In type III gastric carcinoids not associated with hypergastrinemia, which tend to be larger and more aggressive, if they are larger than 2 cm, excision and regional lymph node clearance is recommended.<sup>224,225 and 226,228</sup> Some recommend a similar approach for any carcinoid larger than 1 cm, whereas others recommend it be reserved for tumors in this size range showing histologic invasion. Most tumors smaller than 1 cm are treated endoscopically.<sup>224,225 and 226</sup>

Resection of isolated hepatic metastases may also be beneficial or curative in select patients.<sup>162,217,218 and 219,231,232</sup> In one study,<sup>232</sup> 22% of patients had unilobar disease and could have all tumor resected, whereas in other studies, fewer than 10% of patients were surgical candidates because of more disseminated disease.<sup>231,233</sup> In the 20% with all metastatic disease resected,<sup>232</sup> 5-HIAA levels were normal and 10-year survival was 100%. The role of cytoreductive or debulking surgery in patients in whom all tumor cannot be removed is unclear. No prospective randomized trials have addressed this question. A number of retrospective analyses suggest that such an approach should be considered in selected cases.<sup>20,162,217,218 and 219,231,232,234,235 and 236</sup> A number of studies<sup>218,219,222,231,236,237</sup> recommend debulking mesenteric metastases and removal of compromised intestinal segments, even in the presence of liver metastases. In one study<sup>222</sup> of 138 patients with midgut carcinoids of whom 51 patients were subjected to surgery with the principal aim of removing the primary tumor and debulking mesenteric metastases, the authors concluded that this surgery provided considerable symptomatic relief. A similar study<sup>237</sup> of 75 patients with advanced abdominal carcinoids, all of whom underwent exploratory laparotomy [33% had debulking procedures (excluding liver)], demonstrated a significantly longer survival in those patients who underwent debulking procedures (excluding liver), whether or not liver metastases were present.

The role of cytoreductive hepatic resection or of cryotherapy for patients with multiple hepatic metastases from carcinoids is also unclear.<sup>218,231,235,236,238</sup> In a review of 47 cases of patients with metastatic carcinoids who underwent partial hepatectomy, the mortality rate was 4.3% and the mean survival rate was 6.2 years.<sup>231</sup> In 60% of the patients, the symptoms of carcinoid syndrome resolved after resection. The authors of this review concluded that resection of hepatic metastases may relieve clinical endocrinopathies and that the symptomatic response may last several months.<sup>231</sup> It was recommended that if more than 90% of the imaged tumor could be safely removed, resection should be considered. In a study<sup>238</sup> of 13 patients with metastatic NETs to the liver (including seven patients with carcinoids), complete ablation of all visible tumor was achieved at surgery by cryotherapy in all but one patient. With a mean follow-up of 13.5 months, 92% of the patients were alive and only 17% of the patients with complete ablation had recurrent tumor.<sup>238</sup>

In one study,<sup>239</sup> radiation therapy was used in 44 patients with symptomatic metastatic unresectable carcinoid tumors. Survival was not prolonged; however, substantial palliation was achieved in most cases, with an overall response rate of 80%, including 76% (16 of 21) for abdominal tumors, 92% (12 of 13) for spinal metastases, 63% (five of eight) for brain metastases, and 89% (eight of nine) for bone metastases. Of eight patients with intracranial lesions,<sup>239</sup> none demonstrated progression during follow-up (median dose, 3300 cGy). At present, radiotherapy is primarily used for symptomatic bone metastases, especially to the spine.

Because MIBG is frequently taken up by carcinoids and concentrated, the possibility of using radiolabeled MIBG therapeutically has been evaluated in a small number of patients.<sup>3,240,241,242 and 243</sup> Iodine 125 MIBG or iodine 131 MIBG has been reported to decrease 5-HIAA urine concentrations and control symptomatic metastases in a small number of cases.

## CHEMOTHERAPY

No general agreement on has been reached about when, or even if, chemotherapy should be started in patients with malignant carcinoids. One group with considerable experience<sup>20</sup> suggests that only patients with significant symptoms or disability from malignant disease or syndromes or who have a poor prognosis should undergo chemotherapy. Chemotherapy for metastatic carcinoids has, in general, been disappointing<sup>3,244,245</sup> (Table 38.6-6). Single-agent therapy with doxorubicin,<sup>162,246</sup> 5-fluorouracil,<sup>162</sup> DTIC,<sup>166,247,248</sup> and<sup>249</sup> actinomycin D,<sup>247</sup> cisplatin,<sup>250</sup> alkylating agents,<sup>78</sup> etoposide,<sup>251</sup> streptozotocin,<sup>78</sup> and carboplatin,<sup>252</sup> has provided low tumor response rates of 0% to 30%. In general, the duration of responses is short, usually less than 1 year. Combination chemotherapy for metastatic carcinoid has not been shown to have any clear advantage compared with single-agent chemotherapy. Two-dose combinations have been used of streptozotocin and 5-fluorouracil<sup>43,166,201,246,253,254</sup>; streptozotocin and cyclophosphamide<sup>43</sup>; streptozotocin and doxorubicin<sup>253</sup>; etoposide and cisplatin<sup>255</sup>; DTIC and 5-fluorouracil<sup>256</sup>; and lomustine and 5-fluorouracil<sup>257</sup> with low response rates of 0% to 40% and no apparent significant improvement over the use of single agents alone. Three-drug combinations with 5-fluorouracil, doxorubicin, and cisplatin<sup>258</sup>; DTIC, 5-fluorouracil, and epirubicin<sup>259,260</sup>; and streptozotocin, cyclophosphamide, and 5-fluorouracil<sup>261</sup>; or four-drug combinations of streptozotocin, doxorubicin, cyclophosphamide, and 5-fluorouracil<sup>261</sup> also gave low response rates of 10% to 31% and showed no additional therapeutic advantage over a single agent. Remissions were short-lived, with an average duration of 4 to 7 months.<sup>20,162,166,244</sup> It can be concluded that no combination therapy has clearly had a beneficial effect in the treatment of malignant carcinoids. Given the indolent nature of the tumor, poor efficacy, and undisputed toxicity of chemotherapy and the availability of excellent symptomatic therapy (octreotide and interferon), chemotherapy usually is reserved for advanced tumors with evidence of progression late in the disease course. Selective hepatic artery infusion of 5-fluorouracil had a similar response rate as that reported for systemic 5-fluorouracil.<sup>78</sup>

TABLE 38.6-6. Antitumor Drug Therapy of Carcinoids

## BIOOTHERAPY

Analogues such as octreotide or lanreotide, in addition to controlling symptoms and reducing secretion of 5-HIAA or various peptides, also have been assessed for their antitumor effects<sup>181,183,185,189,191,201,262,263,264</sup> and<sup>265</sup> (see Table 38.6-6). In general, these analogues have a poor tumoricidal effect, decreasing tumor size in only 0% to 17% of patients. However, both somatostatin analogues (lanreotide, octreotide) have a tumoristatic effect, stabilizing the growth of metastatic disease and, in some studies, prolonging survival.<sup>135,181,185,265</sup> The mean survival in the 66 patients treated with octreotide in the Mayo Clinic studies<sup>191,264</sup> was 3 years, which was significantly longer than the 9 to 12 months in the 92 patients treated with chemotherapy in the Eastern Cooperative Oncology Group studies. Similarly, in a phase II study<sup>265,266</sup> examining the effect of octreotide, 150 to 250 mg three times per day, on survival and tumor growth in 20 patients with metastatic carcinoids, 50% of patients had a CT-documented stabilization of metastatic disease that was maintained a minimum of 2 months (median, 5 months). The median survival was not reached at 29 months. Similar results were reported in prospective studies with octreotide or lanreotide in Germany,<sup>267</sup> in Sweden,<sup>185</sup> and in two studies in Italy<sup>183,268</sup> in which 45%, 70%, 80%, and 100% of the patients did not demonstrate tumor progression during treatment, respectively. No prospective study has proven that this tumor stabilization results in increased survival.

Studies<sup>200,201</sup> and<sup>202,206,262,266,269,270,271,272,273,274</sup> and<sup>275</sup> show that human leukocyte interferon or interferon- $\alpha$  causes a decrease in tumor size in a small number (0% to 20%) of patients with metastatic tumors (see Table 38.6-6). However, similar to octreotide, interferon appears to have a tumoristatic effect, stopping further tumor growth and stabilizing the extent of metastatic disease, which may lead to prolonged survival.<sup>201,204,276</sup> In a large prospective study<sup>201</sup> of interferon- $\alpha$  in 111 patients with metastatic disease, 16 patients (14%) demonstrated a greater than 50% reduction in tumor size, whereas 66% demonstrated a stabilization of disease and 19% progressed. In this study, the survival of patients treated with interferon was prolonged compared with the survival of those treated with streptozotocin and 5-fluorouracil. Interferon treatment (3 million to 9 million units three times per week) was associated with tolerable but significant side effects, including flu-like symptoms in 89%, fatigue in 70%, weight loss in 57%, reduction of blood counts in 31% (anemia in 31%, leukopenia in 3%, thrombocytopenia in 14%), increased serum levels of triglycerides in 32%, and increased liver enzymes in 31%.<sup>201</sup> Clinical thyroid disease developed in 76% of patients with thyroid antibodies.<sup>3</sup> In 22 patients,<sup>277</sup> it was found that the induction of the enzyme 2R,5R-oligoadenylate synthetase with interferon treatment correlated with the development of a clinical response; however, it is unknown if this response is predictive of changes in tumor size with interferon treatment. The optimal dose for long-term treatment seems to be 5 to 10 mU three to five times per week; subsequently, however, it is important to titrate the dose individually for each patient.<sup>204</sup> It is recommended that the leukocyte count be used as an indication of the antiproliferative effect of interferon- $\alpha$ , with the goal of reducing the leukocytes to less than  $3 \times 10^9$  per liter.<sup>204</sup>

