comparing a single high dose of intravenous dexamethasone (100 mg) with conventional dose intravenous dexamethasone (10 mg), both followed by 4 mg orally every 6 hours, demonstrated no significant benefit for the initial high-dose bolus.<sup>6</sup> While a prolonged administration of high-dose corticosteroids may have been a more worthy trial regimen, serious toxicities from high-dose dexamethasone have been reported in up to 14% of patients.<sup>4,5,102</sup>

Thus, the results of clinical trials support a role for corticosteroids in the treatment of cord compression, but they have not indicated an advantage for higher versus lower doses. Currently, there is no clear benefit, other than pain relief, from the routine use of high-dose corticosteroids in patients who can otherwise be treated with conventional doses. We recommend an initial 10-mg dose of intravenous dexamethasone. The dose can be increased incrementally if no improvement is detected in the first 4 to 8 hours. After 2 days on a stable dose of intravenous dexamethasone, therapy can be switched to 4 to 8 mg of oral dexamethasone given every 6 hours. Corticosteroid doses are tapered every 4 days in a manner described by Byrne.<sup>103</sup> If neurologic decline results from dose reduction, the dose is maintained at effective levels until dose reduction is possible. Patients without neurologic dysfunction other than back or neck pain should be managed without corticosteroids whenever possible. Maranzano demonstrated that the use of steroids can be safely avoided in selected patients with no evidence of neurologic dysfunction, or with radiculopathy only. Twenty patients were reviewed who had tumors invading less than 50% of the spinal cord diameter and involving not more than two vertebral levels, or greater than two vertebral levels in patients with radiculopathy. All patients received 30 Gy in ten fractions. The results were equivalent or superior to those achieved with the use of dexamethasone.<sup>2,4</sup> Sixteen patients were ambulatory before treatment, and all 20 patients were ambulatory posttreatment. Palliation of pain was achieved in 85% of patients.<sup>1</sup>

There has been and continues to be interest in hypofractionated regimens for palliation of cord compression. A seminal experience in this regard was reported by Greenberg et al.,<sup>4</sup> who treated patients with hypofractionated radiotherapy and initial high-dose dexamethasone. Patients received 100 mg of intravenous dexamethasone and 500 cGy per fraction daily for the first 3 days of treatment. Following a 4-day rest, radiation was continued in 300-cGy fractions to a total dose of 3000 cGy. Fifty-seven percent of patients were ambulatory after treatment. No patients with total paraplegia regained ambulation. Ambulation was preserved in 62% of patients with radiosensitive tumors and 55% of those with less radiosensitive tumors. Patients with renal and prostate tumors had the highest rate of ambulation following treatment, and patients with lung cancer had the least favorable outcome. Although these results are no better than those reported for conventional regimens, the achievement of pain relief in 64% of patients after the first day of treatment was impressive.<sup>4</sup>

Maranzano et al. have addressed several issues regarding the radiotherapy of cord compression including hypofractionation in a series of reports from 1989 to 2000. A prospective study of radiotherapy and corticosteroids without surgical resection was reported in 1995.<sup>2</sup> Of the 209 evaluable patients, 52% had minimal or no neurologic impairment, 39% were paraparetic and unable to walk, and 9% were paraplegic at presentation. Ambulation was maintained in 94% of those with minimal or no neurologic impairment. Treatment consisted of 3000 cGy in ten fractions (used primarily for radioresponsive tumors, i.e., seminoma, lymphoma, myeloma) or the fractionation scheme of Greenberg et al. (500 cGy × 3, 4-day rest, 300 cGy × 5). High-dose intravenous corticosteroid (1 g of methylprednisolone) was used for paraparetic or paraplegic patients, and standard-dose dexamethasone (16 mg/d) was used in all other patients. Sixty percent of paraparetic, nonambulant patients regained their ability to walk. Only 11% of paraplegic patients became ambulatory. Overall, 76% of patients were ambulant after treatment. Sphincter dysfunction improved in 44% of patients. Those with favorable histologies (breast, prostate, lymphoma, myeloma, seminoma, small cell carcinoma) more frequently enjoyed restoration of gait and recovery of bladder function. The median survival for the group was 6 months, and 28% were alive at 1 year. Ambulation before treatment was associated with a median survival of 8 months, versus 4 months for those nonambulant before treatment ( $P = .02$ ). Ambulation after treatment was associated with a median survival of 9 months versus 1 month for nonambulant patients after treatment ( $P < .01$ ). Survival for favorable tumor types was 10 months versus 3 months for unfavorable histologies ( $P < .01$ ). Clearly, early diagnosis of cord compression was the factor that most significantly influenced the outcome in this study. Tumor histology had the greatest influence on outcome in patients with loss of ambulation, bladder dysfunction, or paraplegia. This study also demonstrated that the results of radiotherapy plus corticosteroids compared favorably with the results of laminectomy.<sup>2</sup>

In a subsequent report, Maranzano et al. demonstrated that corticosteroids could be omitted from the treatment of cord compression in selected patients. Twenty patients with cord compression and no neurologic dysfunction, or dysfunction limited to radiculopathy, were evaluated. This group included patients with intact motor and sensory function and tumors involving less than 50% of the spinal cord diameter or fewer than two vertebrae longitudinally. Patients with radiculopathy or greater than two vertebral levels involved were included. Six patients presented with radiculopathy, and 14 patients presented with cord impingement. Radiotherapy consisted of 3000 cGy in ten fractions. Back pain responded in 85% of cases. All patients were ambulatory without support following treatment, including four patients who had required support for ambulation before therapy. These excellent results suggest that routine administration of corticosteroids in patients with asymptomatic early cord compression is not necessary.<sup>1</sup>

More recently, the same authors explored the use of hypo-fractionated regimens for treatment of cord compression. Fifty-three patients with radiographic evidence of cord compression and unfavorable histology with or without neurologic defects, or patients with favorable histology (breast, prostate, myeloma, lymphoma) who presented with plegias, paresis, or low performance status (Eastern Cooperative Oncology Group performance score of less than or equal to 2) and short life expectancy were treated with a single 800-cGy fraction generally delivered via a posterior port. This treatment was repeated after 1 week in responding or stable patients. Of 49 evaluable patients, 4 also received laminectomy, and 4 patients did not receive the second fraction due to systemic disease progression. Pain relief was achieved in 67% of patients, motor function remained intact or improved in 63%. None of the paraplegic patients regained ambulation. The authors claimed that the results were not substantially different from previously published results in similar patients.<sup>2</sup> However, the results were numerically inferior to those achieved with 3000 cGy in ten fractions.<sup>86</sup>

In another publication from this group, two hypofractionated regimens were compared in patients with cord compression from prostate cancer. There was no difference in palliation of pain, neurologic outcome, or survival based on the treatment regimen.<sup>87</sup> These studies have demonstrated that hypofractionated regimens, despite producing more acute toxicity, are reasonably well tolerated and relatively effective. However, split courses and large fraction sizes are fundamentally radiobiologically unfavorable due to the likely presence of tumor hypoxia and the proliferation of tumor during splits in treatment.<sup>125</sup> These considerations combined with the lack of radiographic response data to evaluate the success of these regimens, and the complete absence of data describing late toxicities, prevents the routine recommendation of these schedules. The 800 cGy × 2 regimen may be appropriate for the bedridden paraplegic hospice patient requiring palliation of back pain caused by a cord compression.

In a report from Hanover, Germany, 96 patients with motoric deficits were divided into two subgroups based on the duration of development of motoric deficits: 1 to 13 days (49 patients), group A; and greater than or equal to 14 days (47 patients), group B. The two groups were comparable in pretreatment ambulatory function (33% and 32%, respectively). At 2 weeks and 3 months, more patients were ambulatory in group B (77% and 81%) than in group A (31% and 30%). A separate group of patients (31) with rapid loss of motor function within 48 hours of presentation was evaluated. At 2 weeks and 3 months, only 13% and 15% of patients were ambulatory. In this third group of patients with rapid loss of motor function, 65% had experienced further deterioration by 2 weeks posttreatment.<sup>51</sup> Thus, the success of radiotherapy in reversing paralysis correlates with the rapidity of loss of motor function. Recovery of ambulation occurs more frequently in patients with gradual rather than abrupt loss of ambulation.<sup>51,112</sup> Delays in the recovery of ambulation can last as long as 15 months.<sup>112</sup> These findings are consistent with the results of experimental mechanical cord injury in dogs.<sup>30,31 and 32</sup>

The role of corticosteroids during radiotherapy has not been adequately studied. Although corticosteroids are universally prescribed and subsequently tapered during or after radiotherapy, corticosteroids do not appear to be necessary in patients who present with no neurologic dysfunction.<sup>1</sup> Radiation produces no clinically significant spinal cord edema itself,<sup>25</sup> and the benefit of corticosteroids is temporary.<sup>26</sup> Maintaining corticosteroids during radiation is clearly indicated if symptoms progress on withdrawal; however, routine maintenance of corticosteroids throughout the course of radiotherapy is unnecessary. High-dose corticosteroids have no proven greater efficacy than low-dose corticosteroids and remain controversial. High-dose corticosteroid therapy and radiation was significantly superior to radiation alone in one study, but whether similar results could have been achieved with low-dose corticosteroids was not determined.<sup>5</sup> A prospective study of high- versus low-dose corticosteroids revealed no difference in the rate of ambulatory patients after treatment.<sup>6</sup> Despite this, the routine use of high-dose corticosteroids has been advocated by some investigators.<sup>4,8,103,113</sup>

An analysis of prognostic factors in 153 patients treated with radiotherapy and/or laminectomy for cord compression was reported by Helweg-Larsen et al. As has been shown repeatedly in numerous studies, ambulation pretreatment predicted ambulation posttreatment. Tumor type was shown to influence the interval from initial diagnosis to development of cord compression. Shorter intervals were observed in patients with lung cancer, and the longest intervals were observed in patients with breast cancer ( $P < .0005$ ). Lung cancer patients also had more severe gait dysfunction at diagnosis than did patients with other tumor types ( $P = .003$ ). Likewise, the interval between initial diagnosis of cancer and the development of cord compression was predictive of the severity of gait dysfunction. Shorter intervals were associated with more severe gait disturbance ( $P = .016$ ). Survival posttreatment was dependent on the interval from diagnosis to cord compression, the pretreatment gait function, and most importantly, ambulation posttreatment. The median survival for ambulatory patients posttreatment was 7.9 months compared with 1.2 months for nonambulatory patients posttreatment.<sup>114</sup>

### Radiotherapy Technique

The size and configuration of radiotherapy portals should be designed using all relevant data from the history and physical examination, plain films, bone scans, myelograms, CT, and spinal MRI. An MRI with sagittal views of the entire length of the spine should be carefully studied to identify any additional sites of cord compression before completing the radiotherapy treatment plan. Additional sites of epidural compression can be detected in 10% to 50% of patients depending on the imaging modality and the length of spine evaluated (see [Table 51.2-3](#)).<sup>55,56,57,58 and 59,64,73,115,116</sup> Although MRI is superior to CT myelography, either study is capable of defining vertebral and paravertebral involvement, and either is adequate for treatment planning.

Radiation portals should be centered on the site of epidural compression. Of the 16% to 25% of patients who develop recurrent cord compression after radiation, 64% of early recurrences (within the first 3 months) are within two vertebral bodies of the site of initial compression.<sup>20</sup> Accordingly, radiation portals customarily extend two vertebral bodies above and two vertebral bodies below the site of compression. Adjacent sites of bony involvement and paravertebral masses should also be encompassed in the treatment port. Lesions in the cervical spine, a common site for myeloma, should be treated with opposed lateral fields to reduce radiation exposure of the pharyngeal mucosa. Thoracic spine lesions are generally treated with a simple posterior field. Although the majority of compressing metastases develop in the posterior aspect of the vertebral body, the radiation dose should be prescribed to a depth corresponding to the anterior aspect of the involved vertebral

body. This ensures full-dose delivery to the tumor and adequate treatment of the entire bone. The anterior edge of the affected vertebral body can be determined with a lateral spine simulator film. If this depth equals or exceeds the midplane of the patient, or if beam energies sufficient to prevent greater than a 110% hot spot on the spinal cord are not available, opposed anteroposterior fields should be used. Ad hoc prescription of a depth for posterior fields without measurement of the prescription depth should be discouraged. The lumbar spine is usually treated with opposed anteroposterior fields, since the lumbar vertebrae are generally at midplane.

An important goal of radiotherapy for epidural compression is to deliver an effective palliative dose of radiation expeditiously without exceeding the spinal cord tolerance. To this end, an optimal dose and fractionation scheme has not been established. Radioresponsive tumors, such as neuroblastoma, can be treated with 2000 to 3000 cGy.<sup>117</sup> Epidural cord compression caused by lymphoma more often responds completely when total doses greater than 2500 cGy are employed.<sup>118</sup> Patients with cord compression by malignant melanoma are more likely to respond to total doses greater than 3000 cGy. Complete recovery is more often associated with higher total doses, rather than with the use of large doses per fraction.<sup>119,120</sup>

Initial large daily fractions (400 to 500 cGy) produce more rapid neurologic recovery in animal models with cord compression.<sup>25,113</sup> In contrast, larger doses per fraction provided less durable pain relief from bone metastases<sup>121</sup> and neurologic recovery from cord compression is not superior to that achieved by conventional dose regimens.<sup>4,91,119,122</sup> Nevertheless, some authors continue to recommend delivery of large doses per fraction (400 to 500 cGy) on the first 3 days of treatment to achieve rapid lysis of tumor, followed by smaller doses (200 to 300 cGy) for the remainder of the treatment.<sup>4,9,123</sup> By convention, patients usually receive 200 to 300 cGy per fraction to a total dose not exceeding 3000 to 4000 cGy to the spinal cord in 2 to 4 weeks.<sup>124</sup> The results of several radiotherapy series are summarized in [Table 51.2-5](#).

## CHEMOTHERAPY

Neurologic recovery from spinal cord compression in response to chemotherapy has been reported in adults and children.<sup>126,127,128,129,130,131,132,133,134,135,136,137,138,139,140,141</sup> and <sup>142</sup> In adults, cytotoxic chemotherapy and hormonal therapy have been used to successfully alleviate spinal cord compression from prostate cancer,<sup>130,135,138,139</sup> Hodgkin's disease,<sup>133,140</sup> myeloma,<sup>127,141</sup> germ cell tumors,<sup>131,137</sup> lymphoma,<sup>128,136,141</sup> and breast cancer.<sup>129</sup> The use of chemotherapy combined with radiation was associated with a prolonged survival in patients presenting with epidural cord compression from non-Hodgkin's lymphoma.<sup>142</sup> These studies suggest that in certain cases, chemotherapy should be considered more frequently than is currently accepted. Chemotherapy can be used in combination with radiotherapy for treatment of spinal cord compression,<sup>141</sup> or alone in adults who are not surgical or radiation candidates, but who have chemosensitive tumors such as lymphoma, small cell carcinoma, myeloma, breast, prostate, or germ cell tumors.<sup>127,128,129,130,131,132,133,134,135,136,137,138,139,140,141</sup> and <sup>142</sup>

## PEDIATRIC SPINAL CORD COMPRESSION

Malignant spinal cord compression in children differs from that in adults in several respects including the tumor types that most frequently produce compression, the mechanisms of impingement, and most importantly the approach to treatment. Unlike in adults, motor weakness can be as frequent a symptom as local pain, being present in 82% to 100% of cases.<sup>24,117,143</sup> Neuroblastoma, Ewing's sarcoma, Wilms' tumor, lymphoma, and soft tissue and bone sarcomas are the most frequent tumor types producing compression in children,<sup>22,23</sup> and <sup>24</sup> yet they are infrequently encountered in adults (see [Table 51.2-1](#)). The majority of tumors causing cord compression in children do so via neuroforaminal invasion producing the so-called dumbbell tumors.<sup>22,24,144,145</sup> Unlike treatment of adult malignant spinal cord compression, there is a greater emphasis on the use of chemotherapy in pediatric patients. This is due to the greater chemosensitivity of most pediatric cancers and the profound interest in avoiding iatrogenic spinal deformities and second cancers in children, which can result from radiotherapy.

The most impressive results of pediatric cord compression treatment with chemotherapy were reported by Hayes et al. Fourteen patients with spinal cord compression from neuroblastoma or Ewing's sarcoma received combination chemotherapy alone. All patients with neurologic signs or symptoms (10 of 14) experienced complete or near complete recovery following chemotherapy.<sup>126</sup> Sanderson et al. had similar results. Four of four patients presenting with paraparesis or paraplegias from cord compression by neuroblastoma had complete neurologic recovery following treatment with chemotherapy alone.<sup>134</sup>

When chemotherapy is used for treatment of spinal cord compression, the response to treatment should be monitored closely by a multidisciplinary team including a neurosurgeon, pediatric oncologist, radiation oncologist, and neuroradiologist so that alternate interventions can be instituted quickly to alleviate neurologic progression.

Klein et al. reviewed 112 cases of pediatric cord compression from St. Jude Children's Hospital. Patients with soft tissue sarcomas treated with laminectomy as a component of their overall treatment had statistically superior ambulation following treatment compared with those who received chemotherapy or radiation alone.<sup>22</sup> Raffel et al. studied children with severe cord compression as evidenced by greater than 50% replacement of the spinal canal by tumor on MRI or CT.<sup>24</sup> Twenty-five of 26 children treated with laminectomy improved compared with four of seven treated nonsurgically. Since posterior cord compression resulting from vertebral foramen invasion occurs in a larger percentage of pediatric cases, laminectomy may be of greater benefit than in adults.

However, in a retrospective analysis of pediatric neuroblastoma with cord compression, there was no significant difference based on whether or not laminectomy was used. There were, however, numerically more ambulatory patients following surgical treatment.<sup>145</sup> Thus, pediatric patients with soft tissue or bone sarcomas and severe neurologic dysfunction from compression should be considered for osteoplastic laminotomy or laminectomy followed by adjuvant chemotherapy or radiation. In other circumstances, treatment with initial chemotherapy alone may be appropriate.

## CONCLUSION

Paraplegia from epidural cord compression is preventable if diagnosis and treatment are instituted before severe neurologic deficits develop. A heightened awareness of the significance of new or progressive back pain is the most important factor in the successful treatment of cord compression. Plain films, myelography, MRI, or CT should be obtained when the history and neurologic examination suggest spinal involvement with tumor or cord compression. Corticosteroids should be administered in symptomatic patients when the diagnosis has been established, and oncology, neurology, neurosurgery, and radiation oncology consultants should provide urgent evaluations.

Fortunately, management recommendations can be made despite the lack of definitive randomized trials evaluating contemporary treatments. Treatment recommendations are outlined in [Table 51.2-6](#). Radiotherapy is indicated in all patients with minimal or no neurologic deficits. Radiation should also be administered following surgery in patients who have not previously received radiation. Spinal instability, compression from bone fragments, previous radiotherapy, and neurologic progression during radiotherapy are indications for surgery in appropriate candidates. Surgery should be considered in patients with a life expectancy of greater than 2 months. The surgical approach should be determined by the location of vertebral involvement and direction of compression.

TABLE 51.2-6. Recommendations for Management of Patients with Metastatic Cord Compression<sup>a</sup>

Recommendation
1. Obtain plain films, myelography, MRI, or CT when the history and neurologic examination suggest spinal involvement with tumor or cord compression.
2. Administer corticosteroids in symptomatic patients when the diagnosis has been established, and oncology, neurology, neurosurgery, and radiation oncology consultants should provide urgent evaluations.
3. Administer radiotherapy in all patients with minimal or no neurologic deficits.
4. Administer radiotherapy following surgery in patients who have not previously received radiation.
5. Administer surgery in patients with spinal instability, compression from bone fragments, previous radiotherapy, and neurologic progression during radiotherapy.
6. Administer surgery in patients with a life expectancy of greater than 2 months.
7. Determine the surgical approach by the location of vertebral involvement and direction of compression.

TABLE 51.2-6. Recommendations for Management of Patients with Metastatic Cord Compression<sup>a</sup>

Chemotherapy should be the initial treatment for children with chemosensitive tumors. Patients treated with chemotherapy should be monitored closely so that immediate intervention can proceed if there is an inadequate response or neurologic progression. Children with severe neurologic deficits from cord compression should be considered for primary laminectomy. Adults with chemotherapy-sensitive or hormone-sensitive tumors should receive chemotherapy as an adjuvant or as the primary treatment if radiation or surgery are contraindicated. Corticosteroid therapy remains one of the most effective treatments for acute spinal cord compression.

## INTRODUCTION

Patients with cancer may develop a number of metabolic and endocrinologic problems, frequently to an exaggerated degree. This section reviews metabolic complications of cancer that require urgent therapy for treatment or prevention.

## HYPERCALCEMIA

### EPIDEMIOLOGY

Hypercalcemia is the most common life-threatening metabolic disorder in patients with cancer. The prevalence of this disorder approximates 15 to 20 cases per 100,000 persons.<sup>1,2</sup> The incidence varies depending on the underlying cancer diagnosis, being highest in myeloma and breast cancer (approximately 40%), intermediate in non–small cell lung cancer, and uncommon in colon, prostate, and small cell lung carcinomas.<sup>3,4</sup> and <sup>5</sup>

### DIFFERENTIAL DIAGNOSIS

Hypercalcemia is associated with a wide variety of pathologic states ([Table 51.3-1](#)). Primary hyperparathyroidism and cancer are the two most common causes of hypercalcemia, and both diseases are prevalent.<sup>6,7</sup> Patients who present with a recent onset of symptomatic hypercalcemia and weight loss are more likely to have a malignant disorder. In hypercalcemic patients who require hospitalization, cancer has been previously diagnosed or becomes apparent after minimal diagnostic evaluation in most cases. By contrast, asymptomatic hypercalcemia and chronic symptoms are the most common presentations of primary hyperparathyroidism. The diagnostic evaluation and differential diagnosis of patients with hypercalcemia have been reviewed.<sup>8,9</sup> and <sup>10</sup> Generally, an elevation in serum calcium with a low or normal serum immunoreactive parathyroid hormone (PTH) level, especially when combined with an increase in serum PTH-related protein (see [Parathyroid Hormone and the Parathyroid Hormone–Related Protein](#), later in this chapter) can exclude the diagnosis of primary hyperparathyroidism with high confidence.<sup>11</sup>

Endocrine and metabolic diseases
Primary hyperparathyroidism
Hyperthyroidism
Pheochromocytoma
Osteopetrosis
Infantile hyperphosphatasia
Familial hypercalcemia with hypercalciuria
Cancer
Infectious diseases
Tuberculosis
Coccidioidomycosis
Human immunodeficiency virus infection
Renal insufficiency
Granulomatous diseases
Sarcoidosis
Berylliosis
Dietary and drug related
Vitamin D intoxication
Vitamin A intoxication, retinoids
Calcium supplements
Lithium
Milk alkali syndrome

TABLE 51.3-1. Diseases Associated with Hypercalcemia

Serum calcium is highly bound to albumin, and measurements of total serum calcium fluctuate with changes in serum protein concentrations. Occasional patients with myeloma present with striking elevations of total serum calcium due solely to an increase in serum calcium-binding proteins.<sup>12</sup> Measurements of ionized calcium by ion-specific electrode are essential in such cases. However, for most patients an approximate estimate of the severity of hypercalcemia can be made by using one of several formulas that adjust serum calcium levels for serum albumin concentration, as follows:

$$\text{Corrected [calcium] (mg/dL)}^* = \text{measured [calcium] (mg/dL)} - [\text{albumin}] (\text{g/dL}) + 4.0^{13}$$

## CLINICAL MANIFESTATIONS

Patients with hypercalcemia can present with a wide variety of symptoms affecting multiple organ systems ([Table 51.3-2](#)). The severity of the presentation is not exclusively related to the degree of elevation in serum calcium. Patients with a slight-to-moderate elevation (12 to 13 mg/dL) may be obtunded if the increase has occurred acutely. Conversely, patients with long-standing hypercalcemia (such as those with parathyroid carcinoma) may tolerate a serum calcium greater than 14 mg/dL with few symptoms. Other factors (especially age, performance status, sites of metastases, and hepatic or renal dysfunction) also contribute to the severity of symptoms.

General: dehydration, weight loss, anorexia, pruritus, polydipsia  
 Neuromuscular: fatigue, lethargy, muscle weakness, hyporeflexia, confusion, psychosis, seizure, obtundation, coma  
 Gastrointestinal: nausea, vomiting, constipation, obstipation, ileus  
 Genitourinary: polyuria, renal insufficiency  
 Cardiac: bradycardia, prolonged P-R interval, shortened Q-T interval, wide T wave, atrial or ventricular arrhythmias

**TABLE 51.3-2.** Clinical Manifestations of Cancer-Related Hypercalcemia

In patients with evolving hypercalcemia, fatigue, lethargy, constipation, nausea, and polyuria are the most common initial complaints. It is important to evaluate the serum calcium in patients who have these relatively nonspecific complaints because the combination of polyuria and nausea can lead to rapid dehydration and substantial worsening of the hypercalcemic state. Patients in late stages may present in stupor or coma, and the condition is easily mistaken for diabetic ketoacidosis or drug overdose.

### PATHOPHYSIOLOGY

In the past, cancer-related hypercalcemia was conveniently categorized according to the presence or absence of bone involvement. Hypercalcemia in the former group was believed to be associated with direct bone destruction by cancer cells (so-called local osteolytic hypercalcemia), and the second group was characterized by various humorally mediated mechanisms.<sup>14</sup> However, it is now evident that hypercalcemia, even in patients with extensive osteolysis, is mediated by factors released by malignant cells that ultimately act to resorb calcium from bone. Some of these factors also stimulate calcium reabsorption from the renal tubule, but this effect is secondary in importance to accelerated osteoclastic bone resorption.

#### Parathyroid Hormone and the Parathyroid Hormone–Related Protein

Many patients with cancer-related hypercalcemia have biochemical characteristics suggestive of PTH stimulation, including increased tubular reabsorption of calcium, hypophosphatemia with phosphaturia, and elevated levels of *nephrogenous* cyclic adenosine monophosphate. However, most studies of *ectopic hyperparathyroidism* were based on bioassays or measurements of immunoreactive material.<sup>15</sup> Studies examining PTH-specific mRNA in tumors have confirmed that ectopic PTH production is not a common cause of cancer-related hypercalcemia.<sup>16</sup> Other than cases of parathyroid carcinoma,<sup>17</sup> tumor secretion of authentic PTH by malignant tumors is exceptionally rare.<sup>18,19</sup> Nonetheless, primary hyperparathyroidism caused by parathyroid adenomas is a common feature of the heritable multiple endocrine neoplasia syndromes 1 and 2a.

A PTH-related protein (PTH-RP), which is elaborated by cancer cells and binds to the PTH receptor, has now been fully characterized.<sup>20,21,22</sup> and <sup>23</sup> Genes encoding PTH-RP and authentic human PTH have been mapped to the short arms of chromosomes 12 and 11, respectively. The proteins are homologous for only 8 of the first 13 amino acids in the amino-terminal portion, which contains the receptor-binding domain. PTH-RP is widely distributed in normal tissues such as brain, kidney, parathyroid, skin, atrium, uterus, and breast.<sup>24,25,26</sup> and <sup>27</sup> PTH-RP mediates the effects of a protein known as *Indian hedgehog* that is a negative regulator of chondrocyte differentiation.<sup>28,29</sup> The protein seems to be involved only in local signaling and under normal conditions is not released into the general circulation.

Although at least one case of elevated PTH-RP has been reported in association with a benign tumor (called *humoral hypercalcemia of benignancy*),<sup>30</sup> this phenomenon is extremely rare. PTH-RP appears to be the most common mediator of cancer-related hypercalcemia.<sup>31,32,33,34,35,36</sup> and <sup>37</sup> Increased blood levels of PTH-RP are commonly found in patients with solid tumors (Fig. 51.3-1), particularly patients with squamous (epidermoid) carcinomas.<sup>32,33</sup> and <sup>34</sup> Elevated serum PTH-RP levels have been found in 30% to 50% of hypercalcemic patients with breast cancer,<sup>35,34</sup> and <sup>35</sup> even though this disease was formerly thought to characterize the bone metastasis form of hypercalcemia. The factor does not appear to be associated with most hematologic cancers such as myeloma or lymphoma.<sup>32,33</sup> and <sup>34,36</sup> However, the viral *tax* protein transactivates the PTH-RP gene promoter,<sup>38,39</sup> and high levels of PTH-RP have been reported in patients with human T-cell lymphotropic virus 1–associated leukemia and lymphoma.<sup>40</sup> The factor is elaborated at sites of bone metastases in breast<sup>41</sup> and prostate<sup>42</sup> cancer, and women with high basal levels of immunoreactive PTH-RP in the primary tumor appear more likely to develop metastases in bone than in soft tissues.<sup>43</sup> The absolute serum level of PTH-RP is not affected by hypocalcemic treatment.<sup>44,45</sup> Several studies have shown that patients with high levels tend to have an inferior response when treated with bisphosphonates<sup>46,47</sup> and a poorer life expectancy.<sup>48</sup>

**FIGURE 51.3-1.** Plasma levels of parathyroid-related protein (PTHrP) in normocalcemic control patients with solid tumors, patients with solid tumors with (BM+) or without (BM-) bone metastases or in whom the presence or absence of bone metastases was not determined (BM?), patients with various hematologic cancers, and patients with primary hyperparathyroidism (pHPT). (From ref. 34, with permission.)

### Vitamin D<sub>3</sub>

Elevated serum 1,25 (OH)<sub>2</sub>-vitamin D<sub>3</sub> levels have been reported in patients with Hodgkin's disease, non-Hodgkin's lymphoma, myeloma,<sup>49,50,51</sup> and <sup>52</sup> and occasional patients with solid tumors.<sup>53</sup> This effect probably results from increased enzymatic conversion of 25-OH-vitamin D<sub>3</sub> by 1 $\alpha$ -vitamin D-hydroxylase, similar to well-documented processes that occur in patients with granulomatous disease. However, these observations do not necessarily establish an etiologic association. The measured elevations in serum vitamin D<sub>3</sub> concentrations in such patients have generally been well below levels that are known to cause hypercalcemia in patients with sarcoidosis.<sup>54</sup> The levels are also below serum levels in subjects who have ingested oral calcitriol and who remain normocalcemic.<sup>55</sup> Moreover, serum vitamin D<sub>3</sub> levels may not be appropriately suppressed in hypercalcemic patients with elevated PTH-RP levels.<sup>56</sup> Whether vitamin D<sub>3</sub> plays a critical pathophysiologic role, acting alone or in concert with other factors, or acts merely as a marker of tumor burden is still unclear. Nonetheless, normalization of serum vitamin D<sub>3</sub> levels and resolution of hypercalcemia occur with control of the underlying disease.

### Prostaglandins

Prostaglandins have long been implicated as circulating mediators of cancer-related hypercalcemia, and certain prostaglandins (notably of the E series) have potent

**TABLE 51.3-3.** Therapy for the Treatment of Cancer-Related Hypercalcemia**Intravenous Fluids and Diuretics**

Hypercalcemic patients frequently present with dehydration owing to vomiting and obligate water losses associated with calciuresis. Fluid repletion, usually with isotonic saline, has been a mainstay of acute therapy, because volume expansion and natriuresis can increase renal blood flow and enhance calcium excretion.<sup>74</sup> The rate of fluid administration depends on a clinical estimate of the extent of dehydration, cardiovascular function, and renal excretory capacity. Assuming renal and cardiac functions are adequate, saline infusion at a rate of 300 to 400 or more mL/h can be used for 3 to 4 hours in severely dehydrated patients. Slower hydration is indicated for less severe disturbances or in patients with congestive heart failure or oliguria. Serum calcium, creatinine, potassium, and magnesium should be reassessed frequently during this period.

The heroic degrees of saline hydration and forced diuresis that made up past therapy for cancer-related hypercalcemia<sup>75</sup> are no longer indicated. Such treatment is excessively toxic since it frequently causes fluid overload and occasionally life-threatening pulmonary edema. The resulting weight gain and lower extremity edema that occurs in hypoproteinemic patients with advanced cancer may not resolve during the life of that individual and can be severely disabling. Moreover, hydration (with or without diuretics) is not very effective. In a prospective study of 16 patients with serum calcium greater than or equal to 13.0 mg/dL (3.25 mmol/L), only five patients (31%) achieved normocalcemia with normal saline (4000 cc/d × 2 days).<sup>76</sup> Although furosemide-induced natriuresis theoretically enhances urinary calcium excretion, no controlled studies were ever conducted to indicate that hypercalcemic patients benefit from routine furosemide treatment. Furosemide also increases the risk for developing hypovolemia; the resultant decrease in glomerular filtration may actually stimulate renal calcium reabsorption, inadvertently reinduce dehydration, and worsen the clinical condition. Therefore, the use of furosemide should be restricted to balancing fluid intake and urinary output in patients who have been fully rehydrated. In most hospitalized patients, fluid administration should not be employed alone, and treatment with antiresorptive drugs should be initiated promptly following rehydration for control of hypercalcemia.

**Bisphosphonates**

Bisphosphonates (formerly diphosphonates), chemical analogues of pyrophosphate that are resistant to hydrolysis by pyrophosphatase, have become the most commonly used drugs for the treatment of hypercalcemia. Bisphosphonates adsorb to the surface of crystalline hydroxyapatite and inhibit calcium release from bone by interfering with the metabolic activity of osteoclasts.<sup>77</sup> There are numerous bisphosphonates available or undergoing clinical investigation, including etidronate, clodronate, pamidronate, zoledronate, alendronate, tiludronate, ibandronate, and risedronate. As a class, bisphosphonates have low oral bioavailability (less than 1%), and none of these agents is currently recommended as an oral therapy for hypercalcemia.

Intravenous pamidronate has become the most widely prescribed drug for treatment of hypercalcemia. This drug is well-tolerated and its side effects are usually limited to infusion-site irritation, fever, and flu-like symptoms that occur after the first infusion in approximately 20% of patients. Although multiple doses and schedules have been tested,<sup>78,79</sup> pamidronate is most commonly given at doses of 60 or 90 mg infused over 2 hours. Although the higher dose has been suggested for patients with more severe hypercalcemia (e.g., a total serum calcium greater than 13.0 mg/dL), there are conflicting data whether any substantial dose-response relationship exists above 60 mg.<sup>80,81,82</sup> and <sup>83</sup> Similar doses have been widely used to reduce skeletal morbidity from bone metastases.<sup>84</sup>

Considerable data indicate that the response to pamidronate is inferior in patients whose hypercalcemia is mediated by PTH-RP.<sup>85,86,87</sup> and <sup>88</sup> The hypocalcemic effect also appears to decrease with repeated dosing.<sup>88</sup> This reduced activity is clinically important because PTH-RP is the most common cause of cancer-related hypercalcemia.

Alendronate has also been studied by the intravenous route in hypercalcemia,<sup>89,90</sup> but this formulation is not widely available. The usual doses are 10 or 15 mg administered over 2 hours. Oral alendronate is widely used for treatment of postmenopausal osteoporosis; however, there are no data available supporting oral alendronate as a treatment for hypercalcemia. Based on similarly designed randomized studies compared with etidronate (see Fig. 51.3-2),<sup>78,89</sup> pamidronate and alendronate appear to have comparable degrees of clinical efficacy.

Among other bisphosphonates, etidronate has been compared with pamidronate, alendronate, and gallium nitrate in randomized double-blind studies. The response to etidronate in all three studies was similar: 42%, 33%, and 43%, respectively.<sup>78,83,88</sup> (see Fig. 51.3-2). This result was significantly inferior relative to each of the other agents tested, and these data have largely accounted for its diminished use. Clodronate is available in Europe, but current data suggest that it is not as effective as pamidronate.<sup>91,92</sup> Ibandronate<sup>93</sup> and zoledronate<sup>94,95</sup> are other bisphosphonates undergoing clinical testing that are more potent (on a milligram per milligram basis) than earlier bisphosphonates. However, it is unclear if increased potency will translate to improved clinical efficacy, and early results suggest comparable clinical activity.

**Gallium Nitrate**

Gallium nitrate is a potent inhibitor of bone resorption.<sup>96,97</sup> and <sup>98</sup> Elemental gallium is incorporated into bone<sup>99,100</sup> and renders hydroxyapatite less soluble and more resistant to cell-mediated resorption.<sup>126</sup> However, the drug's principal mechanism of action is inhibition of an ATPase-dependent proton pump that is located in the ruffled membrane of the osteoclast.<sup>101</sup> This effect impairs osteoclast acidification and consequent dissolution of the underlying bone matrix. Randomized double-blind studies have demonstrated superiority of gallium nitrate compared with calcitonin<sup>102</sup> and etidronate<sup>103</sup> for acute treatment of resistant hypercalcemia, and preliminary data from one study also suggested superiority compared with pamidronate (see Fig. 51.3-2).<sup>83</sup>

Following administration as a continuous intravenous infusion (200 mg/m<sup>2</sup>/d over 24 hours for up to 5 days), gallium nitrate induces normocalcemia in 70% to 90% of patients.<sup>83,96,102,103</sup> The maximal hypocalcemic effect occurs several days after the drug has been discontinued; therefore, the drug infusion should be discontinued once the patient has achieved normocalcemia. In earlier studies that used high-dose gallium nitrate as primary cancer treatment, nephrotoxicity was dose-limiting; however, the incidence of renal insufficiency in controlled hypercalcemia studies has been similar to calcitonin, etidronate, and pamidronate.<sup>83,102,103</sup> Like the bisphosphonates, gallium nitrate should be started after the patient has been rehydrated and urinary output ensured. A daily urinary output of 2000 mL should be maintained during the infusion. Concurrent use of highly nephrotoxic drugs, such as aminoglycosides, amphotericin B, and cisplatin, should be avoided.

**Calcitonin**

Pharmacologic doses of calcitonin reduce serum calcium by increasing renal calcium excretion and inhibiting bone resorption.<sup>104</sup> Calcitonin is especially advantageous due to its rapid onset of action (2 to 4 hours)<sup>102,105</sup> and its lack of serious toxicity (other than rare hypersensitivity reactions). Notwithstanding these desirable features, the hypocalcemic effect of calcitonin is relatively weak; the acute response peaks at 48 hours and diminishes thereafter despite continued treatment.<sup>102</sup> Less than 30% of hypercalcemic patients treated with calcitonin as a single agent achieve a normal serum calcium value. High doses of calcitonin (6 to 8 IU/kg every 6 hours) should be employed for acute treatment of hypercalcemia. Absent thrombocytopenia, the drug should be administered intramuscularly rather than subcutaneously to ensure complete absorption. Corticosteroids probably do not enhance the hypocalcemic effects of calcitonin in patients whose underlying disease is not steroid-responsive.<sup>102</sup> The drug does not appear to be effective when administered by nasal insufflation.<sup>106</sup> Because of its rapid action, calcitonin has been increasingly used in combination with more potent antiresorptive drugs such as gallium nitrate and pamidronate, and this combination, in addition to vigorous intravenous hydration, is excellent therapy for critically ill patients with acute severe hypercalcemia.<sup>107</sup>

**Corticosteroids**

Corticosteroids acutely inhibit osteoclast-mediated bone resorption *in vitro*<sup>108</sup> and decrease gastrointestinal calcium resorption.<sup>109</sup> Corticosteroids are most useful in patients whose underlying tumor is responsive to the cytostatic action of these drugs. These diseases include myeloma, lymphoma, leukemia, and occasional patients with carcinoma of the breast (particularly those who have a hypercalcemic flare during hormonal therapy). Corticosteroids do not have consistent hypocalcemic

activity in other diseases<sup>110,111</sup> and should not be used in these conditions due to adverse effects. Prednisone (40 to 100 mg/d or its equivalent) is usually effective in controlling hypercalcemia caused by hematologic cancers; lower doses (15 to 30 mg/d) may suffice for patients with hypercalcemic flares caused by breast cancer. However, most patients who require therapy should be treated with a specific antiresorptive drug.

### Phosphates

An increase in serum phosphorus concentration decreases osteoclastic activity, inhibits calcium resorption from bone, and causes a significant reduction in urinary calcium excretion.<sup>112</sup> However, administration of exogenous phosphate to hypercalcemic patients also shifts calcium from blood to other tissues that can result in severe toxicity. Oral phosphate (0.5 to 3.0 g/d) may be highly effective, particularly in mild forms of hypercalcemia<sup>113</sup>; principal side effects are diarrhea and nausea, which may lead to noncompliance. Serum phosphorus concentrations should be monitored in all patients who receive phosphates, especially patients with decreased renal function or preexisting hyperphosphatemia.<sup>114</sup> Serum creatinine should be regularly monitored to avoid renal insufficiency. When the [calcium × phosphorus product] (expressed in milligrams per deciliter) exceeds 55, phosphate should be discontinued.

Intravenous phosphate is highly effective and the onset of hypocalcemic action occurs more rapidly than with any other hypocalcemic therapy. However, renal failure, hypotension, extraskelatal calcification, and severe hypocalcemia are common sequelae of parenteral phosphate therapy,<sup>115</sup> and the use of intravenous phosphate has largely been abandoned. Although uncommon, these effects have occasionally been seen with oral phosphates.<sup>114,116</sup>

### Plicamycin

Plicamycin (formerly mithramycin) induces hypocalcemia by a direct cytotoxic effect on osteoclasts,<sup>117</sup> thereby decreasing cell-mediated bone resorption. Plicamycin is administered at doses ranging from 10 to 50 µg/kg of body weight. The usual dose is 25 µg/kg or a total dose of 1.5 to 2.0 mg given as a brief infusion. Since the onset of action occurs after 24 to 48 hours,<sup>118,119</sup> doses should not be repeated more frequently than every 2 days. Except for nausea, single injections are generally well tolerated; the incidence of adverse effects (renal insufficiency, hepatotoxicity, thrombocytopenia, and a hemorrhagic diathesis) increases with multiple injections.<sup>120</sup>

## GENERAL APPROACH TO TREATMENT OF HYPERCALCEMIA

Patients with hypercalcemia can be divided according to those who require urgent in-hospital therapy and those for whom outpatient therapy can be considered. [Table 51.3-4](#) presents a list of considerations that influence this level of care decision. Hospitalization should be considered for any patient with a serum calcium greater than 12.0 mg/dL or for any patient with significant signs and symptoms, particularly nausea, dehydration, or confusion. Hypercalcemia that has evolved slowly may rapidly progress after a patient begins vomiting or if mentation is impaired.

Outpatient	Inpatient
Serum calcium <12.0 mg/dL	Serum calcium ≥12.0 mg/dL
No significant nausea	Nausea or vomiting
Able to ingest fluids	Dehydration
Fatigue	Altered mental status
Normal renal function	Renal insufficiency
Stable cardiac rhythm	Cardiac arrhythmia
Mild constipation	Obstipation, ileus
Companion for supervision	Lives alone
Access to emergency care	Limited access to medical care

**TABLE 51.3-4.** Approach to the Management of Patients with Cancer-Related Hypercalcemia: Criteria to Ascertain Level of Care

### EMERGENCY TREATMENT OF HOSPITALIZED PATIENTS

Intravenous hydration should be initiated immediately in patients who require hospitalization. Furosemide should be given only if diuresis is inadequate or to treat problems related to fluid retention. Most patients with significant hypercalcemia (total calcium greater than or equal to 12.0 mg/dL) do not respond satisfactorily to intravenous fluids, and pamidronate, which is now first-line therapy, should be administered shortly after hydration has been started and satisfactory urinary output established. Patients who do not respond to two pamidronate infusions (administered 48 to 72 hours apart) should be considered for additional therapy, such as gallium nitrate. For patients with a serum calcium greater than or equal to 15.0 mg/dL or severe symptoms (e.g., coma, cardiac irritability), calcitonin (8 U/kg as an intramuscular injection every 6 hours for 2 to 3 days) can be added immediately to provide an acute hypocalcemic effect.<sup>107,121</sup> Corticosteroids should also be given, but only if the underlying disease is steroid-responsive. Mithramycin should generally be reserved for patients without thrombocytopenia or significant renal or hepatic dysfunction who do not respond to pamidronate or gallium nitrate. Hypercalcemic patients with marked renal insufficiency (especially those with myeloma) should be considered candidates for immediate dialysis.<sup>122</sup>

### AMBULATORY MANAGEMENT OF HYPERCALCEMIC PATIENTS

One of the major goals of outpatient therapy is to reduce the need for hospitalization. Ambulatory patients must receive clear instructions regarding increased oral fluid intake. The amount of fluid should be stated in terms that the patient and family understand. It is imperative that a family member or companion attend the patient to ensure that nausea caused by worsening hypercalcemia does not lead to further dehydration. Diuretics such as furosemide should not be added since the risk of dehydration outweighs any theoretical benefits in ambulatory patients who are not edematous.