Because of their separate tumoristatic effects and ability to control symptoms, the combination of octreotide and interferon- $\alpha$  were assessed in small numbers of patients with malignant carcinoid syndrome, either alone or in combination with other agents (see Table 38.6-6). With octreotide and interferon, <sup>184,266,278</sup> interferon- $\alpha$  plus 5-fluorouracil,<sup>279</sup> interferon- $\alpha$  and - $\beta$ ,<sup>280</sup> and streptozotocin with doxorubicin and interferon- $\alpha$ ,<sup>274</sup> only low rates (0% to 10%) of decrease in tumor size occurred, which was similar to interferon- $\alpha$  alone. Although some of these combinations, such as octreotide and interferon- $\alpha$ , were more effective than either agent alone at controlling symptoms of the carcinoid syndrome or decreasing 5-HIAA excretion,<sup>204</sup> no clearly increased tumoricidal effect was apparent. In one study<sup>184</sup> involving 21 patients with metastatic NETs (including nine with carcinoids) who were unresponsive to monotherapy with octreotide, an interferon- $\alpha$  plus octreotide combination caused inhibition of tumor growth in 67%. In one patient (6%), a decrease in tumor was noted, whereas in the other 61%, the response was a stabilization of tumor size without further growth over a median period of 12 months (range, 3 to 52 months).<sup>184</sup>

Studies<sup>281</sup> demonstrate that somatostatin analogues (lanreotide, octreotide), but not interferon, can induce apoptosis in carcinoid. In contrast, treatment with interferon- $\alpha$ <sup>276</sup> induced increased expression of bcl-2 in the carcinoids, whereas treatment with somatostatin analogues did not. It was proposed that this induced bcl-2 expression may contribute to keeping the malignant carcinoid cells at G<sub>0</sub> and therefore be one of the mechanisms of the antiproliferative effects of interferon.<sup>276</sup>

## EMBOLIZATION AND CHEMOEMBOLIZATION

Surgical hepatic artery ligation or embolization via interventional radiology has been reported to reduce hepatic tumor bulk alone<sup>20,209,212,214,215,232</sup>; combined with interferon<sup>213</sup>; or as chemoembolization combined with chemotherapy with DTIC, cisplatin, doxorubicin, 5-fluorouracil, or streptozotocin<sup>208,210,211,212</sup> and<sup>213,282,283,284</sup> and<sup>285</sup> (see Table 38.6-6). In one study<sup>209</sup> of 29 patients with metastatic carcinoids, 38% had a decrease in tumor size after embolization; 38% had a greater than 50% decrease in hormone levels and 52% had either. Overall growth stabilization<sup>209</sup> was achieved in 38% for a median duration of 7 months. In two other studies involving 31 patients,<sup>214,215</sup> 19 patients had temporary liver dearterialization and 12 were treated with chemoembolization. After temporary liver dearterialization, 41% had a decrease in metastatic hepatic tumor size, whereas with embolization 50% showed a decrease, and in almost all cases the reduction was present for more than 12 months. Hepatic artery occlusion with chemotherapy or chemoembolization may be more effective than embolization or hepatic artery occlusion alone.<sup>212</sup> In one large study,<sup>212</sup> the percentage of patients who had tumor regression after hepatic artery ligation alone was similar to that for patients receiving chemoembolization (treatment with DTIC and doxorubicin alternating with streptozotocin and 5-fluorouracil) (67% vs. 69%, respectively) (see Table 38.6-6). However, the duration of the response was decreased (4 months vs. 18 months for the combination).

In nine recent studies involving chemoembolization (embolization combined with doxorubicin in ethiodized oil or with 5-fluorouracil, DTIC, doxorubicin, cisplatin, mitomycin C, or streptozotocin),<sup>3,207,208,210,211,282,283,284</sup> and<sup>285</sup> a decrease in tumor size was seen in 33% to 100% of the patients (see [Table 38.6-6](#)). The average decrease in size in one study was 84%.<sup>283</sup> In one study,<sup>283</sup> 47% of patients survived 2 years (median survival, 17 months), and in another study the median survival time was 15 months.<sup>208</sup> Interferon has been compared with and without hepatic artery embolization in 42 patients with metastatic carcinoid tumors.<sup>213</sup> Seventeen patients were embolized and received interferon for 1 year, and the remaining 25 patients received only interferon. At 1 year, 82% with embolization had stable disease or decrease in metastases, whereas 64% of those treated with interferon had stable decrease.<sup>213</sup> Also at 1 year, all patients responding to interferon and those with stable disease were randomized to no interferon or continued interferon (3 mU 3 days per week). One year later, all patients receiving interferon had stable disease as compared with only 40% of those taking no interferon. Survival was significantly longer in patients remaining on interferon. Embolization combined with interferon caused a significantly higher rate of tumor shrinkage than embolization alone in this study but did not prolong survival.<sup>213</sup>

## LIVER TRANSPLANTATION

In contrast to other metastatic tumors to the liver in which liver transplantation has generally given poor results and has been largely abandoned, interest in liver transplantation is increasing for patients with metastatic carcinoids and PETs.<sup>71,286,287,288</sup> and<sup>289</sup> In a review of 103 patients<sup>287</sup> with malignant NETs who underwent liver transplantation (43 carcinoids, 48 PETs), the 2-year and 5-year survival rates were 60% and 47%, respectively. However, recurrence-free survival was less than 24%.<sup>287</sup> Univariate analysis defined favorable prognostic factors as age younger than 50 years, primary tumor in lung or bowel, and pretransplantation somatostatin therapy. Multivariate analysis identified the adverse prognostic factors as begin age older than 50 years and transplantation combined with upper abdominal exenteration or Whipple's resection ( $P < .01$ ). It was concluded<sup>287</sup> that liver transplantation may be justified, particularly in young patients with only hepatic disease.

## INTRODUCTION

The multiple endocrine neoplasia (MEN) syndromes are a group of syndromes characterized by tumors of endocrine organs (Table 38.7-1). MEN 1 affects the parathyroid glands, endocrine pancreas, and pituitary gland, among other organs, whereas MEN 2 affects the thyroid gland, parathyroid glands, and adrenal glands. A great deal has been learned over the last 10 years about the genetics and genotype-phenotype relationships characteristic of these syndromes. Syndromes that were earlier thought to be completely separate [MEN 2B and familial medullary thyroid cancer, (FMTC)] are now known to be closely related to MEN 2A.

Characteristic	MEN 1	MEN 2A	MEN 2B	Familial Medullary Thyroid Carcinoma
Genetics	2q37.3	10q26	10q26	10q26
Genetic defect	RET mutation	RET mutation	RET mutation	RET mutation
RET	No	Always	Always	Always
Parathyroid disease	Yes	Yes	Yes	No
Endocrine pancreas	Yes	No	No	No
Pituitary	Yes	No	No	No
Adrenal	No	No	Yes (pheochromocytoma/paraganglioma)	No
Thyroid	No	No	No	Yes (medullary thyroid carcinoma)
Other	No	No	Yes (lipomas, desmoids, etc.)	No
Mode of inheritance	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal dominant
Gene of RET	Yes/RET	Yes/RET	Yes/RET	Yes/RET
Endocrine endocrine tumors	Yes (parathyroid, pituitary, pancreatic, adrenal, thyroid, pheochromocytoma/paraganglioma)	No	No	No

TABLE 38.7-1. Multiple Endocrine Neoplasia Syndromes and Familial Medullary Thyroid Cancer

## MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

Wermer first described the familial occurrence of tumors involving the pituitary gland, parathyroid glands, and pancreatic islets.<sup>1</sup> The syndrome was initially called *Wermer's syndrome*, subsequently called *multiple endocrine adenomatosis type 1*, and now *MEN 1*. It is now clear that the parathyroid disease is always hyperplasia and that the pancreatic endocrine tumors may be malignant.

MEN 1 is inherited as an autosomal dominant trait.<sup>2</sup> Chromosomal linkage studies localized the genetic defect to the long arm of chromosome 11 (q-13 locus).<sup>3</sup> The gene has subsequently been identified and codes a protein called *menin*.<sup>4</sup> This follows the two-hit theory of neoplasia of Knudson<sup>5</sup> in which an inherited mutation in one chromosome is unmasked by a somatic deletion or mutation in the other normal chromosome, thereby removing the suppressor effect of the normal gene. These results are in contrast to patients without MEN 1 who develop pancreatic endocrine tumors, in whom the pancreatic neoplasms develop homozygous inactivation of the MEN 1 gene in 27% to 39% of cases.<sup>6,7 and 8</sup>

Studies concerning the etiology of primary hyperparathyroidism in patients with MEN 1 suggest that there is a circulating factor in the plasma that stimulates bovine parathyroid cells to proliferate.<sup>9,10</sup> Subsequently, analysis<sup>10,11,12 and 13</sup> of plasma mitogenic activity in MEN 1 patients demonstrated that basic fibroblast growth factor or a closely related factor was present, and circulating antibodies to it have been identified.<sup>11</sup> However, other studies have demonstrated that there is a monoclonal abnormality in the hyperplastic parathyroid glands of patients with MEN 1, suggesting that the hyperplastic process in these glands may not be totally dependent on a circulating factor but rather through inactivation of the MEN 1 gene in a precursor cell.<sup>14</sup>

## CLINICAL PRESENTATION

The peak incidence of symptoms in women with MEN 1 is during the third decade of life, whereas the peak incidence in men is during the fourth decade. In individuals from kindreds, its presence can usually be detected with screening by the age of 18.<sup>15</sup> More than one-half of patients with MEN 1 have adenomas of more than one organ, and approximately 20% have three affected endocrine glands. The frequency of glandular involvement, in descending order, is parathyroid, pancreas, pituitary, adrenal cortex, and thyroid. Both the adrenal cortex and the thyroid typically have benign, nonfunctioning adenomas. Other clinically important tumors these patients develop include gastric carcinoids,<sup>16</sup> bronchial carcinoids (primarily women),<sup>17</sup> and carcinoid tumors of the thymus (primarily men).<sup>18</sup> The frequency of clinical signs and symptoms, in descending order, is hypercalcemia, nephrolithiasis, peptic ulcer disease, hypoglycemia, headache, visual field loss, hypopituitarism, acromegaly, galactorrhea-amenorrhea, and rarely Cushing's syndrome.<sup>19,20 and 21</sup> Patients with MEN 1 have a decreased life expectancy, with a 50% probability of death by age 50. One-half of the deaths are due to a malignant tumoral process or a sequela of the disease.<sup>22,23</sup>

## PARATHYROID GLAND INVOLVEMENT

Primary hyperparathyroidism is the most common abnormality in patients with MEN 1, occurring in 88% to 97% of affected patients.<sup>19,24,25 and 26</sup> The diagnosis is dependent on the detection of elevated serum levels of calcium and parathyroid hormone. Primary hyperparathyroidism is usually the initially recognized clinical manifestation of patients with MEN 1, although in prospectively screened patients, other manifestations may be biochemically detected earlier.<sup>15,27</sup> Occasional patients have clinical manifestations of Zollinger-Ellison syndrome (ZES) before primary hyperparathyroidism.<sup>28</sup> Further, pituitary adenomas or hyperinsulinism may be identified before hypercalcemia.<sup>29</sup> The pathology associated with primary hyperparathyroidism is always hyperplasia or multiple gland disease, although some glands may appear grossly normal.<sup>25,26</sup> Basic fibroblast growth factor has been expressed in the hyperplastic parathyroid glands of patients with MEN 1.<sup>30</sup> The surgical management requires removal of three and a half or four parathyroid glands to control the hypercalcemia. If four glands are removed, immediate autograft of some of the parathyroid tissue into the musculature of the nondominant forearm is recommended.<sup>31</sup> The results of surgery have not been ideal. The incidence of

recurrent or persistent hyperparathyroidism is 16% to 54%, and the incidence of hypoparathyroidism is between 10% and 25%.<sup>32,33</sup> Primary hyperparathyroidism has been shown to adversely affect the medical management of the gastric acid hypersecretion in MEN 1 patients with ZES. Many clinicians recommend initial parathyroid surgery to control hypercalcemia because it facilitates the management of the gastric acid hypersecretion.<sup>34</sup>

## PANCREATIC ENDOCRINE TUMORS

Malignant pancreatic endocrine tumors are the most common MEN 1–related cause of death in MEN 1 kindreds (Table 38.7-2).<sup>23</sup> Pathologic examination of the duodenum and pancreas in patients with MEN 1 demonstrates multiple neuroendocrine tumors.<sup>35,36</sup> and <sup>37</sup> Tumors producing pancreatic peptide are the most common pancreatic endocrine tumor in MEN 1 patients, occurring in 80% to 100%.<sup>38</sup> These tumors cause symptoms only due to the tumor mass itself and thus often present when tumor growth is advanced. Many patients develop functional pancreatic endocrine tumors, sometimes coincident with pancreatic peptide–producing tumors, of whom most have gastrinoma, approximately 20% insulinoma, 3% glucagonoma, and 1% vasoactive intestinal peptide (VIPoma)<sup>19,25</sup> (see Table 38.7-1).

Cause	No. of Patients	Age (y), Median (range)
Malignant islet cell tumor	12	46 (27–89)
Ulcer disease	6	56 (41–72)
Malignant carcinoid tumor	6	53 (42–65)
Hypercalcemia/uremia	3	42 (30–45)
Total	27/59* (46%)	

\*Of 59 patients with multiple endocrine neoplasia type 1 who died, 27 died of causes related to multiple endocrine neoplasia type 1. (From ref. 23, with permission.)

**TABLE 38.7-2.** Multiple Endocrine Neoplasia Type 1–Related Causes of Death in the Washington University Series

A number of studies have suggested that most gastrinomas in patients with ZES and MEN 1 are in the duodenum<sup>37,39</sup> and not in the pancreas. The ideal treatment of the ZES is surgical excision of the gastrinoma; however, in patients with MEN 1, excision of gastrinoma rarely results in normal serum gastrin levels.<sup>40,41</sup> and <sup>42</sup> Because of the low probability of cure and the suggestion that the gastrinoma is less malignant in MEN 1, some have recommended that patients with MEN 1 do not undergo surgery.<sup>43,44</sup> However, familial gastrinoma may still have a malignant course.<sup>23,45</sup> Others recommend surgery if a localized gastrinoma is identified by a gastrin gradient on portal venous sampling or secretin angiogram,<sup>45</sup> if the serum pancreatic peptide concentration is elevated,<sup>46</sup> or if a tumor mass is identified by imaging studies.<sup>45,47</sup> Somatostatin receptor scintigraphy can be used to rule out distant metastases and to evaluate for other primary sites (Fig. 38.7-1).<sup>48</sup> At present, the best approach is still unclear.

**FIGURE 38.7-1.** Somatostatin receptor scintigraphy can be helpful to identify sites of distant metastasis or otherwise undetected second primary tumors in the lungs or mediastinum. In this patient with a malignant nonfunctional neuroendocrine tumor in the body of the pancreas (black arrow), the scintigram revealed a solitary metastasis in the left lateral segment of the liver (white arrow) that was not demonstrated on computed tomographic scan or magnetic resonance imaging.

To date, no studies have demonstrated that surgical resection of gastrinomas in MEN 1 is beneficial. One study suggests that surgical resection of primary gastrinomas in patients with and without MEN 1 decreases the probability of the development of liver metastases,<sup>49</sup> which is the most important negative predictor of survival. Further, when followed for long periods of time, patients with gastrinoma and MEN 1 develop liver metastases at a rate similar to patients with sporadic disease.<sup>50</sup> Therefore, we currently recommend that all patients with ZES and MEN 1 have extensive localization studies including somatostatin receptor scintigraphy. Only patients with unequivocally positive imaging studies and no metastases should undergo surgical exploration with intraoperative ultrasound. Tumors larger than 1 cm identified in the pancreatic head are enucleated, the duodenum is carefully explored by duodenotomy, and solitary or multiple tumors identified are resected; large tumors in the pancreatic body or tail are removed by distal pancreatectomy and splenectomy.<sup>51</sup> Some studies suggest that nearly 50% of large tumors treated in this manner may have lymph node metastases.<sup>47</sup> Other studies have shown that the primary tumor size is not necessarily correlated with the presence of lymph node metastases in particular.<sup>52</sup> Resection of liver metastases from patients with MEN 1 may also be beneficial.<sup>53</sup> Using this approach, while cure of ZES is unusual, resection should reduce the risk of subsequent metastatic disease.<sup>49</sup> No data conclusively demonstrate that this approach increases survival.

MEN 1 is present in 20% of all patients with ZES and 4% of patients with insulinoma.<sup>38,54,55</sup> The exact percentage of patients with VIPoma, glucagonoma, or somatostatinoma with MEN 1 is not known, but is estimated to be low (less than 5%)<sup>38</sup> (see Table 38.7-1). The surgical management of insulinoma and VIPoma in MEN 1 patients has had more frequent biochemical cures than resection for gastrinoma.<sup>56</sup> Medical management of the watery diarrhea in VIPoma is effective using either short-acting or depot somatostatin analogues. Hypoglycemia management in insulinoma is not reliable. Diazoxide and octreotide are available and may be useful for short-term treatment. In patients with MEN 1, insulinoma and VIPoma are frequently solitary large tumors. Resection may result in cure.<sup>45,47,57,58</sup> and <sup>59</sup> Some recommend the use of endoscopic ultrasound to identify the insulinoma in patients with MEN 1.<sup>60</sup> Portal venous sampling for insulin or calcium angiography may also be useful.<sup>45,47,61</sup>

## PITUITARY TUMORS

Pituitary tumors occur in 54% to 80% of patients with MEN 1.<sup>19,21,25</sup> Symptoms may be due to local encroachment including headache and visual field defects. In a review of series, the most common tumor was a prolactinoma (41% to 76%), followed by growth hormone–secreting tumor, nonfunctional tumor, and rarely adrenocorticotropic hormone– or thyroid-stimulating hormone–secreting tumors.<sup>62</sup> Men with prolactinoma may be unable to achieve a penile erection, whereas women may have galactorrhea. Growth hormone–secreting tumors (25%) result in acromegaly.<sup>21</sup> In one study 20% of patients with MEN 1 and gastrinoma had Cushing's syndrome.<sup>63</sup> In all cases in this series, the Cushing's syndrome was of pituitary origin and was mild. Cushing's syndrome may also result from release of adrenocorticotropic hormone–like material from a pancreatic islet cell tumor<sup>38,63,64</sup> or a foregut carcinoid tumor (ectopic adrenocorticotropic hormone). Prolactinomas are generally treated by dopamine receptor agonists (bromocriptine, pergolide, cabergoline). Transsphenoidal pituitary surgery may be indicated to control any detectable pituitary mass lesion in patients with MEN 1. Incompletely resected patients may also be treated with bromocriptine.