The most commonly used therapy is pamidronate (60 to 90 mg intravenously over 2 to 4 hours). The schedule can be titrated according to the patients needs, but the drug is usually given every 7 to 14 days. Oral bisphosphonates are not useful. In patients with PTH-RP-mediated hypercalcemia, neutral phosphorus (1 to 3 g/d in divided doses) can be quite useful in the setting of hypophosphatemia, so long as renal function is maintained. Oral corticosteroids are helpful if the underlying disease is steroid-responsive. The use of calcitonin has largely been supplanted by the bisphosphonates. Plicamycin can also be administered in doses of 10 to 25 µg/kg once or twice per week with close monitoring for evidence of myelosuppression or changes in renal or hepatic function.<sup>123</sup>

### MANAGEMENT OF CHRONIC RECURRENT HYPERCALCEMIA

The management of acute hypercalcemic episodes is relatively straightforward. However, an increasing problem is the patient whose underlying disease is poorly or incompletely responsive to primary antitumor therapy, and who continues to develop multiple episodes of hypercalcemia. In this setting, the primary goal of treatment is to prevent exacerbations that require repeated hospitalization. Several principles underlie the management of such patients. First, hypocalcemic treatment must be given on a chronic schedule and must not be reserved for treatment of acute recurrent episodes, even if the patient is relatively normocalcemic. Second, the dosing schedule of pamidronate, once initiated, can be progressively intensified up to a maximum of 90 mg IV twice per week. Third, hypocalcemic drugs should be continued indefinitely unless the patient has sustained a major antitumor response. Patients should not be declared *pamidronate-resistant*. Rather, the bisphosphonate should be continued on a maximally intensive schedule and additional drugs, including gallium nitrate, calcitonin, oral phosphate, and plicamycin, should be added to the regimen until the serum calcium can be consistently maintained below 12.0 mg/dL.

### HYPERURICEMIA

Uric acid is formed as a result of the sequential catalysis of hypoxanthine and xanthine by xanthine oxidase. Renal insufficiency develops when urine becomes supersaturated with urate and crystals of uric acid form in the renal tubules and distal collecting system.<sup>124</sup> Uric acid stones may also develop, although this

presentation is more commonly associated with chronic hyperuricemia.

Renal complications and arthritis are the most important consequences of acute or chronic hyperuricemia. The disorder occurs most commonly in hematologic neoplasms, particularly the leukemias, high-grade lymphomas, and myeloproliferative diseases.<sup>125,126</sup> and <sup>127</sup> Acute urate nephropathy has also been reported after chemotherapy for solid tumors. Patients at highest risk include those with bulky high-grade lymphomas, patients with high leukocyte counts undergoing remission-induction chemotherapy for acute or chronic leukemia, and individuals with preexisting renal impairment (especially those with ureteral obstruction). Hyperuricemia is also a side effect of certain agents, notably diuretics (thiazides and furosemide), and antituberculosis drugs (pyrazinamide, ethambutol, and nicotinic acid).

## TREATMENT

Recognition of patients at risk is essential for proper therapy. It is essential that prophylactic measures be undertaken *before* cytotoxic therapy is initiated. Drugs that tend to elevate serum urate or that produce an acidic urine (thiazides and salicylates) should be withdrawn. All patients should receive intravenous hydration to correct preexisting deficits of intravascular volume and to ensure continued urinary output. Increased urinary volume decreases the concentration of urate in urine and thus minimizes problems with respect to urate solubility.<sup>128</sup> Although furosemide theoretically promotes increased tubular urate reabsorption, this effect is outweighed by its acute diuretic action; thus, the drug can be safely used to maintain satisfactory urine output so long as fluid status and serum electrolytes are monitored and replaced. Alkalinization of the urine should be initiated to maintain a urine pH greater than or equal to 7.0. Although oral sodium bicarbonate can be used, it is usually simpler to add sodium bicarbonate solution (50 to 100 mmol/L) to intravenous fluids and then to adjust the admixture so that an alkaline urine pH is maintained. Acetazolamide (an inhibitor of carbonic anhydrase) may be used to increase the effects of alkalinization. However, it must be emphasized that alkalinization is secondary to the overall goal of decreasing urinary uric acid concentration by increasing urinary volume.

The mainstay of current drug therapy is allopurinol, which inhibits xanthine oxidase and consequently increases plasma and urinary concentrations of xanthine and hypoxanthine. Although xanthine is somewhat more soluble than uric acid, allopurinol has occasionally been associated with renal failure due to xanthine nephropathy.<sup>129</sup> The drug is generally well tolerated. The most common adverse reaction is a blanching, erythematous skin rash that indicates hypersensitivity. The onset of this reaction is usually delayed for several days after initial administration, and the drug can usually be continued throughout periods of greatest risk in patients who have not had prior exposure. In acute situations, the drug is administered orally once or twice per day in daily doses ranging from 300 to 900 mg. The dose of certain drugs that are metabolized by xanthine oxidase (e.g., 6-mercaptopurine) must be substantially reduced during treatment with allopurinol.

Patients in renal failure and allopurinol-sensitive individuals represent uncommon but difficult management problems.<sup>130</sup> Intravenous administration of uricase has also been useful in certain circumstances.<sup>131,132</sup> In the face of acute oliguria, ultrasonography or computed tomographic (CT) scanning should be used to evaluate possible ureteral obstruction by urate calculi. Administration of intravenous contrast agents for pyelography should be avoided due to an increased risk of acute tubular necrosis.<sup>133</sup> Peritoneal or hemodialysis has been quite effective in reversing renal failure due to urate deposition.

## TUMOR LYSIS SYNDROME

The tumor lysis syndrome occurs as a result of the rapid release of intracellular contents into the blood stream, which then increase to life-threatening concentrations. The syndrome is characterized by hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia.<sup>127,134,135</sup> Lethal cardiac arrhythmias are the most serious consequences of hyperkalemia. Hyperphosphatemia may result in acute renal failure.<sup>136,137</sup> Elevated serum phosphorus may also decrease renal function, which can lead to further reductions in urinary potassium and phosphate excretion. Hypocalcemia, a result of hyperphosphatemia, may cause muscle cramps, cardiac arrhythmias, and tetany.<sup>138</sup>

The tumor lysis syndrome occurs most commonly in diseases with large tumor burdens and high proliferative fractions that are exquisitely sensitive to cytotoxic treatment. These disorders include high-grade lymphomas,<sup>139</sup> leukemias with high leukocyte counts,<sup>140</sup> and (much less commonly) solid tumors.<sup>141,142</sup> The syndrome has been observed not only with agents that have potent myelosuppressive activity, but also with drugs such as interferon- $\alpha$ ,<sup>143</sup> tamoxifen,<sup>144</sup> cladribine,<sup>145</sup> and intrathecal methotrexate.<sup>146</sup> Although not related to tumor lysis, severe hypocalcemia has been associated with estrogenic treatment of prostate cancer<sup>147</sup> and with accelerated bone formation in patients with leukemia.<sup>148</sup>

## TREATMENT

Recognition of risk and prevention are essential to management. Patients at risk should be identified before the initiation of chemotherapy. If possible, intravenous hydration should be started 24 to 48 hours before administration of chemotherapy. Any acid-base or electrolyte disorders should be corrected (although intravenous administration of sodium bicarbonate may aggravate symptoms of hypocalcemia). Treatment with allopurinol should be undertaken along with other measures to minimize hyperuricemia as described previously. Serum electrolytes, uric acid, phosphorus, calcium, and creatinine should be checked every few hours for 3 to 4 days after initiating cytotoxic treatment. The frequency of monitoring should depend on the clinical condition of the patient. If significant hyperkalemia or hypocalcemia become evident, an electrocardiogram should be obtained and the cardiac rhythm should be monitored while these abnormalities are corrected. In most patients, hypocalcemia can be corrected with intravenous administration of calcium gluconate; however, patients who have persistent hypocalcemia should be treated with calcitriol until the syndrome resolves.<sup>149</sup> Hyperkalemia (serum  $[K^+]$  greater than or equal to 5.0 mg/dL) should be treated with an oral sodium-potassium exchange resin (e.g., Kayexalate, 15 g orally every 6 hours) or with combined insulin and glucose therapy.

In the face of acutely worsening renal function after administration of chemotherapy, consideration should be given to the *early* initiation of renal dialysis in order to rapidly control serum concentrations of potassium, calcium, phosphate, and uric acid, as well as other problems related to uremia. The dose of many drugs, especially antineoplastics, requires substantial modification in the presence of renal insufficiency.

## LACTIC ACIDOSIS

Lactic acidosis is a rare but potentially severe metabolic complication in patients with cancer. Type A lactic acidosis results from impaired delivery of oxygen to peripheral tissue and is commonly seen with shock and septicemia. Type B lactic acidosis is associated with a variety of diseases (including diabetes, renal failure, liver disease, infection, and cancer) as well as drugs (such as metformin), toxins, and hereditary diseases.<sup>150,151</sup> and <sup>152</sup> Lactic acidosis is characterized by decreased arterial pH (less than 7.37) secondary to accumulation of blood lactate (greater than 2 mEq/L). The disorder is a consequence of both increased lactate production and impaired use. Lactate is a metabolite of pyruvate and is produced in a cytosolic reaction catalyzed by lactic dehydrogenase, an enzyme with an absolute requirement for nicotinamide adenine dinucleotide (NAD). Consequently, the concentrations of pyruvate, hydrogen ion, and NAD regulate lactate metabolism. Accelerated glycogenolysis increases pyruvate production and decreases tissue oxygen, which in turn decreases levels of NAD. As NAD is depleted, gluconeogenesis is halted and pyruvate increases. Anaerobic metabolism of pyruvate to lactate is increased, which also leads to accumulation of NADH and hydrogen ion.<sup>153</sup>

In a review of 25 cases of lactic acidosis in which the underlying tumor was believed to represent the primary etiologic factor, more than two-thirds were associated with leukemia or lymphoma.<sup>154</sup> The development of lactic acidosis coincided with the onset of progressive disease in the hematologic cancers, whereas most patients with solid tumors had extensive liver metastases. Antiviral drugs, such as azidothymidine and fialuridine, have produced hepatic failure and severe lactic acidosis.<sup>155,156</sup> Typically, the patient with lactic acidosis presents with hyperventilation and hypotension. Nonspecific clinical symptoms such as tachycardia, weakness, nausea, and stupor may proceed to frank shock as the acidosis worsens. Laboratory studies show decreased blood pH, a widened anion gap (greater than 18), and low serum bicarbonate.<sup>151</sup> It must be noted that primary cancer-induced lactic acidosis is a rare event, and the diagnostic workup should always search for other, potentially more treatable causes.

The prognosis for patients with a serum lactate concentration greater than 4 mEq/L is exceedingly poor; however, the outcome is largely determined by the underlying disease and not the acidosis per se. Several reports have suggested that administration of sodium bicarbonate may actually increase lactate and CO<sub>2</sub> production and impair oxygen delivery.<sup>155,156</sup> and <sup>157</sup> Although some deleterious effects of severe acidemia on cardiovascular function could theoretically be ameliorated by sodium bicarbonate,<sup>158</sup> no study has shown a convincing survival advantage for alkali therapy in this condition.<sup>159</sup> Despite ongoing controversy, bicarbonate administration

remains a reasonably safe and conservative therapy.<sup>152,160,161 and 162</sup>

## HYPOGLYCEMIA

Insulin-producing islet cell tumors are the most frequent cause of hypoglycemia in patients with cancer; however, more than 250 cases of hypoglycemia associated with non-islet cell tumors have also been reported.<sup>163</sup> Non-islet cell tumors associated with hypoglycemia tend to be large. In such patients, mesenchymal tumors (fibrosarcomas, leiomyomas, rhabdomyosarcomas, liposarcomas, and mesotheliomas) account for approximately 50% of cases; another 25% are hepatomas.<sup>163,164,165</sup> and <sup>166</sup> Classic symptoms of hypoglycemia (e.g., weakness, dizziness, diaphoresis, and nausea) are nonspecific and may develop slowly. In the initial phases, symptoms tend to be worse in the early morning (due to overnight fasting) and improve after ingestion of food. However, patients may also present acutely with seizures, coma, and focal or diffuse neurologic deficits.

## PATHOPHYSIOLOGY

Several etiologic mechanisms for cancer-related hypoglycemia have been proposed: (1) secretion of insulin-like substances; (2) excessive glucose use by the tumor that exceeds hepatic production; and (3) failure of counterregulatory mechanisms that usually prevent hypoglycemia (e.g., reduction in levels of growth hormone). Various substances with nonsuppressible insulin-like activities have been detected in serum from patients with hypoglycemia. These factors are composed of two general classes: one of relatively low-molecular-weight substances that are soluble in acid ethanol, and the other of high molecular weight that are acid-ethanol precipitable. The low-molecular-weight compounds consist of four peptides, the insulin-like growth factors (IGF-1, IGF-2, somatomedin A, and somatomedin C).<sup>167,168</sup> The IGFs share a high degree of amino acid similarity with proinsulin, are bound by circulating proteins that inactivate them, and mediate their biologic activities after binding to specific cell surface receptors.<sup>167,168</sup> They do not react with antiinsulin antibodies and they have only 1% to 2% of the specific metabolic activity of insulin. Insulin itself has a weak affinity for the IGF-1 receptor but not for IGF-2R. IGFs appear to act as growth factors for various tumors and have been proposed as targets for anticancer therapy.

In most patients with non-islet cell tumors that have been associated with hypoglycemia, serum levels of IGF-1 have been appropriately suppressed, whereas levels of IGF-2 have been relatively normal (as measured by radioimmunoassay).<sup>168</sup> However, it now appears that the high-molecular-weight, nonsuppressible-insulin-like-activities molecule is actually a propeptide of IGF-2, so-called big IGF-2, secreted by tumor cells that are incompletely cleaved.<sup>169</sup> The large size either prevents formation of an acid-labile subunit from binding or impairs binding of a critical molecule (IGF-binding protein 3), which inactivates the protein; thus, the bound molecule retains its biologic activity.<sup>170 and 171</sup>

Accelerated glucose use by large tumors may also account for cancer-related hypoglycemia in some patients. It has been estimated that a 1-kg tumor may use from 50 to 200 g of glucose per day.<sup>172</sup> Since the liver can produce approximately 700 g of glucose per day, hepatic production should theoretically be sufficient to prevent hypoglycemia. However, many patients with hypoglycemia have tumors that weigh several kilograms along with extensive hepatic metastases; thus, the combination of accelerated glucose use with impaired production may lead to hypoglycemia.

Finally, a failure of the usual counterregulatory mechanisms in patients with large tumors may also induce hypoglycemia.<sup>173</sup> Impaired liver function can decrease glycogenolysis and gluconeogenesis. Certain patients with cancer have a depressed hyperglycemic response to the administration of glucagon<sup>174</sup>; depressed secretion of counterregulatory hormones such as glucagon, adrenocorticotropic hormone (ACTH), glucocorticoids, and growth hormone has also been reported. However, there remains little direct evidence to support this hypothesis as an important clinical mechanism of tumor-induced hypoglycemia.

## THERAPY

Therapy of hypoglycemia should match the severity of the condition. As with most paraneoplastic syndromes, specific antitumor therapy is the preferred treatment. To date, chemotherapeutic agents that are cytotoxic for islet cells or that block insulin release or activity have had little effect on production, release, or activity of IGFs. Mild hypoglycemia can usually be managed by increasing the frequency of meals. In patients with more severe or unpredictable symptoms, the administration of corticosteroids and glucagon may afford symptomatic relief. Intravenous infusions of glucose provide temporary support while other specific treatment is administered (i.e., surgery, chemotherapy, or radiation). Under certain circumstances, continuous infusions of glucagon using portable pumps have been used with some success.<sup>173</sup>

## ADRENAL FAILURE

Symptomatic adrenocortical insufficiency due to destruction of cortical tissue by metastatic carcinoma is uncommon. More common are iatrogenic causes such as surgical adrenalectomy, treatment with mitotane (o-p'-DDD) and inhibitors of steroid synthesis such as aminoglutethimide, chronic corticosteroid therapy, and occasionally adrenal hemorrhage.<sup>174,175,176,177,178 and 179</sup> Nonetheless, technical improvements in CT and magnetic resonance imaging have increased the likelihood of making an antemortem diagnosis of adrenal metastases. In one study, 19% of patients with metastatic cancer and enlargement of the adrenal glands by CT scans developed symptoms of adrenal insufficiency.<sup>174</sup> In a separate study wherein 15 patients with metastatic cancer and adrenal enlargement on CT scan were evaluated by ACTH stimulation, one-third were judged to have adrenal insufficiency. Further clinical study revealed symptoms of nausea, anorexia, and orthostatic hypotension in all of these patients.<sup>175</sup> Adrenal insufficiency may thus develop insidiously in patients with adrenal metastasis, and CT scans and ACTH testing may be useful diagnostic tools.

## CLINICAL MANIFESTATIONS

Classic signs and symptoms of adrenal insufficiency include weakness, weight loss, anorexia, hyperpigmentation, and postural hypotension. One or more of these symptoms are evident in almost all patients, but the onset of symptoms is frequently insidious. Circulatory collapse and shock are uncommon but may develop with the onset of infection. Biochemical evaluation frequently reveals a mild acidosis (without an anion gap), hyponatremia, and hypokalemia.

## EVALUATION AND TREATMENT

Because an ACTH-stimulation test is a benign procedure, this test is recommended when symptoms suggestive of adrenal insufficiency are evident. Typically, patients receive Cosyntropin, 0.25 mg intravenously, and serum cortisol is monitored at baseline, 30 minutes, and 1 hour. An increase in serum cortisol of 5 to 7 µg/dL over baseline levels (to a minimum of 15 µg/mL) is considered normal. If adrenal insufficiency is strongly suspected on clinical grounds, steroid replacement (or stress doses of steroids) should be started immediately, and subsequent therapy can be reevaluated when results of the ACTH test become available.

Physiologic glucocorticoid replacement is attained by administration of cortisone acetate (25 mg in the morning and 12.5 mg in the early evening). During periods of stress (e.g., operative procedures or infection), these doses may need to be doubled or tripled. Occasionally, mineralocorticoid replacement (0.05 to 0.1 mg of fludrocortisone) is required in addition to cortisone acetate. In patients with no adrenocortical function whatsoever, maintenance doses of dexamethasone or prednisone do not provide adequate mineralocorticoid coverage and fludrocortisone must be given. Pharmacologic doses of parenteral glucocorticoids are required in the setting of acute adrenal failure and circulatory collapse. Typically, aqueous-soluble forms of hydrocortisone (e.g., sodium succinate salt) at doses of 100 mg intravenously every 8 hours are required. Thereafter, the patient should be monitored for evidence of hyperglycemia, hypokalemia, or hypernatremia.

---

\*Concentrations in milligrams per deciliter can be converted to SI units after multiplication by 0.2495, which yields a concentration expressed in millimoles per liter.

#### INTRODUCTION

Urologic oncologic emergencies may arise secondary to the underlying malignancy, treatment, or unrelated medical conditions. Initial evaluation of symptoms of sepsis, hematuria, urinary obstruction, priapism, and other urologic emergencies leads to diagnosis and initial management. Urologic consultation may be necessary for definitive treatment.

#### URINARY TRACT INFECTION

##### URINARY SEPSIS

Neutropenic sepsis occurs after 1.1% to 14.0% of cycles of chemotherapy, most frequently associated with malignancies that impair granulocyte function or with more intensive bone marrow suppression, such as CHOP-M (cyclophosphamide, doxorubicin, vincristine, prednisone, with methotrexate) or similar regimens.<sup>1,2</sup> Of the sepsis episodes, as many as 8.9% are urosepsis.<sup>1</sup> Urinary tract infections are most frequently associated with urethral catheterization and require surveillance in immunocompromised patients.<sup>3,4</sup>

Treatment includes broad-spectrum antibiotic coverage until sensitivity results are available ( [Chapter 54](#)). Broad-spectrum antibiotic coverage resulting in appropriate empiric antibiotic treatment has been associated with improved survival and shorter hospital stay, compared to inappropriate empiric antibiotic coverage.<sup>5,6</sup> Use of antibiotics before hospital admission, advanced patient age, and male gender have been predictive of a resistant uropathogen.<sup>7</sup>

Altered renal function, flank pain, urinary retention, or other signs or symptoms of urinary obstruction requires immediate evaluation to provide relief. Percutaneous nephrostomy gives direct drainage of an obstructed infected ureter and allows manual irrigation of viscous purulent fluid if drainage is not adequate.

##### PERIURETHRAL ABSCESS

Periurethral abscess is a life-threatening infection of the male urethra and periurethral tissues.<sup>8</sup> Patients present with sepsis and perineal or scrotal abscess or phlegmon. Urethral strictures, found in 60% to 85% of these patients, cause a high urethral voiding pressure, and lead to periurethral extravasation of infected urine, particularly after urethral instrumentation.<sup>8,9</sup> The infection can range from a small abscess confined by Buck's fascia, to an extensive necrotizing fasciitis of the penis, scrotum, and perineum.

The differential diagnosis includes tissue edema, follicular abscess, perirectal abscess, Fournier's gangrene, and penile or urethral cancer.<sup>10,11</sup> Physical examination will identify urethral involvement, extent of phlegmon, and crepitation caused by gas-forming organisms. Urinalysis and culture usually isolate gram-negative and anaerobic bacteria. Retrograde urethrogram will demonstrate diagnostic extravasation of contrast into the periurethral tissues.<sup>12,13</sup>

Treatment of periurethral abscess consists of emergent débridement and suprapubic drainage of urine. In the presulfonamide era, mortality was at least 50%.<sup>9</sup> Broad-spectrum antibiotic coverage for gram-negative organisms and anaerobes, using aminoglycoside and cephalosporins, have been associated with a 1.6% mortality.<sup>8</sup> Additional débridement and skin grafts or secondary wound closure can be required with extensive tissue necrosis.

As many as 20% of patients develop recurrent periurethral abscess during follow-up, apparently due to extensive urethral stricture disease. Evaluation after resolution of sepsis should exclude contributory factors, such as an unstable bladder, urethral diverticula, or watering-pot perineum. Construction of a perineal urethrostomy may prevent abscess recurrence and should be considered if significant urethral disease is present.<sup>8,9,14</sup>

#### CYSTITIS

Cystitis, defined symptomatically as an irritation of the bladder, presents with suprapubic discomfort, frequency, dysuria, and urgency. Severe manifestations include urge incontinence and hematuria. Patients may present with acute exsanguinating hematuria but more commonly develop milder symptoms and pathologic disease. The etiology may be related to a toxic chemical agent, radiation, thrombocytopenia with subsequent bleeding, or myelosuppression with associated infection.

General measures taken in the initial evaluation of patients with cystitis should exclude urinary infection and the presence of malignancy. Symptomatic relief of discomfort on voiding can be obtained with urinary analgesics, such as phenazopyridine hydrochloride (Pyridium). Suprapubic discomfort, frequency, urgency, and urge incontinence require antispasmodics to obtain relief; oxybutynin chloride (Ditropan), propantheline bromide (Pro-Banthine), hyoscyamine sulfate (Cystospaz, Levsin), and flavoxate hydrochloride (Urispas) are used for this purpose. Combinations of drugs, sometimes including antiseptics, are often helpful. These include Urised (methenamine, methylene blue, phenyl salicylate, benzoic acid, atropine sulfate, and hyoscyamine), Pyridium Plus (phenazopyridine, hyoscyamine, and butabarbital), and Azogantrisin (sulfisoxazole and phenazopyridine). Severe symptoms may require belladonna and opium rectal suppositories. Patients with mild voiding dysfunction associated with chronic bladder pain may benefit from a trial of tricyclic antidepressants.<sup>15</sup> Many treatment measures are unique to each etiology.

#### CHEMICAL CYSTITIS

##### *Oxazaphosphorines*

Cyclophosphamide (Cytoxan), the most commonly used oxazaphosphorine, is an alkylating agent first used in the treatment of malignant tumors in Europe in 1957. Currently, Cytoxan has a role in the treatment of solid tumors and lymphomas, as well as benign inflammatory states, Wegener's granulomatosis and rheumatoid arthritis being the most common. Other oxazaphosphorines—ifosfamide, trophosphamide, and sufosfamide—have been used since the 1970s for the treatment of solid malignancies and lymphomas. Dose-limiting toxicity with these compounds is usually urinary tract toxicity.

Urinary symptoms, including frequency, urgency, dysuria, and nocturia, develop in as many as 24% of patients treated with oral Cytoxan.<sup>16</sup> Microhematuria occurs in 7% to 53% of patients and gross hematuria in 0.6% to 15.0%.<sup>16,17,18</sup> and<sup>19</sup> Gross hematuria can range from lightly stained urine to exsanguinating hemorrhage. Symptoms usually occur soon after Cytoxan is given but may occur years later.<sup>17</sup> Malignant lesions, usually transitional cell carcinoma, occur in 2% to 5.5% of patients who receive oral Cytoxan for nonmalignant disease.<sup>16,19,20</sup> The entire urothelium can be affected, but the bladder is the most frequently involved area.

Bladder pathology has been attributed to toxic metabolites of these compounds. Hepatic microsomal cells break down cyclophosphamide to hydroxycyclophosphamide, then by target cells to aldophosphamide, and then to phosphoramidate mustard, the active antineoplastic metabolite, and acrolein, which has no significant antitumor activity.<sup>21,22</sup> and<sup>23</sup> Similarly, ifosfamide is metabolized to iphosphoramidate mustard and acrolein.<sup>22</sup> Urinary excretion of acrolein is believed to be the major source of urothelial toxicity.<sup>22</sup> Most normal cells are able to break down the toxic metabolites and diminish their effect. Glutathione is a naturally occurring thiol that can confer such protection in most cells but is present in low levels in urine.<sup>21</sup> Oxazaphosphorine toxicity has been demonstrated in several animal models with their systemic administration and by instillation of their normal metabolic products directly into the bladder.<sup>24,25</sup> and<sup>26</sup>

Bladder damage from these compounds is cumulative and generally dose-related. "Cytoxan cystitis" occurs frequently and early after intravenous therapy, especially dose-intensive regimens. Fibrosis has been found in as many as 25% of children receiving high-dose cyclophosphamide.<sup>27</sup> Severe hematuria and telangiectasia are more common in these patients.<sup>27</sup> Cystitis usually takes weeks to develop after oral treatment but has been seen after as little as one dose.<sup>28</sup> Oxazaphosphorine cystitis is potentiated by prior pelvic radiation.<sup>17,29</sup>

Laboratory values reveal normal coagulation profiles, a normal platelet count, and negative urine culture. Because these patients are at risk for developing urothelial malignancies, episodes of cystitis and hematuria must be evaluated, including urinalysis and urine cytology. Patients receiving cyclophosphamide develop markedly abnormal cytologies, including marked atypia, increased nuclear size, and bizarrely shaped cytoplasm, which frequently resolves with cessation of the drug.<sup>30</sup> These findings can be suggestive of malignancy and need to be interpreted with caution.<sup>31</sup> Patients with abnormal cytologies that have not been investigated previously should undergo a thorough urologic evaluation. Cystoscopy may reveal a tumor or changes compatible with Cytoxan cystitis (Fig. 51.4-1). Acutely diffuse inflammation is seen. Chronic changes include a pale bladder mucosa with telangiectasia. Areas of edema can be present with patchy hemorrhagic areas that stain with methylene blue, an indicator of mucosal injury.<sup>24</sup> Biopsies reveal hyperemia, hemorrhage, edema, mucosal thinning, and ulceration of the urothelium. Necrosis of mucosa, muscle, and small arterioles and telangiectasia can be present.<sup>24,26,32</sup> Atypia can be prominent, and abundant mitoses often occur.<sup>26,30,32</sup> These findings are similar to those seen after radiation therapy. Mucosal lesions of cyclophosphamide-induced cystitis may be identified early, before the appearance of microscopic hematuria.<sup>33</sup>

**FIGURE 51.4-1.** Cytoxan cystitis. Microscopic hematuria is found in approximately one-half of patients receiving oral Cytoxan. Increased vascularity with fragile "corkscrew" vessels are seen at cystoscopy here. Submucosal hemorrhage adjacent to larger vessels occurred after bladder distention. Fulguration of these small vessels will temporarily alleviate bleeding. Radiation cystitis appears similar at cystoscopy.

Hemorrhagic cystitis is managed by stopping or reducing the drug. Replacing the drug, usually with azathioprine, is necessary in as many as one-third of patients who develop severe cystitis after chronic oral administration.<sup>34</sup> Hydration and diuresis are routinely used to dilute the metabolites in the urine and minimize their toxicity after intravenous administration.<sup>23</sup> The cystitis usually improves within several days after cessation of the drug but can occasionally persist for months. Patients receiving high doses of oxazaphosphorines require additional measures to counter their effects.<sup>35</sup> Bladder irrigation is helpful in many of these patients taking cyclophosphamide.<sup>36</sup>

Sodium 2-mercaptoethane sulfonate (mesna) was designed to function in the urinary tract to detoxify azophosphorine metabolites with urothelial toxicity. Mesna is a sulfhydryl compound that is administered intravenously and rapidly excreted by the urinary tract. After intravenous administration, mesna undergoes oxidation, forming disulfide bonds and making an unreactive dimer (dimesna). One concern regarding such a class of drugs is that they might affect the antineoplastic properties of oxazaphosphorines. Mesna and dimesna are very hydrophilic and do not normally penetrate cells, explaining its antineoplastic sparing effect.<sup>23</sup> This unreactive form—dimesna—is filtered by the kidneys and undergoes tubular reabsorption, where one-third of it is reduced to its active form, mesna, by glutathione reductase.<sup>23</sup> In the urinary tract, the sulfhydryl group of mesna complexes with the terminal methyl group of acrolein, joining the compound to the double bond of acrolein and forming a nontoxic thioether.<sup>23</sup> The presence of mesna also inhibits spontaneous breakdown of cyclophosphamide to acrolein in the urine.<sup>37</sup> In addition to decreasing chemical cystitis, the risk of bladder cancer is significantly reduced when mesna is used in the Sprague-Dawley rat model.<sup>38</sup>

Oral mesna is well absorbed but slow to achieve adequate urinary concentrations. It has an unpleasant taste, which makes patient compliance poor, particularly when there is concomitant administration of a chemotherapy that induces nausea.<sup>21</sup> Mesna is best given intravenously, and the manufacturer recommends three doses. A loading dose equivalent to 20% (wt/wt) of the ifosfamide dose, given 15 minutes before the ifosfamide, is followed by two similar doses 4 and 8 hours after the ifosfamide.<sup>23</sup> Doses as high as 60% to 120% (wt/wt) have been used with cyclophosphamide, given at a similar schedule. The timing of dosages of mesna is important, as the half-life of mesna is 35 minutes, while that of cyclophosphamide is 4 hours.<sup>23,39</sup> Mesna toxicity is minimal, the major side effects being diarrhea, headaches, and limb pain.<sup>21</sup>

Another thiol compound, N-acetyl-L-cysteine, has been used less extensively to ameliorate the effects of oxazaphosphorines. Animal data demonstrate that the bladder is protected when it is given at a dose of 1:1 (wt/wt) with cyclophosphamide in a similar schedule as mesna.<sup>40</sup> Problems with N-acetyl-L-cysteine include a wide distribution in the body with low urinary levels. High intravenous doses or intravesical administration is required to reach effective concentrations.<sup>41</sup> Conflicting data concerning impairment of antitumor activity have not been resolved.

### **Bone Marrow Transplantation**

Hemorrhagic cystitis occurs in approximately 2% of conditioning regimens not containing Cytoxan and is frequently related to thrombocytopenia.<sup>29</sup> The incidence of hemorrhagic cystitis in regimens with cyclophosphamide is 5% to 15%.<sup>29,42,43</sup> and<sup>44</sup> Allogeneic bone marrow and unrelated transplantation appear to have a higher risk than autologous bone marrow transplantation.<sup>42,43</sup> Prior cyclophosphamide, radiation, urethral catheterization, infection (bacterial or previous viral), concurrent medication, or coagulation disorders (thrombocytopenia) can all contribute to the development of hemorrhagic cystitis in these patients. Prior administration of busulfan, an alkyl sulfonate, increases the risk of hemorrhagic cystitis to as high as 36%, compared to 4% in patients receiving the same regimen without prior exposure.<sup>45</sup> Concomitant use of these agents is associated with hemorrhagic cystitis in 0.5% to 50.0% of patients.<sup>29,44,46,47</sup> Patients with acute bleeding have decreased survival compared to patients without bleeding.<sup>43</sup>

Several viruses have been implicated in the etiology of hemorrhagic cystitis in patients undergoing bone marrow transplantation, either as viral reactivation or a new infection. These include polyoma (BK) virus,<sup>29,48</sup> adenovirus,<sup>42</sup> especially adenovirus 11,<sup>48,49</sup> papovavirus, influenza A, and cytomegalovirus.<sup>47,48</sup> Patients in whom viral particles were recovered developed hematuria later after transplantation (55 days)<sup>48</sup> than patients with so-called idiopathic hemorrhagic cystitis (25 to 27 days).<sup>29</sup>

The viral type also had a longer duration than idiopathic cystitis. <sup>48,49</sup> Diagnosis of viral cystitis is improving with polymerase chain reaction technology. <sup>50</sup>

It has been recommended that patients receiving the combination of Cytoxan and busulfan should receive continuous bladder irrigation during treatment. <sup>47</sup> Prophylactic treatment with mesna seems equally efficacious <sup>51,52</sup> and <sup>53</sup> and does not appear to affect engraftment. <sup>54</sup> Mesna 60% (wt/wt) has been an adequate dose in children, but adults appear to require a higher dose [120% to 160% (wt/wt)]. <sup>54</sup> Treatment in these patients is symptomatic.

### **Intravesical Chemotherapy**

Intravesical treatment of superficial bladder tumors with chemotherapeutic agents or biologic modifiers may cause a chemical cystitis or inflammatory response with marked symptoms. Several agents are commonly used. Thiotepa is well tolerated, although 2% to 49% of patients experience cystitis <sup>55,56</sup> and approximately one-third develop hematuria. <sup>55</sup> One-third of patients receiving epodyl <sup>56</sup> and 26% to 50% of patients receiving doxorubicin (Adriamycin) develop cystitis. <sup>56,57</sup> Mitomycin C is best tolerated, with 6% to 33% of patients developing cystitis, and one-third developing hematuria. <sup>55,56</sup> and <sup>57</sup> Most hematuria is microscopic. Significant hemorrhagic cystitis is uncommon with any of these agents. Bladder contractures have rarely been reported in patients receiving thiotepa or mitomycin.

Most patients receiving bacille Calmette-Guérin develop irritative voiding symptoms, which can be the most severe of all intravesical treatments. Biopsies in these patients reveal acute and chronic inflammatory changes and granuloma formation. Urinary analgesics and antispasmodics are particularly helpful in this group. If symptoms are prolonged, isoniazid and acetaminophen or ibuprofen are given until symptoms resolve. It is uncommon for treatment regimens to be stopped because of toxicity. <sup>58</sup>

### **Other**

Oral 9-nitrocamptothecin, a water-insoluble topoisomerase I inhibitor, and other camptothecins are associated with dose-related hematuria in up to 25% of patients. <sup>59</sup> Hematuria may be a chemical cystitis related to the significant urinary elimination of the drug, although it can also be associated with profound thrombocytopenia. Increasing fluid intake to 3 liters/d has been associated with decreased cystitis and ability to finish treatment.

Busulfan, an alkyl sulfonate used in the treatment of chronic granulocytic leukemia, has also been reported as a cause of hemorrhagic cystitis. <sup>45,60,61</sup> As many as 16% of patients in regimens with intravenous busulfan and without cyclophosphamide develop hemorrhagic cystitis. <sup>29</sup> Cystoscopy in these patients reveals generalized inflammation and edema. Biopsies demonstrate metaplastic changes in the urothelium, submucosal inflammation, and telangiectasia. <sup>60</sup> Both cystoscopic and histologic findings are similar to radiation or oxazaphosphorine cystitis. Bladder malignancies have not been associated with its use. Given orally, a cumulative dose of 2 to 5 kg appears necessary to induce these changes. <sup>60,62</sup> Stopping the drug and alleviation of irritative symptoms are the primary treatment.

Other chemotherapeutic regimens that do not include agents with known bladder toxicity appear to be able to induce a cystitis and hematuria without associated thrombocytopenia. <sup>63</sup> The mechanism in these patients is not clear, although bleomycin has been suggested to be the culprit. <sup>63,64</sup>

### **INTRAVESICAL PHOTOTHERAPY**

Kelly and Snell first performed treatment of superficial bladder tumors with "phototherapy" in 1975. Treatment involves administration of an intravenous photosensitizer (usually a hematoporphyrin derivative), waiting 2 days, and then activation of the compound with light. The time lag allows preferential uptake of sensitizer by tumor, with normal tissue levels decreasing, thus increasing the therapeutic index. An optical fiber placed in the bladder through a cystoscope transmits light to activate the sensitizer. Patients whose entire bladder mucosa is illuminated develop marked bladder irritation with suprapubic discomfort, urgency, and urge incontinence. Symptoms can be surprisingly mild the first day after activation but peak in the second and third day. Symptoms improve quickly and usually resolve by 4 to 6 weeks. Cystoscopy initially reveals exuberant local reaction and edema. <sup>65</sup> Biopsies initially reveal coagulative necrosis and hemorrhage. <sup>65</sup> Later, acute and chronic inflammation and atypia are present. <sup>66</sup> The acute response can resolve with little residual effect visually apparent. Bladder fibrosis and reflux are unpredictable side effects of this therapy. Treatment of the acute symptoms includes Foley drainage to put the bladder to rest and B&O suppositories for control of bladder discomfort.

### **RADIATION**

Patients undergoing primary radiotherapy of malignant pelvic tumors, most commonly uterine, bladder, and prostate neoplasms, can suffer direct or incidental damage to the bladder. The risk is increased when urinary infection is present, repeated or high-dose radiation is given, or when surgery has been performed in the area. Cyclophosphamide, given systemically in combination with pelvic radiotherapy, greatly increases the risk of radiation cystitis. <sup>67</sup>

In the first 4 to 6 weeks after treatment, an acute inflammatory response with resultant irritative symptoms or hematuria (or both) develops. Mild symptoms occur in as many as 50% to 82% of patients and generally do not require medication. <sup>68,69</sup>

Hemorrhagic cystitis can occur later, even years after successful treatment, <sup>68</sup> and frequently is associated with tumor recurrence. <sup>70</sup> The time between treatment and development of delayed symptoms (frequency, dysuria, and hematuria) is proportional to the dose received. <sup>69</sup> Patients with late cystitis develop bladder ulcers, bladder fibrosis, and ureteral strictures. They require thorough evaluation, as these patients are at increased risk for transitional cell carcinoma of the bladder. Bladder biopsies should be performed sparingly, as the bladder mucosa heals poorly.

Approximately 3.7% of patients receiving intravaginal intracavitary radiation alone (3200 cGy) for stage I endometrial carcinoma after radical hysterectomy have been reported to develop cystitis. <sup>71</sup> When external-beam radiation (4000 to 5400 cGy) is added, 4.0% to 6.5% of patients develop cystitis. <sup>71,72</sup> Patients undergoing definitive radiation treatment of cervical carcinoma have a risk of cystitis that is dose-related. <sup>70,73</sup> At doses of less than 6000 cGy, the development of cystitis has been strongly linked to recurrent tumor. <sup>70</sup> The incidence of cystitis in this group is 2.8% to 8.0%. <sup>69,74,75</sup> Between 1.2% and 18.0% of patients receiving external-beam radiation (3000 to 8500 cGy) for bladder cancer developed cystitis, <sup>70,76,77</sup> 8% hematuria, <sup>70</sup> and 5% a contracted bladder. <sup>77</sup> Chronic cystitis developed in 15% of patients.

Radiation to the prostate (5000 to 7200 cGy) and draining lymph nodes (5000 cGy) for cure of prostate cancer elicits dysuria and mild to moderate hematuria in 18% to 40% of patients. <sup>78,79</sup> Between 0.8% and 8.3% develop severe dysuria or hematuria, and 3.4% to 9.0% develop strictures or urethral obstruction as a delayed presentation. <sup>78,79</sup> and <sup>80</sup>

During the acute phase, cystoscopy reveals edema, erythema, and increased vascularity, which can be associated with a mild decrease in bladder capacity. Later, the bladder is pale, and telangiectasia is present. Focal areas of hyperemia and bullous edema may be present. Often there is no focal area of bleeding. With extensive damage, necrosis and calcification can occur. Biopsy findings are dose- and time-dependent. In the first 24 hours, there is erythema due to hyperemia. This develops into a diffuse inflammatory response with hyperemia, edema, lymphocytic infiltration, and degeneration of the urothelium with atypia. <sup>68,69,81</sup> Shallow ulcers are occasionally seen but usually occur as a late response. This response lasts up to 4 months after therapy. <sup>82</sup> Later, sclerosing endarteritis, fibrosis, and atrophy occur. There may be edema and an inflammatory infiltrate. There can be ulceration, and healing is poor. <sup>77,82,83</sup> Treatment is symptomatic.

### **ANTIBIOTICS**

While most cystitis seen in the setting of oncologic care is related to antineoplastic agents, penicillins used in the treatment of chemotherapy related infections represent another source. Methicillin, nafcillin, ticarcillin, piperacillin, carbenicillin, and penicillin G have all been implicated. The incidence of cystitis associated with the use of these agents is small, occurring in 4% to 8% of patients. <sup>84</sup> Symptoms are typical of cystitis. Laboratory investigation reveals eosinophilia, pyuria, hematuria, proteinuria, and negative urine cultures. The submucosal deposition of C3, immunoglobulins G and M, and dimethoxyphenylpenicilloyl, a methicillin antigen, supports a hypersensitivity etiology. <sup>84,85</sup> and <sup>86</sup> A diffuse hemorrhagic cystitis is seen at cystoscopy. <sup>85</sup> Biopsies show an intense inflammatory reaction with erosion. <sup>87</sup> With repeated use, the time to development of symptoms shortens. Symptoms usually resolve promptly on cessation of the drug or substitution with an unrelated drug. <sup>85,86</sup>

## BLADDER HEMORRHAGE

Severe cystitis can result in hemorrhage resulting in clot retention and requiring transfusion. If bedside bladder clot evacuation and continuous irrigation are not successful, cystoscopic evacuation of clots with fulguration of bleeding sites will cure most patients ( [Table 51.4-1](#)). Correction of thrombocytopenia before cystoscopy will frequently stop bleeding and is necessary to prevent further bleeding episodes. Patients resistant to conservative therapy have been treated with intravesical instillation of chemical astringents or fixatives started immediately after cystoscopic treatment and cystogram to exclude vesicoureteral reflux. <sup>88</sup> Bladder instillation is performed using gravity drainage with minimal hydrostatic head required for filling.

---

<b>Medical management</b>
Maintain platelet count >50,000/mm <sup>3</sup> .
Correct prothrombin time, partial thromboplastin time with necessary factors, fresh frozen plasma.
Stop medications that adversely affect clotting.
Monitor coagulation, reacting to clotting.
Transfuse with blood as needed.
Sedate as needed.
<b>Bedside management</b>
Place large-bore Foley and evacuate clots with piston syringe.
If irrigation is clear and bladder is empty, replace Foley with three-way catheter for continuous irrigation.
<b>Operative management</b>
<b>Conservative measures</b>
Perform cystoscopic evacuation of clots and fulguration after bleeding parameters are normalized.
Use three-way continuous bladder irrigation after cystoscopy.
<b>Intravesical instillation for hemostasis</b>
Perform cystoscopic evacuation of clots and fulguration after bleeding parameters are normalized.
Obtain cystogram; if no reflux, start continuous bladder irrigation in operating room, choosing one toxic agent (silver nitrate, alum, etc.) first.
<b>If life-threatening bleeding persists, reevaluate medical management, cystoscopy, fulguration, multiple reflux, and consider formalin instillation in operating room. Irrigate bladder with saline afterward to remove residual formalin.</b>

---

**TABLE 51.4-1.** Management of Bladder Hemorrhage

Silver nitrate is a cauterizing agent that results in cellular protein coagulation and eschar formation. A 0.5% to 1.0% water solution as continuous bladder irrigation has been used in the management of radiation and chemical cystitis. <sup>89</sup> Chloride salts in solution or from ulcerated mucosal lesions are avoided as they can result in precipitation of silver chloride. <sup>90</sup> When effective, bleeding usually stops within 24 to 72 hours.

Continuous irrigation with 1% alum is used in a similar manner as silver nitrate. <sup>91,92</sup> Specific toxicities are related to aluminum absorption and include renal dysfunction, altered mental status, and encephalopathy. <sup>93,94</sup>

Formalin is a tissue fixative and embalming agent. Because of its potential toxicity, formalin is used only in the management of patients with life-threatening hematuria unresponsive to other measures. After cystoscopic examination, a 1% to 5% solution of formalin is instilled for 3 to 10 minutes in the operating room. <sup>95,96</sup> and <sup>97</sup> Complications and response are directly related to concentration and duration of exposure. Complications include bladder rupture, vesicorectal or vesicovaginal fistula, renal failure, acidosis, altered mental status, and chemical skin burns. <sup>96,98,99</sup> and <sup>100</sup> Formalin toxicity may be abrogated by dialysis to decrease blood levels and correct the metabolic acidosis.

Formaldehyde exists as a gas and has a maximum solubility of 37% in aqueous solution. A 37% aqueous solution of formaldehyde is equivalent to a 100% solution of formalin. Dilution of formaldehyde to formalin in treatment concentrations is best performed in the pharmacy.

Bladder irrigation with any chemical agent can be irritating, with local pain and bladder spasms requiring medical treatment. Complications related to intravesical instillation of chemical agents include ureteral stricture, bladder fibrosis with loss of volume, and death. <sup>90,91,95,101</sup> With signs of toxicity, the bladder irrigation is changed to water or saline to wash out any residual drug. As bladder healing occurs, hematuria can frequently recur if the underlying pathology still exists.

Other less-tried regimens have been shown to have activity in the treatment of radiation- or cyclophosphamide-induced hemorrhagic cystitis. These include intravesical installation of prostaglandins, <sup>102,103</sup> oral pentosanpolysulphate, <sup>104</sup> conjugated estrogens, <sup>102,103</sup> or hyperbaric oxygen. <sup>105,106</sup> and <sup>107</sup> Open cystotomy with bladder packing has rarely been used. <sup>108</sup>

## URINARY OBSTRUCTION

Urinary obstruction associated with loss of renal function can lead to accumulation of water, urea, and electrolytes as well as loss of renal concentrating ability. Immediately after release of obstruction, these can lead to brisk diuresis, hypovolemia, and shock. Patients are monitored hourly for elevated urine output and if not able to match with oral intake, require intravenous supplementation. <sup>109,110</sup> Rarely, patients with severe fluid and electrolyte disturbances may require dialysis. <sup>111</sup>

## UPPER TRACTS

Malignant ureteral obstruction occurs in as many as 4.4% of patients with advanced cancer. <sup>112</sup> The most common associated malignancies are prostate, bladder, cervical, colon, or lymphoid cancers. <sup>113,114</sup> Definitive radiation treatment of cervical cancer has been reported to have a continuous increasing of risk of 0.15% per year over 25 years. <sup>115</sup> Ureteral obstruction may be an incidental finding on computed tomography imaging and associated with altered renal function. Radionuclide imaging may be helpful if the clinical picture is not diagnostic of obstruction. <sup>116</sup>

Cystoscopic placement of ureteral stents maintains quality of life better than percutaneous nephrostomy. <sup>117</sup> Stent placement may be difficult when the ureteral orifices are obscured by local tumor invasion. Ureteral stents placed for obstruction at the bladder level are more predisposed to bleeding and obstruction than are those placed for retroperitoneal metastases causing extrinsic ureteral obstruction. As many as 49% to 63% of patients with bladder malignancies may end up with percutaneous nephrostomy. <sup>111,113</sup>

Patients undergoing percutaneous nephrostomy placement can usually undergo antegrade placement of a ureteral stent. <sup>118</sup> These stents can be changed cystoscopically, taking care not to lose access to the ureteral orifice. Ureteral stents are generally changed every 3 months to prevent encrustation and obstruction. <sup>119</sup> Minor hematuria and bladder spasms are often associated with ureteral stent placement and treated symptomatically. As many as 5% of patients have significant bleeding, usually associated with tumor invasion in the bladder. <sup>113</sup>

Patients with ureteral obstruction and urinary conduits may require initial percutaneous nephrostomy followed by internalization of the ureteral stent. <sup>120</sup> Percutaneous management with ureteroscopic incision of a benign stricture has been effective in up to 57% of patients. <sup>121</sup> Residual ureteral stricture requiring definitive surgical treatment is uncommon, as most responses to treatment are short-lived. Late strictures after radiation therapy have had limited success with excision and ureteral reimplantation. <sup>115</sup>

Untreated patients with bilateral ureteral obstruction succumb to renal failure within a month. <sup>114</sup> Recovery of renal function after relief of obstruction depends on duration of obstruction and initial renal function. <sup>122</sup> Preservation of renal parenchyma and renal function has been reported as long as 5 months after complete unilateral ureteral obstruction. <sup>123</sup> When there is partial ureteral obstruction, return to normal function has been reported in 68% of patients, with marked improvement in 24%. <sup>114</sup> Patients with ureteral obstruction from hormone-sensitive prostate cancer have had longer survival <sup>111,112</sup> and <sup>113</sup> than those with gastric, pancreatic, or colon cancer. <sup>111,124</sup>

## LOWER TRACT

## Prostate

Urinary voiding symptoms may occur in debilitated patients after surgery, chemotherapy, or significant medical events. Symptoms may range from urinary frequency with decreased force of stream and nocturia to urinary retention.

Urinary retention may be obstructive, pharmacologic, neurogenic, or psychogenic in nature.<sup>125</sup> Patient medical and voiding history is examined with these factors in mind. Urinary tract infection or prostatitis should be detected early and treated appropriately. Manipulation of the urinary tract or prostate in these patients is kept to a minimum to prevent sepsis.

Relief of urinary obstruction with catheter drainage offers immediate relief. Patients with urethral stricture disease, benign prostatic hypertrophy, prostate cancer, meatal stenosis, or phimosis can be challenging to catheterize. Urethral dilation or use of a specialized angulated (Coudé) catheter to pass an enlarged prostate median lobe may be necessary. Placement of suprapubic trochar drainage is performed when urethral catheterization is not possible or there are concerns about promoting sepsis. Individuals especially trained in their use best perform these procedures. Minor surgical procedures can be performed to relieve phimosis or meatal stenosis.

Permanent effects on ability to void can occur after abdominoperineal resection, radical hysterectomy, or extensive pelvic operations that interrupt normal pelvic parasympathetic innervation to the bladder. Temporary loss of voiding may occur secondary to anticholinergic agents that block detrusor activity, pain that results in increased sympathetic bladder neck tone, and narcotics that inhibit the urge to void. Of patients with urinary retention as a presenting complaint, as many as 18% to 23% will reestablish normal voiding if given a voiding trial.<sup>126,127</sup> Of patients with urinary retention after nonurologic surgery, as many as 69% reestablish normal voiding patterns if placed on intermittent self-catheterization, generally within 3 months.<sup>128</sup>

Evaluation of urinary retention associated with nonsurgical medical disorders is less well defined. Assessment of prehospital admission American Urological Association voiding symptom score in all these patients is helpful in identifying patients who may require treatment of prostate obstruction.<sup>129,130,131,132</sup> and <sup>133</sup> Urodynamics may be indicated to distinguish bladder outlet obstruction from impaired detrusor contractility.<sup>134</sup> Transurethral resection of the prostate remains the standard against which other treatment regimens for urinary retention due to benign prostate hypertrophy are measured.<sup>135</sup> Use of alternative methods, such as holmium laser resection, urethral stent, or chronic indwelling catheter drainage, may be dictated by available technology or patient health.

Patients with urinary retention due to prostate cancer had good relief of obstruction 1 month after bilateral orchiectomy.<sup>136</sup> Similar results have been observed using luteinizing hormone–releasing hormone antagonists, although improvement may take longer.<sup>137</sup> Urethral stents have been used to hasten spontaneous voiding.

## Urethra

Patients in whom a catheter cannot be passed may have benign prostatic hypertrophy or urethral stricture disease. A Coudé catheter more easily follows the natural angulation of the urethra into the bladder. A small catheter may pass through a stricture that is not severe.<sup>138</sup> Urethral dilation by trained personnel may be required. Forceful advancement of the catheter is to be avoided, as the integrity of the urethra can be violated, contributing to bleeding, urinary extravasation, local cellulitis, and stricture formation.<sup>139</sup> Cystoscopic placement of a Foley catheter may be required if this occurs. Urethral bleeding after traumatic catheter placement or inflation of a balloon in the urethra will stop when the Foley is in place if coagulation parameters are normal. Urine should be checked for infection and treated appropriately.

A Foley catheter balloon may not deflate, preventing its removal. Scissors removal of the valve will allow drainage if that is the location of the obstruction. Obstruction at a distal level can be relieved by balloon rupture with a spinal needle under ultrasound guidance.<sup>138</sup> Suprapubic or transvaginal routes are preferred, although the transrectal route is technically feasible.

## PRIAPISM

Priapism is the emergent condition defined as sustained painful erection of the corpora cavernosal tissue not associated with sexual stimulation. Two types of priapism have been described, ischemic (low-flow) and nonischemic (high-flow), with different treatment and prognosis.

Ischemic priapism is associated with decreased penile venous outflow and stasis of blood resulting in intracavernosal blood acidosis and low oxygen tension. Ischemic priapism is treated emergently, as irreversible cellular damage and corporal fibrosis, which can result in erectile dysfunction, occur within 24 to 48 hours. Ischemic priapism may be caused by sickle cell disorders, oral or injected medications, or tumor infiltrate.<sup>140,141</sup> and <sup>142</sup> Nonischemic priapism usually results from perineal trauma with injury to the internal pudendal artery with arteriovenous fistula formation.<sup>143,144</sup> and <sup>145</sup> Nonischemic priapism is painless, can increase in tumescence after sexual stimuli, and can be managed electively.

Patient history may reveal drug use, sickle cell anemia, perineal trauma, or malignancy. Priapism is usually found in men but has been reported rarely in women.<sup>146</sup> On physical examination, the corpora cavernosa are rigid. The glans, an extension of the corpora spongiosa, is usually soft. Voiding symptoms may occur in as many as 25% of patients when tumor involves the corpora spongiosa or urethra.<sup>147</sup> Pseudopriapism is characterized by rigidity and edema associated with metastases rather than venous stasis. Pain is thought to be due to tissue anoxia. In malignant priapism, tumor infiltration of the cavernosa or invasion of venous drainage is thought to lead to stasis and thrombosis.

As many as 10% of patients develop priapism related to malignancy.<sup>148,149</sup> Penile metastases are most often symptom-free, with associated priapism in 20% to 53% of patients.<sup>150</sup> Prostate, bladder, and kidney cancer are most commonly involved in adults.<sup>150,151</sup> Leukemia is the most common malignant cause in children.<sup>149,152</sup> Needle biopsy or aspiration of the firm corpora cavernosa can confirm the diagnosis. The management of priapism varies according to cause.<sup>153,154,155,156</sup> and <sup>157</sup>

Treatment of malignant priapism is initially aimed at relief of pain and anxiety with hydration, analgesia, and rest.<sup>153</sup> Treatment of the underlying malignancy can be associated with relief.<sup>150</sup> Hormonal therapy of prostate cancer and chemotherapy of leukemia<sup>156,158</sup> would have higher expectations of response. Radiation is palliative if more emergent relief is needed or therapeutic options are limited. Intracavernosal injection of pharmacologic agents has had anecdotal success.<sup>159,160</sup> Without systemic treatment, survival in malignant priapism is poor, as most patients have metastatic disease at presentation.<sup>150,161,162</sup> Sixty percent of patients died at a median of 4 months (range, 0.2 to 60 months) after developing priapism.<sup>150</sup>

Surgical treatment of priapism involves creation of a shunt between the glans penis and the corpora cavernosa.<sup>163</sup> Under anesthesia, a tru-cut needle placed through the glans into each corpora cavernosum will achieve this. Anoxia occurring during priapism or shunting performed as treatment can result in impotence. A penile prosthesis may be required if the corpora cavernosa become fibrosed and unable to distend in normal fashion.

## PARAPHIMOSIS

Paraphimosis is the pathologic state occurring after retraction of the foreskin proximal to the glans penis, characterized by local swelling and difficulty in returning the foreskin to its normal position. Retention of the preputial ring proximal to the coronal sulcus is associated with tissue tension greater than lymphatic pressure and results in edema of the prepuce and glans. If not reduced, the edema can become massive, associated with pain and skin breakdown. Manual reduction is usually performed, using anesthetic jelly and pressure to remove edema. The penis is grasped with both hands, placing the last three fingers along the shaft. The index fingers are used to pull the foreskin over the glans, while the thumbs push the glans back through the constricting ring of the prepuce.<sup>138</sup> When this is not possible, a local anesthetic block may be required to release the trapped foreskin.<sup>138</sup> A dorsal slit procedure will allow relief of an acute constricting paraphimosis or phimosis if conservative measures fail.

## INTRODUCTION

Brain metastases are a common complication in cancer patients<sup>1</sup> and an increasingly important cause of morbidity and mortality. In adults, brain metastases are the most common cause of brain tumors, occurring five to ten times more frequently than primary tumors.<sup>2,3</sup> In recent years, there have been important advances in the diagnosis and management of this condition.<sup>2,3</sup> and <sup>4</sup> As a result, most patients receive effective palliation, and the majority do not die from their brain metastases. Further studies defining the optimal role of conventional treatments and future advances in the use of chemotherapy, radiosurgery, and more novel cancer therapies may lead to further increases in the effectiveness of treatments for brain metastases.

Brain metastases develop when tumor cells originating in tissues outside the nervous system spread secondarily to directly involve the brain. Intracranial metastases may involve the brain parenchyma, the cranial nerves, the blood vessels (including the dural sinuses), the dura, the leptomeninges, and the inner table of the skull. Of the intracranial metastases, the most common are intraparenchymal metastases, and these are the main focus of this chapter.

## INCIDENCE AND EPIDEMIOLOGY

Brain metastases develop in approximately 10% to 30% of adults and 6% to 10% of children with cancer.<sup>2,3,4,5,6,7,8</sup> and <sup>9</sup> It is estimated that each year in the United States, there are between 97,800 and 170,000 new cases of brain metastases.<sup>2,3,5,9</sup> This number may be increasing as a result of the increased ability of magnetic resonance imaging (MRI) to detect small metastases and prolonged survival due to improvement in systemic therapy.<sup>2,3,9,10</sup> and <sup>11</sup>

In adults, the most common primary tumors responsible for brain metastases are lung (50%), breast (15% to 20%), unknown primary (10% to 15%), melanoma (10%), and colon (5%) (Table 52.1-1).<sup>2,3,5,6,12</sup> In children, the most common sources of brain metastases are sarcomas, neuroblastoma, and germ cell tumors.<sup>2,3,7,13,14</sup> Certain tumors almost never metastasize to the brain parenchyma. These include carcinomas of the esophagus, oropharynx, and prostate and nonmelanoma skin cancers.

Primary Tumor	No. of Patients	Percentage
Lung	270	48
Breast	82	15
Melanoma	50	9
Colon	26	5
Other known primary	72	13
Unknown primary	61	11
Total	561	100

(Pooled data from ref. 178, ref. 16, and ref. 12.)

TABLE 52.1-1. Frequency of Brain Metastases by Primary Tumor Type

## METHOD OF SPREAD AND DISTRIBUTION

The most common mechanism of metastasis to the brain is by hematogenous spread.<sup>2</sup> These metastases are usually located directly beneath the gray-white junction.<sup>14</sup> Brain metastases tend to occur at this site because the blood vessels decrease in size at this point and act as a trap for clumps of tumor cells. Brain metastases also tend to be more common at the terminal “watershed areas” of arterial circulation.<sup>2,14</sup> The distribution of metastases roughly follows the relative weight of (and blood flow to) each area. Approximately 80% of brain metastases are located in the cerebral hemispheres, 15% in the cerebellum, and 5% in the brain stem.<sup>14</sup> For unclear reasons, pelvic (prostate and uterus) and gastrointestinal tumors have a predilection to metastasize to the posterior fossa.<sup>14</sup>

Metastases from breast, colon, and renal cell carcinoma are often single, while melanoma and lung cancer have a greater tendency to produce multiple metastases.<sup>2,3,14</sup> Studies using MRI suggest that the percentage of single metastases is lower than was previously believed, accounting for only one-third to one-fourth of patients with cerebral metastases.<sup>3,15</sup> With the widespread use of MRI and new improvements in MRI contrast agents and resolution, the proportion of multiple metastases probably will be even higher in the future.

## CLINICAL MANIFESTATIONS

It is estimated that more than two-thirds of patients with cerebral metastases experience neurologic symptoms during the course of their illness.<sup>2,3</sup> The clinical features due to brain metastases are extremely variable, and the presence of brain metastases should be suspected in any cancer patient who develops new neurologic symptoms. The majority of patients present with progressive neurologic dysfunction resulting from a gradually expanding tumor mass and the associated edema or, rarely, to the development of obstructive hydrocephalus. Approximately 10% to 20% of patients present acutely with seizures, while another 5% to 10% present acutely as a result of strokes caused by embolization of tumor cells or invasion or compression of an artery by tumor or as a result of hemorrhage into a metastases.<sup>10,16,17</sup> Melanoma, choriocarcinoma, thyroid, and renal carcinoma have a particular propensity to bleed.<sup>10</sup>

The clinical presentation of brain metastases is similar to that of other brain tumors and includes headaches, focal neurologic dysfunction, cognitive dysfunction, and seizures. Headaches occur in approximately 40% to 50% of patients with brain metastases. These headaches are usually dull and nonthrobbing and often are indistinguishable from tension headaches.<sup>18</sup> The headaches are usually on the same side as the tumor, although they can be diffuse. Headaches characteristic of increased intracranial pressure, such as early morning headaches or headaches exacerbated by coughing, bending, and straining, are present in fewer than one-half of patients with brain metastases. These headaches may be associated with nausea, vomiting, and transient visual obscurations. Patients with multiple metastases

and posterior fossa metastases have a higher frequency of headaches.<sup>2</sup> Papilledema is present in fewer than 10% of patients at the time of presentation. Focal neurologic dysfunction is the presenting symptom of 20% to 40% of patients. Hemiparesis is the most common complaint, but the precise symptom varies depending on the location of the metastases.<sup>2</sup> Cognitive dysfunction, including memory problems and mood or personality changes, are the presenting symptoms in one-third of patients, while seizures are the presenting symptom in another 10% to 20%.<sup>19,20,21 and 22</sup>

## DIAGNOSIS

Brain metastases must be distinguished from primary brain tumors, abscesses, demyelination, cerebral infarctions or hemorrhages, progressive multifocal leukoencephalopathy, and effects of treatment, including irradiation necrosis. In a study by Patchell et al.,<sup>23</sup> 11% of patients who were initially thought to have a single brain metastasis eventually turned out to have a different diagnosis after the lesion was subjected to biopsy. One-half of the nonmetastatic lesions were primary brain tumors, while the other one-half were infections. The false-positive rate for diagnosis of multiple metastases is undoubtedly significantly less than the 11% for single metastases. Nonetheless, in any patient where the diagnosis of brain metastases is in doubt, a biopsy should be performed, since this is the only reliable method of establishing the diagnosis.

Breast cancer patients with a single dura-based lesion pose a particular diagnostic dilemma. The incidence of meningiomas is increased in patients with breast cancer so that it is important to differentiate a dura-based metastasis from a meningioma.<sup>24,25</sup> Frequently, imaging studies will be inconclusive, and these patients will require a biopsy or surgical resection of the lesion to establish the diagnosis.

In addition to diagnosing the brain metastases, it is also important to differentiate those patients with single or solitary metastases from patients with multiple brain metastases, since their subsequent treatment will be different. The term *single brain metastasis* refers to an single cerebral lesion, and no implication is made regarding the extent of extracranial disease. In contrast, the term *solitary brain metastasis* describes the relatively rare occurrence of a single brain metastasis that is the only known site of metastatic cancer in the body.<sup>2,14</sup>

## IMAGING STUDIES

Although computed tomographic (CT) scans detect the majority of brain metastases, the best diagnostic test for brain metastases is contrast-enhanced MRI.<sup>15,26,27</sup> This test is more sensitive than enhanced CT scanning or nonenhanced MRI in detecting lesions in patients suspected of having cerebral metastases and in differentiating these metastases from other central nervous system (CNS) lesions.<sup>26,27</sup> Radiographic features that help to differentiate brain metastases from other CNS lesions include the presence of multiple lesions (which helps to distinguish metastases from gliomas or other primary tumors), localization of the lesion at the gray-white junction, more circumscribed margins, and relatively large amounts of vasogenic edema compared to the size of the lesion.<sup>3</sup> Triple-dose contrast administration may help to clarify the presence of metastases in selected patients with equivocal lesions or to detect additional lesions in patients with a single lesion on conventional single-dose contrast MRI.<sup>28,29</sup> Magnetization-transfer MRI, a technique that increases the contrast between enhancing and nonenhancing lesions by suppressing background signal,<sup>27,30,31</sup> may also increase the sensitivity of MRI. However, the usefulness of these approaches is limited by their availability and cost. In general, they may have a limited role in selected patients with a single or a small number of metastases on standard MRI and who are being considered for aggressive local therapy. In these patients, the detection of additional lesions may change the usefulness of surgery or radiosurgery. Functional imaging techniques, such as single-photon emission computed tomography, positron emission tomography, magnetic resonance spectroscopy, and perfusion and diffusion MRI, do not have a role in the diagnosis of brain metastases but may help in differentiating tumor from radiation necrosis.<sup>27</sup>

## BRAIN METASTASES WITHOUT A KNOWN PRIMARY TUMOR

In the majority of patients (80%), brain metastases develop after the diagnosis of systemic cancer (metachronous presentation).<sup>2</sup> However, in some patients, brain metastases may be diagnosed before the primary tumor is found (precocious presentation) or at the same time (synchronous presentation). For patients who present with brain metastases without a known primary tumor, the lung should be the focus of the evaluation. More than 60% of these patients will have a lung primary or pulmonary metastases from a primary tumor located elsewhere.<sup>2,32,33 and 34</sup> Other frequent causes include malignant melanoma and colon cancer, while the primary remains unknown in approximately 25% to 30% of cases.<sup>32,33 and 34</sup> Breast cancer is an uncommon cause of brain metastases without a known primary tumor, possibly due to its earlier detection on physical examination and its tendency to produce brain metastases in the setting of widely disseminated disease.<sup>33</sup> The history and physical examination will demonstrate the site of origin in one-third to one-fourth of patients. In others, the chest radiograph is the most useful test. If it is nondiagnostic, a chest CT scan should be performed, as this significantly increases the likelihood of detecting a lung tumor.<sup>32</sup> These patients should also have a CT scan of the abdomen and pelvis and a bone scan to determine the extent of metastatic disease.

## MANAGEMENT

The management of patients with brain metastases can be divided into symptomatic therapy and definitive therapy. Symptomatic therapy includes the use of corticosteroids for the treatment of peritumoral edema, anticonvulsants for control of seizures, and anticoagulants or inferior vena cava (IVC) filters for the management of venous thromboembolic disease.<sup>3,10</sup> Definitive therapy includes such treatments as surgery, radiotherapy, chemotherapy, and hormonal therapy directed at eradicating the tumor itself.

### SYMPTOMATIC THERAPY

#### **Corticosteroids**

Corticosteroids were first used for treating peritumoral edema by Kofman et al.<sup>35</sup> in 1957 in patients with breast cancer. Subsequently, Galicich et al.<sup>36</sup> introduced the use of dexamethasone in 1961, and this has remained the standard treatment for peritumoral edema ever since. Corticosteroids produce their antiedema effect by reducing the permeability of tumor capillaries<sup>37</sup> and are indicated in any patient with symptomatic edema. Most patients are usually started on dexamethasone, which has the advantage over other corticosteroids of having relatively little mineral corticoid activity, reducing the potential for fluid retention. In addition, dexamethasone may be associated with a lower risk of infection and cognitive impairment.<sup>37</sup> The usual starting dose is a 10-mg load, followed by 4 mg four times daily, although there is some evidence that lower doses (4 to 8 mg/d) may be as effective.<sup>38</sup> While most patients improve symptomatically within 24 to 72 hours, neuroimaging studies may not show a decrease in the amount of edema for up to 1 week.<sup>39</sup> In general, headaches tend to respond better than focal deficits. If 16 mg of dexamethasone is insufficient, the dose may be increased up to 100 mg/d. Steroids are usually tapered after irradiation, although the taper may begin earlier in patients with little peritumoral edema.

Despite their usefulness, corticosteroids are associated with a large number of well-known side effects, including myopathy, weight gain, fluid retention, hyperglycemia, insomnia, gastritis, acne, and immunosuppression.<sup>40</sup> The frequency of these complications can be reduced by using the lowest possible dose of corticosteroids. There is increasing evidence that brain tumor patients on corticosteroids are at increased risk of developing *Pneumocystis carinii* pneumonitis.<sup>41,42</sup> This complication can be prevented by treating patients, especially those older than the age of 50, who are on prolonged courses of corticosteroid with trimethoprim-sulfamethoxazole prophylaxis.<sup>3</sup>

#### **Anticonvulsants**

Seizures are the presenting symptom in approximately 10% to 20% of patients with brain metastases and are present at some stage of the illness in another 10% to 20% of patients.<sup>15,20,21 and 22</sup> Patients with brain metastases who present with seizures should be treated with standard anticonvulsants. To minimize toxicity, the lowest effective dose of medication should be used and polytherapy avoided whenever possible. Electroencephalography may be useful if the diagnosis of seizures is in doubt but is not routinely needed for patients who give a clear history of seizures or do not have symptoms suggestive of seizures.

In addition to the usual complications of anticonvulsants, brain tumor patients experience an increased incidence of particular side effects, especially drug rashes. Approximately 20% of brain tumor patients treated with phenytoin and carbamazepine develop a morbilliform rash, and a small percentage develop Stevens-Johnson syndrome,<sup>43,44 and 45</sup> while patients receiving phenobarbital have an increased incidence of shoulder-hand syndrome.<sup>46</sup>

In addition to producing adverse effects, anticonvulsants also have clinically significant interactions with other drugs commonly used in patients with brain metastases. Phenytoin induces the hepatic metabolism of dexamethasone and significantly reduces its half-life and bioavailability.<sup>47</sup> Conversely, dexamethasone may also reduce phenytoin levels.<sup>48</sup> A number of chemotherapeutic agents commonly used in cancer patients interact with phenytoin, causing the levels to fall and potentially leading to breakthrough seizures,<sup>49</sup> while hepatic enzyme-inducing anticonvulsants, such as phenobarbital and phenytoin, may interfere with chemotherapeutic agents, such as taxol.<sup>50</sup>

Because the risk of seizures in patients with infratentorial metastases is very small, anticonvulsant therapy is usually not indicated. The role of anticonvulsant therapy in patients with supratentorial brain metastases who have not had a seizure is controversial. Cohen et al.<sup>20</sup> retrospectively reviewed 160 patients with brain metastases and who have not had a seizure and found that those patients receiving prophylactic anticonvulsant therapy with phenytoin had the same frequency of late seizures (10%) as patients receiving no treatment.<sup>20</sup> However, two-thirds of patients who developed seizure while on phenytoin had a subtherapeutic serum phenytoin concentration. Glantz et al.<sup>21</sup> conducted a prospective, placebo-controlled, randomized study involving 74 patients and evaluated the efficacy of valproic acid in protecting patients with newly diagnosed brain metastases from seizures. There was no significant difference in the incidence of seizures between patients receiving valproic acid (35%) or placebo (24%), suggesting that prophylactic anticonvulsants were not effective in these patients. Weaver et al.<sup>51</sup> conducted a prospective randomized study of prophylactic anticonvulsants in 100 brain tumor patients, including 60 with metastases who have not had seizures.<sup>22</sup> Overall, 26% of patients had seizures. There was no difference in the seizure rate between patients taking anticonvulsants and those who were on no medications. Recently, Glantz et al.<sup>51</sup> reviewed the evidence concerning the efficacy of prophylactic anticonvulsants. Because the number of patients in these studies was small, they also performed a metaanalysis of the randomized clinical trials addressing this issue. They concluded that there was no statistical evidence showing a significant benefit of prophylactic anticonvulsant.

Because of the increased incidence of allergic reactions in patients with brain metastases receiving anticonvulsant therapy and of the lack of clear evidence that anticonvulsant therapy reduces the incidence of seizures, routine anticonvulsant therapy is probably unnecessary in patients with brain metastases who have not experienced a seizure. Possible exceptions to this are patients with brain metastases in areas of high epileptogenicity (e.g., motor cortex), patients with multiple melanoma metastases,<sup>52</sup> and patients with both brain metastases and leptomeningeal metastases.<sup>10</sup> These patients have a higher incidence of seizures and may benefit from prophylactic anticonvulsant therapy.

### **Venous Thromboembolic Disease**

Venous thromboembolic disease is common in patients with brain metastases, occurring in approximately 20% of patients.<sup>53</sup> The optimal therapy is unknown. These patients are often perceived to be at increased risk of intracranial hemorrhage with anticoagulation because of the vascularity of the tumors and anecdotal case reports of hemorrhage. As a result, the majority of brain metastases patients with venous thromboembolic disease are managed with IVC filters rather than anticoagulation. However, this may not be the optimum approach, since there is a high rate of complications with filtration devices in these patients. In a retrospective study of 42 patients with intracranial malignancy and venous thromboembolic disease treated with IVC filters, the complication rate was 62%. Fifty-seven percent developed IVC or filter thrombosis, recurrent deep venous thrombosis, or postphlebotic syndrome, and 12% developed recurrent pulmonary embolism.<sup>54</sup> In addition to the high complication rate with IVC filters, there is increasing evidence that the risk of intracranial hemorrhage in patients with primary brain tumors who are anticoagulated outside the immediate postoperative period may not be significantly increased.<sup>55</sup> More recently, Schiff and DeAngelis<sup>56</sup> reviewed the experience at the Memorial Sloan-Kettering Cancer Center with anticoagulation in patients with brain metastases who developed venous thromboembolic disease.<sup>56</sup> Of the 42 patients who received anticoagulation at some stage of their treatment, only 3 (7%) experienced cerebral hemorrhage, 2 in the setting of supratherapeutic anticoagulation. These studies suggest that anticoagulation may be more effective than IVC filter placement and is acceptably safe when the prothrombin time is maintained in the therapeutic range, especially in patients with brain metastases that generally do not hemorrhage, such as breast cancer.

### **DEFINITIVE TREATMENT**

The management of brain metastases is directed at relieving neurologic symptoms and achieving long-term control of the tumors. The therapeutic modalities available include surgery, radiotherapy, chemotherapy, and hormonal therapy. The optimal combination of therapies for each patient depends on careful evaluation of numerous factors, including the location, size, and number of brain metastases; patient age, general condition, and neurologic status; extent of systemic cancer; as well as the tumor's response to past therapy and its potential response to future treatments.<sup>3</sup>

### **Surgery**

The role of surgery in patients with brain metastases is to provide immediate relief of symptoms resulting from the mass effect of the tumor, to establish a histologic diagnosis, and to improve local control of the tumor. Recent advances in neuroanesthesia and neurosurgery, including the use of computer-assisted stereotaxy, intraoperative functional mapping, intraoperative ultrasonography, and functional and intraoperative MRI, have significantly improved the safety of surgical resection of brain metastases.<sup>3,57,58</sup>

For surgical candidates, the most important factor to consider is the extent of the extracranial disease. Patients with extensive systemic disease generally have a very limited prognosis and only rarely benefit from surgery. Other important factors influencing the decision concerning surgery include the presence of single or multiple metastases, the location of the tumor, the neurologic status of the patient, and the interval between diagnosis of the primary neoplasm and the brain metastasis.<sup>3,59,60 and 61</sup>

**SINGLE BRAIN METASTASES.** Until relatively recently, the optimal treatment for patients with a single brain metastasis was controversial. A number of uncontrolled retrospective studies suggested that patients with a single brain metastasis who underwent surgical resection in addition to radiotherapy generally had better outcomes than patients treated with radiotherapy alone. However, these studies were limited by the inevitable selection bias resulting from the inclusion of patients in better condition in surgical series.<sup>10,59,60,61,62,63,64 and 65</sup> There are now three randomized prospective studies that have evaluated the role of surgery as an adjunct to whole brain radiotherapy (WBRT) for patients with a single brain metastasis.<sup>23,66,67 and 68</sup>

Patchell et al.<sup>23</sup> were the first to address this issue in a prospective randomized study. Fifty-four patients with or without active systemic cancer and a single brain metastasis were randomly assigned to receive either biopsy of the metastases followed by WBRT (36 Gy in 12 fractions) or surgical resection followed by radiotherapy. Six of the 54 patients (11%) did not have a metastasis and were excluded from the study, leaving 48 patients. The patients treated with surgery and WBRT had fewer local recurrences (20% vs. 52%), improved survival (40 weeks vs. 15 weeks), and a better quality of life as measured by the Karnofsky performance status than did patients receiving WBRT alone. The median time to recurrence for patients receiving surgery and radiotherapy was more than 59 weeks, compared to 21 weeks for patients receiving WBRT alone. A multivariate analysis showed that the factors that correlated significantly with increased survival were surgical treatment of the metastasis, the absence of extracranial disease, longer time to the development of the brain metastasis, and younger age.

A second prospective randomized trial evaluating the role of surgery for patients with single brain metastasis was conducted by Vecht et al.<sup>66,67</sup> In this study, 63 patients with a single brain metastasis documented by CT scanning were randomly chosen to receive either surgery and WBRT or WBRT alone. The radiotherapy dose was an unconventional scheme of two fractions a day of 2 Gy each, for a total of 40 Gy given over 2 weeks. Unlike Patchell's study, patients randomly selected to receive radiotherapy alone did not undergo a stereotactic biopsy to confirm the diagnosis of metastases, and MRI was not performed to exclude multiple small metastases that may have been missed by CT imaging. The overall survival of patients treated with surgery and radiotherapy was significantly longer than that of patients treated with radiotherapy alone (10 months vs. 6 months;  $P = .04$ ). In addition, combined treatment also resulted in significantly increased functionally independent survival (FIS) (7.5 months vs. 3.5 months;  $P = .06$ ). The greatest benefit was seen in patients with stable extracranial disease (median survival, 12 vs. 7 months; median FIS, 9 vs. 4 months). Patients with active extracranial disease had a median survival of only 5 months and a FIS of 2.5 months and did not appear to benefit from the addition of surgery. This is consistent with the concept that the extent of systemic disease largely determines the survival of the patient and overcomes any potential advantage the addition of surgery may have provided in controlling the brain metastasis.<sup>9</sup> Patients older than 60 years had decreased survival rates as compared to younger patients (hazard ratio of dying, 2.74;  $P = .001$ ), consistent with the general importance of age as an adverse prognostic factor for brain tumors.

In contrast to these two studies, a more recent multicenter randomized study conducted by Mintz et al.<sup>68</sup> failed to detect a difference in survival or quality of life between patients who underwent surgery plus radiotherapy and those having radiotherapy alone. In this study, the 43 patients randomly assigned to radiotherapy

alone had a median survival of 6.3 months, while the 41 patients randomly assigned to surgery and radiotherapy had a median survival of only 5.6 months. The failure of this study to demonstrate that the addition of surgery to radiotherapy improved the outcome of patients may be due to the fact that it included patients with a lower baseline median Karnofsky performance score (KPS) and a higher proportion of extracranial disease.<sup>68,69</sup>

A fourth study, conducted by the Radiation Therapy Oncology Group (RTOG) and the Southwest Oncology Group, was initially intended to be a randomized study comparing surgery and radiotherapy to radiotherapy alone. However, because of poor patient accrual, its design was changed to a prospective physician preference trial. Ultimately, 80 of the 97 registered patients were evaluable. Patients treated with surgery and radiotherapy showed greater neurologic improvement (79% vs. 59%), decreased recurrence (22% vs. 45%), and improved survival, when corrected for other prognostic factors, compared to patients receiving radiotherapy alone.<sup>70</sup> Overall, these studies provide support for the use of surgery in addition to WBRT for patients with a single brain metastasis and stable extracranial disease.

**MULTIPLE BRAIN METASTASES.** The role of surgery in patients with multiple brain metastases is usually limited to resection of a large, symptomatic, or life-threatening lesion, to obtain tissue for diagnosis in patients without a known primary tumor, or to differentiate a brain metastasis from other cerebral lesions, such as a meningioma.<sup>3</sup> However, as surgical techniques have improved, the ability to resect multiple lesions is becoming more feasible. In one study, Bindal et al.<sup>71</sup> evaluated the efficacy of surgery in 56 patients with multiple brain metastases. These patients were divided into those who had one or more lesions remaining after surgery (group A; n = 30) and those who had all lesions removed (group B; n = 26). In addition, the patients in group B were matched by tumor type, presence or absence of extracranial disease, and time from diagnosis of primary tumor to diagnosis of brain metastases to a group of patients undergoing surgery for a single metastasis (group C; n = 26). The median survivals for patients in groups A, B, and C were 6, 14, and 14 months, respectively. These results suggest that if all the lesions can be removed surgically in patients with multiple brain metastases, the outcome is significantly improved, and comparable to the outcome of patients who underwent surgery for a single lesion. In a second study, Hernandez-Avila et al.<sup>72</sup> evaluated the outcome of 34 patients with multiple metastases treated with surgery. The median survival of patients with controlled systemic disease was 17 months, compared to only 3.1 months for those with active systemic disease, suggesting that surgery for patients with multiple metastases may be feasible in patients with limited systemic disease. However, in contrast to these studies, Hazuka et al.<sup>73</sup> found that surgery was of little benefit in patients with multiple brain metastases. They reported a series consisting of 28 patients with a single metastasis and 18 patients with multiple metastases. The patients with multiple metastases who underwent surgery and radiotherapy had a median survival of only 5 months, compared to 12 months for those with single brain metastases. In these studies, the surgical morbidity and mortality for patients with multiple brain metastases were low and comparable to those reported for patients with a single metastasis undergoing surgery. However, these conflicting results render it difficult to draw firm conclusions regarding the value of surgical resection in patients with multiple brain metastases.

**RECURRENT METASTATIC BRAIN TUMORS.** Surgery may have a role in patients who develop recurrent disease after standard treatment for brain metastases, especially if there is a single, symptomatic lesion. In an early study, Sundaresan et al.<sup>74</sup> reported the results of reoperation in 21 patients with brain metastasis. Two-thirds of the patients experienced neurologic improvement, and the median duration of the improvement was 6 months. There was no mortality, and only one patient developed increased neurologic deficits after surgery.

Bindal et al.<sup>75</sup> reviewed the experience from M. D. Anderson Cancer Center of 48 patients who underwent reoperation for recurrent brain metastasis.<sup>75</sup> The median interval between the first craniotomy and the diagnosis of recurrence was 6.7 months and the median survival after reoperation was 11.5 months. After surgery, 75% of patients improved symptomatically. Multivariate analysis revealed that survival was negatively affected by the presence of systemic disease ( $P = .008$ ); KPS exceeded 70 ( $P = .008$ ); time to recurrence was less than 4 months ( $P = .008$ ); age exceeded 40 years ( $P = .051$ ); and the primary tumor type was breast or melanoma ( $P = .028$ ). There was no operative mortality. Five patients (10.4%) developed new or increased neurologic deficits after surgery.

Arbit et al.<sup>76</sup> reported the results from Memorial Sloan-Kettering Cancer Center of 109 patients with recurrent brain metastases from non-small cell lung cancer (NSCLC). Thirty-two of these patients (30%) underwent a reoperation. The median interval between the first and second operation was 5 months. The median survival after the second operation was 10 months. The group of patients who underwent reoperation survived significantly longer (median survival, 15 months from the time of the first operation) than a group of 77 patients who did not undergo a second procedure (median survival, 10 months;  $P < .001$ ).

These results provide support for surgical resection of recurrent brain metastases in selected patients with symptomatic lesions. Factors that should be considered include the length of time since the initial operation, location of the recurrent tumor, age and performance status of the patient, extent of extracranial disease, and radiosensitivity of the tumor.<sup>9,77</sup> In general, the sooner the metastasis recurs after initial resection, the less likely reoperation will provide a significant period of palliation.<sup>3,77</sup>

### Radiotherapy

**PRIMARY RADIOTHERAPY.** Radiotherapy has been the mainstay of treatment for patients with brain metastases for more than 40 years. The median survival of patients with brain metastases who are not treated or are treated with corticosteroids alone is 1 to 2 months. Conventional WBRT increases the median survival to 3 to 6 months.<sup>2,3,12</sup> Irradiation is effective in the palliation of neurologic symptoms and also significantly decreases the likelihood of death due to neurologic causes ( Fig. 52.1-1). However, for most patients, overall survival is more likely to be determined by the activity and extent of extracranial disease rather than the success or failure of radiotherapy or surgery in controlling brain metastases.

**FIGURE 52.1-1.** Axial T1-weighted magnetic resonance imaging with gadolinium of 66-year-old man with a single metastasis from colon cancer. **A:** Before whole brain radiotherapy. **B:** After whole brain radiotherapy showing almost complete resolution of the metastasis.

The main goal of radiotherapy for the treatment of brain metastases is to improve neurologic deficits caused by the tumor deposit. The overall response rate is symptom-dependent but ranges from 50% to 85%.<sup>19,78,79</sup> In one study, 74% of patients had improvement of neurologic symptoms, such as headaches, and 65% maintained this for the duration of their lives or for at least 9 months.<sup>80</sup> Cranial nerve deficits improve in approximately 40% of patients. However, the potential for improvement is directly related to the time from diagnosis to radiotherapy.<sup>2,3</sup> Early treatment is generally associated with a better outcome. The majority of patients with significant neurologic dysfunction improve with the use of steroids and radiotherapy, while fewer than 50% of patients with moderate neurologic dysfunction will improve after therapy.<sup>78</sup>

The optimal dose fractionation schedules for patients with brain metastases have been evaluated with randomized trials conducted by the RTOG.<sup>78,81,82</sup> The RTOG completed two trials of several dose-fraction schedules that were subsequently reported together.<sup>78</sup> In the first trial, patients were randomly assigned to 40 Gy in 4 weeks, 40 Gy in 3 weeks, 30 Gy in 3 weeks, or 30 Gy in 2 weeks. The second trial randomly assigned patients to 40 Gy in 3 weeks, 30 Gy in 2 weeks, or 20 Gy in 1 week. The overall response rate and median survival were equivalent in all arms of these studies. The median survival was 18 weeks in the first trial and 15 weeks in the second trial. Brain metastases was the cause of death in 40% of patients in both trials. Patients treated in the shortest time, with larger fractions, responded more quickly, but the duration of the clinical response and the time to progression were similar in each treatment arm. Symptoms were palliated in 75% to 80% of the patients in all treatment arms of these protocols.<sup>82</sup>

To explore the efficacy and toxicity of ultrarapid treatment schedules, the RTOG treated 26 patients with 10 Gy in one fraction and 36 patients with 12 Gy in two

fractions.<sup>83</sup> While the promptness of response, percentage of patients demonstrating neurologic improvement, and overall survival were similar to the more protracted schedules described, the median duration of improvement was only 4 weeks compared to 10 weeks in the protracted radiotherapy trials.