## ADRENAL AND THYROID TUMORS AND LIPOMAS

Adrenal abnormalities may occur in 27% to 36% of patients with MEN 1.<sup>19,25,65</sup> The most common abnormality is a benign, nonfunctional cortical adenoma, although adrenal cortical carcinomas and hyperplasia may also occur.<sup>19,25,66</sup> Adrenal cortical hyperfunction may rarely be found secondary to an adrenal tumor. Adrenal cortical neoplasms are usually nonfunctional in patients with MEN 1. Thyroid adenomas also occur in approximately 5% to 30% of patients with MEN 1 and have little clinical significance.<sup>25</sup> Lipomas are seen with greater frequency in patients with MEN 1, as are cutaneous angiofibromas and collagenomas.<sup>67</sup>

## CARCINOID TUMORS

Gastric carcinoid tumors develop in 7% to 30% of patients with MEN 1 with ZES.<sup>16,62</sup> They arise from gastric enterochromaffin-like cells and thus are also called *ECLomas*. Approximately 18% have metastases, they are usually multiple, and they generally pursue an indolent course.

Thymic carcinoids occur in 0% to 8% of patients with MEN 1, are almost exclusively in men, are usually asymptomatic, and are not associated with Cushing's or carcinoid syndrome.<sup>18</sup> They pursue an aggressive course with distant metastases and are an increasing cause of death in older men with MEN 1.

Bronchial carcinoid tumors occur in 0% to 8% of patients with MEN 1. Eighty percent are in women and 74% are benign; however, they are an occasional cause of death.<sup>17</sup>

## FAMILIAL MEDULLARY THYROID CARCINOMA AND MULTIPLE ENDOCRINE NEOPLASIA TYPES 2A AND 2B

### HISTORY AND PATHOLOGY

In 1959, Hazard and coworkers<sup>68</sup> first described medullary thyroid carcinoma (MTC) and its striking histologic characteristics of cellular argentaffin staining and amyloid production. MTC is associated with three distinct familial syndromes: MEN 2A, MEN 2B, and familial non-MEN MTC, a disease characterized by hereditary MTC without associated endocrinopathies (see [Table 38.7-1](#)).<sup>69</sup>

In 1961, Sipple reported the unusually high incidence of bilateral pheochromocytomas in patients with thyroid malignancy.<sup>70</sup> These patients were later found to have MTC, and the familial disease was inherited as a mendelian autosomal dominant trait with high gene penetrance<sup>71,72</sup> (see [Table 38.7-1](#)). Subsequently, primary hyperparathyroidism was also noted to be part of the syndrome.<sup>73</sup> In 1968, this syndrome of medullary carcinoma of the thyroid gland, pheochromocytomas, and hyperparathyroidism was termed *MEN 2*; now it is called *MEN 2A*. In 1966 Williams and Pollock called attention to the finding that some patients had multiple mucosal neuromas, with or without marfanoid habitus, puffy lips, prominent jaw, pes cavus, and medullated corneal nerves with MTC and pheochromocytomas.<sup>74</sup> For this group of patients the terms *MEN 2B* and *MEN 3* were subsequently suggested.<sup>75</sup> Patients with MEN 2B do not have parathyroid disease. The gene defect in patients with MEN 2A, MEN 2B, and familial MTC is a germline mutation in the RET protooncogene.<sup>76,77</sup>

MTC is a malignant neuroendocrine tumor of the parafollicular thyroid cells or the calcitonin-secreting cells (C cells). Histologically, the MTC in patients with familial MTC, MEN 2A, and MEN 2B appears identical to the MTC occurring sporadically. However, in the familial form of MTC there is bilateral, multifocal involvement, and the cancer usually occupies a position in the superior lateral part of the thyroid lobe at the junction of the upper and middle third. In the sporadic setting, the MTC is usually unilateral. MTC is most malignant in MEN 2B, malignant in MEN 2A, and least virulent in FMTC (see [Table 38.7-1](#)). MTC accounts for 5% to 12% of all thyroid cancers, and only 10% of all MTC is familial.<sup>78</sup> In MEN 2A, approximately 42% to 60% of patients develop pheochromocytoma.<sup>79</sup>

The pheochromocytomas in patients with MEN 2A or MEN 2B usually present in the second or third decade of life and are often bilateral.<sup>78,80,81</sup> and <sup>82</sup> The size of the tumor or tumors in patients with MEN 2A is usually less than 2 to 3 cm, while it is usually larger in patients with MEN 2B. Even in MEN 2A patients with apparent unilateral pheochromocytomas, the contralateral adrenal gland almost always demonstrates medullary hyperplasia on pathologic analysis.<sup>81</sup> Patients with medullary hyperplasia rarely have symptoms of pheochromocytoma. <sup>131</sup>I-metaiodobenzyl guanidine scans in patients with MEN 2A may be useful to predict the presence of a clinically significant pheochromocytoma and can be obtained preoperatively. Pheochromocytomas in patients with MEN 2A or MEN 2B are seldom malignant and are usually within the adrenal gland. Histologically, these tumors are indistinguishable from those occurring sporadically in a nonfamilial setting.

The parathyroid lesions in MEN 2A consist of generalized hyperplasia<sup>26</sup> and should be managed like the parathyroid disease in MEN 1<sup>31,83,84</sup> (see [Table 38.7-1](#)). Approximately 35% of patients with MEN 2A develop primary hyperparathyroidism.<sup>82</sup> The primary hyperparathyroidism in MEN 2A is usually less clinically significant and causes fewer symptoms than the primary hyperparathyroidism in MEN 1.<sup>82</sup>

### CLINICAL PRESENTATION

Any of the neoplasms that make up the syndromes of MEN 2A or MEN 2B may be the presenting problem; however, MTC is a hallmark feature that occurs in nearly 100% of affected individuals. Of 164 patients with MEN 2A, each had MTC, 35 (21%) had pheochromocytomas, and 28 (17%) had primary hyperparathyroidism.<sup>78</sup> In another study of patients with MEN 2A, each had MTC, 40% had pheochromocytomas, and 60% had parathyroid hyperplasia.<sup>85</sup> In patients with MEN 2B, all have MTC and approximately 60% develop pheochromocytomas.<sup>86</sup>

In patients with MEN 2B the MTC presents at an early age and appears more aggressive, since few patients live beyond 30 years of age.<sup>87</sup> In some kindreds, the MTC in MEN 2B may be less malignant and individuals may live longer.<sup>88</sup> The characteristic appearance of MEN 2B patients is often the first sign of disease (see [Fig. 38.7-1](#)) and may suggest the diagnosis before other clinical abnormalities. However, with investigation by measuring calcitonin, the MTC is always present at the time of clinical recognition (see [Table 38.7-1](#)).

Patients may initially seek medical advice because of episodic spells with headache, dizziness, or symptoms of irritability and nervousness. It is unusual for patients with MEN 2A to present with symptoms related to parathyroid disease.<sup>69</sup>

### PREOPERATIVE EVALUATION AND SCREENING

When a suspicion of FMTC, MEN 2A, or MEN 2B exists, precise diagnosis depends on detection of missense mutations in the RET protooncogene in peripheral leukocytes. Several studies in individuals from families with MEN 2A have been able to predict the inheritance of MEN 2A by detection of missense mutations in RET.<sup>85,90,91,92</sup> and <sup>93</sup> Screening of new patients or family members for mutations in RET involves polymerase chain reaction amplification and DNA sequence analysis for detection of known point mutations in exons 10 and 11 (codons 609, 611, 618, 620, and 634) for MEN 2A and FMTC and exon 16 (codon 918) for MEN 2B. If a RET mutation is detected, each individual (100%) develops MTC. Further, if a RET mutation is absent, the individual does not need any additional testing. Virtually all patients with MTC have either elevated basal or stimulated plasma levels of calcitonin (CT). Patients who present with clinically apparent disease usually have basal plasma CT levels exceeding 1 ng/mL.<sup>94</sup> Generally, there is a direct correlation between the tumor mass of MTC and plasma calcitonin levels.<sup>95</sup>

Minimal plasma elevations of plasma CT are indicative of MTC in patients who have no other clinical evidence of the neoplasm.<sup>95</sup> Some patients with normal basal plasma CT levels have an increase to abnormal levels following calcium infusion (15 mg/kg over 4 hours) or pentagastrin injection (0.5-mg/kg bolus). Short bolus calcium injection (2 mg of calcium gluconate per kilogram over 1 minute) also provokes elevated plasma CT levels in MTC patients. The peak plasma CT levels in patients with MTC are highest with the combination test of calcium and pentagastrin injection.<sup>96</sup>

The presence of inherited MTC can be currently diagnosed in individuals from kindreds before detectable elevations in plasma calcitonin levels. Surgery performed based solely on detection of RET mutations always demonstrates MTC or C-cell hyperplasia.<sup>92,97,98</sup> It is necessary in patients with MEN 2A or MEN 2B to exclude a pheochromocytoma before undertaking surgery for MTC. Pheochromocytomas can be excluded by measuring normal urinary levels of epinephrine, norepinephrine, vanillylmandelic acid, and metanephrines. If an elevated level is detected, pheochromocytoma localization studies should be done. Abdominal computed tomography and magnetic resonance imaging are frequently helpful in localizing the pheochromocytoma, but additional more sensitive studies may be needed.<sup>99,100</sup> Metaiodobenzylguanidine is concentrated into pheochromocytoma cells and provides a means to functionally localize these tumors using scintigraphy.<sup>100</sup> The

sensitivity of this method varies from 79% to 91%, with a specificity of 94% to 99%.<sup>100</sup>

## SURGICAL MANAGEMENT

The ability to diagnose MTC in patients at risk for FMTC allows the physician to diagnose and treat this malignancy in an early preclinical stage. Should one diagnose MTC in a patient from a MEN 2A kindred, it is absolutely essential that the remainder of the family members at risk be screened. It is in this situation that RET testing has the greatest utility. Patients diagnosed by genetic testing have surgically curable C-cell hyperplasia or carcinoma confined to the thyroid gland.<sup>92</sup>

MEN 2A or MEN 2B patients with pheochromocytoma merit evaluation of both adrenal glands. Pheochromocytomas in MEN 2 syndromes have not been extraadrenal, nor have they been malignant.<sup>80</sup> Before surgical exploration, all patients need effective  $\alpha$ -adrenergic receptor blockade.<sup>86,100</sup> Phenoxybenzamine should be administered 1 to 2 weeks before surgery, starting with a dose of 10 mg twice daily and increased to a usual dose of 10 to 20 mg three times daily.<sup>100</sup> The end point is normotension with mild to moderate asymptomatic postural hypotension (15 mm Hg) accompanied by symptoms of a blockade including nasal stuffiness.  $\beta$ -Adrenergic blockade is usually not required<sup>101</sup> except in patients with persistent sinus tachycardia.<sup>86,100</sup> The  $\beta$  blocker should never be administered before the institution of  $\alpha$ -adrenergic blockade, because this may result in unopposed  $\alpha$  agonism with hypertensive crisis.<sup>100</sup>

At operation, if a solitary pheochromocytoma is present, it should be resected. Some advocate only resecting abnormal adrenal glands confirmed by palpation,<sup>102</sup> while others recommend routinely resecting both adrenal glands.<sup>81</sup> Some patients have had unilateral adrenalectomy and remained asymptomatic with normal urinary catecholamines for a mean follow-up of 8 to 12 years.<sup>80,102</sup> We use preoperative radioiodinated metaiodobenzyl guanidine scan or magnetic resonance scan to determine unilateral versus bilateral adrenal involvement in these patients. With imaging studies to localize the adrenal tumor, laparoscopic methods are now used to remove it.<sup>103</sup> Patients with MEN 2A undergoing unilateral adrenalectomy should be followed carefully at 6-month or yearly intervals, since a second adrenal tumor may be diagnosed biochemically before it is clinically apparent.

The surgical management of familial MTC is total thyroidectomy with a central lymph node dissection. It is essential that a total thyroidectomy be performed, because the MTC is always bilateral.

## POSTOPERATIVE FOLLOW-UP

In patients with MEN 2A and MEN 2B, MTC is the disease that is most frequently lethal. The MTC in patients with MEN 2B seems to be more virulent than in patients with MEN 2A<sup>87</sup> (see [Table 38.7-1](#)), although a group of children with MTC in the setting of MEN 2B have been reported, some of whom appear to be cured of MTC. Survival of patients with MEN 2A is dependent on the extent of MTC at initial surgical resection.<sup>94</sup> Data suggest that the survival rate of patients with MTC in the presence of MEN 2A is excellent.<sup>104</sup>

With the widespread availability of reliable radioimmunoassays for CT, an individual patient can be easily followed postoperatively. Detection of an elevated basal plasma CT level or the finding of an abnormal response to calcium and pentagastrin indicates recurrent or persistent disease. In patients with metastatic MTC, it is unclear what is the best strategy. Radioactive iodine ablation, thyroid suppression, and radiation therapy have not been helpful. MTC is relatively insensitive to chemotherapy. Because of the indolent nature of the tumor, most have chosen not to aggressively treat metastatic disease.

The 10-year survival of MTC is approximately 80% to 90%. Aggressive surgical resection has been used to locally control recurrent MTC, and one-third of individuals can be rendered biochemically disease free.<sup>105</sup> However, it must be remembered that in patients with MEN 2A, the MTC may be well tolerated. The average life expectancy of patients with MTC and MEN 2A is over 50 years.<sup>106</sup> The current best therapy for familial MTC is early diagnosis and complete resection of intrathyroidal disease at initial surgery. Ablation of extrathyroidal disease when detected as persistent or recurrent elevations of plasma CT levels following total thyroidectomy requires the development of effective systemic adjuvant treatment.

## INCIDENCE

In the United States the incidence of soft tissue sarcoma is approximately 7800 new cases per year. A little more than 50% of these new patients go on to die of the disease.<sup>1</sup> The relatively small number of cases seen and the great diversity in histopathologic presentation, anatomic site, and biologic behavior have made a comprehensive understanding of these disease entities extremely difficult. They are, however, ideal prototypes to demonstrate the important role of multidisciplinary management. It is clear that soft tissue sarcoma, diagnosed at an early stage, is eminently curable. When diagnosed at the time of extensive local or metastatic disease, soft tissue sarcoma is rarely curable.

Analysis of population based data from Connecticut<sup>2</sup> suggests an increase in incidence in both men and women, greater for women.

## ETIOLOGY AND GENETICS

Most soft tissue sarcomas have no clearly defined etiology, although multiple associated or predisposing factors have been identified ( [Table 39.1-1](#)). Data suggest that genetic mutations in pluripotent mesenchymal stem cells give rise to malignant clones that differentiate along pathways that resemble normal histogenesis. Alterations in the RB-1 and p53 genes are detected in a substantial proportion of sarcomas.<sup>3,4</sup> The importance of these cell regulatory genes in the pathogenesis of sarcoma is highlighted by the high incidence of germline mutations in patients with hereditary retinoblastoma, and by identification of germline mutations in p53 in the

Li-Fraumeni syndrome.<sup>5,6</sup> A genetic predisposition to soft tissue sarcoma has also been associated with neurofibromatosis,<sup>7,8</sup> and familial adenomatous polyposis.<sup>9</sup>

	Sarcoma	Gene	Chromosome	Refers
Neurofibromatosis type 1 (von Recklinghausen disease)	Malignant peripheral nerve sheath tumor	NF1	22q12	44
Retinoblastoma	Soft tissue, sarcomatous	Rb1	13q14	43,46
Li-Fraumeni syndrome	Soft tissue, sarcomatous	TP53	17q21	4,47
Gardner's syndrome	Fibrosarcoma, desmoid tumor	APC	5q21	43,49
Werner's syndrome (adult progeria)	Soft tissue	WES	16p12	45
Gardner's syndrome (juvenile of anterior syndrome)	Fibrosarcoma, rhabdomyosarcoma	PFC	4q21	1
Crohn's colitis	Gastrointestinal sarcoma	Takara	Takara	41,42
Tuberous sclerosis (Bourneville disease)	Rhabdomyosarcoma, rhabdomyosarcoma	TSC1 TSC2	9q34 16p13	43-45

**TABLE 39.1-1.** Genetic Predisposition to Soft Tissue Sarcoma

The most common tumors in patients with neurofibromatosis are in the central nervous system. In a 42-year follow-up study, 47% of all malignancies were nervous system tumors.<sup>10</sup> This review confirms the high incidence of malignant tumors in patients with neurofibromatosis: approximately 46% of all patients with this disease develop either a malignant tumor or a benign central nervous system tumor.<sup>10</sup> This prevalence is slightly higher in those with a family history of neurofibromatosis than in those with sporadic cases, but is common in both. Relatives of such patients, whether with a family history or not, are also at risk of developing malignant tumors. The development of pheochromocytoma also is a complication of neurofibromatosis.<sup>11</sup> Approximately 5% of patients with neurofibromatosis develop malignant peripheral nerve sheath tumors (MPNSTs).<sup>10</sup>

Genetic predisposition to malignancy is well established in the form of an autosomal dominant gene in 8% to 9% of children with soft tissue sarcomas.<sup>12</sup> Survivors of retinoblastoma with the associated Rb gene abnormality often develop tumors later in life with a high incidence of sarcomas; the best documented is osteosarcoma.<sup>13</sup> A follow-up study of members of Li-Fraumeni families with childhood rhabdomyosarcoma found additional cancers including carcinoma of the breast, soft tissue sarcomas, lung cancer, skin cancer, leukemia, pancreatic cancer, and brain tumors.<sup>14</sup>

It is important to emphasize that in patients who have retinoblastoma, the increased risk of a second primary is enhanced by radiotherapy,<sup>15</sup> which is dose dependent.

Familial adenomatous polyposis, a subset of which is Gardner's syndrome, is commonly associated with the development of intraabdominal desmoids.<sup>16</sup> These tumors behave as low-grade fibrosarcomas, although constant debate exists as to the histopathologic classification and distinction between the desmoid tumor and aggressive fibromatosis (see below, in Pathologic Classification). However, their natural history of slow growth with accompanying invasion of contiguous structures increases the risk of subsequent mortality when managed inappropriately.

The development of soft tissue and bone sarcoma as a result of exposure to radiation has been known since 1922.<sup>17</sup> Although uncommon, these sarcomas usually have a poor prognosis. In a review of 160 patients,<sup>18</sup> the antecedent diseases for which the radiation was given were predominantly breast and cervical cancer and lymphoma (Fig. 39.1-1). External radiation therapy was given to 99% of the patients, 14% of whom received additional treatment with temporary or permanent radioisotope implantation. One patient inadvertently ingested radium. The subsequent tumor that developed was most commonly an osteogenic sarcoma, followed by soft tissue tumors, particularly malignant fibrous histiocytoma (MFH) and angiosarcoma or lymphangiosarcoma (see Fig. 39.1-1). No significant difference in survival was found between patients with bone tumors and those with soft tissue sarcomas. Survival was not affected by site, latency period, and the amount of radiation received initially, nor were there any differences for patients receiving chemotherapy for their sarcomas. The three factors in the Cox multivariate analysis that had a significant unfavorable association were presentation with metastatic disease ( $P = .017$ ), incomplete or no operative resection ( $P = .004$ ), and tumor size of at least 5 cm ( $P = .007$ ). Tumor grade was not significant in any analyses, but only 6% of the patients had low-grade tumors.<sup>18</sup>

**FIGURE 39.1-1.** Radiation-associated soft tissue sarcoma: antecedent disease for which radiation was given and histopathology of sarcomas that developed in 160 patients at Memorial Sloan-Kettering Cancer Center. AS, angiosarcoma; LA, lymphangiosarcoma; MFH, malignant fibrous histiocytoma; OS, osteogenic sarcoma. (From ref. 18, with permission.)