While the studies of the RTOG failed to identify the best dose and fractionation schedule for the treatment of brain metastasis, they allowed the identification of clinical factors associated with better survival.<sup>84,85</sup> Patients with breast cancer and no soft tissue metastases, ambulatory lung cancer patients with no extracranial disease, or other ambulatory patients with no extracranial metastases had a median survival of 28 weeks versus 11 weeks for the remaining patients. There was no survival advantage to any fractionation scheme, even among this selected group of patients.

To examine the role of irradiation dose escalation in this prognostically favorable subset of patients with brain metastases, the RTOG randomly assigned 309 of these patients to either 30 Gy in 10 fractions or 50 Gy in 20 fractions.<sup>86</sup> The median survival of the 30-Gy arm was 18 weeks, and that of the 50-Gy arm was 17 weeks. The 1-year survival rate, response rate, time to achieving response, duration of response, and time to progression were the same for both arms, suggesting that there was no therapeutic benefit to dose escalation.

Another approach that has been explored to improve the results of WBRT for patients with brain metastases is the use of accelerated fractionation. Accelerated fractionation is a technique that uses multiple fractions of radiotherapy per day with the goal to decrease overall treatment time and reduce the risk of tumor cell repopulation. The RTOG performed a phase I and phase II trial of accelerated fractionation for patients with single or multiple brain metastases with controlled, stable, or absent primary disease or in patients with uncontrolled primary disease but no evidence of extracranial metastases.<sup>87</sup> The entire brain was treated twice daily with 1.6-Gy fractions to a total dose of 32 Gy and then a twice-daily boost to encompass all of the disease. The boost dose was increased in successive groups from 16 Gy to 22.4 Gy to 32 Gy to 42.4 Gy. The median survival increased from 4.2 months at a 48-Gy total dose to 5.3 months at a 54.4-Gy total dose to 4.8 months at 60 Gy to 6.4 months at 70.4 Gy. The 1-year survival for 48 Gy was 15%, and the other arms had a 30% 1-year survival. Based on these encouraging results, the RTOG conducted a randomized phase III study comparing accelerated hyperfractionated radiotherapy (1.6 Gy b.i.d.) to a total dose of 54.4 Gy versus standard therapy consisting of 30 Gy in 10 daily fractions in patients with unresected brain metastases, limited systemic disease, and good KPS ( $\geq 70$ ). There were 429 evaluable patients, two-thirds of whom had lung primaries. However, the median survival in both groups was 4.5 months, suggesting that there was no benefit of accelerated hyperfractionation over conventional therapy.<sup>88</sup>

The use of biochemical modification (irradiation sensitizers) of irradiation effect has also been explored in patients with brain metastases. However, the results to date have been generally disappointing. Studies using radiosensitizers, such as misonidazole<sup>89</sup> and bromodeoxyuridine,<sup>90</sup> failed to show any additional benefit over radiotherapy alone. Nonetheless, there continues to be interest in irradiation sensitizers and agents, such as gadolinium texaphyrin,<sup>91,92</sup> RSR 13,<sup>93</sup> and pentoxifylline,<sup>94</sup> are currently being evaluated in clinical trials. There is also interest in the concurrent use of radiotherapy with chemotherapeutic agents, such as the topoisomerase II inhibitor lucanthon.<sup>95</sup>

There is currently no consensus on the optimal irradiation schedule for patients with brain metastases. The standard treatment regimen for brain metastasis now includes all of the dose ranges evaluated in the early RTOG studies<sup>78</sup> and is dependent on such issues as the severity of CNS symptomatology, extent of systemic disease, and physician preference. Typical irradiation treatment schedules consist of total doses of 30 to 50 Gy in 1.5- to 4-Gy daily fractions. The most common treatment schedule employed consists of 30 Gy in 10 fractions over 2 weeks.<sup>96</sup> For patients with good prognosis who are likely to survive more than 1 year, more prolonged fractionation (e.g., 40 Gy in 2-Gy fractions) may reduce the long-term morbidity from irradiation.

**POSTOPERATIVE RADIOTHERAPY.** The goal of postoperative WBRT in patients with solitary brain metastasis is to destroy microscopic residual cancer cells at the site of resection and at other locations within the brain. Theoretically, this should reduce the recurrence rate and prolong survival. Although it is standard practice for patients to receive postoperative radiotherapy as adjuvant therapy to surgery, until recently the value of this approach was based only on retrospective studies ( [Table 52.1-2](#) ).<sup>97,98,99,100,101</sup> and <sup>102</sup> Some of these studies demonstrated that adjuvant WBRT reduced the recurrence rate,<sup>98,99,102</sup> and two studies demonstrated prolonged survival.<sup>98,102</sup> Recently, Patchell et al.<sup>103</sup> published the results of a randomized trial that examined the role of postoperative WBRT in patients with single metastasis. <sup>103</sup> In this study, 95 patients underwent surgical resection of the metastasis and were then randomly assigned to treatment with WBRT (50.4 Gy in 28 fractions) or no further treatment. Patients who received irradiation were significantly less likely to fail in the brain (18% vs. 70%;  $P < .001$ ), and this was true both at the original site of disease (10% vs. 46%;  $P < .001$ ) and other areas of the brain (14% vs. 37%;  $P < .01$ ). Treated patients were also less likely to die of neurologic causes (14% vs. 44%;  $P = .003$ ), but there was no difference in overall survival (48 vs. 43 weeks;  $P = .39$ ) or duration of functional independence (37 vs. 35 weeks;  $P = .61$ ) between the treated and untreated groups. The results of this study suggest that postoperative WBRT in patients with a resected solitary metastasis significantly reduces the incidence of neurologic death but has little impact on the overall survival of the patient, who is mainly dependent on the extent of systemic disease. The authors of this study concluded that the reduction of neurologic death justifies the routine use of postoperative radiotherapy. However, the relatively small size of this study precluded any subgroup analysis. As a result, it remains unclear whether all patients who undergo surgical resection should also receive adjuvant radiotherapy. There may be certain groups of patients, such as those with radio-resistant tumors, such as melanoma or renal cell cancer, for whom WBRT may not be useful after complete surgical resection of the metastases. In addition, the long-term neurocognitive complications of WBRT and its effects on quality of life have not been fully evaluated.

**TABLE 52.1-2.** Studies Evaluating the Role of Postoperative Radiotherapy

**LATE TOXICITY.** An important benefit of aggressive treatment for brain metastases is the likelihood that some patients will become long-term survivors. In these patients, late complications of WBRT can be debilitating. These complications include leukoencephalopathy and brain atrophy leading to neurocognitive deterioration and dementia; brain necrosis resulting in more specific neurologic sequelae, depending on the site of necrosis; and communicating hydrocephalus, causing cognitive, gait, and bladder dysfunction.<sup>10,40,104</sup> Neuroendocrine dysfunction, such as hypothyroidism, may also occur.<sup>40,105</sup> The risk for late complications from WBRT is related to total dose, fraction size, patient age, extent of disease, and neurologic impairment at presentation.<sup>106</sup> Prior or concurrent chemotherapy may also effect the occurrence of late CNS toxicity. If WBRT is to be given, a dose-fraction schedule should be used, which takes into account the overall clinical status of the patient while maximizing the palliation of symptoms and, if appropriate, minimizing the risk of long-term complications. In a retrospective review by DeAngelis et al.<sup>104</sup> of 70 patients treated with postoperative radiotherapy using no less than 300-cGy fractions, 11% showed evidence of dementia.<sup>104</sup> Therefore, patients with good prognosis, such as those with single brain metastasis with no or controlled systemic disease, are best treated with daily fractions of 200 cGy or less to decrease the likelihood of long-term CNS toxicity (e.g., 40 to 45 Gy in 1.8- to 2.0-Gy daily fractions).

**REIRRADIATION.** Occasionally, patients are reirradiated with whole brain or partial brain radiotherapy at the time of brain recurrence. The percentage of patients who undergo reirradiation is quite small, since most patients who recur within the CNS also have progressive extracranial disease and are treated with supportive measures only. However, there are times when recurrence of brain metastasis develops in a patient with controlled systemic disease. Patients with a solitary or a few ( $\leq 3$ ) metastases are candidates for treatment with radiosurgery, as this will have less toxicity than repeating WBRT (discussed later in [Stereotactic Radiosurgery](#)) and is more likely to be effective than systemic therapy. Other patients should be considered for treatment with systemic chemotherapy or hormonal therapy. For patients not eligible for radiosurgery or systemic therapy, treatment with whole or partial brain radiation may be indicated. Several retrospective studies have addressed this issue.<sup>107,108,109</sup> and <sup>110</sup> A recent review evaluated 189 patients from three separate studies who were reirradiated.<sup>109</sup> The overall clinical response rate was 42% to 75%, and the median survival from the time of reirradiation was between 3.5 and 5 months. The published techniques of reirradiation include doses from 8 Gy in 2 weeks to

30.6 Gy in 3 weeks, with the median of approximately 20 Gy in 2 weeks, but there is no consensus on which dose fractionation schedule is appropriate or how long after the initial course of radiotherapy it is appropriate to reirradiate.<sup>110</sup> Some investigators have argued that reirradiation should be considered for patients who remain in good general condition but experience neurologic deterioration 4 or more months after a satisfactory response to the initial course of WBRT.<sup>110</sup> The tolerance of the brain is more than likely to be exceeded by reirradiation but, with the limited survival of these patients, there are inadequate data to evaluate the consequences of this treatment.

### Stereotactic Radiosurgery

Stereotactic radiosurgery is a technique of external irradiation that uses multiple convergent beams to deliver a high single dose of radiation to a radiographically discrete treatment volume.<sup>111</sup> Radiosurgery can be performed with high-energy roentgenograms produced by linear accelerators, with gamma rays from the gamma knife and, less frequently, with charged particles, such as protons produced by cyclotrons.<sup>112</sup> All the stereotactic irradiation techniques result in rapid fall-off of dose at the edge of the target volume, resulting in a clinically insignificant radiation dose to normal nontarget tissue. Metastases are usually small (<3 cm) radiographically discrete lesions that are noninvasive, rendering them ideal targets for radiosurgery.<sup>113</sup>

An increasing number of uncontrolled studies confirm the effectiveness of stereotactic radiosurgery in treating brain metastases (Table 52.1-3). To date, more than 1780 patients with more than 2700 lesions have been reported in the literature.<sup>111,113</sup> Radiosurgery produces local control rates of 73% to 94% and is associated with a 5% to 10% risk of irradiation necrosis. The median survival from these series ranges from 6 to 15 months, with an average of 9.4 months.<sup>3,111,112,113,114,115,116,117,118,119,120,121,122,123,124,125,126,127,128,129,130</sup> and <sup>131</sup> In a multiinstitutional trial involving 116 patients treated with radiosurgery for single brain metastasis using a mean dose of 17.5 Gy, local tumor control was obtained in 99 patients (85%).<sup>116</sup> The 2-year actuarial tumor control rates for the entire group was 67% ± 8%, with a plateau in the curve at 18 months. In a multivariate analysis, better local control was obtained in patients who received WBRT in addition to radiosurgery and in those patients with "radioresistant" histologies (melanoma and renal cell carcinoma). In the largest series to date, Alexander et al.<sup>114</sup> reported the results of radiosurgery using a linear accelerator for the treatment of 248 patients with 421 metastatic lesions. At the time of radiosurgery, 77 patients had no evidence of systemic disease, while 171 patients had stable systemic disease. Of the lesions treated, 126 were classified as radioresistant (melanoma, renal cell carcinoma, and sarcoma), with the remaining 295 lesions representing all other histologies. With a median observation period of 26 months, 48 of 421 lesions (11%) progressed within the radiosurgery volume. The actuarial 1-, 2-, and 3-year local control rates were 85%, 65%, and 65%, respectively. Radioresistant histologies had statistically equal control rates as other lesions. The median survival for the entire group was 9.4 months, measured from the radiosurgery treatment. In a multivariate analysis, the absence of systemic disease (relative risk, 4.4; *P* = .0001) and age younger than 60 years (relative risk, 1.6; *P* = .002) were factors associated with improved survival. The development of symptomatic irradiation necrosis requiring reoperation for increasing mass effect and steroid dependency occurred in 7% of patients in this series.

TABLE 52.1-3. Radiosurgery for Brain Metastases: Results of Representative Series

The optimal role for radiosurgery in patients with brain metastases and its effectiveness in prolonging patient survival remains unclear. However, a recent study by Kondziolka et al.<sup>132</sup> comparing WBRT to WBRT with radiosurgery for patients with multiple metastases (two to four) was stopped at interim analysis because of the significantly better tumor control seen in the group receiving both treatments. In this study, 27 patients with two to four brain metastases (all ≤25 mm in diameter) and a known primary tumor were randomly assigned to WBRT alone or with radiosurgery. Combination therapy was associated with a much lower rate of local failure at 1 year (8% vs. 100%) and a longer median time to local failure (36 vs. 6 months). However, there was no significant improvement in median survival (11 vs. 7.5 months; *P* = .22), which was related to the extent of extracranial disease. An RTOG trial (95-08) is currently under way in which patients with one to three untreated brain metastases will be randomly assigned to WBRT or WBRT and radiosurgery. The study will provide further data on the usefulness of adding radiosurgery to WBRT.

The studies by Patchell et al.,<sup>23</sup> Vecht et al.,<sup>66</sup> and Noordijk et al.<sup>67</sup> indicate that there is a survival advantage for patients with a single brain metastasis treated with surgery and radiotherapy as compared to radiotherapy alone. Many clinical investigators believe that radiosurgery can act as an alternative to surgical resection.<sup>111,113,115,117,121,131</sup> Moreover, radiosurgery has several potential advantages over surgery. It can be used to treat metastases in surgically inaccessible areas of the brain, such as the brain stem. Since it is a noninvasive procedure that can be performed on an outpatient basis, it is associated with less morbidity than surgery. In addition, there is increasing evidence that radiosurgery may also be more cost-effective than surgery.<sup>131,133</sup> In the study by Mehta et al.,<sup>133</sup> the average cost per week of survival was \$310 for radiotherapy, \$524 for resection plus irradiation, and \$270 for radiosurgery plus irradiation.<sup>133</sup>

While there are no completed randomized trials comparing radiosurgery to surgery, Auchter et al.<sup>117</sup> identified 122 patients who met the selection criteria used by Patchell et al.<sup>23</sup> and were treated with WBRT (median, 37.5 Gy) followed by a radiosurgery boost (median, 17 Gy). The overall local control rate was 86%, with an actuarial median survival of 56 weeks and a neurologic median survival of KPS greater than 70 of 44 weeks. These results are comparable to the surgery and irradiation therapy arms of the studies by Patchell et al.,<sup>23</sup> Vecht et al.,<sup>66</sup> and Noordijk et al.<sup>67</sup> and better than the arms of the whole brain treatment alone. In a second retrospective study, Muacevic et al.<sup>134</sup> compared 52 patients with single brain metastasis treated with surgery and WBRT with 56 patients treated with radiosurgery alone. The 1-year local tumor control rates after surgery and radiosurgery were 75% and 83%, respectively, and the 1-year neurologic death rates were 37% and 39%, respectively, suggesting that the local tumor control rates are similar in the two groups. The 1-year survival rate and median survival were 53% and 68 weeks, respectively, in the surgical group and 43% and 35 weeks, respectively, in the radiosurgical group. The shorter overall survival time in the radiosurgery group was related to higher rate of death from systemic disease. Brandt et al.<sup>135</sup> also compared surgery and radiosurgery in a series of 56 patients. In this study, the median survival of the radiosurgically treated patients was 11.4 months, comparable to the 10.4 months for the surgically treated patients. In a fourth study, by Shu et al.,<sup>136</sup> patients with single brain metastases treated with radiosurgery had a median survival of 16 months. In contrast, Bindal et al.<sup>137</sup> conducted a retrospective study comparing 34 consecutive patients treated with radiosurgery with 62 clinically matched patients treated surgically. The median survival for patients treated surgically was 16.4 months, compared to 7.5 months for those treated with radiosurgery (*P* = .0009). Based on these results, the authors concluded that surgery was superior to radiosurgery for the treatment of a single brain metastasis. However, the low local control rate in the radiosurgically treated patients in this study (61%) and differences in the extent of systemic disease between the surgery and radiosurgery groups may have accounted for the poor results of radiosurgery. Ideally, a prospective randomized study comparing surgery to radiosurgery in the treatment of single brain metastases would resolve the issue of the relative efficacy of these two treatments. However, previous attempts at such a study have been unsuccessful due to poor patient accrual as a result of patient or physician preference (or both) for either surgery or radiosurgery.

The role of WBRT in patients treated with radiosurgery is controversial, especially for patients with relatively radioresistant tumors, such as melanoma.<sup>121,131</sup> In the study by Patchell et al.,<sup>103</sup> 37% of patients failed in other sites within the brain if they did not receive whole brain irradiation. While some studies have shown improved local control in patients who received whole brain radiotherapy in addition to radiosurgery,<sup>116</sup> overall patient survival is generally not increased.<sup>114,123,131</sup> Currently, most centers treat patients with brain metastases with both radiosurgery and whole brain radiotherapy (Fig. 52.1-2) and limit the use of up-front radiosurgery alone to cases for which there are no alternatives, such as prior high-dose irradiation to the head and neck area or when the patient refuses whole brain radiation therapy. However, there are several retrospective studies suggesting that for selected patients, radiosurgery alone may be as effective as the combination of radiosurgery and WBRT, with potentially less morbidity.<sup>138,139,140</sup> and <sup>141</sup> In a study by Sneed et al.,<sup>138</sup> the outcome of 62 patients with up to four newly diagnosed brain metastases treated with radiosurgery alone were compared with 43 patients with newly diagnosed metastases treated with the combination of radiosurgery and WBRT. The median

survival and the 1-year local freedom from progression (FFP) were the same for radiosurgery alone and for radiosurgery and WBRT (median survival, 11.3 vs. 11.1 months; 1-year local FFP, 71% vs. 79%, respectively). More patients treated with radiosurgery failed in the brain (new metastases or local failure or both) than those receiving the combination of radiosurgery and WBRT (brain FFP at 1 year, 28% for radiosurgery compared to 69% for the combination of radiosurgery and WBRT). However, brain control, allowing for successful salvage of a first failure, was not significantly different between the two groups. This study suggests that omission of WBRT in the initial management of patients treated with radiosurgery for up to four brain metastases does not appear to compromise survival or intracranial control and allows for salvage therapy as indicated. A second small retrospective study of 35 patients with melanoma brain metastases found no difference in survival between the patients treated with radiosurgery and the combination of radiosurgery and WBRT.<sup>139</sup> A third study by Pirzkall et al.<sup>140</sup> comparing the outcome of 158 patients with one to three brain metastases treated by radiosurgery with 78 patients treated with radiosurgery and WBRT also found no statistical difference in survival and local control between the two groups, although there was a trend toward improved local control and increased survival in the group that received WBRT. Randomized studies comparing radiosurgery and the combination of radiosurgery and WBRT are currently under way to assess survival, quality of life, and cost-effectiveness in patients with newly diagnosed brain metastases.

**FIGURE 52.1-2.** A 48-year-old woman with non–small cell lung cancer presenting with lethargy and left-sided weakness. **A:** Axial T1-weighted magnetic resonance imaging shows a 3-cm enhancing metastasis in the right anterior parietal lobe and a smaller 1-cm metastasis in the left parietal lobe. The right parietal lesion was resected, and the left parietal lesion was treated with stereotactic radiosurgery (1800 cGy), followed by whole brain radiation therapy. **B:** Follow-up magnetic resonance imaging 6 months later showing no residual tumor at either site. Twenty months after her surgery, the patient remains well neurologically, with no evidence of recurrent metastases in her brain. However, she has developed recurrent disease in her lung.

**COMPLICATIONS OF RADIOSURGERY.** Acute complications within the first week of treatment are uncommon, occurring in fewer than 10% of patients.<sup>114,128,129,142</sup> These include seizures (2.3% to 6.1%), headaches, exacerbation of preexisting neurologic deficits (2% to 6%), nausea (especially in patients receiving more than 375 cGy to the area postrema) and, rarely, hemorrhage.<sup>125</sup> The risk of seizures can be reduced by treating patients with anticonvulsants before the radiosurgery procedure.<sup>114</sup> Patients with lesions near the posterior fossa may benefit from premedication with antiemetics. Acute neurologic deficits can be reduced by using doses of less than 30 Gy.<sup>113</sup>

Subacute complications occurring within 6 months of treatment consists of alopecia in patients whose scalp received more than 4.4 Gy of irradiation<sup>114</sup> and neurologic deterioration due to necrosis and peritumoral edema.<sup>113</sup>

Chronic complications due to irradiation necrosis occur in approximately 8% to 16% of patients. These patients present with increased seizures, headaches, or worsening neurologic deficits.<sup>113,114,120</sup> These side effects can usually be treated with corticosteroids. However, 5% to 10% of patients develop severe symptomatic necrosis and may require surgical resection.<sup>113,114</sup> Cranial nerve palsies are rare and develop in fewer than 1% of patients.<sup>142</sup>

**PROGNOSTIC FACTORS.** Young patients with good performance status, limited extracranial disease, and one or two small lesions are particularly suited to treatment by radiosurgery.<sup>113,114,131</sup> Poor prognostic factors include poor performance status (<70), progressive systemic disease, large tumor size, infratentorial location, and multiple metastases (more than two lesions).<sup>113,119,122</sup> The efficacy of radiosurgery appears to be independent of the histology of the lesion. Radioresistant tumors, such as renal cell carcinoma,<sup>143</sup> malignant melanoma,<sup>144,145</sup> and NSCLC<sup>146</sup> have statistically the same control rate as other tumors.<sup>111,113</sup>

**SUMMARY.** The introduction of radiosurgery over the last decade represents one of the major advances in the treatment of brain metastases. For patients with a single small asymptomatic or mildly symptomatic lesion, radiosurgery can probably be used as a substitute for surgery with comparable outcomes.<sup>113,117</sup> Radiosurgery also has an important role in patients with recurrence of brain metastasis after whole brain radiotherapy and, perhaps, in the initial treatment of patients with several metastases and limited systemic disease.

### **Interstitial Brachytherapy**

Interstitial brachytherapy involves the implantation of radioactive nuclides into the wall of the surgical cavity to deliver an additional dose of radiation to the residual tumor while limiting the irradiation to the surrounding brain. The relatively sharp border between metastases and the surrounding brain renders them ideal lesions for brachytherapy. Brachytherapy for metastases has been evaluated in several small uncontrolled studies using iodine 125 sources, and median survivals have ranged from 9 to 18.3 months.<sup>147,148</sup> and <sup>149</sup> Although brachytherapy is rarely performed for small lesions suitable for radiosurgery, it may have a limited role for metastases that are too large for radiosurgery.

A more recent brachytherapy strategy involves using a photon radiosurgery system. This is a battery-powered miniature x-ray generator with an attached probe that can be placed stereotactically into metastases at the time of craniotomy to deliver a single fraction of high-dose radiation (12.5 Gy) in less than an hour.<sup>149,150</sup> Preliminary results suggest that this procedure is well tolerated and produces effective local tumor control.<sup>149,150</sup>

### **Chemotherapy**

The role of chemotherapy for the treatment of patients with brain metastases has not been defined. At present, chemotherapy is rarely used as part of the overall management of brain metastases. Traditionally, it had been assumed that the blood–brain barrier prevented chemotherapeutic agents from entering the CNS. However, there is evidence that the blood–brain barrier is in fact partially disrupted within brain tumors.<sup>151</sup> This suggests that other factors may also contribute to the generally disappointing results of chemotherapy for brain metastases, such as the intrinsic resistance to chemotherapy of many tumors that metastasize to the brain; the use of chemotherapeutic agents designed to penetrate the blood–brain barrier rather than agents known to be most effective against the primary malignancy; and the tendency for brain metastases to develop after the failure of primary chemotherapeutic agents to control systemic disease.<sup>151,152</sup>

Although the overall results of chemotherapy for brain metastases have been generally disappointing, a number of uncontrolled studies have demonstrated favorable response rates in brain metastases from chemosensitive tumors, such as breast cancer, small cell lung cancer (SCLC), and germ cell tumors.<sup>2,3,151,152</sup>

Patients with metastatic breast cancer have been treated with chemotherapy since 1970. In the largest series to date, Rosner et al.<sup>153</sup> treated 100 consecutive breast cancer patients with brain metastases with several chemotherapy regimens, including cyclophosphamide, 5-fluorouracil, and prednisone, or with this regimen together with methotrexate and vincristine. These patients had not received prior chemotherapy for their systemic disease. Overall, 50% of patients had an objective response (10% had a complete response, and 40% had a partial response). In addition, 9% had stable disease. The median duration of remission for complete responders was 10 months and, for partial responders, it was 7 months. Rosner et al.<sup>154</sup> subsequently treated an additional 26 patients with progressive brain metastases from breast cancer with four different chemotherapeutic regimens: cyclophosphamide, 5-fluorouracil, and prednisone; cyclophosphamide, 5-fluorouracil, and prednisone together with methotrexate and vincristine; cyclophosphamide and doxorubicin (Adriamycin); and mitomycin and vinblastine (Velban).<sup>154</sup> Objective responses were seen in 61% of patients, while another 15% had stable disease. The median survival for responders was 12 months, compared to 2.4 months for nonresponders. Interestingly, prior

systemic chemotherapy did not affect the response of the brain metastases, arguing against the concept of the brain as a pharmacologic sanctuary.

Franciosi et al.<sup>155</sup> treated 56 patients with brain metastases from breast cancer with the combination of cisplatin and etoposide for a maximum of six cycles and observed complete responses in 13%, partial responses in 26%, and stable disease in 21% of patients. The median survival was approximately 8 months. Boogerd et al.<sup>156</sup> treated 20 patients with cyclophosphamide, methotrexate, and 5-fluorouracil, or cyclophosphamide, doxorubicin, and 5-fluorouracil. Seven patients had recurrent disease after WBRT. Objective tumor regression occurred in 76% of patients after two cycles of chemotherapy. The median duration of neurologic remission was 30 weeks, and the median survival was 25 weeks. When the results of these chemotherapy patients were compared to 29 historic controls treated with WBRT, the neurologic response rate, duration of response, and median survival were better in those patients treated with chemotherapy.

Several other small series have reported responses to a variety of regimens, including a combination of drugs combining thioguanine, procarbazine, dibromodulcitol, lomustine (CCNU), 5-fluorouracil, and hydroxyurea designed to improve the efficacy of CCNU.<sup>157</sup> Recently, there has also been a report of patients with brain metastases from breast cancer responding to high-dose chemotherapy.<sup>158</sup>

There have also been many studies evaluating the response of brain metastases from SCLC to chemotherapy.<sup>151,159</sup> Kristensen et al.<sup>159</sup> reviewed 12 patient series with a total of 116 patients published between 1981 and 1990. Eleven of these studies contained an epipodophyllotoxin and, in five, this was combined with either cisplatin or carboplatin. The overall response rate to chemotherapy without irradiation in patients with intracranial metastases at diagnosis was 76%, while the response rate at relapse was 43%. These results suggest that intracranial metastases from SCLC respond to chemotherapy as readily as other metastatic locations of SCLC.

Favorable responses have also been seen with chemotherapy for metastases from choriocarcinoma, germ cell tumors, and ovarian cancer.<sup>151,160,161</sup> and <sup>162</sup> The results of chemotherapy for brain metastases from less chemosensitive tumors, such as NSCLC and melanoma, have been generally disappointing. However, newer regimens, such as thioguanine, procarbazine, dibromodulcitol, CCNU, 5-fluorouracil, and hydroxyurea<sup>157</sup>; carboplatin and etoposide<sup>155</sup>; cisplatin and etoposide<sup>163</sup>; cisplatin and tenoposide<sup>164</sup>; and tenoposide alone<sup>165</sup> for NSCLC<sup>166</sup> and temozolamide for melanoma have produced slightly higher response rates. In a study by Franciosi et al.,<sup>155</sup> 43 patients with NSCLC were treated with cisplatin and etoposide. The combined complete and partial response rates were 30%, and median survival was 8 months.

Overall, these studies suggest that chemotherapy has some activity against brain metastases, especially from chemosensitive tumors, such as breast cancer, SCLC, and choriocarcinoma. In these patients, chemotherapy may have a role as palliative therapy in patients with recurrent disease after radiotherapy or possibly as initial treatment in patients with small asymptomatic tumors. As newer drugs are introduced, the effectiveness of chemotherapy for brain metastases may improve.

### Hormonal Therapy

In patients with hormone-responsive tumors, such as breast cancer, there are anecdotal reports of patients responding to hormonal agents, such as tamoxifen<sup>167</sup> and megestrol acetate.<sup>168</sup>

## PROGNOSIS

The median survival of patients with untreated brain metastases is approximately 1 month.<sup>169</sup> The addition of steroids increases survival to 2 months,<sup>14,79</sup> while whole brain radiotherapy further improves survival to 3 to 6 months.<sup>12,78,79,85,170,171</sup> Patients with single brain metastases and limited extracranial disease who are treated with surgery and WBRT have a median survival of approximately 10 to 16 months.<sup>23,64,66,67</sup> Favorable prognostic factors include the absence of systemic disease, young age (<60 years), good performance status (KPS  $\geq$ 70), long time to development of metastasis, surgical resection, less than three lesions, and possibly response to steroids.<sup>2,3,64,78,85,172,173,174</sup> and <sup>175</sup> Patients with brain metastases as the only manifestation of an undetected primary tumor also have a favorable prognosis, with an overall median survival of 13.4 months.<sup>176</sup> Breast cancer patients with brain metastases generally have a more favorable prognosis than brain metastases from other types of primary tumor.<sup>82,84,85</sup> On the other hand, patients with colorectal carcinoma tend to have a poorer prognosis.<sup>177</sup> This may be due to the tendency of these patients to have a higher frequency of cerebellar metastases, which are associated with an adverse prognosis.

Recently, Gaspar et al.<sup>173</sup> performed a recursive partitioning analysis of prognostic factors from three RTOG brain metastases trials and identified three prognostic classes. Class 1 patients had a KPS of 70 or higher, were younger than 65 years of age, had a controlled primary and no extracranial metastases, and had a median survival of 7.1 months. Class 3 patients had a KPS of less than 70 and a median survival of 2.3 months. Class 2 patients included all remaining patients and had a median survival of 4.2 months. Agboola et al.<sup>174</sup> evaluated the validity of this classification system in 125 patients with brain metastases treated with surgical resection and WBRT. The median survival in classes 1, 2, and 3 were 14.8 months, 9.9 months, and 6 months, respectively. Use of this classification may identify patients most likely to benefit from treatment and potentially allows new therapies to be evaluated on homogeneous patient groups.<sup>174,175</sup>

## INTRODUCTION

Metastases often represent diffuse systemic or untreatable spread of a primary neoplasm. However, selected patients with metastases isolated to the lung may be resected safely and achieve prolonged survival compared to patients with unresectable metastases. In general, patients with complete resection of pulmonary metastases have associated prolonged survival (regardless of histology) compared to patients with unresectable metastases. This observation is surprising because surgery alone cannot control micrometastases. After complete resection of pulmonary metastases (including multiple and bilateral metastases), the long-term survival rate (more than 5 years) may be expected in approximately one-third of patients.

## HISTORICAL PERSPECTIVE

The history of resection of pulmonary metastases has been reviewed.<sup>1,2</sup> One of the earliest resections for pulmonary metastases was performed after resection of a chest wall sarcoma in 1882 by Weinlechner.<sup>1</sup> In 1883, Kronlein<sup>3</sup> resected a recurrent chest wall sarcoma in a young woman. The patient lived for several years after the surgery and died of recurrent disease. The first resections of a pulmonary metastasis as a separate procedure were described in 1926 by Divis<sup>4</sup> and in 1930 by Torek.<sup>5</sup> One of the first long-term survivors of any pulmonary metastasectomy was reported by Barney and Churchill<sup>6</sup> after resection of a metastasis from a patient with renal cell carcinoma. Local control of the primary tumor was achieved, and the patient survived for 23 years after resection of the metastasis and died from unrelated causes. Alexander and Haight<sup>7</sup> reported the first large series (25 patients) of metastasectomy in 1947. Multiple metastases from osteochondroma of the tibia were resected in 1953 by Mannix, with the patient surviving more than 2 years.<sup>1</sup> Other authors<sup>8,9</sup> and <sup>10</sup> have noted that certain clinical characteristics may enable clinicians to identify patients with more favorable disease-free and overall survival rate prognoses. Since the late 1970s, resection of solitary and multiple pulmonary metastases from sarcomas and various other primary neoplasms have been performed with long-term survival in up to 40% of patients so treated.<sup>11</sup>

## IDENTIFICATION OF PULMONARY METASTASES

Routinely, clinicians may evaluate patients for pulmonary metastases based on screening chest roentgenograms ( [Fig. 52.2-1](#)) obtained at various intervals after resection of the primary. Although their specificity exceeds 95% when nodules consistent with metastases are identified, their sensitivity [compared to computed tomography (CT) of the chest] is low, and this deficiency has prompted some clinicians to screen patients at high risk of recurrent metastases with CT chest scans ([Fig. 52.2-2](#)). Duda et al.<sup>12</sup> examined 130 patients with soft tissue and bone sarcomas. Sixty-six patients had no evidence of pulmonary metastases on chest x-ray (CXR) and subsequently had linear tomography or CT of the chest performed. Only 1 of 53 patients with a normal CXR and no local recurrence had an abnormal tomogram. Two patients of 13 with locally recurrent sarcoma and a normal CXR had an abnormal tomogram. The authors concluded that a screening CXR in the absence of local recurrence is the most cost-effective test. However, tomograms should be performed for evaluation of the extent of disease (e.g., pulmonary metastases) in patients with locally recurrent sarcomas.<sup>12</sup>

**FIGURE 52.2-1.** Chest x-ray (posteroanterior and lateral views) of patient with multiple metastases from malignant fibrous histiocytoma. The number and location of these metastases preclude resection.

**FIGURE 52.2-2.** Correlation of chest x-ray and computed tomography in a patient with pulmonary metastases from soft tissue sarcoma. Serial chest x-rays (A,B) and corresponding computed tomography of the chest (C,D) were taken 4 months apart. The patient subsequently underwent median sternotomy and complete resection of bilateral pulmonary metastases.

CT has replaced linear tomograms as the examination of choice in patients with suspected pulmonary metastases<sup>13</sup> (see Fig. 52.2-2). CT scans of the chest provide a sensitive and specific noninvasive examination for patients with pulmonary metastases.<sup>14,15</sup> and<sup>16</sup> CT scans of the chest are sensitive and identify smaller nodules (3 to 7 mm) earlier than conventional linear tomography, although these nodules may not necessarily be metastases. Theoretically, earlier detection and treatment of metastases can improve survival. However, in one study that detected occult metastases during median sternotomy with bilateral lung exploration, survival was not improved over patients having a single thoracotomy, even though a significant percentage of patients would be expected to have occult metastases.<sup>17</sup>

Magnetic resonance imaging (MRI) is routinely performed to evaluate the local site of resection for recurrence. MRI is not routinely helpful for the radiographic diagnosis of pulmonary metastases; rather, CT of the chest is preferred.<sup>18</sup> MRI is helpful when the pulmonary metastases are of great size and may abut or invade the mediastinum.<sup>19</sup> Pulmonary metastases from sarcomas “push” tissue rather than invade, and exploration is often required to determine the extent of host-tumor interactions. The MRI may assist the surgeon in planning the approach needed for resection of these complex intrathoracic neoplasms.

Lucas et al.<sup>20</sup> examined the role of whole body [<sup>18</sup>F]fluorodeoxyglucose positron emission tomography (FDG PET) in the diagnosis of pulmonary metastases from soft tissue tumors. The authors made 70 comparisons between FDG PET and chest CT for the identification of lung metastases. The sensitivity of FDG PET was 86.7% and the specificity was 100% (13 true-positive, two false-negative). CT of the chest had a sensitivity of 100% and a specificity of 96.4%. However, FDG PET identified 13 other sites of metastases. The authors suggested that FDG PET might be used for evaluation of local recurrence as well as pulmonary and extrathoracic metastases. The use of all three modalities (CT of the chest, MRI, and FDG PET) may most accurately define the total extent of disease. The cost effectiveness of these three examinations has not been studied.<sup>20</sup>

## SELECTION OF PATIENTS FOR SURGERY

Predictors for improved survival have been studied retrospectively for various tumor types to allow the clinician to identify selected patients who will optimally benefit from pulmonary metastasectomy.<sup>8,11,21,22,23,24</sup> and<sup>25</sup> These “prognostic indicators” are clinical, biologic, and molecular criteria, which describe the biologic interaction between the metastases and the patient, and the association of the two with prolonged survival. These prognostic indicators may be used to identify those patients who are most likely to benefit after resection of pulmonary metastases. Many patients with metastases will not benefit from surgery because of a biologically aggressive tumor [e.g., extensive disease, a short disease-free interval (DFI) between control of their primary tumor and identification of unresectable pulmonary metastases, and rapid metastatic growth]. Biologic characteristics also differ with the tumor histology.

Analysis of prognostic indicators in groups of patients with pulmonary metastases from heterogeneous tumors describe prolonged survival in patients with resectable metastases.<sup>8,23</sup> Within this group of resectable patients, longer DFI, longer tumor-doubling time (TDT), fewer numbers of metastases, and specific primary histology may be favorably associated with improved survival.<sup>8,21,22,24</sup> A disadvantage of studying prognostic indicators in heterogeneous groups of neoplasms is the wide variability in biologic characteristics of metastases, particularly among different primary neoplasms. The study of pulmonary metastases from patients with the same tumor histology will provide better information on prognostic indicators that may influence survival after resection of these metastases.

Pastorino and colleagues<sup>26</sup> retrospectively reviewed more than 5000 patients with metastases treated with resection. Overall, actuarial 5-year survival was 36%, 10-year survival was 26%, and 15-year survival was 22%. Patients could generally be staged by the presence of favorable clinical indicators. These indicators included a DFI of more than 3 years, a solitary pulmonary nodule, and germ cell histology.<sup>26</sup>

Kandioler and colleagues<sup>27</sup> confirmed the biologically favorable characteristics of patients with pulmonary metastases who could be completely resected of their disease. Overall median survival for a heterogeneous population of patients with pulmonary metastases was 60 months.

## PREPARATION OF THE PATIENT FOR METASTASECTOMY

The patient's overall medical condition and prior treatment must be considered in planning resection of pulmonary metastases. As with any patient undergoing thoracotomy, the patient must have sufficient physiologic reserves to withstand the anesthesia and the surgical procedure. Routine blood chemistries, chest roentgenogram, and CT of the chest and abdomen are routinely performed. CT of the area of primary neoplasm and other studies may be obtained to evaluate the site for local recurrence.<sup>28</sup> Only if appropriate system-related symptoms were identified, such as headaches or neurologic deficits, or bone pain, would a brain CT or bone scan, respectively, be obtained. The evaluation of pulmonary function includes arterial blood gas measurement, xenon ventilation-perfusion lung scans, DLCO (carbon monoxide diffusing capacity of the lungs), and maximal oxygen consumption (MVO<sub>2</sub>). These studies are obtained to evaluate the patient's suitability for general anesthesia and one-lung anesthesia and to estimate the potential for sufficient postoperative pulmonary reserve. Cardiac assessment (e.g., electrocardiogram, stress test) may be necessary for older patients. For patients previously treated with Adriamycin chemotherapy, an echocardiogram should be obtained to evaluate ejection fraction as a measure of extent of cardiomyopathy.

If preoperative chemotherapy has been given, surgery should be delayed a minimum of 4 weeks or longer to allow for sufficient bone marrow recovery [for low absolute leukocyte count (fewer than 5000 cells per mm<sup>3</sup>) or low platelet count (fewer than 50,000 per mm<sup>3</sup>)]. If marrow suppression precludes recovery of platelets, then perioperative support with platelet transfusions may be required. Absolutely no smoking is permitted for a minimum of 2 weeks before surgery to enhance pulmonary hygiene. Patients are encouraged to use an incentive spirometer several times daily. The patient is routinely admitted to the hospital the morning of surgery.

In the operating room, two large-bore intravenous lines, a radial arterial line, and oxygen saturation monitors are placed. A central line is not routinely used for wedge resections of the lung. A Foley catheter is placed routinely if the operation is expected to exceed 3 hours or if a thoracic epidural catheter is placed for perioperative analgesia. The pertinent radiographic examinations (chest roentgenograms and CT scans of the chest) are displayed prominently in the operating room. After intubation with a single-lumen endotracheal tube, a bronchoscopy is performed to evaluate the distal trachea and tracheobronchial tree. A double-lumen endotracheal tube is used to facilitate sequential exposure and palpation of the lungs.

## SURGICAL INCISIONS

Surgical procedures for resection include single thoracotomy, staged bilateral thoracotomy, or median sternotomy. These procedures have almost no mortality and minimal morbidity.<sup>11,17,29,30,31,32,33</sup> and<sup>34</sup> The procedure chosen does not influence survival in patients resected of all disease; however, various advantages and disadvantages are inherent to each approach (Table 52.2-1). Patients with pulmonary metastases may also undergo multiple procedures for re-resection of metastases, with prolonged survival after complete resection.<sup>35,36</sup> and<sup>37</sup>

Median sternotomy Advantages	Disadvantages
<ul style="list-style-type: none"> <li>• Excellent exposure of the entire anterior thorax.</li> <li>• Allows for sequential resection of the lungs.</li> <li>• Difficult exposure of the left lower lobe.</li> <li>• Limited exposure of the posterior thorax.</li> </ul>	<ul style="list-style-type: none"> <li>• Limited exposure of the posterior thorax.</li> <li>• Limited exposure of the left lower lobe.</li> <li>• Limited exposure of the posterior thorax.</li> <li>• Limited exposure of the left lower lobe.</li> </ul>
Posterolateral thoracotomy Advantages	Disadvantages
<ul style="list-style-type: none"> <li>• Excellent exposure of the posterior thorax.</li> <li>• Excellent exposure of the left lower lobe.</li> <li>• Excellent exposure of the posterior thorax.</li> <li>• Excellent exposure of the left lower lobe.</li> </ul>	<ul style="list-style-type: none"> <li>• Limited exposure of the anterior thorax.</li> <li>• Limited exposure of the right lower lobe.</li> <li>• Limited exposure of the anterior thorax.</li> <li>• Limited exposure of the right lower lobe.</li> </ul>
Video-assisted thoracoscopic surgery (VATS) Advantages	Disadvantages
<ul style="list-style-type: none"> <li>• Excellent exposure of the posterior thorax.</li> <li>• Excellent exposure of the left lower lobe.</li> <li>• Excellent exposure of the posterior thorax.</li> <li>• Excellent exposure of the left lower lobe.</li> </ul>	<ul style="list-style-type: none"> <li>• Limited exposure of the anterior thorax.</li> <li>• Limited exposure of the right lower lobe.</li> <li>• Limited exposure of the anterior thorax.</li> <li>• Limited exposure of the right lower lobe.</li> </ul>

**TABLE 52.2-1.** Advantages and Disadvantages of Various Surgical Resections

For median sternotomy, the patient is positioned supine with the entire anterior thorax exposed from the neck to the umbilicus and laterally to the anterior axillary line. The sternum is divided and the lungs sequentially deflated. The pulmonary ligament is divided to mobilize the lung completely. The deflated lung is palpated to identify metastases, and these are resected with a surgical stapling device or other means (laser or Bovie electrocautery). The deflated right lung may be brought completely into the field by placing folded sponges behind the hilum (for elevation). Metastases may be resected with the lung inflated, but the metastases must be marked with a suture, and metastases deep within the parenchyma may be difficult to resect with wedge excision alone. The lung is reinflated.

Exposure of the left lower lobe through a median sternotomy may be more difficult than exposure of the other lobes because of the overlying heart. With appropriate gentle traction on the pericardium, the left lower lobe can be exposed readily and brought into the operative field. Technical aids, such as an internal mammary artery retractor, may provide for better exposure, particularly for basilar (left lower lobe) tumors or posterior hilar left lower lobe masses.

The posterolateral thoracotomy is a familiar and “standard” approach to pulmonary resection for carcinoma of the lung, although several authors encourage median sternotomy for both resection of lung carcinoma<sup>38</sup> and for pulmonary metastases.<sup>17</sup> In contrast to median sternotomy, posterolateral thoracotomy (either with division of the latissimus dorsi or “muscle sparing”) may be more uncomfortable for the patient during the postoperative convalescence. Improvements in postoperative pain management with intercostal nerve analgesia, thoracic epidural analgesia, and patient-controlled analgesia can control or even eliminate postoperative pain. The posterior or posterolateral thoracotomy does provide better exposure for metastases located posterior and near the hilum, particularly on the left side, and limits the surgeon to one hemithorax. In only rare circumstances would bilateral thoracotomies be performed in the same patient during the same operation.

## RESECTION OF PULMONARY METASTASES

Patients with bilateral metastases may be explored with a median sternotomy, staged bilateral thoracotomies, or posterolateral thoracotomy. Prior evaluation of patients with sarcomas and unilateral nodules demonstrated bilateral metastases in 38% to 60% of patients.<sup>17,38</sup> Postresection survival from median sternotomy and from bilateral staged thoracotomies is similar.<sup>17</sup> Numbers of nodules, presence of unilateral or bilateral nodules, location of nodules, and the size of various nodules can be identified and, if required, resected through a median sternotomy. A median sternotomy is recommended for the initial exploration and resection in patients with unilateral or bilateral nodules, and in patients with pulmonary metastases from osteogenic sarcoma (OST) or soft tissue sarcoma (STS), and should be considered the procedure of choice in patients with suspected bilateral metastases.<sup>32,34</sup> Multiple authors have advocated median sternotomy for lobectomy for resection of primary carcinoma of the lung,<sup>38,39</sup> and 40<sup>40</sup> particularly in patients with impaired pulmonary function. A posterolateral thoracotomy approach may be required for left lower lobectomy in patients with obesity, cardiomegaly, or an elevated left hemidiaphragm.<sup>38</sup>

All nodules are resected with a margin of normal tissue. Nodules should not be “shelled out,” because viable tumor cells remain on the periphery of the resected area. Often the decision of margin adequacy is the surgeon’s alone, because lung parenchyma may become distorted around the nodule after resection, giving the illusion of a “positive” or “close” margin. Mediastinal lymph nodes can also be examined for potentially rare involvement from pulmonary metastases.<sup>10,41</sup>

Laser-assisted pulmonary resection using the neodymium:yttrium aluminum garnet laser may provide a better means of resecting pulmonary metastases than with the surgical stapler.<sup>25</sup> Disadvantages of laser resection may include longer operating time and the potential for prolonged postoperative air leaks; however, use of the laser may enhance preservation of lung parenchyma with less distortion.<sup>42</sup> Bovie electrocautery may also spare lung parenchyma by removing the metastases with minimal distortion of remaining lung. Air leaks can be sealed by the use of fibrin glue.<sup>43</sup>

Thoracoscopic resection or video-assisted thoracic surgery (VATS) using high-resolution video cameras may be helpful for diagnosis of metastases<sup>44,45</sup>; however, its usefulness is limited to metastases identified on the surface or outer one-third of the lung. Metastases within the lung parenchyma may be undetectable with this technique.<sup>46</sup> Landreneau and associates<sup>47</sup> have described minimal morbidity and no mortality in 41 patients who underwent 52 thoracoscopic pulmonary resections for small lesions (less than 3 cm) in the outer one-third of the lung parenchyma.

At this time, wedge resection of pulmonary metastases using VATS techniques has no proven advantage over resection using standard “open” techniques. Even patients at increased physiologic risk from thoracotomy may tolerate a simple wedge resection of the lung without difficulty. VATS may be inadequate to detect all metastases. McCormack and colleagues<sup>48</sup> demonstrated that a combination of chest CT and VATS had a 56% failure rate to detect and resect all lesions. The frequency of bilateral and occult metastases, particularly in sarcoma, precludes the use of thoracoscopy. Thoracoscopy *may* play a role in highly selected patients with a solitary metastasis of nonsarcomatous origin with a long DFI.

Complications specific to thoracoscopic resection of pulmonary metastases have been described. The subjective risks of an incomplete, inadequate, or inconsistent operation must be compared to the benefits of the VATS approach. The surgeon must consider the technical skills required, the desired objectives for the patient, the instrumentation available for manipulation of the lung and other thoracic organs, and an assessment of the risk of a “closed” versus “open” procedure. An inadequate resection of pulmonary metastases may cause more morbidity than the benefits achieved by VATS. The obvious chest wall implant from tumor seeding has devastating effects on the patient.<sup>49</sup> Postoperative pain from periosteal injury affects some patients. Patient selection remains a critical step in the appropriate use of VATS in thoracic surgical oncology.<sup>50</sup> VATS is considered appropriate for diagnosis or intrathoracic staging ( Fig. 52.2-3).

**FIGURE 52.2-3.** A: Computed tomography with a peripheral nodule in a 45-year-old man with a prior history of a superficial melanoma (Clark’s level 2) removed from his forearm 2 years previously. B: Video-assisted thoracic surgery resection was performed for complete resection of a granuloma. No other intrathoracic lesions were noted. The patient has remained free of disease from his melanoma. An open procedure, thoracotomy, was avoided. Minimal scarring is present.

## SURVIVAL ANALYSIS

Survival may be absolute or actuarial and is usually calculated from the time the surgical procedure is performed until death or the date of last follow-up. For example, patients followed for a minimum of 5 years (survivors) or until death provide an absolute 5-year survival rate (number patients alive of all patients studied); patients followed for varying periods (i.e., 2 to 7 years) may be evaluated using an actuarial survival curve. Actuarial survival and disease-free survival may be estimated using the method of Kaplan and Meier.<sup>51</sup> Patients, grouped into two or more populations, are defined as meeting or not meeting an objective criteria and compared so that differences in survival can be evaluated. Univariate analysis (or comparisons between groups) may be made using the generalized Wilcoxon test of Gehan<sup>52</sup> or log-rank test; if sample sizes are small, the Thomas exact test<sup>53</sup> may be used. Cox's proportional hazards model<sup>54</sup> would be used to determine the relative effect of various prognostic indicators on survival. Univariate analysis identifies the most important prognostic indicators. Multivariate analysis evaluates the predictive ability of two or more prognostic indicators to provide additional prognostic value.

## RESULTS OF RESECTION OF SARCOMATOUS PULMONARY METASTASES

An evaluation of prognostic indicators and results of resection of pulmonary metastasectomy is difficult, because numerous primary histologies are often combined to discuss the value of pulmonary metastasectomy. Although identification of trends is helpful, analysis of factors that are associated with improved survival depend on a single histology and a group of patients sufficiently large from which to draw conclusions. Prognostic indicators have been reviewed to assess their association, singularly and in combination, with postresection survival in patients with pulmonary metastases and to assist clinically in better selecting appropriate patients for resection of pulmonary metastases. Age and gender of the patient; histology, stage, grade, and location of the primary tumor; disease-free survival; number of nodules on preoperative radiologic studies; whether the metastases are unilateral or bilateral, or synchronous or metachronous; and TDT all may be evaluated preoperatively. In addition, resectability, technique of resection, nodal spread, the number of metastases and their location, and re-resection may be examined postoperatively.

## OSTEOGENIC SARCOMA

Pulmonary metastases from OST occur in up to 80% of patients who relapse after treatment for their primary neoplasm, whether or not they receive adjuvant chemotherapy.<sup>55,56</sup> and <sup>57</sup> Ninety percent of all recurrences occur within 3 years.<sup>58</sup> Because these metastases are often isolated to the lungs, surgical resection may render a significant number of patients disease-free and enhance long-term survival.<sup>44,55,56,59,60</sup> and <sup>61</sup> The 5-year survival rate may range up to 50%.<sup>62</sup>

Various groups have evaluated survival and prognostic factors in patients with pulmonary metastases from OST. Series from the National Cancer Institute in the early 1980s evaluated 80 patients with primary OST of the extremity. Forty-three patients developed pulmonary metastases. Thirty-nine patients were deemed resectable and underwent one or more thoracic explorations for resection of their metastases. The 5-year survival rate was 38%. Various prognostic factors were analyzed. Fewer number of nodules (three or less), longer DFI, resectable metastases, and fewer metastases identified and resected were associated with longer postthoracotomy survival. A multivariate analysis did not find any combination of factors to be more predictive than the number of nodules identified on preoperative tomograms.<sup>9</sup> Surgical resectability was the only predictive factor associated with prolonged survival for recurrent OST.<sup>55</sup>

Chemotherapy has been effective in prolonging the DFI between the surgical treatment of the primary tumor and the appearance of pulmonary metastases. Chemotherapy offers no survival advantage in treating bulk metastases from OST; however, chemotherapy may prevent or cure micrometastatic disease not amenable to surgery.<sup>60</sup> Goorin et al.<sup>55</sup> reported on 113 patients treated with adjuvant therapy for primary OST. Adjuvant chemotherapy improved event-free survival over surgery alone ( $P = .00$ ) for primary OST. Relapses occurred in the lungs in more than 80% of patients. Survival after relapse was not influenced by chemotherapy. The only factor associated with improved survival after relapse (in the lungs) was complete resection of all metastases, rendering the patient disease-free ( $P = .03$ ).<sup>55</sup>

More recently, the value of chemotherapy for treatment of patients with pulmonary metastases from OST was examined by Antunes and colleagues<sup>63</sup> in a review of 198 patients operated on for OST of the limbs. The patients were treated with a combination of chemotherapy and surgery. The patients received three cycles of preoperative chemotherapy with methotrexate, Adriamycin, and cisplatin. Patients underwent surgery approximately 1 month later and received chemotherapy postoperatively (Adriamycin and ifosfamide). With chemotherapy and surgery for pulmonary metastases, the 3-year survival rate was 61%, compared to 79% in patients without metastases. Of all patients with pulmonary metastases who died, they died of progressive pulmonary metastases. Chemotherapy to achieve a biologic response, followed by surgery for "salvage" and local control, followed by more chemotherapy for micrometastatic disease, is a reasonable and effective means of treatment of pulmonary metastases from OST. Patients with synchronous pulmonary metastases with their primary tumor have a worse survival rate, even with chemotherapy and complete resection.<sup>64,65</sup>

## SOFT TISSUE SARCOMAS

STSs comprise a family of nonossifying malignant neoplasms arising from mesenchymal connective tissues. As with OST, local recurrence is common (20%), and metastases are predominantly to the lungs<sup>66</sup> (Fig. 52.2-4). Casson et al.<sup>67</sup> evaluated determinants of 5-year survival in 58 patients who had complete resection and who were followed until death or for a minimum of 5 years. Absolute 5-year survival was 25% (15 of 58 patients). Favorable prognostic factors included TDT of more than 40 days, unilateral disease, three or fewer nodules identified on preoperative tomograms, two or fewer metastases resected, and tumor histology (median survival of 33 months for malignant fibrous histiocytoma vs. 17 months for all others). Using multivariate analysis, the number of nodules (four or more) was the most significant prognostic indicator. The addition of tumor histology (malignant fibrous histiocytoma) improved the predictive ability of this model.<sup>67</sup>

**FIGURE 52.2-4. A:** Overall survival for patients with pulmonary metastases from soft tissue sarcoma. Patients were selected for surgery based on the potential for complete resection of their metastases. The 5-year survival rate was 25%. (From ref. 103, with permission.) **B:** Survival for resectable and nonresectable patients with pulmonary metastases from soft tissue sarcoma. Patients with complete resection have an associated survival advantage over patients with incomplete resection or unresectable metastases. (From ref. 103, with permission.)

One study<sup>10</sup> evaluated 67 patients with histologically documented pulmonary metastases from STS treated at the National Cancer Institute. Significant preoperative predictors of enhanced survival included TDT (more than 20 days), number of metastases on preoperative tomograms (four or fewer nodules), and the DFI (more than 12 months). Predictive ability was improved when all three prognostic factors were combined. These patients represent the patients who have the best response (i.e., prolonged postresection survival) to pulmonary metastasectomy.<sup>10,68</sup>

Patients with recurrent pulmonary metastases and complete resection also have improved postresection survival.<sup>35,36</sup> and <sup>37</sup> Increased age and female gender were associated with an increased risk of death from disease in resected patients with recurrent pulmonary metastases in contrast to initial isolated pulmonary

metastases.<sup>36</sup> Resectable patients and those with one metastasis have the best postresection survival.<sup>35</sup>

Chemotherapy given before resection of pulmonary metastases has variable impact on postresection survival. In a study of patients with pulmonary metastases from STS,<sup>68</sup> chemotherapy (doxorubicin, cyclophosphamide, and dacarbazine) was given before metastasectomy. Time from treatment initiation to thoracotomy ranged from 1 to 57 months. Patients were grouped according to response. Five patients had a complete response (not surgically confirmed) and recurred 5 to 57 months later. Seven patients had a partial response. Twelve patients had either no change or progression. Thirty-eight procedures were performed. Resectable patients had a median survival of 30 months and an actuarial 5-year survival rate of 25% (see Fig. 52.2-4A). Complete resection was associated with an improved survival compared to unresectable patients (see Fig. 52.2-4B). No differences were found in postresection survival between any groups. Postthoracotomy survival cannot be predicted from initial response to this chemotherapy regimen.<sup>69</sup>

Adriamycin and ifosfamide have activity in more than 20% of patients with metastatic sarcoma. In addition, the combination of both chemotherapeutic agents may be greater than either single agent. The value of chemotherapy as an adjuvant is unknown, but several studies suggest a modest relapse-free and survival benefit. The authors<sup>70</sup> correctly note that patients with STSs should be studied in prospective clinical trials. Newer and more active chemotherapeutic agents are needed.<sup>70</sup>

## CHILDHOOD SARCOMAS

Primary sarcomas of childhood, such as Ewing's sarcoma and rhabdomyosarcoma, commonly spread to the lungs<sup>71,72</sup>; however, other sites of metastasis are frequent, with the exception of metastases associated with OST. Chemotherapy remains the major treatment modality for metastases in multiple sites. Pulmonary resection for metastases may be required to document metastases in the lungs or to assess the tumor's response to chemotherapy or the viability of the remaining tumor. Resection of all disease in the lung may enhance postresection survival in these children with resectable metastases. Children undergoing median sternotomy for resection of pulmonary metastases from OST have almost a complete recovery of preoperative pulmonary function.<sup>73</sup>

Ewing's sarcoma and OST metastasize preferentially to the lungs in children and may be resected. Patients with resectable pulmonary metastases from Ewing's sarcoma have prolonged survival (actuarial 5-year survival rate, 15%; median, 28 months) compared to those patients explored but found to have unresectable metastases (no survivors beyond 22 months; median survival, 12 months;  $P = .0047$ ). Patients with four or fewer nodules have better survival than patients with four or more nodules.<sup>74</sup> Other studies<sup>71,72,75</sup> support these findings.

OST metastasizes preferentially to the lungs.<sup>61</sup> Resection of pulmonary metastases from OST also results in prolonged postresection survival.<sup>44,55,59,76,77</sup> Adjuvant therapy, such as chemotherapy<sup>55,59,60,76</sup> or lung irradiation,<sup>79,80</sup> may also be valuable, particularly for micrometastases. Post resection survival may be as high as 40% at 5 years.<sup>44</sup>

## NONPULMONARY METASTASES FROM SARCOMAS

Location of sarcomatous recurrence or metastases may vary by the original location or histology of the primary tumor. Biopsy of suspicious lesions is needed to confirm the presence of local recurrence or distant metastases. A needle biopsy, or a core biopsy, may be considered.<sup>81</sup>

Metastases from OST and STSs occur most commonly in the lungs but may also occur in other organs. Potter et al.<sup>82</sup> noted that only 53% of recurrences in those patients completely resected of primary sarcoma recurred in the lung. In another early study<sup>82</sup> of 255 patients with STS treated with preoperative chemotherapy and radiation followed by limb-sparing surgery, 85 patients developed metastatic disease (isolated local recurrence, 13; isolated pulmonary metastases, 43; lung and other, 11; and multiple sites, 18). Poor 2-year survival rate (less than 10%) occurred in those patients with multiple recurrence sites. Resection of isolated metastases appears to benefit a portion of patients with metastatic disease.<sup>82</sup> More recently, Billingsley et al.<sup>83</sup> noted that, in patients with primary extremity sarcoma, 23% of all patients develop metastases. Of these patients, 73% develop pulmonary metastases. Other sites of metastasis include the skin and soft tissues of the head and neck, trunk, and extremities.<sup>83</sup>

In contrast to the expected pulmonary site for metastases, myxoid liposarcomas may metastasize preferentially to extrathoracic sites. In one study from the University of Texas M. D. Anderson Cancer Center in Houston,<sup>84</sup> 102 patients with myxoid tumors had 33 distant recurrences. Extrapulmonary soft tissue sites were the most common (e.g., the retroperitoneum, chest wall, pleura, pericardium, pelvic sidewall, and soft tissue of the back;  $n = 31$ ), whereas pulmonary metastases were rare ( $n = 2$ ). In this study, pleomorphic tumors more frequently recurred in the lung (10 of 18 patients recurred: three of ten extrapulmonary, seven of ten pulmonary) than did the myxoid tumors ( $P < .05$ ; myxoid vs. pleomorphic).<sup>84</sup>

Angiosarcoma is a high-grade aggressive sarcoma with local recurrences likely in 20% of patients and distant metastases in 49%. The location of metastases is commonly the lungs, lymph nodes, soft tissues, bone, liver, and other sites.<sup>85</sup>

In another study,<sup>86</sup> of 981 patients with sarcoma, 65 were noted as having developed hepatic metastases. Most patients ( $n = 61$ ) had an intraabdominal primary site of high-grade leiomyosarcoma. Even with resection in 14 patients, all recurred; however, a median survival of 30 months was achieved. The opportunity for complete resection of hepatic metastases is rare, but complete resection of hepatic metastases must be considered to obtain a survival advantage.<sup>87</sup>

In patients with brain metastases from STSs, complete resection may also provide a survival advantage (14 months vs. 6 months) compared to patients with incomplete resection. The authors concluded that complete resection of brain metastases from STS patients with a good performance status (Karnofsky performance score greater than 70) is associated with a good prognosis. Even if synchronous lung metastases were present, complete resection of all metastases provided the patient with a survival of 11.8 months (median).<sup>88</sup>

## COLORECTAL NEOPLASMS

Colorectal metastases commonly spread to local or regional nodes or are trapped in the liver through the portal venous drainage. Patients with prior colorectal neoplasms have had pulmonary metastases resected with prolonged postresection survival. An absolute distinction cannot be made between a single carcinomatous metastasis and a primary bronchogenic carcinoma except by direct visual comparison between the two neoplasms. As with other isolated pulmonary metastases, patients with pulmonary metastases from colorectal carcinoma may be resected safely with low morbidity and mortality and long-term survival (see Fig. 52.2-4). Reports<sup>89,90,91,92,93</sup> and <sup>94</sup> describe 5-year survival rates ranging from 21% up to 50% after resection of pulmonary metastases from colon carcinoma. Differences in age and gender of the patient and location, grade, and stage of the primary colorectal cancer are not associated with either improved or worsened survival after resection of these metastases. Patients with metachronous liver lesions excised for cure may also be candidates for resection of pulmonary metastases. Sauter et al.<sup>95</sup> evaluated 49 patients with isolated pulmonary metastases ( $n = 18$ ) and hepatic metastases ( $n = 31$ ). Patients with pulmonary metastases had a 47% 5-year survival rate compared to patients with hepatic metastases (5-year survival, 19%). Of 1578 patients treated for colon and rectal cancer, 117 of 1013 patients with rectal carcinoma (11.5%) and 20 of 565 patients with colon cancer (3.5%) recurred in the lungs.<sup>96</sup> In 66 patients who underwent resection of pulmonary metastases from colorectal adenocarcinoma, patients with a solitary metastasis had a longer postresection survival than others.<sup>94</sup> The 5-year survival rate was 38% in both studies. In another study of 62 patients,<sup>93</sup> metastases less than 3 cm in diameter were associated with improved survival.

In a series from the Mayo Clinic, McAfee et al.<sup>97</sup> reported 139 patients who underwent resection of pulmonary metastases from colorectal carcinoma. Operative mortality was 1.4%. Overall, the 5-year survival rate was 30.5%, and the median follow-up was 7 years. Patients with a solitary pulmonary metastasis and those with a preoperative carcinoembryonic antigen (CEA) level of less than 4.0 ng/mL had a better postthoracotomy than others. A longer DFI and metastases smaller than 3 cm in diameter were not associated with improved survival.

Patients with resection of colon metastases from the lung and the liver have a survival advantage with complete resection.<sup>98,99</sup> Forty-eight patients had both liver and lung metastases. Twenty-five patients underwent resection of these metastases, and the remaining 23 patients did not. Median survival was longer after resection of the last metastasis than in those individuals who did not undergo resection (16 months vs. 6 months;  $F < .001$ ). The authors also noted that patients with metachronous resections survived longer than patients with synchronous resections (median of 70 months vs. 22 months;  $P < .001$ ). Robinson et al.<sup>100</sup> noted that the ideal candidate for resection is a patient younger than 50 years old with a solitary liver metastasis and a 4-year interval between the colorectal cancer resection and the occurrence of the pulmonary metastasis. The patient least suited for resection is one older than 70 years with multiple liver metastases and synchronous

disease.<sup>100</sup> In addition, a French study<sup>101</sup> examined 43 patients who previously had undergone complete resection of hepatic metastasis and then developed pulmonary metastases. The median survival was 19 months, and the 5-year survival was estimated to be 11%. Patients with a CEA of more than 0.5 ng/mL had a significantly lower probability of survival than those with lower levels (less than 0.5 ng/mL;  $P = .0018$ ).<sup>101</sup>

In patients with colorectal metastases to both liver and lung, complete resection is generally associated with improved survival. Whether the liver metastases occur first and then the lung metastases, or whether lung metastases occur first followed by liver metastases, complete surgical resection tends to be associated with longer survival. Poorer survival was noted in those patients who cannot be completely resected or who are deemed unresectable without operation. Of the total population of patients with colorectal metastases, those individuals with completely resectable lung or hepatic metastases represent a small percentage and one with the most favorable "biology" of the tumor. The surgeon can take advantage of this biologically favorable subset of patients. With complete resection of both lung and hepatic metastases, survival may be enhanced.

## BREAST CARCINOMA

Patients with metastases from breast carcinoma usually do poorly because metastases occur in multiple sites. Patanaphan and colleagues<sup>102</sup> described 145 patients with metastatic breast carcinoma (145 of 558; 26%) in whom bone (51%), lung (17%), brain (16%), and liver (6%) metastases occurred. Overall median survival was 12 months for patients with lung metastases, most of whom were treated with palliative chemotherapy, irradiation, or both.<sup>102</sup> Lanza and associates<sup>103</sup> reviewed 44 women with a prior history of breast cancer who underwent pulmonary resection for new pulmonary lesions. Seven patients were excluded who had benign nodules ( $n = 3$ ) or unresectable metastases ( $n = 4$ ). In 37 resectable patients, actuarial 5-year survival was 50% (Fig. 52.2-5). A DFI of more than 12 months was associated with a longer median survival (82 months) and 5-year survival rate (57%) compared with patients with a DFI of less than 12 months (15 months median; 0% 5-year survival;  $P = .004$ ). Estrogen receptor-positive status tended to be associated with a longer postthoracotomy survival ( $P = .098$ ). Another favorable prognostic factor included positive receptor status of the primary tumor that was associated with improved 3-year survival (61%) compared to negative receptor status (38%). Resection of solitary metastasis resulted in a 35% 5-year survival rate compared to 0% for resection of five or more metastases.<sup>104</sup> More recently, favorable selection of patients has enabled survival to increase up to 62% at 5 years in one series.<sup>105</sup>

**FIGURE 52.2-5.** Overall survival for patients after resection of pulmonary metastases from breast carcinoma. The 5-year survival rate was 50%.

Staren et al.<sup>174</sup> evaluated 33 patients treated with surgical resection of pulmonary metastases from breast carcinoma and compared the results to that of 30 patients treated primarily with systemic chemotherapy and hormonal therapy. Patients having complete resection of metastases had a better median survival than patients with medical therapy, particularly when single nodules were compared (58 months median survival vs. 34 months, respectively). The 5-year survival rate in patients treated with some surgical resection was 36%, compared to 11% in those patients treated with other than surgical treatment.

## TESTICULAR NEOPLASMS

Nonseminomatous testicular tumors can be diagnosed by the occurrence of new pulmonary nodules identified on CXR or by CT scan.<sup>106,107</sup> Metastatic testicular seminoma most commonly is identified as mediastinal nodal enlargement. CT scan, therefore, is more accurate in diagnosis of seminomatous metastases than plain chest roentgenograms.<sup>108</sup>

Cytoreductive surgery for disseminated nonseminomatous germ cell tumors of the testis may be performed after chemotherapy for removal of residual metastatic disease. The response to chemotherapy may be assessed when no further reduction in size of the nodules is noted. The majority of patients require retroperitoneal lymph node dissections (69%), although thoracotomies may be required in 18% of patients. Several authors<sup>109,110</sup> and<sup>111</sup> evaluated 80 patients with germ cell tumors and lung metastases treated with chemotherapy and subsequent surgery. Thirty-five percent ( $n = 28$ ) achieved complete response after chemotherapy. Thirty-six patients with partial response underwent surgery for resection of metastases in the abdomen ( $n = 17$ ), the lungs ( $n = 15$ ), or both ( $n = 4$ ). Twenty-seven of 36 patients achieved complete response after both chemotherapy and surgery. Carter et al.<sup>112</sup> noted that extensive pulmonary metastases (unresectable metastases) are a predictor of ultimate treatment failure.

Liu and colleagues<sup>113</sup> evaluated the role of pulmonary metastasectomy for testicular germ cell tumors over a 28-year period. The typical patient was young (median age, 27 years) and complete resection generally could be accomplished. Most of these patients had already undergone chemotherapy. Viable metastasis was present in 44% of the patients; 25% had metastasis to other sites after resection of their pulmonary metastasis. Overall, the 5-year survival rate was 68%, and for the patients diagnosed after 1985, the survival rate was 82%. The authors of the study noted that extrathoracic metastasis (nonpulmonary visceral sites) as well as the presence of viable tumor in the resected specimens were adverse prognostic indicators. Of interest was the observation that preoperative tumor markers were normal in the majority of patients and that patients with multiple metastases predominated. Approximately one-half of the patients had synchronous presentation of their metastasis, and 66% of patients had no viable tumor; mature teratoma and fibrosis/necrosis were equally represented. Patients with metastases outside the pulmonary parenchyma and elevated tumor markers from viable tumor had a worse prognosis. Parenchymal resection not only removed all identifiable disease but also provided a measure as to the effectiveness of their chemotherapy treatment.<sup>113</sup> More recently, 28 patients with pulmonary metastases from germ cell/testicular neoplasms were treated with bleomycin, etoposide, and cisplatin. Complete response was achieved in 21 patients (75%), and a complete response was achieved in 11 patients. Resection of residual mass was necessary in 12 patients with normalized serum markers. Overall, the cure rate was 89.3%. Resection of the residual mass was recommended for histology and may modify subsequent treatment.<sup>114</sup>

The value of repeat surgical resection of pulmonary metastasis has not been as well studied as individuals having only one resection. In one report of 396 operations in 330 patients,<sup>27</sup> the authors identified a subgroup of 35 patients who had undergone reoperation for pulmonary metastasis. In this group, the 5- and 10-year survival rates were 48% and 28%, respectively. The favorable prognostic factors included a DFI of more than 1 year. No survival advantage was associated with histology (epithelial carcinoma, osteosarcoma, or STS). In this patient population, successful repeat surgical resections of pulmonary metastasis and survival advantage are probably related to a favorable biologic behavior. The specific criteria for this favorable behavior are not yet known.<sup>27</sup>

## GYNECOLOGIC NEOPLASMS

Fuller and colleagues<sup>115</sup> from the Massachusetts General Hospital reviewed a 40-year experience of treating 15 patients with pulmonary metastases from gynecologic cancer, which included primary tumors involving the cervix (6), endometrium (3), and ovary (2), as well as two uterine sarcomas and two choriocarcinomas. The 5-year survival rate was 36%. Lesions less than 4 cm in diameter and a DFI of more than 36 months were associated with prolonged survival.

Levenback et al.<sup>116</sup> reviewed 45 patients with pulmonary metastases from uterine sarcomas. Most patients (71%) had unilateral lesions, and 51% had only one lesion. The 5-year survival rate was 43%. Unilateral metastases or fewer numbers of metastases were not significantly associated with prolonged survival.

Kumar<sup>181</sup> reviewed 97 patients with metastatic gestational trophoblastic disease; chemotherapy was the treatment of choice. Selective thoracotomy in patients with

solitary lung metastases reduced the treatment time and need for further aggressive chemotherapy. Overall, 2-year survival after diagnosis was 65%. A DFI of less than 1 year was associated with poorer survival.

Barter et al.<sup>117</sup> studied 2116 patients with primary cervical malignancy between 1969 and 1984 and found 88 patients (4.16%) with pulmonary lesions consistent with metastases. Prognosis was poor with chemotherapy only (median survival, 8 months; only 2 of 88 long-term survivors). Imachi et al.<sup>118</sup> identified 50 of 817 patients (6.1%) treated for carcinoma of the uterine cervix who developed pulmonary metastases. Eighty-one percent of patients had local recurrence or other metastases, and chemotherapy was given. The authors suggest that surgery may be considered for patients with pulmonary metastases without extrathoracic metastases. Resection of pulmonary metastases from squamous cell carcinoma (SCC) of the uterine cervix also has been described.<sup>119</sup>

## RENAL CELL CARCINOMA

Various series have examined the value of resection of pulmonary metastases from renal cell carcinoma. Five-year survival rates have ranged from 21%<sup>120</sup> to 60%.<sup>121</sup> Schott et al.<sup>122</sup> reported 39 of 938 patients (4.1%) with pulmonary metastases after nephrectomy for renal carcinoma. Patients with pulmonary metastases less than 2 cm in diameter and limited to one site had prolonged survival and DFI compared to other patients. Dernevik and colleagues<sup>120</sup> resected 33 patients for pulmonary metastases and evaluated them with a minimum follow-up period of 5 years or until death. Longer DFI (more than 1 year) was better than a shorter DFI (less than 1 year). Pogrebniak and associates<sup>121</sup> from the National Cancer Institute reported 23 patients who underwent resection of pulmonary metastases from renal cell carcinoma, 18 of which had previous interleukin-2-based immunotherapy. Resectable patients (15 of 23; 65%) had a longer survival (mean, 49 months; median not yet reached) compared to unresectable patients (median, 16 months,  $P = .02$ ). Postresection survival did not depend on tomogram nodules, resected nodules, or the DFI.<sup>123</sup>

The 5-year survival rate after complete resection was 44% in one study of 50 patients undergoing resection of metastases from renal cell carcinoma.<sup>123</sup> Twelve patients had repeat resection (42% 5-year survival after second resection). Complete resection was the most important factor associated with 5-year survival.

## MELANOMA

The overall biologic behavior of melanoma cannot be predicted. Most commonly, pulmonary metastases occur in addition to other visceral sites, and overall long-term survival is poor. Immunotherapy has been used with some favorable results. In the rare patients who present with isolated pulmonary metastases, resection may be associated with long-term survival.<sup>124</sup> Current 5-year survival ranges from 4.5% to 25%. In a large series of 1521 patients with American Joint Committee on Cancer stage IV melanoma, 5-year survival was only 4% (median survival, 8.3 months).<sup>125,126</sup>

Gorenstein and colleagues<sup>127</sup> evaluated 56 patients with histologically proven pulmonary metastases from melanoma. The overall postresection survival was 25% at 5 years. Patients with earlier primary-stage melanoma, or patients with metastases to the lungs as the first site of metastasis, had longer postresection survival than other patients. Location of the primary tumor, histology, thickness, Clark level, nodal metastases, TDT, or type of resection of the primary tumor was not associated with improved postresection survival.

Harpole et al.<sup>128</sup> evaluated pulmonary metastases in 945 patients with melanoma out of a population of 7564 melanoma patients. Bilateral and multiple metastases were present in the majority of these patients. Multivariate predictors of survival included complete resection, DFI, chemotherapy, two or fewer metastases, negative lymph nodes, and histologic type. The 5-year survival rate for all patients ( $n = 7564$ ) was 4%, in contrast to 20% 5-year survival in patients with resection of pulmonary metastases.

## SQUAMOUS CELL CARCINOMA

Patients with primary SCC outside the lungs frequently have disease metastasize to the lungs. These secondary lung neoplasms may be resected with subsequent survival benefit.<sup>129</sup> With solitary pulmonary lesions after treatment of primary SCC elsewhere in the body, the origin of the lesion is uncertain. The lesion may represent a solitary metastasis, a primary bronchogenic carcinoma, or a benign process. The recommended treatment for such a solitary lesion is bronchoscopy thoracic exploration and excisional biopsy. If a SCC is identified, a lobectomy and mediastinal lymph node dissection should be performed in the same manner as if the lesion were a second primary neoplasm. Less desirable is a generous wedge excision and mediastinal lymph node dissection, because local control may be limited.

Finley et al.<sup>130</sup> described factors associated with improved survival in patients with SCC metastases from head and neck cancers. These included complete resection, control of primary tumor, early stage of the head and neck primary, one nodule on CXR, and longer DFI (more than 2 years) from primary resection. Complete resection of all malignant disease was associated with a 5-year survival rate of 29%. The number of nodules was not significantly associated with survival. In eight patients with more than one nodule, median survival was 2 years, and no 5-year survivors were reported. Therefore, the benefits of resection of multiple pulmonary metastases from head and neck primary SCC are not completely clear. In another study of 44 patients,<sup>131</sup> 5-year survival after pulmonary resection was 43%. Mazer et al.<sup>131</sup> noted that single nodules, primary tumor stage, or absence of locoregional recurrence were not associated with enhanced survival. The presence of mediastinal disease was associated with the worst outcome.

Lefor and colleagues<sup>132</sup> attempted to correlate primary carcinomas of the head and neck with subsequent development of pulmonary metastases or second primary lung carcinomas. An algorithm was used that considered the DFI, histology, radiographic findings, and characteristics of the lung lesion, as well as the identification of mediastinal lymphadenopathy. The authors recommended that treatment of indeterminate lesions be treated as primary lung carcinomas (e.g., with lobectomy and mediastinal lymph node dissection) because this strategy provides the best local control of the disease and potential for cure.

## WILMS' TUMOR

Patients with Wilms' tumor may present with pulmonary metastases at diagnosis or relapse after initial treatment.<sup>133</sup> Early diagnosis using CT may identify metastases in up to 36% of patients.<sup>134</sup> Pulmonary metastases may be resected safely from children with Wilms' tumor.<sup>71,135</sup> In contrast,<sup>136</sup> 211 patients entered on the National Wilms' Tumor Study whose initial relapse was in the lungs did not show any survival advantage to resection of pulmonary metastases compared to treatment with chemotherapy and whole lung irradiation.

## METASTASIS OR PRIMARY BRONCHOGENIC CARCINOMA?

Pulmonary metastases from sarcomas or other distinctive nonpulmonary neoplasms are usually easy to diagnose. However, solitary carcinomatous metastasis from breast or colon, or SCC metastasis from head and neck primary tumors, are difficult to distinguish from primary lung carcinoma. Patients with two or more pulmonary nodules can be considered to have metastases. In tumors without a propensity for bilaterality (e.g., nonsarcomatous histology), a solitary pulmonary nodule may be approached through a lateral thoracotomy incision. A generous wedge excision or lobectomy and mediastinal lymph node dissection should be performed. The final pathology may suggest histology amenable to adjuvant therapy.

Traditionally, a comparison of the primary neoplasm and the lung nodule using light microscopy has been the only method for determining origin of the lung nodule or neoplasm. Electron microscopy<sup>137</sup> or specific molecular or genetic characteristics may identify more precisely the origin of such neoplasms. Monoclonal antibodies can assist in discriminating between primary bronchogenic adenocarcinoma and colon carcinoma metastatic to the lung.<sup>138</sup> Characteristics of amplified K-ras oncogene expression present in the primary tumor can be used to identify pulmonary metastases.<sup>139</sup> Monoclonal antibodies can identify colorectal carcinoma metastases.<sup>140</sup> The monoclonal antibody was not sufficient to discriminate primary lung from metastatic adenocarcinoma. Flow cytometry and DNA analysis have been used<sup>95,141,142</sup> to describe primary carcinomas of the lung and to distinguish them from metastases.

Algorithms have been developed<sup>132</sup> for patients with SCCs of the head and neck who develop pulmonary nodules after treatment. Characteristics of metastases and of primary lung carcinoma were examined in an attempt to better direct subsequent therapy.

## RECURRENT PULMONARY METASTASES

If pulmonary metastases recur in the lungs, resection can again be accomplished safely with prolonged postthoracotomy survival.<sup>143</sup> Patients are screened by the criteria in [Table 52.2-2](#). Patients with pulmonary metastases may undergo multiple procedures for re-resection of metastases, with prolonged survival after complete resection. Several studies have reviewed results of multiple resections for recurrent pulmonary metastases. Rizzoni and associates<sup>37</sup> described 29 patients with recurrent pulmonary metastases from STSs who underwent two or more resections of pulmonary metastases. Patients with favorable tumor biology [resectable metastases, longer TDT, three or fewer nodules, longer DFI (more than 6 months)] had longer survival. No operative mortality occurred, and the complication rate was 7.5%. Median survival was 14.5 months and overall 5-year survival was 22%. Resectable patients had a median survival of 24 months. These findings were confirmed by Casson and colleagues,<sup>35</sup> who described 39 patients with adult STSs. Thirty-four patients were resectable (median survival, 28 months; 5-year survival, approximately 32%). Unresectable patients had a median survival of 7 months. Survival after resection of a solitary recurrent metastasis was 65 months (median) compared to patients with two or more nodules (median, 14 months;  $P = .01$ ).

---

Pulmonary parenchymal nodules or changes consistent with metastases
Absence of uncontrolled extrathoracic metastases
Control of the patient's primary tumor
Potential for complete resection
Sufficient pulmonary parenchymal reserve after resection
Additional criteria for partial or complete resection of pulmonary metastases:
Provide a diagnosis
Evaluate the effects of chemotherapy on residual disease
Obtain tumor for markers, immunohistochemical studies, vaccine, etc.
Palliate symptoms
Decrease tumor burden

---

**TABLE 52.2-2.** Criteria for Resection of Pulmonary Metastases

Repeat resection of pulmonary metastasis may salvage a subset of pediatric patients with sarcomatous histologies, including OST, nonrhabdomyosarcoma STS, and Ewing's sarcoma. At the National Cancer Institute, 70 patients underwent at least one reoperation between 1965 and 1995.<sup>144</sup> Osteosarcoma predominated (36 patients), and single-wedge resection was the most common operation performed (84%). The authors noted that complete resection was the most important and favorable prognostic factor. Patients with complete resection had improved survival compared with those who were incompletely resected. Median survival was 2.25 years; in resectable patients, median survival was 5.6 years, compared to 0.7 year in unresectable patients ( $P < .0001$ ). The authors concluded that an aggressive surgical approach in patients with small numbers of nodules, a longer DFI, and the ability to obtain a complete resection is warranted and associated with prolonged survival.<sup>144</sup>

## EXTENDED RESECTION OF PULMONARY METASTASES

Pneumonectomy or other extended resection of pulmonary metastases may be performed safely in selected patients with associated long-term disease-free survival. Fewer than 3% of all patients undergoing resection of pulmonary metastases will require an extended resection. Pneumonectomy or *en bloc* resection of pulmonary metastases with chest wall or other thoracic structures, such as diaphragm, pericardium, and superior vena cava, have been performed in a small number of patients with good results.<sup>145</sup> In this series of pneumonectomy ( $n = 19$ ) and other extended resection ( $n = 19$ ), the 5-year actuarial survival rate was 25%. Mortality was 5% and occurred in those patients having pneumonectomy often after multiple prior wedge resections for metastases.

Pneumonectomy is performed infrequently for resection of pulmonary metastases. The need for pneumonectomy may be evident in the large metastases that involve the majority of one lung and that compress the heart and shift the mediastinum ([Fig. 52.2-6](#)). In a French study of 42 patients treated over 10 years,<sup>146</sup> 29 patients underwent pneumonectomy for sarcoma; 12 for carcinoma; and one for a lipoma. Most metastases were centrally located. Two postoperative deaths occurred, and four patients had major complications; five patients (12%) had recurrences in the residual lung. The median survival was only 6.25 months, and the 5-year survival rate was 16%. The standard surgical mortality for operations for pulmonary metastases is less than 1%. Patients with large centrally located metastases may require pneumonectomy for complete resection. Although mortality for pneumonectomy for pulmonary metastases corresponds to mortality for other histologies, the 5-year survival rate of only 16% demands careful selection of patients before resection. The authors suggest that young patients, those with a long DFI, and those with normal CEA levels (e.g., patients with metastases from colorectal carcinoma) be considered as potential candidates for pneumonectomy for pulmonary metastases.<sup>146</sup>

**FIGURE 52.2-6.** **A:** Chest roentgenogram with a massive pulmonary metastasis from malignant fibrous histiocytoma compressing and shifting the mediastinum into the contralateral hemithorax. Compression of the heart and airway is noted. Impairment of ventilation to the involved hemithorax and secondary compression of the contralateral hemithorax further impairs ventilation. **B:** Chest computed tomography with a massive pulmonary metastasis from osteogenic sarcoma compressing the superior vena cava, right heart, and right lung, and shifting the mediastinum into the left chest. Resection often requires extracorporeal support to allow decompression and manipulation of the heart and pulmonary veins. An approach to the right pulmonary artery and veins and the right mainstem bronchus via a median sternotomy allows for control of the pulmonary vasculature and airway before removal of the tumor.

The value of pneumonectomy was also examined by retrospective review of the International Registry of Lung Metastases.<sup>147</sup> Of the 5206 patients who were enrolled, 133 patients (2.6%) had undergone pneumonectomy for pulmonary metastases between 1962 and 1994. Eighty-four percent of these patients underwent complete resection, and the 30-day mortality rate was 3.6%. Five-year survival was 20% with complete resection. For incomplete resection, the perioperative mortality was 19%, and the majority did not survive beyond 5 years. The authors identified favorable prognostic factors of single metastasis, negative mediastinal lymph nodes, and complete resection. The authors concluded that pneumonectomy might be performed safely with adequate long-term survival.<sup>147</sup>

Intraatrial extension of sarcoma through the pulmonary vein is rare but may also be safely treated with pulmonary resection and pneumonectomy, and resection of the tumor from the left atrium ([Fig. 52.2-7](#)). Extracorporeal circulatory support (cardiopulmonary bypass) is required.<sup>148</sup>

pulmonary metastases from OST<sup>152</sup> or STS.<sup>68,154</sup>

## TUMOR-DOUBLING TIME

TDT is calculated<sup>155,156</sup> and<sup>157</sup> by measuring the same metastasis on similar studies (e.g., serial chest roentgenograms) separated by a minimum of 10 to 14 days. The most rapidly growing nodule is selected, and changing diameters of the metastasis is plotted on semilogarithmic paper. A formula may be used to precisely calculate TDT:

$$\text{TDT} = T \left[ \ln \frac{2}{3} \times \ln (M2/M1) \right] = 0.231 \times T / \ln(M2/M1)$$

where  $\ln$  is the natural logarithm,  $M1$  is the first measurement,  $M2$  is the second measurement, and  $T$  is the number of days between measurements.

Metastases from the same primary may or may not grow at similar rates, because differing growth rates between tumor nodules reflect heterogeneity of metastases from the primary. The TDT indirectly reveals the biologic nature or aggressiveness of the metastases, which influences the patient's postresection survival. The TDT may vary based on the size of the metastasis itself or the effect of chemotherapy.