Given the increased use of radiation therapy as a primary treatment modality for breast cancer, concern has been expressed that an increased incidence of sarcoma might be expected. In one study<sup>19</sup> all 122,991 women with breast cancer in Sweden from 1958 to 1992 were followed, and 116 soft tissue sarcomas were found. There were 40 angiosarcomas and 76 other sarcomas. As expected, angiosarcoma correlated with lymphedema [relative risk = 9.5 (3.2 to 28.0)] but not radiation therapy. For other sarcomas, there was a dose-response relationship with exposure to radiation therapy.

Lymphedema has long been established as a factor in the development of lymphangiosarcoma. The most well-recognized association is with the postmastectomy, postirradiated lymphedematous arm, described by Stewart and Treves.<sup>20</sup> This is not a radiation-induced sarcoma because the lymphangiosarcoma develops in sites both inside and outside of the irradiated field, in the edematous extremity. Similar advanced sarcomas have been seen following filarial infection and chronic lymphedema. Lymphangiosarcoma can arise in filarial lymphedema and remain localized for relatively long periods of time.<sup>21</sup>

The issue of trauma as a possible predisposing factor is more controversial. Often a minor episode of injury is the factor that draws attention to the presence of a mass, implying a causative association that is not real. Abdominal desmoid tumors commonly follow parturition.<sup>22</sup> However, they can occur in the extremity and may be associated with antecedent vigorous physical activity. They may be multifocal.<sup>23</sup>

Chemical agents have been implicated in the etiology of soft tissue sarcoma. Through the years there have been conflicting reports about the relationship between occupational exposure to phenoxyacetic acids found in some herbicides and chlorophenols (found in some wood preservatives) (Table 39.1-2).<sup>24,25,26,27,28,29</sup> and <sup>30</sup> Other authors have pointed to the inherent problems in occupational epidemiology in relationship to the source material for soft tissue sarcoma, among them, (1) possible recall bias in self-reported exposure data; (2) soft tissue sarcomas not consistently classified in the International Classification of Diseases, which is organ based; (3) variation in the operational definition of soft tissue sarcomas; and (4) because of their rarity, difficulty recruiting sufficient patients for a case-control study, and cohorts would have to be extremely large to identify an increase in risk.<sup>31,32</sup> Nevertheless, some studies have suggested a link between phenoxy herbicide exposure in forestry workers, farmers, and railroad workers and subsequent development of sarcoma,<sup>33</sup> whereas other studies from the United States, New Zealand,

and Finland have not confirmed this relationship.<sup>26,30,34</sup>

Location	Author	Year	No. Cases	Relative Risk	95% Confidence Interval
North Sweden	Barkid and Sankara <sup>26</sup>	1979	46	5.3	2.4-11.3
South Sweden	Ekman et al <sup>30</sup>	1981	99	6.8	2.4-21.3
New Zealand	Smith et al <sup>34</sup>	1984	82	1.5	0.7-3.3
England and Wales	Morgan and Scherer <sup>27</sup>	1984	190	1.15	0.84-1.59
New York State Veterans service	Greenwald et al <sup>32</sup>	1984	261	1.7	0.75-4.0
Vietnam Administration patients Veterans service	Kang et al <sup>33</sup>	1986	254	1.83	0.84-4.0
Kansas	Boer et al <sup>31</sup>	1986	133	1	0.7-1.6

**TABLE 39.1-2.** Case-Control Studies of Relationship between Exposure to Phenoxy Herbicides and Incidence of Soft Tissue Sarcoma

Interestingly, it has been suggested<sup>35</sup> that such exposure may be tissue type specific (i.e., MFH and leiomyosarcoma having a herbicide association, but none being found for liposarcoma).

An increased incidence of soft tissue sarcomas was seen in a cohort of 1520 industrial workers exposed for more than 1 year to 2,3,7,8-tetrachlorodibenzo-p-dioxin,<sup>36</sup> but other studies did not substantiate these findings.<sup>37,38</sup>

The issue of dioxin as a risk factor remains controversial. A population-based case-control study assessed the risk of soft tissue sarcomas in Vietnam veterans, including those potentially exposed to Agent Orange, which contains dioxin, and found no increased risk among any subset of veterans compared with control groups.<sup>39</sup> Another study found no increased risk for Vietnam veterans compared with men who had never been in Vietnam.<sup>40</sup> The risk for subgroups of veterans who were more likely to be exposed to Agent Orange, compared with their unexposed counterparts in Vietnam, was not statistically significant.

Several chemical carcinogens have an established role in the development of hepatic angiosarcomas: thorotrast, vinyl chloride, and arsenic (including Fowler's 1% arsenic solution).<sup>34,41,42</sup> and<sup>43</sup> A review of pesticides and cancer<sup>44</sup> has again linked the phenoxy herbicides to soft tissue sarcoma and lymphoma, but again questions the causal relationship of these agents.

Chemotherapy for pediatric malignancies has been associated with the subsequent development of osteogenic sarcomas<sup>45</sup>; a relationship with the development of soft tissue sarcomas has not been demonstrated.

### CYTOGENETIC ABNORMALITIES

It is important to emphasize that extensive cytogenetic abnormalities occur in soft tissue sarcoma (Table 39.1-3). These are usually associated with high-grade tumors, but are not consistent between tumors. For example, an analysis of 36 tumors,<sup>46</sup> pleomorphic soft tissue sarcomas were examined. Multiple complex karyotypes were identified and at least 24 recurrent abnormalities (defined by their presence in at least five cases) were detected. However, none of the selected rearrangements was specific for any one of a particular subgroup. It seems unlikely at the present time, therefore, that cytogenetic analysis can help differentiate the pleomorphic sarcomas. Conversely, specific changes have been identified in selected sarcomas. The best examples are the classical translocation in Ewing's sarcoma (primitive neuroectodermal tumor), t(11;22)(q24;q11.2-12), and the translocation seen in synovial sarcoma t(X;18)(p11.2;q11.2). In these situations, these genetic abnormalities can be used as a diagnostic tool.

Tumor Abnormality	Chromosomal Abnormality	Recurrent Genetic	Frequency	Reference

**TABLE 39.1-3.** Chromosomal Changes in Soft Tissue Sarcoma

Multiple other studies of genetic abnormalities have been published. Abnormalities of INK4A (coding for p16 and p19ARF on 9p21) and INK4B have been correlated with poor survival.<sup>47</sup> These chromosomal alterations occur in 15% of patients with high-grade sarcomas. In myxoid liposarcoma, the presence of the TLS-CHOP fusion protein has now been firmly established<sup>48</sup> and is considered a definitive diagnostic tool for these tumors.

### DISTRIBUTION

Soft tissue sarcomas can occur in any site throughout the body. Almost 50% of all soft tissue sarcomas appear in the extremities (Fig. 39.1-2), with two-thirds of extremity lesions occurring in the lower limb, and 30% intraabdominally divided equally between visceral and retroperitoneal lesions.

**FIGURE 39.1-2.** Distribution by site of soft tissue sarcomas in 3968 patients aged 16 or older admitted to Memorial Sloan-Kettering Cancer Center between July 1982 and July 1999.

## PATHOLOGIC CLASSIFICATION

Soft tissue tumors generally are categorized according to the normal tissues they mimic.<sup>49,50</sup> Many soft tissue neoplasms have been described, reflecting the diversity of soft tissues in the body (Table 39.1-4).<sup>50</sup> Although most soft tissues arise from embryonic mesoderm, tumors of the peripheral nervous system (ectoderm), and some tumors of uncertain histogenesis are included as soft tissue neoplasms.

TABLE 39.1-4. Histologic Classification of Soft Tissue Sarcoma

Soft tissue tumors may be benign or malignant, and a variety of borderline lesions are also recognized. The ratio of benign to malignant tumors is certainly more than 100:1. The soft tissue sarcomas are the malignant tumors that arise in soft tissues. The precise pathogenesis of the vast majority of the sarcomas is uncertain. Unlike carcinomas, sarcomas do not demonstrate *in situ* changes, nor does it appear that sarcomas originate from benign soft tissue tumors. An exception would appear to be the development of MPNST in patients with neurofibromatosis.

Although each of the sarcomas has distinguishing histologic characteristics, the different types of sarcoma have many common clinical and pathologic features. Sarcomas are characterized by local invasiveness. The pattern of metastasis of most sarcomas is hematogenous. Lymph node metastases are uncommon, with the exception of selected cell types usually associated with childhood sarcoma (Table 39.1-5).<sup>51,52</sup> and <sup>53</sup> Grossly, most sarcomas are similar, with a pale tan fish flesh appearance (although liposarcomas may be soft and yellow). The clinical behavior of most types of sarcoma also is similar, determined more by anatomic location, grade, and size, than by specific histologic pattern.<sup>54</sup>

Histopathology	Stage <sup>51</sup>		Stage <sup>52</sup>		Stage <sup>53</sup>	
	No. of Total Metastases/No. of Patients	Percentage of All Patients	No. of Total Metastases/No. of Patients	Percentage of All Patients	No. of Total Metastases/No. of Patients	Percentage of All Patients
Leiomyosarcoma	35/1000	3.5	36/103	35.0	4/102	4.0

 Note: a maximum of 10 metastases.  
 Data are for only metastatic leiomyosarcoma and rhabdomyosarcoma.