Pulmonary metastases initially grow exponentially, and the growth rate slows with increased size. Growth may also be expressed by "Gompertzian" kinetics,<sup>158,159</sup> which considers a gradual diminution in TDT with time and increased size of the metastasis. TDT only reflects the growth rate during the interval measured.

TDT is not a significant predictor of postresection survival in patients with pulmonary metastases from OST.<sup>9,25</sup> TDT of more than 20 days in patients with STS resulted in a better postthoracotomy survival than those patients with rapid TDTs (less than 20 days). One study of patients with STS<sup>68</sup> found no correlation between TDT and postresection survival.

## RESECTABILITY

Complete resection consistently correlates with improved postthoracotomy survival for patients with pulmonary metastases. If pulmonary metastases cannot be completely removed, the postthoracotomy survival is shortened for patients with most tumors in comparison to those individuals completely resected.

## ENDOBRONCHIAL OR NODAL METASTASES

Involvement of mediastinal lymph nodes from pulmonary metastases is rare. Udelsman et al.<sup>41</sup> noted that patients with endobronchial metastases from adult STSs have a short postresection survival rate. Seven of 11 patients with endobronchial metastases lived 6 months or less. Jablons et al.<sup>68</sup> found that survival is poor (5 months) in patients with mediastinal lymph node involvement from STSs compared to patients without nodal metastases (31 months).

## MULTIVARIATE ANALYSIS OF PROGNOSTIC INDICATORS

Multivariate analysis of prognostic factors may define which patients are most likely to achieve long-term survival. Separate prognostic variables may be combined to enhance the predictive value for survival. Jablons et al.<sup>68</sup> noted the DFI, gender, resectability, and truncal location in patients with pulmonary metastases from STSs to be the best predictors of postthoracotomy survival. Putnam et al.<sup>10</sup> noted that a DFI of more than 12 months, a TDT of more than 20 days, and four or fewer nodules on preoperative full lung tomograms as a single prognostic indicator was the best predictor of postthoracotomy survival in patients with pulmonary metastases from STSs. Roth et al.<sup>25</sup> compared prognostic indicators in patients with OST and STS. TDT, number of metastases on preoperative full lung tomograms, and DFI, when combined, improved predictive ability over any single indicator or pair of indicators.

## NOVEL TREATMENT STRATEGIES

### MOLECULAR AND GENETIC STRATEGIES

Molecular events associated with pulmonary metastases have been identified in patients with OST. Amplification of the MDM2 gene (the human homologue of a murine p53 binding protein) may regulate p53 protein function by inactivating the protein and deregulating or enhancing tumor growth. In one small study,<sup>160</sup> no detectable MDM2 gene amplification in primary OST was found compared to 14% of metastases (three pulmonary metastases, one local metastasis). Amplification of MDM2 may be associated with metastases and tumor progression in OST.

In STS, alterations (mutations) of the p53 gene (a tumor suppressor gene) may provide for uncontrolled cell growth. Restoration of normal p53 (wild-type) in STS may provide for more controlled cell growth or even programmed cell death (apoptosis). In one *in vitro* study,<sup>161</sup> transduction of wild-type p53 into STSs bearing mutated p53 genes altered the malignant potential of the tumor. After transduction, transfected cells expressed wild-type p53, decreased cell proliferation, decreased colony formation in soft agar, and demonstrated decreased tumor formation in severe combined immunodeficient (SCID) mice *in vivo*. The ability to restore wild-type p53 function in STS *in vitro* and in SCID mice may ultimately be considered as future therapy for patients with STS.<sup>161</sup> Other investigations have shown that pulmonary metastases from STS can develop from clonal expansion of primary tumor cells bearing p53 mutations.<sup>162</sup> Examination of tissue specimens from OST and STS demonstrated p53 mutations in 25% of OSTs, yet in only 1 of 16 metastases.<sup>163</sup> Use of specific molecular markers may provide better selection of patients who will optimally benefit from surgery, chemotherapy, or other treatment modalities.

Other targets of gene therapy may include those chemotherapy-resistant tumors or those tumors with greater propensity for metastatic spread. Overexpression of the MDR1 gene product P glycoprotein is an important predictor of poor prognosis in osteosarcoma patients treated with chemotherapy. In these patients, the MDR phenotype is not *de novo* more aggressive (e.g., more metastatic); however, the poor outcome of patients with the MDR phenotype related to P glycoprotein overexpression is related to the cells' failure to respond to cytotoxic drugs.<sup>164</sup>

In another study,<sup>165</sup> 42% of patients with OSTs had metastases that expressed ErbB-2 and correlated with early development of pulmonary metastasis and poor survival. ErbB-2, therefore, may enhance tumor growth and promote metastases. These authors recommended that ErbB-2 might be considered as a prognostic factor for patients with osteosarcoma.

ErbB-2 protein is expressed in approximately 42% of osteosarcomas. It has been strongly correlated with early pulmonary metastasis and poor survival. ErbB-2 may enhance tumor aggressiveness and metastasis in osteosarcoma. As a marker, ErbB-2 may be useful as a prognostic indicator.<sup>165</sup>

A rodent model of OST has been developed with high propensity for pulmonary metastases. In this metastatic tumor model, matrix metalloproteinase 2 activity is increased as well as expression of vascular endothelial growth factor messenger RNA.<sup>166</sup>

Gene therapy strategies are being studied also. Systematic delivery of recombinant adenovirus (Ad) vector containing herpes simplex virus thymidine kinase (TK) gene [with an Osteocalcin (OC) promoter (Ad-OC-TK)] supplemented with the prodrug acyclovir (ACV) may be an effective strategy for osteosarcoma metastases to the lungs.<sup>167</sup>

Preclinical studies noted that, after Ad-OC-beta-gal administration, specific beta-gal expression was found in tumor cells deposited in the lung. Induced rat osteogenic lung metastases in nude rats were followed by systemic Ad-OC-TK and intraperitoneal ACV treatment, resulting in decreased numbers of tumor nodules and increased survival in treated animals compared to controls. Ad-OC-TK/ACV may be a future treatment for pulmonary metastases from osteosarcoma. Other preclinical treatment methods may include nebulized interleukin-2 liposomes.<sup>168</sup>

## REGIONAL DRUG DELIVERY TO THE LUNG

Novel drug delivery systems may enhance chemotherapy treatment effects by increasing drug concentration in lung tissues and minimizing systemic effects of such treatment. In many patients, surgery has been used as salvage treatment after maximal chemotherapy response has been achieved. Systemic toxicity may limit the amount of chemotherapy given to an individual patient. Regional drug delivery to the lungs minimizes systemic drug delivery, preventing systemic toxicity; however, this technique dramatically increases the drug delivered to the lung over a short period. This isolated lung perfusion technique may be done unilaterally, with the contralateral lung serving as an "oxygenator" while the ipsilateral lung is perfused. Bilateral pulmonary perfusion may be performed, although extracorporeal circulatory support (cardiopulmonary bypass) is required.

Preclinical studies in rodents with experimental pulmonary metastases from a methylcholanthrene-induced syngeneic sarcoma <sup>169,170</sup> and <sup>171</sup> have shown that chemotherapy may be delivered to pulmonary tissue in significantly higher concentrations than with systemic delivery. Minimal to no systemic toxicity was noted. In this model, isolated single-lung perfusion with Adriamycin (doxorubicin) was safe and effective. <sup>169</sup> This simple microsurgical technique was performed in rats. After left thoracotomy, the pulmonary artery and pulmonary vein were isolated and clamped. The lung was flushed before infusing doxorubicin. The infusion occurred over 10 minutes. Then the drug was flushed out before removing the cannulas and restoring circulation. A perfusion concentration of 255 mg/L caused less general toxicity than a systemic dose equivalent to 75 mg/m<sup>2</sup>, the extraction ratio was 58%, and the pulmonary tissue concentration of Adriamycin was 25-fold higher than with the systemic dose. The technique was also effective: Nine of ten animals treated at 320 mg/L had complete eradication of metastases from an implanted methylcholanthrene-induced sarcoma. <sup>169</sup>

Previous clinical studies of lung perfusion <sup>172,173</sup> have shown higher drug concentrations in pulmonary tissue, although clinical tumor response has been mixed. Johnston and colleagues <sup>173</sup> described a continuous perfusion of the lungs with Adriamycin (single lung, continuous perfusion) as a safe technique and subsequently applied their technique clinically. Drug concentrations in normal lung and tumor generally increased with higher drug dosages. Two of eight patients had major complications: One patient developed pneumonia and sternal dehiscence; one patient developed respiratory failure 4 days after lung perfusion. No objective responses occurred (none of four patients with sarcomas). Although continuous perfusion with a pump circuit offers some theoretical advantages, the technique is cumbersome, equipment-intensive, and time-consuming, and it has the inherent problem of the incompatibility of Adriamycin and heparin. Pass et al. <sup>172</sup> examined isolated single-lung perfusion with tumor necrosis factor- $\alpha$ , interferon- $\gamma$ , and moderate hyperthermia for patients with unresectable pulmonary metastases. No hospital deaths occurred, and a short-term (less than 6 months) decrease in nodule size was noted in 3 of 15 patients.

Phase I studies in patients with unresectable pulmonary metastases from STS are currently under way at the University of Texas M. D. Anderson Cancer Center. A paucity of effective treatment and the potential for high drug concentrations for pulmonary metastases by regional lung perfusion warrants further clinical study.

## INTRODUCTION

Metastatic cancer in the liver can represent the sole or life-limiting component of disease for many patients with a variety of tumor histologies, including colorectal cancer, ocular melanoma, neuroendocrine tumors, and, less commonly, other histologies. The liver is a common site of hematogenous metastases for tumors arising in the gastrointestinal tract, presumably because of the unique venous drainage through the portal venous system to the liver. On the other hand, factors that predispose ocular melanoma to metastasize almost exclusively to liver are unknown; liver metastases must occur through hematogenous spread via the arterial system. Once metastases to the liver are diagnosed, the prognosis is generally poor. Even with aggressive therapy, the median survival for patients with ocular melanoma in the liver is between 2 and 7 months<sup>1,2</sup> and 12 to 24 months for patients with colorectal cancer.<sup>3</sup> Because of the unique vascular anatomy of the liver, a number of regional therapies designed to maximize efficacy while minimizing systemic toxicity have been under clinical evaluation. For patients with colorectal cancer the ability to resect disease is associated with 5-year disease-free survival in 20% to 50% of patients,<sup>4,5,6,7</sup> and patients with liver metastases from functional neuroendocrine tumor can derive substantial palliative benefit from resection.<sup>9,10</sup> Infusional therapy is administered into the hepatic artery using intermittent percutaneous catheterization with or without particle embolization of the tumor neovasculature or via continuous hepatic artery infusional (HAI) therapy with indwelling implantable pumps. Local ablative therapy is administered via laparotomy or percutaneously placed probes or needles to deliver cryotherapy or radiofrequency ablation of tumors or direct injection of cytotoxic agents such as ethanol. Combined approaches have been used, such as adjuvant HAI after resection or local ablation, in an attempt to prolong disease control in the liver. Newer regional therapies, such as isolated hepatic perfusion (IHP) or intraarterial delivery of gene-modified viral vectors are being evaluated.

Much of the data regarding regional therapy for hepatic metastases relate to colorectal cancer because of its high incidence. It is estimated that 150,000 new cases of colorectal carcinoma occur annually in the United States and approximately 75,000 deaths occur.<sup>11</sup> Synchronous hepatic metastases are identified in 10% to 20% of patients with colorectal cancer<sup>12</sup> and are the sole or life-limiting component of disease in up to 60% of patients.<sup>13</sup> Only a small proportion of patients have resectable disease<sup>14</sup> and therefore the vast majority of patients are best suited for a regional therapy as mentioned previously. This section reviews the natural history of patients with hepatic metastases and the advances in imaging modalities. The results of resection alone or with adjuvant therapy for patients with resectable disease are presented as well as results with other regional therapies such as local ablative techniques, HAI therapies, and newer approaches such as IHP ( [Table 52.3-1](#)).

Treatment	Advantages	Disadvantages
Resection	5-year survival 20-50% for colorectal cancer patients	Requires curable or low limited number of patients suitable
Infusional therapy		
Catheterization	Can palliate large symptomatic tumor deposits	May require repeated procedures; catheterization
Hepatic artery infusion	Effects are prompt Minimal symptoms; low incidence, low high response rates Percutaneous for high hepatic metastases, reducing systemic toxicity	Large treatment are usually necessary Implantable pump is expensive, requires long survival
Local ablative therapy (cryotherapy, radiofrequency ablation, ethanol injection)	Can ablate established hepatic metastases Minimal injury to normal hepatic tissue	Requires operative procedure in right tract cases (cryotherapy) Does not treat microscopic disease Limitation on size and number of lesions that can be treated

**TABLE 52.3-1.** Various Regional Treatments under Clinical Evaluation for Cancers Confined to the Liver

## NATURAL HISTORY OF LIVER METASTASES

The natural history of hepatic metastases from various histologies has been largely derived from retrospective studies and without the benefit of routine imaging modalities currently available. For patients who are staged using computed tomography (CT), magnetic resonance imaging (MRI), or, for patients with neuroendocrine tumors, somatostatin receptor scintigraphy, survival may appear better than historic controls for whom the number and extent of hepatic metastases were not easily quantified ([Fig. 52.3-1](#)). In addition, it has become increasingly apparent that there is considerable variability in the rate of progression of disease in the liver. This is reflected by the fact that in patients with colorectal cancer metastatic to liver, there are occasional long-term survivors, and there is a considerable disparity between median and mean survival (see [Fig. 52.3-1](#)). In one series from Roswell Park Cancer Institute of 30 patients with untreated colorectal cancer metastatic to liver, the mean survival was 16 months, with a range of 2 to 58 months.<sup>15</sup> A classification system for staging of hepatic metastases has been proposed based on the number and distribution of lesions in the liver.<sup>16</sup> Heterogeneity in tumor progression has also been demonstrated in patients with neuroendocrine tumors metastatic to liver.<sup>17</sup>

**FIGURE 52.3-1. A:** Survival in patients with untreated colorectal cancer with metastases confined to the liver based on percent hepatic replacement of less than or equal to 20 (*dotted line*) or greater than 20 (*solid line*). **B:** Survival in patients with metastatic ocular melanoma with or without hepatic metastases. (Modified from refs. 19 and 22.)

In an older series of 125 patients with colorectal metastases to liver staged primarily with technetium 99 sulfur colloid scans, the overall median survival was 12.5 months.<sup>3</sup> Extent of disease and histologic grade of the tumor were the two most important factors influencing survival. Those with four or more nodules, hepatomegaly, or abnormal liver test results had a median survival of less than 12 months. The immediate cause of death was liver failure in almost 90% of patients despite the coexistence of metastases to other sites in 40% of patients. In another series of 175 patients with hepatic metastases from colorectal cancer, factors potentially influencing survival were subjected to a multifactorial analysis.<sup>18</sup> Although median survival in the group was only 6.1 months, one patient survived for 67 months. Extent of disease as reflected by the number of hepatic nodules, bilobar disease, or abnormal liver test results was independently correlated with survival. Stage of the primary tumor and number of positive lymph nodes also correlated with outcome. In a series from the United Kingdom of 90 patients with colorectal cancer metastatic to liver there was a median survival of 10.3 months.<sup>19</sup>

In a more recent series of 544 patients with unresectable colorectal liver metastases documented by laparotomy, CT, or ultrasound, the factors that independently predicted outcome on multivariate analysis were performance status, extent of liver disease (number of involved segments), abnormal liver test results (prothrombin time and alkaline phosphatase), and site of primary.<sup>14</sup> Those with no adverse factors (i.e., normal performance status and liver test results) had a 1-year survival of 46%. The apparent beneficial effect from chemotherapy in retrospective studies of patients with liver metastases from colorectal cancer and other histologies<sup>3,14,18,20</sup> probably reflects selection bias rather than true treatment effect. In general, patient factors such as gender or age do not influence survival, whereas performance status, which reflects tumor burden, does.<sup>3,14,18,19</sup>

In patients with treated primary ocular melanoma the overall 5-year survival is approximately 70%, but once metastases occur the liver is the sole or life-limiting component of disease in 70% to 80% of patients.<sup>2,21</sup> Age older than 50 years and male gender are associated with a shorter survival after recurrence,<sup>2</sup> but the most important factor influencing outcome is the presence of liver metastases<sup>22</sup> (see Fig. 52.3-1). In one study, median survival in patients with recurrence was 19 months, but only 7 months when the liver was involved.<sup>22</sup> Although survival is longer in patients with liver metastases diagnosed by screening (5 vs. 3 months) and in those receiving treatment (5 vs. 2 months), the differences in terms of individual patient benefit are negligible and highlight the grave prognosis associated with liver metastases.<sup>1</sup>

Ayoub and coworkers reported outcome in more than 1500 patients with metastases from unknown primary tumors.<sup>20</sup> Five hundred patients had metastases to liver, of whom 27% (135 patients) eventually had primary tumors diagnosed arising from lung, colon or rectum, or pancreas. The presence of liver metastases was associated with a significantly shorter survival, but was most favorable in those with neuroendocrine histology. Sutliff and coworkers have shown that the pattern of progression in patients with metastatic gastrinoma to liver is highly variable.<sup>17</sup> Over a follow-up interval of 29 months, 5 of 19 (26%) demonstrated no growth of tumor, whereas 42% had rapid growth in less than 1 year. Tumor progression, most commonly in liver, is the main determinant of survival in patients with gastrinoma.<sup>23,24</sup> For patients with other functional neuroendocrine tumors, liver metastases and the development of the uncontrolled sequelae from excess hormone production are the main causes of death.<sup>25</sup>

## IMAGING OF HEPATIC METASTASES

Currently there are several imaging options available for assessment of liver metastases. Considerable advancement in imaging technology has made it possible to accurately detect the number, size, and distribution of hepatic lesions and frequently distinguish between malignant or benign lesions. The most commonly used tests include CT scan, MRI, ultrasound, and, more recently, positron emission tomography using the glucose analogue, [<sup>18</sup>F]fluorodeoxyglucose. Ultrasound is commonly used for screening because of its availability and relative inexpensiveness, but has its most important application as an intraoperative modality to assess suitability for resection and to gauge the adequacy of treatment when using cryotherapy. In general, intraoperative ultrasound identifies 20% more occult lesions in the liver compared with CT scan<sup>26</sup> and therefore should be used before any contemplated resection.

CT scan is used most commonly to assess a patient with possible hepatic metastases. It has the advantages of being widely available and, by using new generation rapid acquisition scanners, the entire chest, abdomen, and pelvis can be evaluated in a single study.<sup>5</sup> Moreover, the use of rapid helical or spiral CT allows for a scan of the entire abdomen in a single breath hold, eliminating the problem of respiratory misregistration. Because liver tumors have a variable degree of vascularity and derive their perfusion from the arterial tree, CT arteriography has been used to enhance the sensitivity of the test, particularly for hypovascular lesions, but involves placement of a catheter and injection of contrast into the superior mesenteric artery with capture of images during both the arterial and portal venous phase of hepatic perfusion.<sup>27</sup> Dual arterial and venous phase CT scans after intravenous injection of contrast agent using high-speed helical CT scanners are now commonly used in place of CT arteriography,<sup>28</sup> but may have limited additional sensitivity for detection of hypovascular tumors compared with portal phase CT alone.<sup>29</sup> On the other hand, because hypervascular lesions are frequently isoattenuating in relation to normal liver parenchyma, arterial phase helical CT detects more liver metastases than conventional portal venous phase CT in this setting.<sup>30</sup>

MRI scanning is also used routinely and has particular advantages for imaging of focal liver lesions. Two contrast agents with liver specificity are currently being used; one is manganese pyridoxal disphosphate, a paramagnetic agent taken up by hepatocytes, and the other is superparamagnetic iron oxide particles, which are taken up by the reticuloendothelial system.<sup>31,32 and 33</sup> The optimal MRI protocols for evaluation of liver lesions vary depending on the available equipment and contrast agents being used. Although there are disadvantages with MRI because of motion artifact from the heart or aorta, it can distinguish benign cysts or hemangiomas from malignant lesions based on characteristic findings on T1 versus T2 spin-weighted sequences.<sup>31</sup>

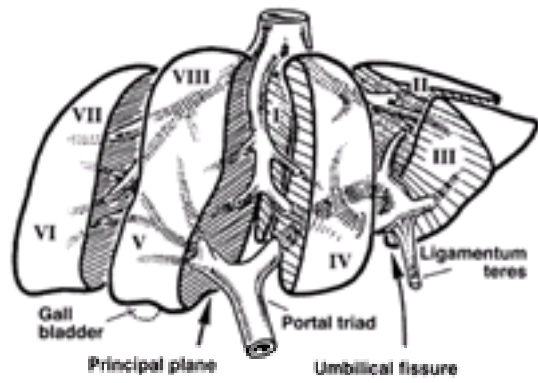

Positron emission tomography scanning uses the glucose analogue [<sup>18</sup>F]fluorodeoxyglucose, which is selectively retained in malignant tissue because of increased glucose metabolism compared with nonneoplastic tissue. It has been shown to have sensitivity comparable with CT scan and can often distinguish benign and malignant lesions, but has potential for false-positive findings in abscesses and false-negative findings in hepatocellular carcinoma.<sup>34</sup> Somatostatin receptor scintigraphy has been used with increasing regularity and is extremely accurate in imaging neuroendocrine tumors,<sup>35,36 and 37</sup> with the exception of insulinoma, and may be superior to MRI in detecting islet cell tumors in liver.<sup>35</sup> In addition, because hemangiomas are not visible on somatostatin receptor scintigraphy, the study can be used to distinguish benign versus malignant lesions when there are equivocal findings on CT or MRI.<sup>38</sup>

## RESECTION OF HEPATIC METASTASES

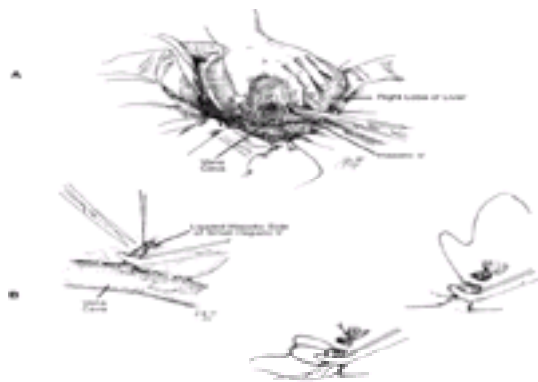

### RESECTION OF METASTATIC DISEASE: TECHNICAL CONSIDERATIONS

The benefit of resection in selected patients with hepatic metastases from colorectal cancer and potentially other histologies, such as neuroendocrine tumors, has been fairly well established in the literature. Several advances in hepatic surgery have made hepatic resection a more routine procedure with minimal patient morbidity. Initial evaluation of the abdominal cavity at exploration should be carefully done to exclude the presence of extrahepatic disease. Intraoperative ultrasound should be routinely used to screen for the presence of deep-seated or occult metastases, and resection should be based when possible on functional anatomic

considerations, including segmental resection, to preserve unaffected hepatic parenchyma and minimize blood loss during resection ( Fig. 52.3-2). The liver is mobilized, including division of the falciform and left or right triangular ligaments, depending on the nature of the resection. A cholecystectomy is performed, and the small direct venous branches between the liver and vena cava are systematically isolated, ligated, and divided ( Fig. 52.3-3). The division of the portal triad structures and hepatic vein on the side of resection are being done more frequently with the use of vascular stapling devices. It is usually possible to isolate and divide the hepatic vein in its extrahepatic position before commencing parenchymal dissection. Vascular inflow occlusion via the Pringle's maneuver and maintenance of a low central venous pressure minimizes blood loss during dissection of the hepatic parenchyma.<sup>39,40</sup> Extensive resection involving contiguous vena caval resection or reimplantation of the hepatic veins are rarely indicated but have been reported.<sup>41,42</sup> Argon beam coagulation helps with hemostasis after resection. Drains are not routinely used in uncomplicated hepatic resection, and early ambulation of the patient is advisable. The mortality associated with major hepatic resection is less than 5% and is most commonly secondary to inadequate hepatic synthetic reserve<sup>5,6,7</sup> and<sup>8</sup> (Table 52.3-2). Other complications from hepatic resection include biliary fistula, hemorrhage, and abscess or wound infection.<sup>6</sup>

**FIGURE 52.3-2.** Segments of the liver used in planning hepatic resection. The principal plane divides the right and left lobes of the liver. Extent of hepatic resection planned on the basis of an understanding of the segmental anatomy of the liver has resulted in minimal morbidity and mortality associated with the procedure. (Modified from ref. 6.)

**TABLE 52.3-2.** Results of Resection of Colorectal Liver Metastases from Selected Series

### RESULTS OF HEPATIC RESECTION FOR COLORECTAL CANCER

The overall 5-year survival after resection of hepatic metastases in patients with colorectal cancer ranges from 25% to almost 40% in recent series (see Table 52.3-2). Factors associated with improved outcome after resection in most series include tumor- and treatment-related variables. Patient characteristics, such as age or gender, have not been identified as significant prognostic variables, but elevation in preoperative serum carcinoembryonic antigen levels is associated with poorer outcome in most series.<sup>43,44</sup> and<sup>45</sup> Tumor-related factors associated with poor outcome after resection include positive lymph node status of the primary tumor, a disease-free interval between resection of the primary tumor and liver metastases less than 1 year, and the presence of extrahepatic disease, including regional periportal lymph nodes. With respect to the liver metastases, factors that generally reflect advanced tumor burden, such as increasing number of lesions,<sup>43,46,47</sup> size of largest lesion larger than 5 or 10 cm,<sup>47,48</sup> bilobar distribution of disease,<sup>49,50</sup> percent hepatic replacement,<sup>51</sup> or weight of resected specimen,<sup>43</sup> have been shown to predict shorter survival compared with those without these parameters ( Fig. 52.3-4). Satellitosis,<sup>48,52</sup> tumor grade,<sup>43,44</sup> and ploidy<sup>53</sup> have been reported as negative prognostic variables. Treatment or technical factors predictive of poor outcome include positive resection margin,<sup>46,48,50,54</sup> margin smaller than 1 cm,<sup>55</sup> and, in some studies, intraoperative transfusion.<sup>44,52</sup> Repeat hepatic resection in selected patients has been reported with 5-year survival rates ranging from 21% to 26%.<sup>56,57,58,59</sup> and<sup>60</sup>

**FIGURE 52.3-4.** Five-year overall survival in patients undergoing resection of hepatic metastases from colorectal cancer based on number of lesions. Survival is

better in patients with one lesion (*open square*) compared with those with two or three (*filled triangles*) or four or more lesions (*filled boxes*). (From ref. 45, with permission.)

Fong and coworkers<sup>45</sup> have developed a clinical scoring system using five widely used and available clinical and pathologic parameters to predict outcome after resection of colorectal liver metastases (Table 52.3-3). Based on the outcome of 1001 patients undergoing resection with curative intent, an increasing clinical risk score was associated with decreased survival (Fig. 52.3-5). Of note, patients with a clinical risk score of 5 had an actuarial 5-year survival of only 14% and in fact no patient had survived 5 years at the time of the report. These data provide a basis for stratification of patients at high risk of recurrence after hepatic resection and may provide a method of selecting those suitable for adjuvant treatments postoperatively.

Score	Survival (%)			
	1-Y	3-Y	5-Y	Median (mo)
0	93	72	60	74
1	91	66	44	51
2	89	60	40	47
3	86	42	20	33
4	70	38	25	20
5	71	27	14	22

\*Each risk factor is one point: node-positive primary, disease-free interval less than 12 months, greater than one tumor, size greater than 5 cm, carcinoembryonic antigen greater than 200 ng/mL. (Modified from ref. 45.)

**TABLE 52.3-3.** Clinical Risk Score for Tumor Recurrence in Patients Undergoing Resection for Colorectal Metastases to Liver <sup>a</sup>

**FIGURE 52.3-5.** Five-year overall survival in 1001 patients with metastatic colorectal cancer to the liver undergoing resection with curative intent. Outcome was analyzed based on the absence or presence of various prognostic factors as outlined in Table 52.3-3. Patients with 0 or 1 prognostic factor had improved survival compared with those with increasing numbers of adverse prognostic variables ( $P < .0001$ ). *Open box* score = 0; *filled triangle* score = 1; *open circle* score = 2; *filled circle* score = 3; *filled box* score = 4; and *open triangle* score = 5. (From ref. 45, with permission.)

### POSTHEPATIC RESECTION ADJUVANT HEPATIC ARTERY INFUSIONAL OR INTRAVENOUS THERAPY IN COLORECTAL CANCER

Several nonrandomized clinical investigations in the United States, Germany, and Japan suggest a potential advantage for the use of adjuvant chemotherapy after complete surgical resection of hepatic metastases in patients with colorectal carcinoma. Using weekly hepatic arterial infusion of 5-fluorouracil (5-FU) at a dose of 15 mg/kg for an intended course of 6 months, investigators at M. D. Anderson Cancer Center noted an extrahepatic-only recurrence rate of 33% and a liver-only recurrence rate of 17% in 20 patients.<sup>61</sup> At 39 months of follow-up, 50% of patients were alive and free of disease. In a nonrandomized but prospective study, Lorenz and colleagues from Germany found a nonsignificant prolongation in median survival ( $P = .064$ ) of 52 months in 60 patients treated with resection followed by hepatic arterial therapy with either floxuridine (FUDR) or 5-FU with or without leucovorin (LV) versus 33 months in 21 patients treated with surgery alone. Furthermore, these investigators noted a marked delay in the time to hepatic recurrence from 17 months to 63 months ( $P = .015$ ) in patients treated with adjuvant chemotherapy versus those treated with surgery alone.<sup>62</sup> With a median follow-up of more than 2 years, Okuno and colleagues studied the recurrence rate in 18 patients treated with surgical resection followed by hepatic arterial interleukin-2 plus 5-FU (250 mg) and mitomycin C (4 mg) given weekly for 6 months and found an overall recurrence rate of 22% with no recurrences in the liver (17% lung; 6% pelvis).<sup>63</sup> More recently, investigators in Japan performed a retrospective investigation of 174 patients who had been treated with hepatic resection for metastases resulting from colorectal carcinoma and identified three separate groups, including those treated with surgery alone (66 patients), surgery plus hepatic artery infusion (78 patients), and surgery plus peripheral venous infusion (30 patients).<sup>64</sup> The hepatic arterial therapy consisted of 5-FU, 50 mg/m<sup>2</sup>/d × 14 days, plus bolus injections of an anthracycline analogue, aclarubicin (40 mg), suspended in a lipid contrast medium given every 3 to 6 months for up to 3 years. These investigators noted that the patients treated with surgery followed by hepatic artery infusion had a significantly decreased hepatic recurrence rate and a more prolonged disease-free and overall survival compared with either of the other groups and had a 5-year survival rate of 35% compared with 13% for those treated with surgery plus peripheral venous infusion therapy and 9% for those treated with surgery alone. Investigators from Tokyo retrospectively analyzed 115 patients with hepatic-only metastatic colorectal carcinoma treated with potentially curative therapy with resection alone (40 patients) versus surgery followed by either hepatic arterial (28 patients) or intraportal vein (ten patients) 5-FU/LV, with or without mitomycin C, versus surgery followed by either oral or systemic intravenous mitomycin C, or 5-FU, or oral tegafur with or without uracil (37 patients).<sup>65</sup> These investigators found an overall 5-year survival for all patients of 42.2%. Estimates of median survivals from the published graphs show survivals of 35, 43, and 60 months for those patients treated with surgery alone versus surgery plus HAI versus surgery plus systemic therapy, respectively. Although these differences did not reach statistical significance, the disease-free survival appeared to be statistically worse in patients treated with surgery alone compared with those who received systemic adjuvant therapy. Nonami and colleagues from Japan, in a nonrandomized trial, treated patients with metastatic colorectal carcinoma using surgery alone (26 patients) or surgery followed by hepatic arterial 5-FU (250 mg/kg/d × 14 days) plus an anthracycline (20 to 40 mg/kg days 1 and 8), plus mitomycin C (4 to 8 mg/kg days 1 and 8) (31 patients) every 3 months for 1 year.<sup>66</sup> These investigators noted an approximately 12% 5-year survival rate for patients treated with surgery alone versus 57% for those treated with surgery followed by hepatic artery chemotherapy.

Based on relatively promising results from nonrandomized studies, several groups have conducted prospective randomized studies with the goal of defining the role of adjuvant chemotherapy in patients with metastatic colorectal carcinoma treated with complete surgical resection of hepatic metastases. As shown in Table 52.3-4, an intergroup trial randomized 109 patients with isolated hepatic metastases from colorectal carcinoma to treatment with either surgery alone (56 patients) or surgery followed by continuous hepatic artery infusion of FUDR for four cycles plus systemically administered 5-FU for 12 cycles (53 patients).<sup>67</sup> Although none of the survival differences reached a statistically significant level, those patients treated with surgery followed by chemotherapy enjoyed a 63% 5-year survival versus 32% for those treated with surgery alone. The median survival for those treated with surgery plus chemotherapy of 34.2 months was less, albeit not significantly less, than those treated with surgery (47.5 months). A significant decrease in overall recurrence rate was noted for the group treated with surgery plus chemotherapy (42% vs. 66%) as well as a decrease in hepatic-only recurrences (26% vs. 55%) compared with those treated with resection alone. Investigators from Memorial Sloan-Kettering Cancer Center randomized 74 patients with hepatic-only disease to surgery followed by hepatic arterial FUDR and dexamethasone plus systemic therapy with 5-FU plus LV for 6 months and 82 patients to surgery followed by systemic therapy with 5-FU/LV alone for 6 months.<sup>68</sup> These investigators found a statistically significant improvement in 2-year survival rate of 86% for those treated with both HAI and systemic chemotherapy versus those treated with surgery followed by systemic chemotherapy alone (72%) ( $P = .023$ ) (see Table 52.3-4). Furthermore, although the overall recurrence rates were not different between the two groups, there was a marked decrease in hepatic recurrence in the group treated with the addition of HAI chemotherapy (10% vs. 40%,  $P = .00012$ ). Toxicities were similar for the two groups of patients, with the exception of a greater incidence of grade 3 to 4 diarrhea and an 18% incidence of hyperbilirubinemia (greater than 3) in those patients

treated with the addition of the hepatic artery therapy. In all but one patient, the bilirubin returned to normal.

Group	Regimen	No. of Patients	Survival		Recurrence

**TABLE 52.3-4.** Prospective Randomized Trials of Adjuvant Chemotherapy following Hepatic Resection in Patients with Metastatic Colorectal Cancer

Lygidakis and colleagues from Greece found an almost threefold increase in median survival from 11 to 30 months and a decrease in hepatic recurrence rates from 40% to 0% in patients treated with surgery followed by chemoimmunotherapy.<sup>69</sup> Chemoimmunotherapy consisted of splenic and gastroduodenal artery infusion of interferon-g and interleukin-2 emulsified in radiographic contrast medium. In addition, patients received bolus transarterial infusion of mitomycin C, carboplatin, 5-FU, LV, and an anthracycline analogue every 3 to 6 months for 3 years. In contrast to these studies, Lorenz and colleagues from Germany prospectively randomized a total of 226 patients to treatment with surgery alone (113 patients) versus surgery followed by hepatic arterial 5-FU (1000 mg/m<sup>2</sup>/d) plus LV (200 mg/m<sup>2</sup>/d) given for 5 days each month for 6 months (see Table 52.3-4). The investigators found no difference in overall median survival or time to disease progression and concluded that it was highly unlikely that the addition of chemotherapy to surgical resection would improve survival by more than 15%.<sup>70</sup> However, the power of this study to detect differences was markedly reduced by a substantial decrease in the number of patients completing the chemotherapy (only 34 of 113 randomized to the adjuvant arm). These studies generally support the use of adjuvant chemotherapy after surgical resection of hepatic metastases in high-risk patients with colorectal carcinoma.

### NEOADJUVANT THERAPY FOR INITIALLY UNRESECTABLE COLORECTAL HEPATIC METASTASES

Chemotherapy has also been used in a neoadjuvant setting for those patients initially deemed inoperable with the goal of enabling resection. Bismuth and coworkers treated 53 patients with initially unresectable disease with systemic chemotherapy, which included 5-FU/LV and oxaliplatin, for an average of 8 months before resection and for at least 6 months after surgery. Major hepatectomy was performed in 37 patients and minor resections in the balance of patients. Although surgical complications occurred in 14 patients, there was no operative mortality. Although hepatic recurrence was observed in 66% of patients, the overall 5-year survival was found to be 40%, suggesting a potential role for neoadjuvant chemotherapy in patients initially considered unresectable.<sup>71</sup>

### RESULTS OF RESECTION FOR NONCOLORECTAL CANCERS

Series of hepatic resection for tumor histologies other than colorectal cancer have been reported, but the benefit of this approach has not been conclusively demonstrated. Table 52.3-5 summarizes outcomes of selected series of patients with different histologies. There are anecdotal reports of long-term survivors after hepatic resection for noncolorectal gastrointestinal primary tumors such as gastric or pancreatic cancer<sup>72,73</sup>; however, this is not considered standard treatment as most patients with advanced upper intestinal adenocarcinomas have recurrences at multiple sites in addition to liver such as lymph nodes and peritoneum. Five-year survival in patients undergoing resection of neuroendocrine hepatic metastases ranges from 10% to 54%.<sup>10,74,75,76,77</sup> and<sup>78</sup> Chen and coworkers reported that outcome was significantly improved in patients undergoing resection compared with a retrospectively matched cohort who did not undergo resection.<sup>77</sup> Actuarial 5-year survival after resection of clinically isolated hepatic metastases in breast cancer patients is reported between 9% and 18%.<sup>79,80</sup> Based on the typical systemic pattern of recurrence in patients with advanced breast cancer, this approach must be considered palliative in nature with little expectation of long-term disease control. Other histologies for which hepatic resection has been reported include metastatic soft tissue sarcoma<sup>81</sup> and cutaneous<sup>82</sup> or ocular<sup>83</sup> melanoma. Actuarial 5-year survival of 60% has been reported for patients undergoing resection for tumors arising from the genitourinary tract, including testicular, adrenal, ovarian, renal, uterine, and cervix.<sup>84,85</sup> Presumably, patients with noncolorectal cancers and hepatic metastases were selected for operation based on factors thought to be favorable such as a long interval of radiographically isolated and resectable liver metastases and good operative risk.

### INFUSIONAL THERAPY FOR HEPATIC METASTASES

#### HEPATIC ARTERY INFUSIONAL THERAPY: TECHNICAL CONSIDERATIONS

HAI therapy has had substantial clinical application based on the development of an implantable pump (or port) that can deliver a continuous infusion of therapeutic agents via the hepatic artery and the availability of agents that have an established pharmacokinetic advantage for HAI delivery because of a high first-pass extraction in liver and a concentration-dependent therapeutic effect. The implantable pump is a low-profile dual-chamber device that is placed in a subcutaneous pocket over the lower abdominal wall connected to a catheter that is positioned in the gastroduodenal artery for infusion of agents into the liver via the hepatic artery.<sup>86</sup> The pump is activated by filling the inner chamber with saline or therapeutic agent and as the inner reservoir expands it compresses a hydrofluorocarbon gas contained in the outer chamber from a gas to a liquid (see Chapter 29.2). The body temperature then expands the gas, thereby compressing the inner chamber's contents through a resistor to maintain constant flow into the arterial catheter.

The two most important technical considerations in placing the device are to ensure that the entire liver is perfused with the therapeutic agent and that no extrahepatic visceral perfusion occurs. Typically patients undergo preoperative angiography to define the arterial anatomy of the liver. All accessory or aberrant arterial vessels should be ligated. In addition, careful dissection of the gastroduodenal artery and hepatic artery should be performed to ensure that no collateral flow to the viscera occurs. Distribution of the infusate is assessed with fluorescein intraoperatively and postoperatively using technetium 99–labeled albumin scintigraphy before commencing therapy. Interestingly, a positive arterial nuclide scan using technetium 99–labeled macroaggregated albumin has been shown to predict tumor response to subsequent intraarterial therapy.<sup>87</sup>

As an alternative, an arterial catheter connected to a subcutaneously placed port can be used that is accessed with a noncoring Huber's needle and the infusate delivered by an external programmable infusion pump.<sup>88</sup> This device has been used because of the considerably higher cost of the implanted pump although

maintenance costs are higher with the port. Fordy and coworkers evaluated the frequency of treatment interruptions and complication rates associated with the use of either device in 95 patients undergoing a total of 959 treatment cycles.<sup>88</sup> The port was associated with a significantly higher incidence of catheter blockages requiring nurse intervention, and in ten cases the needle dislodged during infusion. Because of the higher complication rate with ports, there were treatment interruptions in 5.7% of treatments compared with only 1.7% for pumps. Curley and coworkers reviewed the technical aspects of arterial port or pump placement in 180 patients<sup>89</sup> and found aberrant hepatic arterial anatomy in 37% of patients. Ligation of the variant vessel is normally all that is required except in rare circumstances in which temporary occlusion of the variant vessel results in severe ischemia of one hepatic lobe. In this case, a two-cannulae system may be necessary. Although the early complication rate (within 30 days of the procedure) is 5% for both ports and pumps, the late complication rate is twofold greater for ports (49%) versus pumps (28%). Operative mortality from placement of any device is less than 1%.<sup>90</sup>

Treatment responses have been reported to be the same after HAI therapy in colorectal cancer patients with aberrant arterial anatomy compared with those with normal anatomy by some<sup>89</sup> but not by others.<sup>91</sup> Burke and coworkers found that aberrant arterial anatomy occurred in 18% of patients and was associated with reduced effectiveness after 4 months of therapy.<sup>91</sup> Complete perfusion of the liver is essential for adequate delivery of drug to tumor<sup>92</sup> and if incomplete or misperfusion is demonstrated after catheter placement, it can usually be corrected by selective angiography and coil embolization of the necessary artery.<sup>93</sup> It also appears that surgeon experience is an important factor in minimizing complications during device placement.<sup>94</sup> Because of the desire to minimize complications and treatment interruptions in patients with a potentially limited life expectancy, the implanted pump is most commonly used.

It has long been known that established tumor metastases derive their blood supply from the arterial anatomy.<sup>95</sup> FUDR is a 5-FU derivative<sup>96</sup> that has a high first-pass extraction in liver, 94% to 99% compared with 20% to 55% for 5-FU.<sup>97,98</sup> After injection of FUDR into the hepatic artery or portal vein, the mean concentration of FUDR in liver is similar, but tumor concentrations of FUDR are significantly higher after intraarterial injection.<sup>99</sup> Furthermore, FUDR is rapidly cleared from the systemic circulation and has a short (less than 10-minute) serum half-life. Other drugs with a short serum half-life and for which there is a pharmacokinetic advantage for intraarterial therapy include cisplatin, doxorubicin, mitomycin C, and bischlorethynitroureas.<sup>4</sup>

### HEPATIC ARTERY INFUSIONAL THERAPY FOR COLORECTAL CANCER

A number of phase II studies have evaluated continuous HAI of FUDR administered over a 14-day interval repeated every 28 days in patients with colorectal cancer metastatic to liver, many of whom had failed prior systemic therapy with 5-FU.<sup>99,100</sup> These studies documented that HAI with FUDR or 5-FU consistently resulted in overall response rates substantially greater than that seen with systemic therapy. In ten reported trials, the mean response rate was 42% (range, 15% to 83%) and median survival ranged from 12 to 26 months.<sup>101</sup> However, the initial results with FUDR administered via HAI were associated with an unacceptable incidence of biliary toxicity manifested by ischemic cholangiopathy and increased serum bilirubin (Table 52.3-6). Several modifications have been made to the initial regimens to optimize efficacy and minimize toxicity, including alternating FUDR and 5-FU,<sup>102</sup> reducing the dose of FUDR, and adding LV<sup>103</sup> and dexamethasone.<sup>104</sup>

Regimen	Regimen	No. of Patients	Clinical Response (%)	Biliary Sclerosis (%)	Survival (%)	Toxicity (%)
Kemeny <sup>99</sup>	0.3 mg/kg/d FUDR	46	42	10	17	8
Chang <sup>100</sup>	0.3 mg/kg/d FUDR	24	79	20	17	25
Kemeny <sup>101</sup>	0.3 mg/kg/d FUDR, leucovorin, 15 mg/m <sup>2</sup> d, and 20 mg dexamethasone	42	49	3	—	8
Yang <sup>102</sup>	0.3 mg/kg/d FUDR + 5-FU, 15 mg/m <sup>2</sup> d, into subcutaneous day 15, 22, 29 with weekly cycle	54	34	1	—	—

FUDR, fluorouracil.

TABLE 52.3-6. Hepatic Arterial Infusion Therapy Toxicity

Kemeny and coworkers reported that 0.3 mg/kg/d of FUDR, 15 mg/m<sup>2</sup>/d of LV, and 20 mg of dexamethasone administered as a 14-day infusion to 33 previously untreated patients with metastatic colorectal cancer to liver resulted in an overall response rate of 78% and a median duration of survival of almost 25 months.<sup>104</sup> In 29 previously treated patients, the regimen resulted in an overall response rate of 52% and a median survival of 13.5 months. The addition of dexamethasone was associated with a significantly lower incidence of biliary sclerosis compared with the same regimen without dexamethasone (3% vs. 21%, respectively) without adversely affecting response rates (75% vs. 69%, respectively).

A number of prospective random assignment trials were reported in the 1980s and 1990s comparing FUDR administered via HAI to either systemic therapy or best supportive care (Table 52.3-7). In general, all studies demonstrated a significantly superior response rate for HAI compared with systemic therapy, but this did not consistently translate into a survival advantage due to several possible explanations. Three of the five studies conducted in the United States, including the two largest, allowed patient crossover, thereby obscuring any potential survival advantage for HAI therapy. The dose of FUDR used in these trials, 0.3 mg/kg/d, was associated with significant toxicity, resulting in treatment interruptions for many patients. In addition, technical difficulties with pump placement or function prevented some patients from receiving HAI therapy. For example, in the Northern California Oncology Group trial, 9 of 67 patients randomized to HAI therapy did not receive therapy because of technical difficulties with pump placement or function, and of 50 evaluable patients receiving HAI therapy, one-half of the patients terminated therapy because of toxicity rather than disease progression.<sup>105</sup> Twenty-eight of 65 patients receiving intravenous therapy crossed over to HAI therapy, and although median survival was longer in those treated with HAI versus intravenous only, these differences may be due largely to a favorable selection bias in those able to undergo crossover treatment. Another prospective random assignment trial from the Memorial Sloan-Kettering Cancer Center evaluated response and survival for patients with laparotomy-confirmed unresectable disease confined to liver treated with HAI or intravenous therapy.<sup>106</sup> Although there was a significantly higher response rate with HAI therapy compared with intravenous therapy (50% vs. 20%, respectively), no overall survival differences were observed. Of note, in both studies in which crossover was allowed, the responses to those previously treated with intravenous therapy were lower than those treated initially with HAI. In the study from the National Cancer Institute, significant biliary sclerosis was observed in 21% of patients.<sup>107</sup> In an unplanned subgroup analysis, there was a significant survival advantage in the group with histologically negative periportal lymph nodes who received HAI therapy. Because patients in the intravenous therapy arm did not have the benefit of surgical staging, improved outcome in the HAI node-negative group was presumably due to more accurate surgical staging and exclusion of those with occult extrahepatic disease. The other United States trial that did not allow crossover to HAI therapy was from the Mayo Clinic, and no difference in overall survival was observed between groups.<sup>108</sup>

Regimen	Regimen	Response Rate		Biliary Sclerosis		Survival	
		No. of Patients	Response (%)	No. of Patients	Sclerosis (%)	No. of Patients	Survival (%)
Kemeny <sup>99</sup>	0.3 mg/kg/d FUDR	46	42	10	10	17	17
	0.3 mg/kg/d FUDR, leucovorin, 15 mg/m <sup>2</sup> d, and 20 mg dexamethasone	42	49	3	3	—	—
Chang <sup>100</sup>	0.3 mg/kg/d FUDR	24	79	20	20	17	17
	0.3 mg/kg/d FUDR, leucovorin, 15 mg/m <sup>2</sup> d, and 20 mg dexamethasone	24	79	20	20	17	17
Kemeny <sup>101</sup>	0.3 mg/kg/d FUDR, leucovorin, 15 mg/m <sup>2</sup> d, and 20 mg dexamethasone	42	49	3	3	—	—
	0.3 mg/kg/d FUDR, leucovorin, 15 mg/m <sup>2</sup> d, and 20 mg dexamethasone	42	49	3	3	—	—
Yang <sup>102</sup>	0.3 mg/kg/d FUDR + 5-FU, 15 mg/m <sup>2</sup> d, into subcutaneous day 15, 22, 29 with weekly cycle	54	34	1	1	—	—
	0.3 mg/kg/d FUDR + 5-FU, 15 mg/m <sup>2</sup> d, into subcutaneous day 15, 22, 29 with weekly cycle	54	34	1	1	—	—

TABLE 52.3-7. Hepatic Arterial Infusion Therapy: Randomized Trials in Colorectal Cancer

Two European studies did show a survival advantage, but patients were randomized to HAI therapy or best supportive care, which included cytotoxic therapy in only one-third of patients, a control treatment arm not commonly used in the United States. The study from the United Kingdom treated patients with 0.2 mg/kg/d of FUDR, which was well tolerated.<sup>109</sup> Overall survival and improved quality of life were observed in the treated versus best supportive care group in whom intravenous chemotherapy was administered for palliation of symptoms only. The French study also demonstrated a survival benefit with HAI therapy; only one-half of the patients in the control arm received systemic therapy.<sup>110</sup>

Two metaanalyses of the published prospective random assignment trials have concluded there is a modest survival advantage to HAI therapy<sup>111,112</sup> (Fig. 52.3-6). Currently, there is another ongoing prospective random assignment trial in the United States (cancer and leukemia group B 9841). This is a noncrossover design trial with stratification parameters for extent of hepatic involvement, prior chemotherapy, and the presence or absence of synchronous primary disease. The HAI treatment arm will receive a 14-day infusion of 0.18 mg/kg/d of FUDR, 10 mg/m<sup>2</sup> of LV, and 20 mg of dexamethasone, a combination previously associated with a 78% response rate and a low incidence of biliary toxicity.<sup>104</sup> The systemic therapy arm will receive 425 mg/m<sup>2</sup>/d of 5-FU and 20 mg/m<sup>2</sup>/d of LV for 5 days.

**FIGURE 52.3-6.** Five-year overall survival in patients with metastatic colorectal cancer to the liver treated with hepatic artery infusional (HAI) therapy using a floxuridine-based regimen compared with systemic therapy (No HAI). Survival curves based on a metaanalysis of the published literature of phase III random assignment trials comparing these two treatment strategies. HAI therapy has a significantly improved survival compared with those treated with no HAI therapy (Log rank test,  $P = .0009$ ). (From ref. 112, with permission.)

## OTHER APPLICATIONS OF HEPATIC ARTERY INFUSIONAL THERAPY

HAI therapy has been used with other agents for patients with various histologies, including interleukin-2 and chemotherapy for colorectal cancer patients,<sup>113</sup> doxorubicin for hepatocellular cancer patients,<sup>114</sup> and carboplatin<sup>115</sup> or fotemustine<sup>116</sup> for patients with metastatic ocular melanoma to liver. Leyvraz and coworkers treated 31 patients with ocular melanoma metastatic to liver with 100 mg/m<sup>2</sup> as a 4-hour infusion weekly for 3 weeks followed by a repeat cycle every 21 days via an implanted intraarterial port.<sup>116</sup> Objective radiographic responses were observed in 12 of 30 assessable patients (40%), and the median duration of response was 11 months. These data are similar to those reported with chemoembolization<sup>117</sup> and show encouraging activity in a disease for which there are no good options.

## INTERMITTENT HEPATIC ARTERY INFUSION THERAPY

The use of HAI therapy requires a surgical procedure coupled with the risk of infection and bleeding associated with the requirement for the placement of a semipermanent catheter and port. One approach to circumvent the cost and toxicities associated with chronic indwelling devices is the use of an intermittently placed percutaneous hepatic arterial catheter. The feasibility of this approach has been demonstrated by several groups.<sup>118,119</sup> Jung and colleagues demonstrated the safety and feasibility of the approach in 21 patients with primary or metastatic cancer in the liver. Major complications requiring catheter removal and reimplantation occurred in 19% of patients. Patients with metastatic breast cancer to the liver were treated with percutaneous hepatic artery infusion of cisplatin, 120 mg/m<sup>2</sup> (31 patients), or vinblastine, 2 mg/m<sup>2</sup> (26 patients), daily for 5 days each month via percutaneous hepatic artery catheters.<sup>71,120</sup> Partial responses were noted in 19% of patients treated with platinum and 36% of those treated with vinblastine, and toxicities were found to be acceptable with both regimens. Experience using this approach in 36 patients treated at the University of Nebraska has been published.<sup>121</sup> Patients entered onto this trial had unresectable hepatic metastases from colorectal carcinoma and were treated with FUDR plus LV continuously for 4 days via hepatic arterial infusion followed in 1 week by intravenous continuous infusion 5-FU and oral LV for 21 days each month for six cycles followed by maintenance systemic 5-FU and oral LV. The overall response rate was 45%, with a median survival of 1 year.

## HEPATIC ARTERY INFUSION WITH VENOUS FILTRATION

An interesting approach to enable the use of high doses of chemotherapy while limiting systemic toxicities involves the use of venous filtration wherein high doses of cytotoxins may be administered into the arterial supply while the liver and hepatic venous blood is collected via a catheter positioned in the retrohepatic vena cava and in which balloons are inflated above and below the hepatic veins to isolate and collect hepatic venous effluent. The collected blood is passed through a charcoal-containing device capable of filtering the cytotoxic compounds and returned to the systemic circulation. This technique was originally developed by Ravikumar and coworkers at Yale University School of Medicine.<sup>122</sup> They applied this approach to 23 patients with primary or metastatic hepatic cancers using either high doses of 5-FU (1000 to 5000 mg/m<sup>2</sup>) in 12 patients or doxorubicin (50 to 120 mg/m<sup>2</sup>) in nine patients. Each patient received at least two treatments with a 3-week interval between treatments. The extraction efficiency of the system was 64% to 91% and accompanied by acceptable toxicity. The most common toxicity was neutropenia and transient hypotension due to the catecholamine-depleting effects of the charcoal filters and diminished cardiac return during the procedure. Dose-limiting myelotoxicity was observed at 5000 mg/m<sup>2</sup> of 5-FU and 120 mg/m<sup>2</sup> of doxorubicin. Similar results were obtained from investigators at M. D. Anderson Cancer Center in ten patients with unresectable hepatocellular carcinoma wherein dose-limiting toxicities were encountered at 120 mg/m<sup>2</sup> of doxorubicin. This approach holds promise for the delivery of relatively high doses of chemotherapy into an isolated organ; however, because the isolation is not complete, systemic toxicities limit drug exposure; thus, the value of this approach clearly requires further investigation.

In an attempt to simplify the technique, Ku and colleagues from Japan have developed a single-catheter technique of hepatic isolation and charcoal hemoperfusion that required only a single cutdown rather than the three needed for the double-balloon technique described previously.<sup>123</sup> They compared their single-catheter technique with the original technique as developed by Ravikumar in 16 patients, with either primary or metastatic cancer to the liver. Nine of these patients were treated using the new technique and seven using the original double-balloon technique. Although this group found either technique feasible and relatively safe, their study suggests that the single-catheter technique may result in a significant decrease in systemic exposure, presumably due to greater efficiency of removal of the cytotoxin from the venous effluent. The hemofiltration concept was further tested in 23 patients with hepatic metastases from colorectal cancer (seven previously treated with 5-FU/LV) who were treated with hepatic arterial chemotherapy using a combination of mitomycin (30 to 50 mg/m<sup>2</sup>) and epirubicin (60 to 90 mg/m<sup>2</sup>) combined with intraperitoneal cisplatin (60 mg/m<sup>2</sup>) coupled with a venous filtration catheter placed in the retrohepatic inferior vena cava.<sup>124</sup> This high-dose regimen was supplemented with four subsequent cycles of the same agents given at more standard doses. The investigators found this regimen to be feasible and associated with acceptable toxicities that included grade 3 to 4 hematologic (12%), gastrointestinal (19%), and hepatic effects (9%) and pain (9%). They identified an overall response rate of 59%, with a median duration of response of 10 months and an overall median survival of 14 months. In a subsequent study from investigators in Belgium, hemofiltration was used in eight patients with unresectable hepatic metastases from colorectal carcinoma. This group used hepatic arterial infusion of 5-FU, mitomycin C, and doxorubicin. They noted a 46% overall response rate with essentially negligible major gastrointestinal or renal toxicities.<sup>125</sup>

## ISOLATED HEPATIC PERFUSION

IHP is a regional treatment that has been used at a limited number of centers since its original clinical application in the 1950s<sup>126</sup> and is similar to isolated limb perfusion used for extremity melanoma or sarcoma in which the cancer-bearing region is perfused with a recirculating closed circuit containing a reservoir, heat exchanger for delivery of hyperthermia, and roller pump (see Chapter 29.3).<sup>127</sup> IHP is administered via a major operative procedure during which the liver is extensively mobilized to prevent leak of systemic perfusate during treatment. Venous outflow is from a cannula positioned in an isolated segment of the retrohepatic

inferior vena cava and arterial inflow is through a cannula or cannulae placed in the gastroduodenal artery and sometimes in the portal vein. During perfusion the splanchnic portal venous and inferior vena caval blood flow is temporarily occluded and must be shunted to the systemic circulation using a venovenous bypass circuit similar to that used in hepatic transplantation procedures.<sup>128</sup>

Because of its technical complexity, the morbidity associated with the procedure reported in older series, and the lack of documented efficacy using chemotherapeutics alone,<sup>127</sup> it has not gained widespread or consistent clinical evaluation. However, in the early 1990s, several centers initiated trials of IHP using tumor necrosis factor (TNF) and melphalan with the benefit of continuous intraoperative leak monitoring using radiolabeled erythrocytes or albumin to ensure minimal or no leak of perfusate during treatment.<sup>129</sup> There are data from three centers in Europe and the National Cancer Institute in Bethesda, Maryland, reporting results with IHP using TNF and melphalan (Table 52.3-8). De Vries and coworkers treated nine patients with advanced unresectable metastatic cancer confined to liver and reported a considerable treatment mortality of 33% but did observe significant antitumor activity.<sup>130,131</sup> However, the median duration of response was only 18 weeks, and median survival was 10 months. Oldhafer and coworkers reported a series of 12 patients of whom six received TNF and melphalan.<sup>132</sup> Tumor biopsies obtained on posttreatment day 1 showed tumor necrosis in most patients and there was an overall radiographic response rate of 50% and a median survival of 11 months. A Swedish group treated 11 patients and had an operative mortality of 18%. Antitumor activity was observed in three of six patients with ocular melanoma to liver and in zero of five patients with colorectal cancer. The modest antitumor activity may be secondary to the low doses of agents used, only 0.2 to 0.3 mg of TNF and 0.5 mg/kg of melphalan, which are considerably lower than the maximum safe tolerated doses determined in phase I trials at the National Cancer Institute.<sup>127,133</sup>

**TABLE 52.3-8.** Summary of Isolated Hepatic Perfusion Trial Using Tumor Necrosis Factor and Chemotherapeutics

Alexander and coworkers from the National Cancer Institute reported results in 34 patients with metastatic unresectable cancers confined to liver using 1 mg of TNF and 1.5 mg/kg of melphalan.<sup>134</sup> Treatment mortality was 3% and despite the fact that most had received previous therapy and many had advanced tumor burden in liver, there was an overall radiographic response rate of 75%. Responses were consistent across all histologies treated, including ocular melanoma and colorectal cancer and observed in those with advanced disease (Table 52.3-9). More recently, results in 51 patients with isolated unresectable colorectal cancer confined to liver treated with IHP using TNF and melphalan or melphalan alone followed by HAI therapy using FUDR and LV have been presented by the group.<sup>135</sup> Seventy-three percent of patients had failed previous systemic therapy with a 5-FU–based regimen. There was one treatment-related mortality (2%). Of note, the overall responses remained similar to their initial report, 77% for patients treated with TNF and melphalan IHP and 74% for patients treated with IHP using melphalan alone, but median time to progression in liver was significantly prolonged with the addition of HAI therapy (10 months vs. 14.5 months, respectively). These data suggest that continued clinical evaluation of IHP for patients with advanced refractory metastatic cancers confined to liver is warranted.

	No. of Patients	Partial Response or Complete Response	Percentage

### Chemoembolization

Chemoembolization involves the administration of chemotherapy followed by vascular occlusion using a variety of agents such as degradable starch microspheres, gelatin powders, polyvinyl chloride, or pledgets. Responding patients usually undergo multiple procedures over time as tumors and vasculature regrow. This approach has been widely applied in the treatment of primary hepatocellular carcinoma (see Chapter 33.5). For patients with metastatic cancer, the most common application is in patients with unresectable metastases from carcinoid or islet cell tumors. Because most tumors are highly vascular and have an indolent course in many patients, a partial response can provide long-term palliation. Furthermore, many patients who do not achieve an objective response have improvements in symptoms resulting from hormonal secretion. The overall objective response rate tends to be in the range of 30% to 50%, and the great majority of patients show reduced hormone secretion and improvement of symptoms (Table 52.3-10). Although there has been a shift in practice from embolization alone to chemoembolization with a variety of agents, there is no clear evidence that the use of chemotherapy improves response or patient outcome.<sup>136</sup>

Author	Histology	Treatment	No. of Patients	Response		Median Survival (mo)
				Objective	Symptomatic

**TABLE 52.3-10.** Outcome in Patients with Neuroendocrine Tumors Metastatic to the Liver after Chemoembolization

Chemoembolization has also been attempted for patients with colorectal cancer metastatic to the liver. In contrast to neuroendocrine tumors, most patients with

A number of studies were published in the early 1990s from centers reporting their initial experience with the technique. Zhou et al. from the Shanghai Medical University in China reported a series of 107 patients with primary liver cancer treated with cryotherapy<sup>146</sup> and observed a 5-year survival of 15% for 49 patients treated with cryotherapy. Onik and coworkers reported a series of 59 patients with unresectable hepatic metastases treated with cryosurgery.<sup>147</sup> At a median follow-up of 21 months the disease-free survival rate was 27% and overall survival was 52.5%. The number of tumors treated ranged from one to 16, and 73% of patients treated had bilobar disease and many had tumors directly abutting major vessels. Ravikumar and coworkers reported an initial series of 32 patients treated with cryosurgery resulting in a 2-year disease-free survival of 28% and overall survival of 62%.<sup>148</sup> A second series from the same investigator<sup>26</sup> reported results in 21 patients undergoing cryosurgery and at a median follow-up of 16 months. In both series, the liver recurrence rate was approximately 25% to 30%, and one-half of patients failed systemically. Preketes and coworkers have reported their results of cryosurgery in 38 patients with unresectable multiple liver metastases from colorectal carcinoma.<sup>149</sup> They report a 12.5% 2-year survival rate for the 11 patients receiving cryotherapy alone.

Currently, the world literature reports results in more than 900 patients treated with the technique,<sup>150</sup> with more recent reports detailing patient, treatment, and tumor parameters associated with successful outcome.<sup>151,152,153,154</sup> and <sup>155</sup> Seifert and Morris reported that 116 patients with colorectal cancer treated with cryotherapy had an overall morbidity of 28%.<sup>154</sup> There was a single mortality secondary to treatment (0.9%). Factors found to be independently correlated with favorable outcome after therapy are listed in [Table 52.3-13](#). In a second report of 85 patients presumably also included in the first series, the mean disease-free interval at the cryosite was 42 months and was 60% at 3 years.<sup>155</sup> The median hepatic disease-free interval was 15 months and 17% at 3 years. Weaver and coworkers reported a median survival of 34 months and an 82% hepatic recurrence rate in 136 patients undergoing 158 cryotherapy procedures.<sup>153</sup> Repeat<sup>156</sup> and laparoscopic treatments<sup>157,158</sup> have been reported.

**TABLE 52.3-13.** Factors with Independent Prognostic Significance in Colorectal Patients Undergoing Cryotherapy of Hepatic Metastases

A single prospective random assignment trial evaluating cryosurgery versus conventional resection in patients with liver metastases from a variety of histologies has been reported.<sup>159</sup> Liver recurrences and overall survival were similar in both groups, and the authors concluded that cryotherapy is as effective as surgical resection for liver metastases. However, the heterogeneous nature of the patients treated and the unconventional treatment administered routinely to patients postoperatively make the interpretation of the data difficult. Others have reported results in patients with neuroendocrine<sup>160</sup> or other tumors<sup>161,162</sup> of the liver and have reported good palliation and a greater than 90% reduction in circulating tumor-related functional proteins (i.e., gastrin or 5-hydroxyindoleacetic acid) in more than 90% of patients for a median of 10 to 13 months after cryotherapy.<sup>160,163</sup>

In general, cryotherapy is considered a safe and effective means for treating hepatic tumors of all histologies with low morbidity. Cryotherapy has also been used in conjunction with hepatic resection to assist in resection of a deep-seated lesion,<sup>164,165</sup> treat an inadequate margin after resection,<sup>166</sup> and in addition to resection to preserve hepatic tissue.<sup>167</sup> The main advantage of cryotherapy over surgery is the minimal damage suffered by the normal hepatic parenchyma and the avoidance of the risk of hemorrhage and damage to bile ducts that occurs during parenchymal dissection. Most patients experience an increase in liver enzymes to approximately twice normal, with normalization by postoperative day 5. Leukocytosis and low-grade fevers are common. Hemorrhage from the probe tract is generally easily controlled with pressure, packing with absorbable gelatin sponge or absorbable knitted fabric, or both. Complications related specifically to cryotherapy include pleural effusions in 6%, hepatic cracking with associated intraoperative hemorrhage in 4%, biliary fistula in 3%, abscess in 1.7%, and myoglobinuria with renal failure in 1.4%.<sup>150,168</sup>

### CRYOTHERAPY PLUS ADJUVANT CHEMOTHERAPY

Given the potential value of adjuvant chemotherapy in the setting of hepatic resection, it may be reasonable to expect a similar improvement in outcome with the addition of adjuvant chemotherapy to other local ablative therapies, including cryotherapy. A study from Australia (38 patients) and one from New Zealand (30 patients) investigated the value of adjuvant chemotherapy after cryotherapy in patients who had hepatic colorectal metastases that were deemed inoperable.<sup>149,169</sup> Each of these groups of investigators found the regimen of hepatic cryotherapy followed by hepatic arterial chemotherapy using 5-FU plus LV to be relatively safe and well tolerated, and each found a similar median survival of approximately 18 months in patients treated with the combined approach. In a small group of 11 patients nonrandomly treated with cryotherapy alone in the Australian trial, the investigators noted a median survival of only 8 months, suggesting that adjuvant chemotherapy may well be a useful adjunct to hepatic cryotherapy. Using systemic 5-FU plus LV, a group of investigators from Roswell Park Cancer Institute found that the use of this adjuvant systemic chemotherapy in four patients treated with prior cryotherapy was highly toxic and recommended caution when combining systemic adjuvant chemotherapy with cryotherapy.<sup>170</sup>

### MICROWAVE TISSUE COAGULATION AND RADIOFREQUENCY ABLATION

Another form of local ablative therapy for liver tumors is percutaneous microwave or hyperthermic coagulation. A probe inserted into the middle of a tumor emits microwaves or radiowaves from its tip, which heats the surrounding tissue. Energy penetrates a few centimeters into the surrounding tissue, causes molecular vibration of dipoles (particularly of water), and is converted to heat, resulting in tissue coagulative necrosis. A single electrode emitting 2450 MHz for 60 seconds produces coagulation necrosis of a spindle-shaped region approximately 2 cm in diameter.<sup>171</sup> Evaluation of the zone of necrosis in real time can be achieved with ultrasound, which shows strong hyperechogenic foci representing cellular destruction. Percutaneous microwave coagulation has efficacy in ablating hepatocellular tumors up to 6.5 cm in diameter.<sup>172</sup> Microwave therapy has advantages over laser photocoagulation as a larger zone of necrosis can be obtained with a shorter treatment.<sup>173</sup> In contrast to other forms of local ablation, the zone of cellular destruction does not extend beyond the tip of the electrode. This allows precise treatment at the deep edge of the tumor where ultrasound visualization is often limited.<sup>171</sup>

A number of studies have been reported outlining results in patients treated with percutaneous or open radiofrequency thermal ablation (RFA) ([Table 52.3-14](#)). The success of RFA in successful ablation of primary or metastatic tumor deposits within the liver is influenced by the expertise and diligence of the treating physician to ensure that an adequate zone of thermal necrosis has been delivered to the entire tumor. For large tumors, this requires multiple consecutive propregnant placements and, because the zone of thermal necrosis cannot be definitively imaged with intraoperative ultrasound, it is somewhat difficult to determine which areas within a large tumor have or have not been adequately treated. Solbiati and coworkers reported results in 29 patients with 44 hepatic metastases ranging in size from 1.3 to 5.1 cm in diameter.<sup>174</sup> The authors report successful ablation of all identifiable tumor in 91% of treated metastases, but a local progression rate of 34%. Liviaghi and coworkers subsequently reported a series of 14 patients with liver metastases and one patient with a primary cholangiocarcinoma treated with RFA.<sup>175</sup> Fourteen of 25 lesions were completely obliterated and ranged in size from 1.2 to 3.9 cm. Partial necrosis in 12 additional lesions was noted, with diameters ranging from 1.5 to 4.5 cm. Nagata and coworkers reported results of RFA treatment in 173 patients with primary or hepatic cancers.<sup>176</sup> Additional therapy, including arterial embolization, radiotherapy, immunotherapy, and systemic chemotherapy, were also combined with RFA treatment in this series. Treatments were administered percutaneously, and more than 80% of patients underwent more than four sessions of RFA. In 45 patients treated with metastatic tumor deposits, there was no response or disease progression in 53%. Cuschieri and coworkers reported results of microscopically administered ultrasound-guided RFA of hepatic tumors and successfully achieved total ablation in seven of eight patients with metastatic colorectal cancer to the liver.<sup>177</sup> At the time of publication, follow-up ranged from 6 to 20 months, and eight of ten patients remained free of tumor. The largest series of patients treated with RFA was reported by Curley and coworkers from the M. D. Anderson Cancer Center.<sup>178</sup>

The investigators treated 123 patients with RFA either using the percutaneous or open operative technique with ultrasound guidance. A total of 169 tumors ranging in size from 0.5 to 12 cm (median diameter, 3.4 cm) were ablated. Three-fourths of patients underwent open operative RFA, and there were no treatment-related deaths in the study. The authors report three tumor recurrences in 169 treated lesions (1.8%) at a median follow-up of 15 months (see [Table 52.3-14](#)). The low recurrence rate may be due to the fact that many patients were treated operatively to facilitate probe placement and more reliably assess adequacy of therapy. In addition, the authors used inflow occlusion via the Pringle's maneuver, which may have enhanced the effectiveness of the thermal ablation. However, it should be noted the intraoperative use of RFA does not take full advantage of its technology. For example, the small probe size and the fact that the tissue is cauterized along the track eliminates the risk of bleeding from the probe track or cracking of the liver on removal of the probe. For patients undergoing operative local ablative therapy, the use of cryotherapy allows one to use real-time intraoperative ultrasound to accurately assess the adequacy of the zone of destruction, which is more difficult to assess using RFA. In practice, the technology behind the various local ablative therapies is evolving, and, as smaller probe sizes are developed and techniques for monitoring adequacy of tissue destruction are refined, the advantages of one form of ablative therapy over another may become increasingly obscure.

Author	No. of Patients	Local Recurrence Rate

**TABLE 52.3-14.** Local Recurrence after Radiofrequency Ablation of Hepatic Neoplasms

### RADIOFREQUENCY ABLATION PLUS ADJUVANT CHEMOTHERAPY

A group of investigators from Japan investigated the feasibility of combining intrahepatic artery 5-FU (750 to 1250 mg) administered as a weekly 5-hour infusion with RFA therapy in nine patients with hepatic metastases from colorectal carcinoma.<sup>179</sup> These investigators found the combination to be feasible and safe with three of nine patients surviving for more than 2 years. Clearly, the potential value of adjuvant chemotherapy in the setting of local therapy using radiofrequency should be further investigated.

### INTERSTITIAL LASER PHOTOCOAGULATION

Interstitial laser photocoagulation is a minimally invasive technique for local ablation of tumors first developed in 1983.<sup>180</sup> A thin optical fiber is inserted percutaneously into the center of a liver tumor and a laser light is delivered to the tip of the fiber. The laser light emitted from the fiber tip is absorbed as heat by the surrounding tumor. The laser light penetrates the surrounding tissue in an isotropic fashion around the fiber tip. In general, 1 to 2 W of continuous near-infrared laser energy is delivered for durations of 300 to 1000 seconds. Most of the work has been performed with a neodymium:yttrium aluminum garnet laser. Cells in the target volume undergo coagulative necrosis resulting from protein denaturation at temperatures greater than 60°C.<sup>181</sup> Special diffusion fiber tips have been developed to allow even scatter and penetration of the laser light throughout the tumor, avoiding a local charring effect that subsequently blocks laser penetration.<sup>182</sup>

As with cryotherapy, the zone of tissue necrosis can be followed in real time by ultrasound and MRI.<sup>183</sup> The accuracy of ultrasound during the treatment of large tumors is inferior to the results with cryotherapy.<sup>184</sup> Tumors up to 9 cm have been treated with this technique using multiple probes and multiple treatment sessions. In general, a single probe is adequate for a tumor 0.5 cm in diameter. If multiple probes are necessary, they are spaced 1.0 to 1.5 cm apart. This is adequate to achieve complete homogeneous necrosis between the fiber tips.<sup>184</sup> As with cryotherapy, this treatment is less effective in tumors close to large vessels, as the blood flow cools the adjacent tissue, preventing thermal necrosis. The advantage over cryotherapy is the small size of the delivery fibers, allowing accurate and safe percutaneous insertion.

Clinical reports of interstitial laser photocoagulation are limited. Amin and coworkers reported results in a total of 55 tumors with interstitial laser photocoagulation.<sup>185</sup> Eighty-two percent of tumors had a partial response (greater than 50% necrosis identified on CT imaging), and 38% underwent complete necrosis. Metastases smaller than 4 cm responded better than larger tumors. Complications were minimal, but included pain, subcapsular hematoma, and pleural effusion. Nolsoe and coworkers reported a pilot study of 11 patients with 16 colorectal liver metastases.<sup>186</sup> Twelve of 16 tumors were considered completely destroyed by the procedure, including a 3.7-cm tumor. No serious complications were encountered. Amin and coworkers compared interstitial laser photocoagulation in 54 colorectal liver metastases with percutaneous alcohol injection in 22 tumors.<sup>184</sup> They report that 52% of tumors treated with photocoagulation had complete necrosis of the tumor on dynamic CT scan compared with zero patients receiving alcohol injection. There were no major complications in either group, but pain was more significant in the alcohol-injected group.

In summary, interstitial laser photocoagulation is a safe and simple technique for treating small localized liver tumors. The zone of necrosis is smaller than with cryotherapy, thereby requiring multiple probes per tumor. This makes following the progression of cellular destruction with ultrasound more difficult and increases the chance of leaving viable cells. Further refinements in imaging may make this treatment more successful.

### PERCUTANEOUS ETHANOL INJECTION

Percutaneous ethanol injections into malignant deposits in the liver have most broadly been applied to the treatment of patients with hepatocellular carcinomas. The density of tumors associated with hepatocellular carcinoma and the common occurrence of this malignancy in the setting of severe underlying hepatic disease lends itself to this form of local therapy as opposed to surgical resection, which is often not possible in patients with severe underlying hepatic cirrhosis. Currently, there are no randomized studies comparing the value of percutaneous ethanol injection with any of the other local modalities for the treatment of patients with hepatic malignancy. Thus, its value relative to other local techniques is uncertain. However, there have been several series of patients with hepatocellular carcinoma treated by percutaneous ethanol injection reported in the literature, primarily from investigators in Japan and Italy. In patients with hepatocellular carcinoma with either single or multiple hepatic tumors treated with curative intent, the investigators from Japan found 3- and 5-year overall survival rates of 62% to 65% and 28% to 52%, respectively.<sup>187,188</sup> The 3-year recurrence rate for these patients was approximately 60% to 65%, with the vast majority of new recurrences occurring in portions of the liver not previously treated with ethanol injections. The 3- and 5-year overall survival rates were slightly better in the studies from Italy (approximately 70% and 40%, respectively); however, these differences may well be attributed to the differences in the underlying hepatic disease, which is an important prognostic factor.<sup>189,190</sup> Patients classified as Child's A have a 2-year survival, approximately twofold greater than those patients classified as Child's C (approximately 90% vs. less than 40%, respectively). In addition to Child's classification, the prognosis of patients with hepatocellular carcinoma is negatively influenced by a greater number of deposits of carcinoma as well as increasing size of the deposits and elevated pretreatment  $\alpha$ -fetoprotein levels.<sup>191</sup> Although generally restricted to patients with tumors smaller than approximately 3 to 5 cm in size, Livraghi and colleagues published their experience with percutaneous ethanol injection in 108 patients with hepatocellular carcinoma with tumors larger than 5 cm and performed in a single session under general anesthesia. Despite the size of the lesions treated, this group found a 3-year survival of 57% for those in patients with single lesions measuring 5.0 to 8.5 cm and 42% for those with multiple lesions measuring 5 to 10 cm.<sup>192</sup> The overall rate of major complications in this study was less than 5%, thus suggesting that percutaneous ethanol injections may be a useful modality even in the setting of lesions up to 10 cm in size.

Although no randomized comparisons between percutaneous ethanol injection and hepatectomy have been performed, several studies address this issue through retrospective comparisons or the use of contemporary patient cohorts. In a cohort study from Spain,<sup>193</sup> patients with solitary hepatocellular carcinomas smaller than or equal to 4 cm were treated with surgical resection (n = 33) or percutaneous ethanol injection (n = 30). Despite a significant increased proportion of Child's A patients in the surgically treated group (91% vs. 33%) and a decreased proportion of patients with ascites (6% vs. 47%), these authors found that the overall survival rates in the two groups were not different. Similar results were obtained in a study of 40 patients with solitary hepatocellular carcinomas smaller than 2 cm in diameter treated

by Kotoh and colleagues wherein 17 were treated with hepatectomy, 12 with percutaneous ethanol injection, and 11 with a combination of percutaneous ethanol injections and arterial embolization with gel-containing mitomycin C and Adriamycin. These authors found no difference in median survival (3.5 to 4.0 years) or recurrence rates (70% to 80%) between patients undergoing hepatectomy versus those treated with ethanol injection with or without arterial embolization despite a greater proportion of patients with Child's class A disease in the surgically treated group (73% vs. 36%).<sup>194</sup> In a large retrospective analysis of 391 patients, Livraghi and colleagues found no difference in 3-year survival for 120 patients treated by surgical resection (79% Child's A; 40% Child's B) versus 155 treated by percutaneous ethanol injection (71% Child's A; 41% Child's B); however, they noted a significantly inferior (threefold lower) survival for those patients who were not treated with either percutaneous ethanol injection or hepatectomy.<sup>195</sup> Similarly, Orlando and colleagues used a matched historic comparison group to compare the outcome of this untreated group (65 patients) with small hepatocellular carcinomas (smaller than 4 cm) with 35 patients treated by percutaneous ethanol injection and found that the 3-year survival of patients treated with percutaneous ethanol injections was superior to the historic comparison group (33% vs. 14%, respectively), but that the primary difference in survival outcome was restricted to those patients with Child's A disease (71% vs. 21%, respectively) whereas those with Child's B had a similar, but poor, 3-year survival outcome regardless of whether they were treated with percutaneous ethanol injections or left untreated (9% for both groups).<sup>196</sup> These results suggest that percutaneous ethanol injections may be associated with a more favorable outcome compared with those patients who are treated with best supportive care only and that clinical outcome with this form of local therapy may be similar to that of hepatectomy.

Given the potential value of percutaneous ethanol injections and transcatheter arterial embolization, several groups have combined these two approaches. In 86 patients with Child's class A or B cirrhosis and large hepatocellular carcinomas (3.1 to 8.0 cm), Lencioni and colleagues found 69% and 47% 3- and 5-year survivals, with 56% and 82% recurrence rates at 3 and 5 years in patients treated with transcatheter arterial chemoembolization (gelatin sponge with epirubicin emulsified in iodized oil) followed by percutaneous ethanol injection.<sup>197</sup> Investigators in Germany compared the survival of 132 patients with inoperable hepatocellular carcinoma nonrandomly treated with best supportive care (45 patients) or percutaneous ethanol infusion (15 patients), or transcatheter arterial chemoembolization (33 patients), or the combination of both local therapies (39 patients).<sup>198</sup> These investigators found that patients treated with a combination of percutaneous ethanol infusion and transarterial chemoembolization had an improved survival when compared with those patients treated with either chemoembolization alone or with best supportive care only. However, patients treated with chemoembolization alone had larger and more advanced hepatic disease compared with those treated with ethanol alone or the combination of local therapies, as ethanol injections (either alone or combined with chemoembolization) were reserved for those patients with fewer than three lesions with none larger than 5 cm in size. Those assigned to supportive care had disease too advanced to be treated by either chemoembolization or alcohol injections. Given these caveats, the supportive care group had the worst median survival compared with any of the treatment groups (2 months vs. 25 months in the combination group). Although these data support the use and feasibility of combining transarterial chemoembolization with percutaneous ethanol injection, the true value of this combined approach versus either approach used individually requires further investigations using a randomized prospective trial design.

## RESULTS OF WHOLE LIVER IRRADIATION WITH OR WITHOUT CHEMOTHERAPY

Early studies demonstrated that whole liver radiation produces temporary palliation of pain for patients with cancer metastatic for the liver.<sup>199</sup> However, it was soon discovered that doses greater than 30 to 35 Gy could produce a condition that has become known as *radiation hepatitis*.<sup>200,201</sup> and <sup>202</sup> Radiation hepatitis is better described as radiation-induced liver disease (RILD), as the pathologic evaluation shows no evidence of hepatitis. Patients who develop RILD present 2 weeks to 3 months after the completion of radiation therapy with weight gain and bloating, and, in severe cases, confusion. Jaundice as a presenting symptom is uncommon (and suggests that the patient has already developed impending liver failure). Physical examination reveals anicteric ascites and painful hepatomegaly. Laboratory evaluation shows a marked elevation of alkaline phosphatase out of proportion to the typically modest increases in alanine aminotransferase, aspartate aminotransferase, and bilirubin (which tends to be unconjugated), elevations in prothrombin time and partial thromboplastin time, and thrombocytopenia. Paracentesis and radiologic studies (CT, MRI, or both) fail to show progressive disease. Liver biopsy reveals venoocclusive disease pathologically identical to that resulting from a variety of insults. Although most patients recover in 1 to 2 months, 10% to 20% develop overt liver failure and death.<sup>203,204</sup>

A tolerable whole liver dose produces only short-term palliation and patient survival ( [Table 52.3-15](#)). This is true regardless of whether the radiation is given daily or twice daily in 1.5-Gy fractions. To attempt to improve on these results, whole liver radiation has been combined with systemic and hepatic arterial chemotherapy. The most widely used drugs have been 5-FU<sup>205</sup> and FUDR,<sup>206,207</sup> as both are cytotoxic and radiosensitizing agents. The objective response rates and survival after combination chemoradiotherapy appears to be somewhat superior to that obtained by radiation alone ( [Table 52.3-16](#)). Whole liver radiation tolerance does not seem to be affected by the concurrent use of fluoropyrimidines in contrast with other chemotherapeutic agents such as alkylating agents or mitomycin C, <sup>208,209</sup> and <sup>210</sup> which appear to increase RILD risk. Tolerable courses (5% chance of RILD) for whole liver radiation in patients who have not received alkylator therapy appear to be 21 Gy in 3-Gy fractions, 25 Gy in 2.5-Gy fractions, and 30 Gy in 2-Gy fractions.

Regimen	Dosage*	No. of Patients	Median Survival (mo)	Radiation-Induced Liver Disease†

irradiation ranged from 10 minutes to 4.5 hours as a function of the size and number of lesions.<sup>215</sup> In another approach, permanent <sup>125</sup>I seeds have been implanted at the time of laparotomy or under ultrasound guidance.<sup>216</sup> The maximum tumor size in this latter series was smaller than 5 cm. Additional phase II experience is required to assess the efficacy of these approaches.

External-beam irradiation can be used to treat patients with localized unresectable metastatic cancer to the liver. These efforts have been based on the hypothesis that, just as substantial fractions of the liver can be resected if the remaining fraction can support liver function, focal high-dose liver radiation can be safely administered if sufficient normal liver is spared. As summarized in the chapter on hepatobiliary cancer (see [Chapter 33.5](#)), conformal planning can use beams not confined to the axial plane to reduce normal liver irradiation.<sup>217,218</sup> Furthermore, three-dimensional planned treatment has allowed the development of a quantitative understanding of the relationships among dose, volume, and risk of complication.<sup>218,219</sup>

A phase I and II trial for patients with unresectable hepatic cancer using either standard two-dimensional techniques<sup>220</sup> or three-dimensional conformal external-beam irradiation combined with hepatic arterial FUDR have demonstrated that high-dose focal radiation can produce up to a 50% response rate in previously treated patients.<sup>221,222</sup> However, the freedom from hepatic progression in one study was only 29% at 1 year, suggesting that higher doses will be required to produce long-term control.<sup>222</sup> More recent results support the hypothesis that the dose delivered is an important prognostic factor in both local control and survival for patients with metastatic colorectal cancer. In this study, dose is prescribed (to a maximum of 90 Gy) according to the fraction of normal liver that is spared based on a normal tissue complication probability model (see [Chapter 33.5](#)). Patients who could receive greater than or less than 70 Gy have a median survival in excess of 17 months, which approaches that achieved by surgical resection. Dose was an independent prognostic factor, and was not correlated with tumor size.<sup>223</sup>

## CONCLUSIONS

Despite the fact that isolated hepatic metastases are a significant clinical problem frequently associated with a poor prognosis, there are evolving regional treatment strategies that increasingly expand the options available for patients afflicted with this condition. For patients with resectable hepatic deposits primarily of colorectal, neuroendocrine, or genitourinary origin, the benefit in terms of overall survival or palliation appears to be well established. For patients undergoing resection for colorectal cancer, various patient, tumor, and treatment variables have been identified as important prognostic factors and can be used to select patients for adjuvant therapy. For those with unresectable colorectal cancers confined to the liver, HAI therapy using FUDR-based regimens have high response rates, but the influence on overall survival has not been conclusively demonstrated. Local ablative therapies have the advantage of being able to ablate local tumor deposits, but their influence on overall survival has not been demonstrated. As the technology behind local ablative treatments advances, they will no doubt become more widely used alone or in combination with postablation HAI, systemic therapy, or both. Chemoembolization has been used in patients with advanced cancers of the liver and can result in palliation in a significant percentage of those treated. Newer therapies, including IHP and gene therapy, are under active clinical evaluation and may gain more widespread acceptance with further refinement of treatment in the future. HAI of a recombinant adenoviral construct containing the wild-type p53 gene is being evaluated in patients with metastatic colorectal cancer to the liver.<sup>224</sup> The range of regional therapies highlight the acknowledged importance and difficulty in treating hepatic metastases and provide an expectation that durable complete disease control within the liver with an associated improvement in quality of life and overall survival may be routinely achieved.