TABLE 39.1-5. Soft Tissue Sarcomas: Histologic Type and Lymph Node Metastasis

## GRADING OF SARCOMA

After establishing the diagnosis of sarcoma, the most critical piece of information the pathologist can provide to the clinician is histologic grade. The pathologic features that define grade include cellularity, differentiation, pleomorphism, necrosis, and number of mitoses. Unfortunately, the criteria for grading are neither specific nor standardized. Furthermore, several grading scales are used: a four-grade system (Broders),<sup>55</sup> a three-grade system (low, intermediate, high) as recognized by the American Joint Commission on Cancer (AJCC),<sup>56</sup> and a binary system (high vs. low) as used at Memorial Hospital.<sup>50</sup> Even when there is agreement about the number of grades to be used, expert pathologists disagree about specific criteria for defining grade.<sup>57,58,59</sup> and <sup>60</sup>

The possible clinical implications are obvious. In adjuvant chemotherapy trials high grade was defined differently at different centers, making comparison of results between trials, and combining results of multiple trials, extremely hazardous. For example, tumors of 240 patients who participated in the Scandinavian Sarcoma Group adjuvant trial for high-grade extremity sarcoma were reviewed by a panel of reference pathologists. A four-grade system was used in this trial; only patients with grade III or IV sarcomas were eligible. On review, 5% of the patients were considered ineligible because their tumors actually were low grade.<sup>61,62</sup> Furthermore, although it did not influence eligibility, there was considerable discordance between the original pathologists and the reference pathologists with regard to whether a lesion was grade III or IV. Although the adjuvant regimen did not affect survival (see below, in [Adjuvant Chemotherapy](#)), a difference in survival was noted between patients with tumors of these two grades as assigned by the reference pathologists.

Many pathologists consider mitotic activity and degree of necrosis to be the most important pathologic features.<sup>63</sup> To define a practical grading system, the European Organization for Research on the Treatment of Cancer (EORTC) studied the histologic features of tumors from 282 patients who participated in their adjuvant chemotherapy trial, and correlated the pathologic findings with outcome.<sup>64</sup> In multivariate analysis, only mitotic count (less than 3, 3 to 20, and greater than 20 mitoses per 10 consecutive high power fields), the presence or absence of necrosis, and tumor size predicted survival.

Mutation of p53, nuclear overexpression of p53, and a high Ki-67 proliferation index are associated with high grade and poor survival.<sup>65</sup> As yet, however, these biologic markers have not been shown to be independent indicators of prognosis and cannot be used to grade sarcomas.

Several tumors that are considered sarcomas have no recognizable normal tissue counterpart (e.g., alveolar soft part tumor, Ewing's sarcoma, epithelioid sarcoma). These tumors often have unique clinical features and usually are not graded. However, note that Ewing sarcomas are considered high-grade, undifferentiated sarcomas.

## DIFFERENTIAL DIAGNOSIS

In addition to sarcoma, the differential diagnosis of a soft tissue mass includes a variety of benign lesions, as well as primary or metastatic carcinoma, melanoma, and lymphoma. Accurate diagnosis requires an adequate and representative biopsy of the tumor, and the tissue must be well fixed and well stained. Antibodies for immunohistochemical staining are available commercially, and this technique is readily applicable to paraffin-embedded tissues. The most useful immunohistochemical markers are the intermediate filaments (e.g., vimentin, keratin, desmin, leukocyte common antigen, S-100). In addition, the pathologist should be prepared to process tissue from selected cases for electron microscopy, cytogenetic studies, or molecular analysis. This implies that certain diagnoses are considered by the clinician, that the diagnostic biopsy is obtained appropriately, and that the clinician and pathologist communicate before the biopsy is performed to

ensure that the necessary steps are taken in handling the tissue.

Cytogenetic analyses reveal clonal chromosome alterations in the majority of sarcomas.<sup>66</sup> Consistent chromosomal abnormalities have been identified in several soft tissue tumors,<sup>61,62,67,68,69,70,71,72,73,74,75,76,77,78,79,80,81,82,83</sup> and <sup>84</sup> but cytogenetic analysis is labor intensive and requires short-term culture of the sarcoma cells. Fusion genes resulting from chromosomal rearrangements may be detected by reverse transcriptase polymerase chain reaction. This technique has been quite effective in diagnosing and distinguishing among the small cell sarcomas. [Table 39.1-3](#) describes some of the genetic changes identified in soft tissue sarcoma. Fluorescent *in situ* hybridization using probes to locate specific chromosomal abnormalities may become clinically useful, but is unavailable for routine diagnostic use at this time. Supernumerary ring chromosomes, seen in mesenchymal neoplasms of low or borderline malignancy, such as dermatofibrosarcoma protuberans, may be identified with this technique.

As might be expected from a group of rare, diverse, but related tumors, there may be considerable disagreement among pathologists regarding the specific histologic diagnosis in individual cases. When pathologic material from 424 patients who entered into Eastern Cooperative Oncology Group (ECOG) sarcoma trials was reviewed by a panel of expert pathologists, 10% of cases were rejected as not being sarcoma, and for 14% of the remaining cases there was disagreement with respect to the histologic subtype.<sup>85</sup> Similarly, in the Southeastern Cancer Group experience with 216 patients, 6% were determined not to have sarcoma, and in 27% the type of sarcoma was deemed incorrect by the reviewers.<sup>86</sup> In the Scandinavian Sarcoma Group experience, the specific histologic diagnosis was disputed in 20%.<sup>61</sup>

Overall, the three most common histopathologic subtypes are MFH, liposarcoma, and leiomyosarcoma. Some types of sarcoma occur with greater frequency in certain age groups or in specific locations, forming clinicopathologic syndromes that permit standardized treatment strategies. The distribution of common histologic types among different age groups is demonstrated in [Figure 39.1-3](#). The most common extremity sarcomas are liposarcoma, MFH, tendosynovial sarcoma, and fibrosarcoma, although a variety of other histologic types are seen. Most retroperitoneal sarcomas are liposarcomas or leiomyosarcomas. The distribution of histologic type by site is shown in [Figure 39.1-4](#).<sup>87</sup>

**FIGURE 39.1-3.** Age distribution of common histologic types of soft tissue sarcomas.

**FIGURE 39.1-4.** Predominant histology by site of soft tissue sarcomas in 3968 patients aged 16 or older admitted to Memorial Sloan-Kettering Cancer Center between July 1982 and July 1999. MFH, malignant fibrous histiocytoma; MPNT, malignant peripheral nerve tumor.

The most frequently encountered chest wall sarcomas are desmoids, liposarcomas, and myogenic sarcomas.<sup>88</sup>

Virtually all gastrointestinal sarcomas were previously classified as leiomyosarcomas or leiomyoblastomas.<sup>89</sup> It is now recognized that many gastrointestinal sarcomas do not express markers of myogenic differentiation and are better classified as gastrointestinal stromal tumors, or, if they exhibit neural differentiation, gastrointestinal autonomic nerve tumors (GANT).<sup>90</sup> The pattern of recurrence is intraabdominal, including liver metastasis.<sup>89</sup>

Overall, leiomyosarcoma is the most common type of genitourinary sarcoma in the adult<sup>91</sup> and arises in the bladder, kidney, or prostate, usually in older individuals. Rhabdomyosarcoma arising in paratesticular tissues is a disease of young men. Three major types of uterine sarcoma are recognized: (1) leiomyosarcomas, tumors of the myometrium; (2) mesodermal mixed tumors (malignant mixed Müllerian tumors), composed of elements of carcinoma and sarcoma; and (3) endometrial stromal sarcoma, the least common, which arises from endometrial stroma and usually has an aggressive behavior.

Approximately 10% to 15% of all sarcomas occur in children. The majority of pediatric patients have small cell sarcomas, including embryonal rhabdomyosarcoma and the Ewing's sarcoma and primitive neuroectodermal tumor spectrum (see [Chapter 44.2](#)).

## CLINICOPATHOLOGIC FEATURES OF SPECIFIC TYPES OF BENIGN AND MALIGNANT SOFT TISSUE TUMORS

### TUMORS OF FIBROUS ORIGIN

There are a variety of benign tumors and tumor-like lesions of fibrous tissue that must be distinguished from true fibrosarcoma. These lesions may also be confused with reactive or reparative processes. A variety of names have been used to designate identical or overlapping entities. In addition, there are a variety of fibrous proliferations of infancy and childhood that resemble lesions in the adult, but are associated with a better prognosis. Features of lesions that may be mistaken for sarcoma are summarized in the following sections.

#### **Nodular Fasciitis**

Nodular fasciitis, also called *pseudosarcomatous fasciitis*, is a benign lesion usually seen in adults aged 20 to 40, although it has been reported in both older and younger patients.<sup>92,93</sup> The typical lesion grows rapidly over several weeks reaching a size of 1 to 2 cm. Growth is usually self-limited, and lesions rarely are larger than 5 cm. Tenderness or soreness is a common complaint. The upper extremity is the most common site, especially the volar aspect of the forearm. Nodular fasciitis generally arises in the subcutaneous fascia or the superficial portions of the deep fascia. Histologically, the lesions are nodular, nonencapsulated masses, consisting of plump, immature fibroblasts arranged in short, irregular bundles or fascicles. Because of their cellularity, rapid growth, and high mitotic activity these lesions may be mistaken for fibrosarcoma. Recurrence is uncommon after simple excision.

## **Fibroma**

Fibroma is a general term that has been applied to a group of poorly defined benign lesions that arise in the skin or soft tissues. Most are effectively treated by simple excision. Fibroma of tendon sheath is a slowly growing dense fibrous nodule that is attached to the tendon sheath, found most frequently in the hands or feet.<sup>94</sup> Recurrence may occur after local excision.