#### INTRODUCTION

Most of the more than 560,000 people in the United States who die of cancer each year have tumor metastasis.<sup>1</sup> Bone is the third most common organ involved by metastasis, behind lung and liver.<sup>2</sup> In breast cancer, bone is the second most common site of metastatic spread, and 90% of patients dying of breast cancer have bone metastasis.<sup>2,3</sup> Breast and prostate cancers metastasize to bone most frequently, which reflects the high incidence of both of these tumors, as well as their prolonged clinical courses.<sup>2</sup> Other tumors that commonly cause symptomatic bone metastases include kidney and thyroid cancer and multiple myeloma. The increasing age and size of the population leads to an increased number of cases of cancer. This, coupled with longer patient survival, increases the incidence of metastatic lesions to bone. Patients with bone metastasis from breast cancer have an average 2-year survival from the time of presentation with their first bone lesion. As more patients are living with bone metastases, the challenge is to improve their quality of life.

Current management of skeletal cancer involves a multimodality approach, including systemic therapies (chemotherapy, hormone and immune therapies, and other drugs such as bisphosphonates), radiation (external-beam and targeted radioisotopes), and surgery. Medical, radiation, surgical, and orthopedic oncologists, with diagnostic assistance from radiologists and pathologists, form a multidisciplinary team to manage these complex and often very ill patients. Early detection and aggressive management of metastases should be the goal, to maintain and maximize patients' quality of life and functional level. Nihilism is no longer appropriate. However, due to economic considerations and a dearth of data to support intensive surveillance for metastases, physicians may be lulled into a sense of complacency. Currently, care is optimized in only a fraction of patients with bone metastases.

#### PRESENTATION

Patients with metastatic disease to the skeleton most often present with pain as the principal symptom. The pain associated with bone metastasis comprises two components: biologic and mechanical. *Biologic pain* is related to the local release of cytokines and chemical mediators by the tumor cells, periosteal irritation, stimulation of intraosseous nerves by these mediators, and the pressure or mass effect of the tumor tissue within the bone. *Mechanical pain* is related to the loss of bone strength and stiffness caused by the metastatic lesion, which leads to activity-related pain. Mechanical pain is seen most often with osteolytic lesions but can also occur in osteoblastic lesions, because the disorganized pattern of tumor-related bone lacks structural integrity.

The initial pain pattern of a metastasis mimics that of primary bone tumors and osteonecrosis. The symptoms are intermittent but may be sharp and severe. Pain tends to be worst at night and may be partially relieved by activity. As the lesion progresses, symptoms become more constant and take on a more mechanical character.

Patients with metastatic disease can present with a pathologic fracture. Pathologic fractures most often occur with osteolytic lesions. The majority of pathologic fractures are seen in patients with metastatic breast cancer. In one study, the incidence of pathologic fracture was 8% in 1800 cancer patients, with 53% of those fractures occurring secondary to breast cancer metastases.<sup>4</sup> Other malignant culprits for pathologic fracture in this series were kidney in 11%, lung in 8%, thyroid in 5%, lymphoma in 5%, and prostate in 3%.<sup>4</sup>

Hypercalcemia of malignancy occurs in 5% to 10% of patients with bone metastasis and is seen predominantly in breast cancer, multiple myeloma, and squamous carcinomas of the lung. Thirty percent of patients with breast cancer will develop hypercalcemia during the course of their disease.<sup>5</sup> Hypercalcemia is mediated by multiple factors: local osteolysis caused by the skeletal metastasis, parathyroid-like hormone released by the tumor cells and having both a local (paracrine) and systemic (endocrine) effect, and disuse osteolysis related to the immobility of these patients.

Neurologic abnormality related to spinal cord compression can occur with spinal metastasis. Knowledge of the course and character of neurologic symptoms is important in directing the radiographic evaluation and treatment plan. Neurologic compromise secondary to spinal involvement with metastasis has a major impact on quality of life and function.

Systemic issues include generalized debilitation, leading to immobility. Bed rest exacerbates hypercalcemia and can lead to atelectasis, thromboembolic disease, and skin pressure necrosis. In addition, patients with systemic malignancy who are immobilized are prone to developing disseminated intravascular coagulation. Careful screening for these conditions is imperative in the management of these patients. Doppler ultrasound tests are a convenient and sensitive way of identifying deep venous thrombosis. Loss of ambulatory ability is a poor prognostic factor in metastatic disease, particularly spine disease. Performance status should be specifically quantified as part of the preoperative evaluation.<sup>6,7</sup>

#### PATHOGENESIS

The pattern of metastatic involvement of bone is related to blood flow. Metastases most commonly occur in the more heavily vascularized parts of the skeleton, particularly the axial skeleton, including the ribs and the vertebral column, as well as the proximal ends of the long bones.<sup>8</sup> Batson's plexus is a low-pressure, high-volume, valveless system of vertebral veins that communicates with the pelvic venous plexus. The high number of vertebral metastases in prostate cancer is attributed to Batson's plexus. Arterial spread may also be important. The patterns of metastatic distribution to bone seen after intracardiac injection of tumor cells in animal models are similar to those seen clinically.<sup>9</sup> Histopathologic evaluation of metastatic development and distribution in these animal models confirms that the metastatic lesions originate at the terminal end of the major arteries supplying the bone.<sup>10</sup> Specific radiographic evaluation of metastatic disease in the spine indicates a role for arterial spread as well.<sup>11</sup>

A great deal of research has been conducted recently into the mechanisms of tumor metastasis. Tumor metastasis is believed to be related to several factors: angiogenesis, which allows for primary tumor growth and subsequent access to the systemic circulation to colonize secondary sites<sup>9</sup>; adhesion via cell surface

molecules, which allow tumor cells to attach to other cells and to extracellular matrix components; invasion, mediated by proteolytic enzymes such as matrix metalloproteinases,<sup>12,13</sup> which allow tumor cells to pass across extracellular matrix barriers; and proliferation, which is mediated by growth factors and the uncoupling of the normal mechanisms of cell growth and suppression. Of particular interest in bone metastases is the ability of tumor-released factors to cause osteolysis. There is evidence that this osteolysis is mediated by stimulation of osteoclastic bone resorption by tumor cytokines and direct bone degradation by tumor cells.<sup>8</sup> Matrix metalloproteinases appear not only to mediate the ability of tumor cells to invade via basement membrane hydrolysis but also directly to degrade bone matrix.<sup>12,13</sup> Better understanding of the molecular mechanisms of metastatic tumor spread allows for the development of new therapies to target these areas, as well as more effective use of existing techniques.

## DIAGNOSTIC EVALUATION

A careful history and physical examination, including careful breast or prostate evaluations and thyroid palpation, remain the cornerstone for identification of the site of primary disease in patients who present with a bone lesion without a known primary tumor. In those patients with a history of cancer and a new bone lesion, the coexistence of disease other than metastasis must be ruled out.

Plain radiographs remain the most specific test for diagnosing bone diseases. Scintigraphy is extremely sensitive and practical for use in metastatic evaluation, because it can screen the entire body at one time. Certainly, any abnormality found on bone scan should be correlated with plain radiographs.

Metastatic disease is characterized by the presence of multiple bone lesions. Single metastases occur rarely and must be differentiated from primary bone tumors. Typically, the so-called solitary metastasis is merely the first of many lesions to be identified. Thyroid and renal cancers and myeloma (plasmacytoma) are the most likely to present with an isolated metastasis. Even patients with these favorable cancers typically develop widespread disease, suggesting that there is unrecognized dissemination of cancer at the time that the first bone metastasis is identified.<sup>14,15</sup>

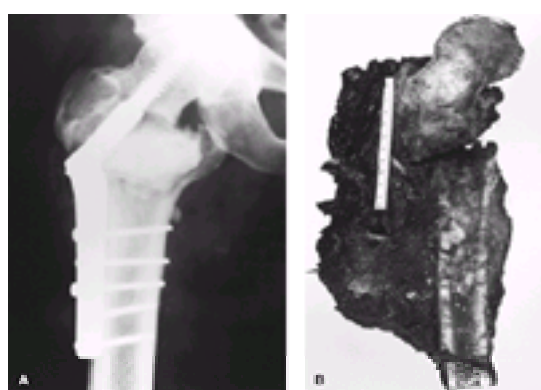

Diagnostic workup entails the use of several laboratory tests to help narrow the differential diagnosis and identify the primary site of disease. A basic screening panel includes a complete blood cell count with platelets, to evaluate for anemia and myelosuppression; serum calcium, phosphorus, and alkaline phosphatase levels to identify markers of bone turnover and evaluate for hypercalcemia; and assessment of serum electrolytes, liver function tests, and an erythrocyte sedimentation rate for systemic evaluation. If clinically indicated, such additional specific tests as the following can be ordered: parathyroid hormone level, to evaluate for metabolic bone disease; serum or urine protein electrophoresis or b<sub>2</sub>-microglobulin if multiple myeloma or lymphoma is suspected; or specific markers such as cancer antigen 125 for breast cancer or prostate-specific antigen for prostate cancer. Biochemical markers of bone turnover, such as urine N-telopeptide and urine deoxypyridinoline, also are noted to have a significant association with the probability of bone metastasis.<sup>16</sup>

The technique of screening blood and marrow with polymerase chain reaction (PCR) or reverse transcriptase-PCR (RT-PCR) for specific tumor cell DNA is being investigated as a tool for diagnosing metastatic disease and following the response to systemic therapy. The attraction of PCR technology is that it can detect a very small number of tumor cells (1 tumor cell in 10 to 100 million normal cells), potentially identifying patients with marrow or circulating cancer cells who are at risk for the development of clinical metastases. As technology improves, the genetics of tumors are being better defined and the PCR technique is becoming more standardized, such that it is likely to prove a useful adjuvant in the diagnosis of, and monitoring of therapeutic response in, bone metastases patients.<sup>17</sup>

Chest radiography and computed tomographic (CT) scans of the chest, abdomen, and pelvis also are used in the diagnostic workup of bone lesions without a known primary lesion. These studies can help to identify the primary tumor in 85% of patients, as well as identifying additional sites of metastatic disease.<sup>18</sup> They are particularly useful because the predominant lesions causing metastases of unknown origin are lung and renal carcinomas.

A firm diagnosis must be obtained before a fracture involving a solitary bone lesion is fixed internally. Magnetic resonance imaging (MRI) can be helpful in differentiating pathologic fracture due to osteoporosis from that due to metastatic disease, particularly in the spine. MRI is also helpful in delineating the soft tissue extension and component of tumors involving bone. When the diagnosis cannot be discerned from clinical information and the baseline tests of plain films and bone scan, MRI can be a helpful diagnostic adjuvant.<sup>19,20</sup>

Solitary bone lesions warrant a biopsy before treatment. Primary bone sarcomas occur in the same population under consideration for metastatic disease. Lytic phases of dedifferentiated chondrosarcoma and Paget's sarcoma can also produce pathologic fractures ( Fig. 52.4-1). In addition, metabolic bone disease is in the differential diagnosis of skeletal abnormalities in this older age group (older than 40 years). Brown tumor of hyperparathyroidism can produce multiple lytic bone lesions, and osteoporosis can lead to pathologic fracture, particularly in the spine. Osteomalacia can mimic metastatic disease by producing multiple fractures throughout the skeleton, resulting in a bone scan indistinguishable from that seen with multiple metastatic foci. All of these entities must be distinguished from metastatic disease, as the management of such conditions is very different from that for metastases.

**FIGURE 52.4-1.** Dedifferentiated chondrosarcoma presents as a predominantly lytic, destructive lesion in an older patient, mimicking a metastatic lesion. Internal fixation in this case is inappropriate, and a biopsy is needed to exclude the presence of a primary bone tumor, particularly with a solitary bone lesion such as this. **A:** Compression hip screw and cement used for internal fixation of a fractured chondrosarcoma. **B:** Gross appearance of the resected bone after removing the screw. White-gray cartilage percolates across the fracture site and down the intramedullary canal.

Bone scan can be of further assistance in planning a biopsy. When the symptomatic lesion involves a weight-bearing bone, biopsy worsens the fracture risk by creating a new hole in the bone cortex. Bone scan can identify other bone lesions and possibly locate one that can be subjected to biopsy with greater ease and less morbidity.

CT-guided needle biopsy is usually satisfactory when the lesion is osteolytic, offering diagnostic accuracy of 80%. When the lesion is osteoblastic or exhibits a thick overlying cortical rim, inserting a needle and obtaining an adequate tissue sample is extremely difficult. Such cases necessitate open surgical biopsy. Regardless of whether the biopsy of a weight-bearing bone is performed by closed or open technique, there is a genuine fracture risk. Weight bearing must be protected until bone healing occurs, which experimentally has been shown to require at least 6 weeks. Sufficient tissue for immunohistochemical studies should always be obtained to improve the ability of the biopsy to yield a definitive tissue diagnosis.

## TREATMENT GOALS

There are four main goals in managing patients with metastatic disease to the skeleton: pain relief, preservation and restoration of function, skeletal stabilization, and local tumor control (e.g., relief of tumor impingement on normal structures, prevention of release of chemical mediators that have local and systemic effects).

Symptomatic relief is usually satisfactory from a combination of radiation and medical therapy. Most patients without a fracture do not require surgery for the bone metastasis; however, fractures are best treated by operative internal fixation. Even when fractures can heal by nonoperative therapy, the protracted treatment time required for closed management is inappropriate, as this period generally is increased by the presence of tumor negatively affecting the ability of the fracture to heal.

The goals of surgical intervention vary in metastatic tumor patients. Primary goals are to allow immediate weight bearing and return to activity, not necessarily to promote fracture healing. Prosthetic replacement and stabilization with polymethyl methacrylate are frequently selected, whereas such techniques would be avoided in the treatment of nonneoplastic fractures.

The duration of any management course must be carefully considered in a patient with a limited life expectancy. Generally, pathologic fractures through weight-bearing bones (e.g., femur) should be treated if the patient has more than 1 month to live, whereas non-weight-bearing bones should be treated if life expectancy is more than 3 months. Definitions and indications for treatment of impending fractures are discussed later in [Impending Fractures: Prophylactic Fixation](#). Impending fractures warrant fixing if (1) such repair will help to eliminate the need for narcotic analgesics or will reduce the patient's overall pain by approximately 50%, (2) equally effective nonoperative treatments are lacking, or (3) treatment for the impending fracture is significantly safer or more effective than surgery once the bone has fractured completely.

Management and intervention should be tailored to the patient's overall prognosis and life expectancy. The medical goals of patient comfort and independence are predominant in these situations. Increasing importance is being placed on quality-of-life issues and measures in these patients, and the goals of therapy have shifted from maximization of duration of life to maximization of pain management and function. Outcome measures and quality-of-life assessment tools are being actively investigated. The Functional Living Index–Cancer (FLIC); Functional Assessment of Cancer Therapy Scale (FACT), Short Form 36 (SF-36); Karnofsky Scale; International Society of Limb Salvage–Musculoskeletal Tumor Society (ISOLS-MSTS) assessment; and Toronto Extremity Salvage Score (TESS) are tools currently in use. The Memorial Sloan-Kettering Cancer Center (MSKCC) is moving toward use of the FACT and away from the FLIC.<sup>21,22,23 and 24</sup> Other tools are being developed and validated that pertain not only to patients with cancer but also to those with musculoskeletal issues. These new functional assessments strive to combine the recently developed American Academy of Orthopaedic Surgeons Modems with oncologic assessments such as the Health-Related Quality of Life (HR-QOL) and the FACT. These tools will become increasingly important in evaluating the efficacy and value of new therapies for patients with metastatic bone disease.

## IMAGING OF BONE LESIONS

### PLAIN RADIOGRAPHY

Plain radiographs are the foundation of evaluation, surgical planning, and monitoring of metastatic lesions of bone. Radiographs are a fast, inexpensive, and readily available technique for evaluating bone metastases. Other techniques may be more sensitive, but radiographs give the best integration of overall bone structure and alignment and correlate best with clinical features. Therefore, plain radiography should be the first test ordered in the evaluation of bone pain.

Three radiographic patterns of metastatic disease typically are seen: osteolytic, osteoblastic, and mixed.<sup>25</sup> Because of variations in the bone microenvironment and clonal differentiation of tumors, different patterns may exist throughout the skeleton or within a single bone. Prostate cancer metastases are classically osteoblastic, breast cancer bone lesions usually show a lytic or mixed pattern, and lung cancer metastases are predominantly lytic. Radiographic variability can also be seen during the course of therapy, as the radiographic appearance of a lesion changes during treatment. Osteoblastic areas seen radiographically correspond to the reaction of the host bone to the metastases, not to the tumor itself. Fast-growing tumors tend to have a lytic or mixed pattern, and the bone reaction cannot keep pace with the rate of tumor growth. Reactive bone often lacks mechanical strength, as it forms in a random pattern lacking normal Haversian structure.

Periosteal changes can also occur with metastatic disease to the bone. Rapidly growing tumor can elevate the periosteum, causing an irregular periosteal reaction. Lung cancer and prostate cancer with cortical involvement commonly display this pattern. Stress fracture through the underlying bone lesion can also be associated with periosteal reaction. Nevertheless, periosteal elevation is usually a hallmark of primary bone neoplasm; therefore, sarcoma should be excluded when periostitis is present.

Radiographs assist greatly in surgical planning. Disease spreads diffusely within long bones. In patients with proximal femoral metastases in whom radiographic evaluation is confined to the hip, potential lesions distal in the femur are overlooked. It is important that the entire bone be imaged, so that all lesions can be addressed and stabilized during the same operative procedure.

Finally, sequential radiographs of involved areas are important for monitoring response to treatment, local recurrence, and disease progression. X-ray films of subsequently symptomatic regions are important for identifying further metastatic foci, allowing for early intervention and management. In addition, certain tumors (most notably multiple myeloma) do not stimulate the increased bone turnover required for positive readings on bone scan. Patients with such tumors are best evaluated for other foci of skeletal disease by a plain radiographic skeletal survey.

### BONE SCINTIGRAPHY

Technetium diphosphonate bone scans are extremely valuable in identifying occult bone lesions and diagnosing metastatic disease. Whereas 30% to 50% of bone mineral must be lost for a lesion to appear on plain radiograph, bone scans show skeletal involvement much earlier. Bone scintigraphy is an essential part of cancer staging for skeletal metastases, identifies sites of both symptomatic and asymptomatic lesions, and locates potential sources of referred pain. In 85% of patients with metastatic cancer to bone and a single symptomatic focus, multiple additional foci will be seen on bone scan. Certain tumors, such as lung cancer and melanoma, grow rapidly and evoke little reactive bone formation, leading to false-negative scans. In addition, multiple myeloma is notorious for resulting in false-negative bone scans. Bone scans lack anatomic detail and, although they can localize the site of involvement, the specific characteristics of the lesion are not visualized. Bone scan results should be correlated with additional imaging modalities such as plain-film radiographs or CT scans.

Bone scintigraphy can be used to evaluate the response to chemotherapy, hormone therapy, or radiation therapy, by reflecting the biology of the lesion and the extent of the host response. The method has been most useful in evaluating treatment in breast cancer patients. Up to 15% of patients will experience an initial increase in radioisotope uptake on bone scan with treatment, called the *flare phenomenon*.<sup>26</sup> This reflects new bone formation as a healing response around the quiescent lesion. Over time, the surrounding bone heals, and osteoblast activity, which is estimated by the uptake on bone scan, will diminish. Development of additional scintigraphic lesions early in treatment does not necessarily reflect disease progression. Instead, this can reflect healing and ossification of areas where the tumor did not evoke a response initially.

A limitation of the bone scan technique is that it measures solely the metabolic activity of the bone and not its structural integrity. Biologic control of the tumor does not necessarily translate into mechanical restoration of the skeleton. Therefore, close correlation of follow-up bone scan information with plain radiographs or CT scanning is necessary.

### COMPUTED TOMOGRAPHY

CT scanning is very effective in evaluating the three-dimensional integrity of bone and the characteristics of lesions identified on bone scan.<sup>27</sup> It helps to confirm the presence of metastatic disease, particularly when evaluating lesions localized to the pelvic and shoulder girdles. Spine lesions can also be imaged by CT scans but are better evaluated by MRI in most circumstances.<sup>28</sup> CT scanning is superior to MRI in demonstrating bone mineral content and cortical integrity and is therefore more useful in evaluating the structure of the involved bone. MRI will often show extensive marrow involvement in a bone, even though the structural integrity is preserved. CT scans help to discriminate between the presence of cellular and structurally significant disease.

### MAGNETIC RESONANCE IMAGING

MRI is an excellent technique for evaluating bone marrow, which is the first site of metastatic involvement of bone.<sup>19,28,29 and 30</sup> Though it is very sensitive for this indication, it is nonspecific. However, MRI is particularly useful in round cell lesions such as leukemia, lymphoma, and multiple myeloma, which replace the marrow space. The high fat content of bone marrow translates to high signal intensity or brightness on T1-weighted and low signal intensity on T2-weighted images. This essentially provides a contrast medium juxtaposed to the tumor, which, because of its high water content, has high signal intensity on T2-weighted and low signal intensity on T1-weighted images.

MRI provides good three-dimensional anatomic information throughout the skeleton and is excellent in defining soft tissues and delineating soft tissue involvement by tumor. In the spine, MRI is especially useful because it is sensitive for tumor involvement, shows sagittal and cross-sectional alignment, and details tumor present in the spinal canal, dural impingement, and spinal cord compression. MRI is particularly helpful in distinguishing between pathologic fracture due to osteoporosis and

that due to tumor. This is particularly important for postmenopausal women, who may experience both metastatic disease and osteoporosis.<sup>30</sup> MRI is useful in the evaluation of skeletal metastatic disease but is an imperfect discriminator and therefore requires close correlation with additional studies and the clinical situation.

## POSITRON EMISSION TOMOGRAPHY

Positron emission tomographic (PET) scanning is a newly used tool in the evaluation of metastatic bone disease. Though nonspecific, PET scans identify metabolically active areas by their differential uptake of radiolabeled glucose ([<sup>18</sup>F]fluorodeoxyglucose), similar to the technetium labeling of areas of bone turnover in bone scan. PET scanning was used in a study of 29 patients with bone metastases and an unknown primary tumor in whom conventional diagnostic workup had failed.<sup>31</sup> In these 29 patients, all but one known metastatic site was visualized by PET scan, and additional metastatic sites were identified in 5 patients. PET was able to identify the primary tumor in only 7 of these 29 patients (24%).<sup>31</sup> Data regarding the current clinical relevance of PET scanning are limited. The technique is used predominantly in an investigational role. However, PET scanning does show utility in selected instances for diagnosis of bone and soft tissue metastases.

## THERAPEUTIC MODALITIES

Multiple therapeutic modalities are available in the armamentarium for management of metastatic disease to bone. These modalities comprise three broad categories: systemic therapy, radiation therapy, and surgery.

### SYSTEMIC THERAPY

Systemic therapies include chemotherapy, bone marrow transplantation, hormone therapy, immunotherapy, and medications. The medical oncologist directs the majority of systemic management. Systemic chemotherapy with antineoplastic agents is primary tumor-specific. Until the development of bisphosphonates, no specific drugs were directed to the general entity of bone metastases. Bisphosphonates have shown great utility in the management of patients with metastatic bone lesions, most notably in cases of breast cancer and multiple myeloma.

#### **Bisphosphonates**

Bisphosphonates are stable analogs of naturally occurring inorganic pyrophosphate. They inhibit the precipitation of calcium phosphate *in vitro* and biologic calcification *in vivo*. They also inhibit bone resorption, particularly that occurring in certain metastatic lesions of bone. The mechanism by which bisphosphonates inhibit bone resorption is inhibition of osteoclasts by interruption of the mevalonate metabolic pathway and, possibly, by causing osteoclast apoptosis as well.

First-generation bisphosphonates such as clodronate and etidronate, second-generation drugs such as tiludronate and pamidronate, and third-generation medications such as ibandronate and zoledronate, have differing potencies and effects. The bisphosphonates are generally safe compounds with few side effects. The drugs are not metabolized in the human body, with 50% to 60% of each dose rapidly absorbed by bone, followed by slow renal elimination; the other 40% to 50% is rapidly excreted by the kidneys.

Bisphosphonates have proven efficacy in the treatment of hypercalcemia of malignancy, Paget's disease of bone, osteoporosis, and bone metastasis in breast cancer and multiple myeloma. Pamidronate is approved for use in hypercalcemia of malignancy, Paget's disease, and bone metastasis, whereas therapeutic approval for other bisphosphonates varies: Etidronate is approved for use in hypercalcemia of malignancy, alendronate for the treatment of osteoporosis, and tiludronate for the treatment of Paget's disease. Pamidronate, 90 mg by IV infusion every 3 to 4 weeks, is the dosing regimen that has been shown to provide the most rapid onset of pain reduction and increased mobility, with minimal side effects.<sup>32</sup> Several large randomized trials have been performed to analyze the efficacy of pamidronate in the management of metastatic bone lesions.<sup>33</sup>

Theriault et al.<sup>33</sup> reported on their randomized, double-blind trial involving 372 patients with breast cancer and at least one lytic bone lesion who received standard hormone therapy. The skeletal morbidity was significantly reduced in the patients receiving pamidronate; however, there was no significant difference in survival or objective bone response rate. Not until 6 months was a difference observed between the two groups, at which point the curves diverged, with an upward shift of the placebo group's skeletal event rate curve, though the curves for both treatment groups maintained the same slope.<sup>34</sup>

Hortobagyi et al.<sup>35</sup> reported on their randomized, double-blind trial involving 382 patients with metastatic breast cancer and lytic bone lesions who were receiving standard chemotherapy. Again, a significantly decreased risk of bone lesion complications was seen in the pamidronate group as compared to the placebo group.<sup>35</sup>

Berenson et al.<sup>36</sup> reported on their randomized, double-blind trial of 392 patients with stage III myeloma and at least one lytic bone lesion who were receiving either first-line or second-line antimyeloma chemotherapy. There was a significant reduction in skeletal events in the pamidronate group, although survival was not different between the pamidronate and placebo patients. Again, the skeletal event curves of the pamidronate and placebo groups diverged, in this instance from the initiation of the study. The placebo group's curve was shifted upward, but the two curves continued to have similar slopes, as was seen in the breast cancer trials.<sup>36</sup>

In light of the outcomes from these large randomized trials, bisphosphonates have been added to the therapeutic armamentarium in the treatment of bone metastasis due to breast cancer or multiple myeloma. Although bisphosphonates have not been proven to be efficacious in managing bone metastasis due to other tumors, theoretically these compounds should be of value in all cancers causing lytic bone lesions. There is also evidence that bisphosphonates may actually prevent the development of bony metastases. In several animal models, injected tumor cells failed to establish colonies in bone that had been pretreated with bisphosphonate.<sup>37,38</sup> The magnitude of benefit of bisphosphonates in other cancers, its possible early use in the management of patients with metastatic disease, and the details of the mechanism of action of this drug class all warrant further investigation. Despite their benefits, bisphosphonates act over the course of several months. When a more rapid response is needed, radiation therapy or surgery (or both) still are required.

#### **Chemotherapy and Hormone Therapy**

Because of the significant percentage of patients with breast cancer who develop metastatic bone lesions, the effects of chemotherapy and hormone therapy on these lesions have been investigated. The goals of chemotherapy and hormone therapy in patients with metastatic disease involving bone are pain control, disease stabilization, and reduction of the risk of morbid skeletal events (e.g., pathologic fracture). In a series of patients from the M. D. Anderson Cancer Center who were treated with 5-fluorouracil, doxorubicin, and cyclophosphamide, bone lesions showed an 18% complete and a 65% partial response to the regimen. Hormone-sensitive breast carcinoma has a predilection to metastasize to bone; therefore, hormone therapy can be effective in these cases. As with other therapies, a peritreatment lesion "flare" may occur that makes the evaluation of overall response difficult. However, the use of chemotherapy and hormone therapy in metastatic breast cancer has been shown to prolong survival and can render patients better able to respond to bone lesion-specific therapy such as bisphosphonates or systemic radionuclides, reducing overall skeletal morbidity.<sup>39</sup>

### RADIATION THERAPY

#### **External-Beam Radiation Therapy**

Radiation is an important technique for treatment of tumor that has metastasized to the bone. The indications for radiation therapy are pain relief and suppression of local tumor growth. Suppression of local tumor growth is important in the treatment of impending fractures, after surgical fixation of metastatic lesions, and in the treatment of neural compression. This is exemplified by irradiation of tumor for spinal cord compression. Tumor reduction and pain relief can begin immediately, particularly for very radiosensitive round cell tumors. Thoughtfully planned treatment with high-energy radiation causes minimal morbidity, and the benefits far exceed the risks in most situations. Radiation is of therapeutic value in patients with localized symptomatic lesions and should be considered in all but the few cases in which either the disease is very responsive to systemic treatment (e.g., germ cell tumor, lymphoma) or the lesions are resectable for cure.

Despite its efficacy, radiation therapy should not be used indiscriminately. Marrow fibrosis can be a late complication that precludes chemotherapy. The radiation oncologist must collaborate with the medical oncologist and surgical personnel to optimize treatment. This interdisciplinary cooperation is critical in the management of an impending fracture. Occasionally, a lesion will heal with radiation therapy, especially if it is mechanically protected.<sup>40</sup> Treating an isolated lesion may allow the radiation oncologist to use a narrower radiation field. However, fracture and subsequent intramedullary fixation necessitate treatment of the entire bone, which can be

difficult to implement if a radiation treatment protocol has already been applied within the new field.

More than 80% of patients with a limited number of well-localized bony metastases can be treated effectively by external-beam irradiation. <sup>41,42 and 43</sup> High-dose radiation, coupled with careful subsequent observation, is suitable, cost-effective oncologic management for most cancer patients, especially if the available chemotherapeutic regimens are not well established. Radiation may render the patient asymptomatic and control the disease for an extended period.

Patients with numerous areas of skeletal involvement require systemic therapy. Chemotherapy or endocrine therapy is the most appropriate. If symptoms persist over the course of several months, alternative management for localized disease should be considered. External-beam irradiation to the most symptomatic or potentially troublesome areas should be used to supplement systemic therapy. Hemibody radiation or systemic radionuclide therapy should be considered for widely disseminated bone disease. <sup>44,45 and 46</sup>

Metastases involving the spine are best treated early in the course of disease because progression can produce grave morbidity. <sup>47,48</sup> The spine should be braced until the lesions can heal. Irradiation of a weight-bearing bone such as the femur should be undertaken only after careful evaluation of the potential fracture risk produced by the underlying lesion (as discussed later in [Impending Fractures: Prophylactic Fixation](#)). There is an increased risk of pathologic fracture in the peri-irradiation period due to an induced hyperemic response at the periphery of the tumor. This weakens the adjacent bone and increases the risk of spontaneous fracture. Mechanical protection is important until the bone's structural integrity has been restored. Identification of disease progression and management of associated morbidity by the treatment team is very important during the course of irradiation, because other treatments often are suspended during this time. The interdisciplinary communication essential for high-quality treatment often is best provided through a medical practice environment in which all the specialists are in geographic proximity. This minimizes the need for excessive travel by the patient who is experiencing a limitation in mobility and is at risk for fracture.

**TREATMENT PLANNING.** Data from a patient's medical history, physical examination, bone radiographs, and three-dimensional imaging help to direct radiation fields. The radiation fields should include all soft tissue masses as identified by the aforementioned studies. The margin of normal tissue treated around the lesion is variable. The goal, as in surgery, is to avoid having to treat the same bone on multiple occasions. MRI is used to image proximal and distal lesions in the spine. Appropriate radiation portals can then be defined to avoid repetitive irradiation of the spinal cord. Careful planning in this fashion avoids overtreatment and complications such as transverse myelitis, bowel toxicity, and peripheral edema.

Radiation suppresses hematopoiesis in the bones within the treatment portal. Marrow suppression is a more significant concern in patients receiving chemotherapy, as combined myelosuppression can be severe. Aggressive chemotherapy regimens that depress stem cell populations are the most dangerous in this regard. Complete blood cell counts must be closely monitored, often on a daily basis.

**PAIN RELIEF.** Irradiation achieves at least partial relief of pain in 80% to 90% of patients. <sup>49</sup> The speed of response varies. When the cause of pain is neurologic, tumor regression can be prompt and relief rapid. Spinal cord compression from lymphoma is a classic example of this phenomenon. <sup>50,51</sup> Most symptomatic bony metastases begin to respond over the course of 10 to 14 days. Seventy percent of patients experience some pain relief within 2 weeks of starting therapy and, within 3 months, 90% of patients achieve pain relief. <sup>52</sup> Tong et al., <sup>53</sup> from the Radiation Treatment Oncology Group (RTOG), found that approximately 55% to 70% of patients who responded initially did not develop recurrent pain in the treatment field. These data support other studies that note sustained pain relief for 1 year or more in 55% to 65% of patients. <sup>54</sup> There is no convincing evidence that different histologic cancers respond differently to irradiation. Although undoubtedly there are some variations, they seem to be as great among cancers of the same histologic type as they are between primary cancer types. <sup>55</sup>

Evaluation of pain relief and tumor responsiveness has failed to account properly for the mechanical contribution to pain. Even when cancer cells respond well to therapy, lytic tumors may lack matrix, and thus the underlying bone may require more time to restore its mechanical strength. This may explain the clinical observation that radiation is less successful in palliating lung and kidney cancer lesions, which tend to be predominantly lytic. The RTOG reported that patients with breast and prostate metastases, cancers that have a significant amount of associated matrix, derived better pain relief from irradiation than did patients with long bone lesions from other primary tumors. <sup>53</sup> Patients with more severe and frequent pain as well as those in whom other treatments have failed are in a poor prognostic category.

When patients do not achieve relief on a therapeutic schedule consistent with that already described, a separate etiology should be considered for the pain. The clinician should have a high index of suspicion for comorbid conditions. A sudden increase in pain after the start of treatment may indicate that a pathologic fracture has occurred. Radiographic and orthopedic evaluation should be obtained before the radiation course is continued.

**RADIATION DOSE AND FRACTIONATION.** The optimal dose and fractionation regimen for palliative therapy of metastatic bone lesions is debated. <sup>42,49,56</sup> Dose, duration, and fractionation of treatment are interrelated concerns. Metastatic cancer patients with limited life expectancies should receive effective treatment over as short a time course as possible. Short-term toxicity is the major concern in patients with pathologic fractures because of their reduced life expectancies. Short-course irradiation minimizes the number of treatments and necessary travel time while producing high response rates.

The RTOG's randomized study of differing dose fractionation schedules in 759 patients reported no significant difference in pain relief among five different schedules of fractionation (270 cGy × 15, 300 cGy × 10, 300 cGy × 5, 400 cGy × 5, and 500 cGy × 5). <sup>43,53</sup> Complete pain relief and the elimination of the need for narcotic analgesics occurred more frequently with protracted fractionation. According to Blitzner's reanalysis of the RTOG data, <sup>43</sup> the 270 × 15 or 300 × 10 regimens were most effective. At the Royal Marsden Hospital, 288 patients were treated for painful bony metastases with either 800 cGy × 1 or 300 cGy × 10. <sup>42,57</sup> The response rate in each arm of the trial was 80%. Retrospective analysis of single low-dose (400- to 1500-cGy) versus multiple moderate-dose (2000- to 4000-cGy) programs have shown remarkably little difference. <sup>58,59</sup> These studies indicate that there is no consistent dose-response relationship governing pain relief after the irradiation of bone metastases. The heterogeneous nature of patients studied, however, and differences in posttreatment survival times may mask such a relationship.

Some authorities continue to recommend higher doses and longer courses of irradiation to palliate bone metastases. The effectiveness of high-dose therapy is supported by Arcangeli and Micheli, <sup>60</sup> who reported that doses of more than 4000 cGy effected a higher complete response rate. Therefore, patients with a projected long survival and good performance status may be best treated by a full dose (more than 4000 cGy) with conventional fractionation.

Patients with disseminated bone metastases are candidates for hemibody radiation. <sup>56</sup> This method is an alternative for patients for whom localized treatment would be inadequate and effective systemic therapy is lacking. The usual protocol is the administration of 6 to 10 Gy in one fraction to the upper, middle, or lower body. Premedication with antiemetics and corticosteroids and hydration are necessary to treat the acute radiation effects. Response rates are consistently in excess of 70%, with more than 20% of patients experiencing complete pain relief and fewer than 50% requiring additional irradiation for recurrent bone pain. Toxicity occurs in fewer than 10% of patients, and severe toxicity is less common in treatment of the middle or lower body. Prostate cancer appears to be particularly well suited for this form of therapy: Persistent palliation of pain until death has been noted in 82% of patients receiving upper body irradiation and in 67% of those receiving lower body irradiation. However, concerns regarding the permanent impact on bone marrow reserve, with the possible future need for chemotherapy in these patients, has made hemibody radiation less popular, particularly in the setting of available systemic radiopharmaceuticals that target metastatic foci and do not carry similar systemic risks.

### **Systemic Radionuclides**

The systemic administration of radionuclides can be very effective in treating symptomatic bone metastases. This approach is appealing as compared with any other local or systemic therapy in that it treats all involved sites rapidly and selectively, thereby reducing toxicity and enhancing the therapeutic ratio. <sup>46</sup> Strategies include using a carrier that seeks the tumor or a vehicle that localizes in bone matrix. The antineoplastic effect both relieves pain and allows for healing of the underlying bone lesion. Iodine 131 is the prototype, localizing within well-differentiated thyroid carcinoma cells.

Strontium 89 is the most commonly used radioisotope in bony metastatic disease and is advocated for a variety of primary cancer histologic types. <sup>61,62</sup> It localizes in the mineral of bone by combining with the calcium component of hydroxyapatite. Actively calcifying areas concentrate most of the isotope, just as with radionuclide scintigraphy. Therefore, it has particular efficacy in osteoblastic lesions, such as those occurring with metastatic prostate or breast cancer. Degradation of the isotope in the host bone administers local short-acting radiation to the adjacent tumor cells. <sup>89</sup>Sr has very good response rates ranging from 51% to 91%. Patients with prostate cancer showed more than 80% symptomatic improvement after <sup>89</sup>Sr therapy. The only significant toxic effect of <sup>89</sup>Sr is myelotoxicity, with a 25% reduction in platelets and leukocytes, and it is usually temporary.

The low-energy  $\beta$ -emission of  $^{89}\text{Sr}$  is safer and better tolerated than are high-energy isotopes such as orthophosphate 32. Other radiopharmaceuticals are also available, including such isotopes as  $^{186}\text{Re}$ , tin-11m-diethylenetriaminepentaacetic acid,  $^{153}\text{Sm}$ , and gallium nitrate. The mechanism of action relates to the half-life of the isotope in the lesion, the penetrance and mean energy of emitted radioactive particle, and the delivered dose. Isotopes with short half-lives, such as  $^{186}\text{Re}$ , emit both  $\gamma$  rays, permitting imaging of lesions, and  $\beta$ -particles, which confer therapeutic value. All agents cause bone marrow suppression, which is worse in heavily pretreated patients undergoing chemotherapy. However, premedication, as is required with hemibody radiation, is not necessary with the use of systemic radionuclides.

Radiopharmaceuticals can cause an initial exacerbation of pain (the flare response) in 10% to 15% of patients. A flare response can indicate good overall analgesic value.<sup>63</sup> In addition, it has been shown that  $^{89}\text{Sr}$  can be safely used in conjunction with external-beam irradiation, either in patients who have previously received wide-field radiation and present with symptomatic bony lesions or in patients who have not received previous external-beam irradiation and so can receive external-beam irradiation subsequent to treatment with  $^{89}\text{Sr}$ .<sup>64,65</sup>

## SURGERY

### General Considerations

**BONE MECHANICS.** Bone strength depends on a combination of material and structural properties.<sup>66</sup> Material properties are of greatest importance when overall bone geometry remains unchanged. Alterations in bone mineral content influence strength and stiffness exponentially.<sup>67</sup> Alterations in bone proteins after chemotherapy or radiation therapy may influence the ability of bone to reconstitute. Bone structural properties reflect the underlying geometry and distribution of material in space, integrating the contribution of medullary trabecular bone and cortical compact bone. Both lytic and blastic lesions dramatically alter the bone modulus of elasticity and reduce bone strength. Lytic disease reduces bone strength more so than blastic metastases.<sup>68,69</sup> However, blastic metastases also reduce bone strength secondary to the disorganized nature of this tumor-related bone.

Most of the compressive strength of bone is due to its mineral component, whereas it is the combination of mineral and protein that lends strength in tension.<sup>70</sup> During normal activity, most forces are either of compression or tension. Torsional or rotational forces, which come into play when the lower extremity is planted and the patient pivots, are also important.<sup>71</sup> These forces typically occur during transfers such as getting into and out of a chair. Bone is weakest in torsion. A single 6-mm drill hole, the size used for bone biopsy, reduces torsional strength 50%.<sup>71,72</sup> and<sup>73</sup> Larger defects create even greater stress risers, decreasing torsional strength by 70% and more.<sup>68</sup> Defects larger than the diameter of the bone are termed *open segment defects* and can reduce both bending and torsional strength as much as 90%. Weak bone tends to fracture in a transverse configuration, as compared with normal bone, which fractures in an oblique or spiral pattern. Overall bone alignment usually is good in pathologic fractures as long as a large destructive lesion is not present.

**BONE BIOLOGY.** The local presence of cancer precludes bone healing in most pathologic fracture situations. The rapid growth of metastatic lesions overwhelms the healing response. Gainor and Buchert<sup>4c</sup> evaluated 123 patients with pathologic long bone fractures. Healing occurred in 45 of the 129 fractures (35%). Healing rates were related to tumor type: In this series, 67% of fractures due to multiple myeloma, 44% of fractures due to renal cancer, and 37% of fractures due to breast cancer healed. No pathologic fractures due to lung cancer healed.

The length of patient survival correlated best with fracture healing rates, although healing was considered multifactorial. The five factors that related to the healing of pathologic fractures included diagnosis, survival, internal fixation, postoperative irradiation, and chemotherapy.<sup>4c</sup> Melanoma and lung and colorectal cancers failed to heal. Lesions due to multiple myeloma and breast and renal cancers tended to heal most frequently; however, they also occurred earlier in the course of these diseases, while other therapeutic options still remained. Survival was directly related to diagnosis, and this correlated with improved healing rates for patients living longer than 6 months. Rigid internal fixation supplemented with bone cement was found to increase the probability of bone union. Bone cement not only contributes to stability but also may present a mechanical obstacle to tumor growth in the fracture region. High doses of postoperative radiation (>3000 cGy) were associated with poor healing. Because of the variety of agents and therapeutic courses of chemotherapy, this series could not extrapolate the influence of chemotherapy on fracture healing. However, other studies suggest that healing is reduced 50% by such common agents as methotrexate and doxorubicin.<sup>74</sup>

Other systemic factors may make a contribution to fracture healing in patients with metastatic bony lesions, including osteoporosis, hormone manipulation, and cachexia.

### Fracture Treatment

Management of pathologic fractures with internal fixation or prosthetic replacement is the most effective and expedient means by which to control pain and restore function. Effective orthopedic procedures for metastatic disease convert open segment to closed segment defects, restore bone strength in bending and torsion, and allow immediate weight bearing. Stabilization of a fracture requires control of the proximal and distal fracture fragments. In this respect, fracture location is an important consideration, and management strategies are different for epiphyseal, metaphyseal, and diaphyseal locations.

**EPIPHYSEAL FRACTURES.** Epiphyseal fractures present the easiest problem. Fracture healing is not a consideration, even with nondisplaced fractures, because it almost never occurs. Resection of the fracture and associated diseased tissue is appropriate, and arthroplasty should be performed, usually involving a cemented implant. Stem length should be chosen to treat existing or potential lesions within the same bone. Widespread use of bisphosphonate therapy may reduce the need for long-stemmed prostheses in the future.

**METAPHYSEAL FRACTURES.** Metaphyseal fractures are more complex. The fracture geometry, quality and quantity of residual bone, and histologic subtype must be considered. It is especially important to judge the fracture healing potential using the Gainor criteria discussed in the previous [Bone Biology](#) section. If a patient is early in the course of treatment, effective systemic therapies are available, and the tumor is sensitive to irradiation, internal fixation can support the bone while healing occurs. Lymphoma, occasionally myeloma, and breast cancer are the tumor types for which a long-term, bone-healing strategy has merit.