## **Elastofibroma**

Elastofibroma is a rare, slow-growing benign tumor that characteristically arises between the lower portion of the scapula and the chest wall of older individuals.<sup>95,96</sup> These lesions, which typically occur in workers who have done repetitive manual tasks for years, are thought to be reactive. Elastofibromas grow as ill-defined masses, often measuring 5 to 10 cm in diameter. They may occur bilaterally and rarely have a familial association. Histologically, these lesions consist of swollen eosinophilic collagen and elastic fibers, and stain intensely for elastins. Complete excision is curative.

## **Superficial Fibromatoses**

Superficial fibromatoses arise from the fascia or aponeurosis and generally are small and slow growing. Palmar fibromatosis is associated with flexion contractures (Dupuytren's contracture), and is by far the most common form, afflicting as many as one in five persons aged 65 and older. This condition is more common in men than in women and tends to be familial. Although benign, these lesions have a tendency to recur after simple excision. Plantar fibromatosis (Ledderhose's disease) tends to occur in a somewhat younger age group, but may occur with greater frequency in patients with palmar fibromatosis. Penile fibromatosis (Peyronie's disease), which causes pain and curvature of the penis on erection, is much less common. The fibrous mass in Peyronie's disease primarily involves fascial structures, the corpus cavernosum, and rarely, the corpus spongiosum. Peyronie's disease is more common in men with palmar and plantar fibromatosis than in the general population.

## **Desmoid Tumor**

The desmoid was originally described as a tumor of the abdominal wall in women who had recently been pregnant, but these rare, slow-growing fibrous tumors may arise at any site in the body. The desmoids have been classified by location as abdominal, extraabdominal, intraabdominal, and mesenteric. As is the case for other sarcomas, site affects management, but it is unclear whether the distinction by site is biologically significant. The term *aggressive fibromatosis*, often applied to these lesions, especially when they occur in the retroperitoneum, belies their potential for invasion and progressive growth. Although desmoids do not metastasize, for clinical management these tumors are best considered low-grade fibrosarcomas.<sup>16</sup> Retroperitoneal desmoids, along with fibromas, osteomas, and epidermoid cysts, are among the extracolonic manifestations in patients with familial adenomatous polyposis coli that characterize Gardner's syndrome.<sup>97,98</sup> Multifocal desmoids of the extremity have been recognized,<sup>23,99</sup> usually in young women.

In a clinicopathologic study based on Finnish hospital records, the incidence of desmoid was estimated at 2 to 4 cases per 100,000. Of the 89 cases, 49% involved the abdomen. Only one patient had Gardner's syndrome, although familial bone abnormalities were noted in some patients. Four populations were defined: juvenile (age  $4.5 \pm 3.5$  years), fertile ( $27.2 \pm 4.4$  years), middle age ( $43.9 \pm 6.9$  years), and old ( $68.1 \pm 4.4$  years). The juvenile desmoid was primarily an extraabdominal tumor of girls, whereas abdominal wall tumors of women were dominant in the fertile age group. Among middle-aged patients, abdominal wall tumors predominated, but the proportion of men and women was equal. In the oldest age group, both abdominal and extraabdominal tumors occurred without a gender difference. These investigators reported that the growth rate in premenopausal women was statistically greater than the rate of growth observed in male patients.<sup>100</sup>

Among 131 patients with desmoid tumors treated at Memorial Hospital, of whom 39% presented with recurrent disease, the female to male ratio was 1:6. Approximately one-half of these tumors arose in the extremity; 15% were retroperitoneal, 12% arose in the abdominal wall, and 10% were chest wall tumors. Four patients had Gardner's syndrome. In univariate analysis, local failure was more common among patients aged 18 to 30 years, those with marginal or inadequate excision, those who presented with recurrent disease, and those who did not receive radiation for gross residual disease. In multivariate analysis, only presentation with recurrent disease and inadequate margins of resection were independent prognostic features. Gender had no influence on recurrence. The probability of local failure following excision was estimated at 37%. Eleven deaths were attributable to recurrent disease, including one patient who developed pulmonary metastases; none of the 11 patients had an extremity primary.<sup>16</sup> Management of patients with desmoid tumors is discussed later in this chapter in the section [Desmoids \(Aggressive Fibromatoses\)](#).

## **Fibrosarcoma**

Fibrosarcoma may occur in patients of any age, but most commonly are seen persons aged 30 to 55 years. These tumors have no characteristic clinical findings. Pathologically, they consist of elongated fibroblast-like cells arranged in a uniform, vesiculated growth pattern. Intersection or interlacing of the fascicles often yields a herringbone pattern on light microscopy. Well-differentiated fibrosarcomas are rich in mature collagen.

## **FIBROHISTIOCYTIC TUMORS**

These tumors, originally thought to arise from histiocytes that had fibroblastic potential, almost certainly are fibroblastic in origin. Thus, the term *fibrohistiocytic* is merely descriptive of their appearance.

### **Fibrous Histiocytoma**

These benign tumors usually present as solitary, slowly growing nodules, although up to one-third are multiple. Histologically, they consist of fibroblastic and histiocytic cells often arranged in a cartwheel or storiform pattern. When such lesions occur in the skin, they are often called dermatofibromas or sclerosing hemangiomas. Superficially located lesions usually are cured by simple excision.<sup>101</sup> Deeper lesions should be resected with a wider margin of normal tissue to prevent local recurrence.<sup>102</sup>

### **Xanthoma**

Xanthoma refers to a collection of lipid-laden histiocytes and is seen in diseases associated with hyperlipidemia. These lesions generally occur in cutaneous or subcutaneous locations, but may involve deep soft tissues. Presumably, xanthomas are reactive lesions.

### **Dermatofibrosarcoma Protuberans**

Dermatofibrosarcoma protuberans<sup>103,104</sup> is probably best considered a low-grade sarcoma. This lesion may occur anywhere in the body, but more than 40% occur on the trunk, 20% in the head and neck, and 40% on the extremities. This lesion typically presents in early or midadult life, beginning as a nodular cutaneous mass. The pattern of growth is usually slow and persistent, and as the lesion enlarges over many years, it becomes protuberant. Large lesions often are associated with satellite nodules. Dermatofibrosarcoma protuberans is histologically similar to benign fibrous histiocytoma, but grows in a more infiltrative pattern, spreading along connective tissue septa in deep areas. The central portion of the tumor consists of a uniform population of plump fibroblasts arranged in a distinct ordered pattern. Unlike fibrous histiocytoma, dermatofibrosarcoma protuberans stains positive for CD34, suggesting a neural origin.<sup>105</sup> More than 75% of these tumors have a ring chromosome, probably of chromosome 17 origin, superimposed on a normal karyotype<sup>106</sup> (see [Table 39.1-3](#)).

Up to 50% recur after simple excision.<sup>104,107</sup> Occasionally, areas of increased pleomorphism and mitotic activity occur, especially in recurrent lesions. Metastases occur rarely to lung or to lymph nodes.<sup>107</sup> Because of their locally aggressive nature, these lesions may ultimately lead to amputation or even death because of extensive invasion. A variant with melanin pigmentation (Bednar's tumor) also is recognized.<sup>108</sup>

### **Malignant Fibrous Histiocytoma**

The term MFH was first introduced in 1963 to describe a group of malignant soft tissue tumors with a fibrohistiocytic appearance.<sup>109</sup> Since then, this entity has become the most commonly diagnosed extremity sarcoma. A number of subtypes have been described, including myxoid, giant cell, inflammatory, angiomatoid, and pleomorphic types. With advances in pathologic techniques, it has been claimed that a specific line of differentiation can be identified in the overwhelming majority of patients with pleomorphic MFH.<sup>110</sup> Nonetheless, this designation has been useful clinically.

MFH characteristically is a tumor of later adult life with a peak incidence in the seventh decade, although it may occur in younger adults. MFH usually presents as a painless mass; the most common site is the lower extremity, followed by the upper extremity and the retroperitoneum.<sup>111,112</sup>

## TUMORS OF ADIPOSE TISSUE

### *Lipomas*

Lipomas are the most common of all benign neoplasm and may arise in any location where fat is normally present. Lipomas may be deep seated in the mediastinum or retroperitoneum where they may attain massive size. Multiple lipomas are occasionally seen in a familial pattern. *Lipomatosis* is a term applied to a poorly circumscribed overgrowth of mature adipose tissue that grows in an infiltrating pattern.

Well-differentiated lipomas are composed of fat cells, but are demarcated from surrounding fat by a thin fibrous capsule. These tumors usually are found within subcutaneous fat, but may occur anywhere in the body. In spindle cell lipoma, mature fat is replaced by collagen-forming spindle cells; this lesion typically arises in the posterior neck and shoulder in men between the ages of 45 and 65. Pleomorphic lipoma is a closely related lesion. Local excision of lipoma and these variants is generally curative. The term *atypical lipoma* is used by some to describe these benign lesions; others use atypical lipoma to describe a well-differentiated liposarcoma that arises in a subcutaneous or intramuscular location.<sup>113,114</sup>

Angiolipomas present as subcutaneous nodules, usually in young adults. The most common site is the upper extremity. Angiolipomas rarely reach more than 2 cm, but they often are painful, especially during their initial growth period. Microscopically, these tumors consist of adipocytes with interspersed vascular structures. Myxoid and fibroblastic angiolipomas are recognized.

### *Angiomyolipoma*

The term *angiomyolipoma* is used for a nonmetastasizing renal tumor that is composed of fat, smooth muscle, and blood vessels. Angiomyolipoma is more common in women than in men and is seen in association with tuberous sclerosis. Although angiomyolipoma is usually well demarcated from normal kidney, it may extend into the surrounding retroperitoneum. Angiomyolipomas may be solitary or multicentric and may produce abdominal pain or hematuria. Wide excision is curative. Angiomyolipomas of the liver have also been described.<sup>115</sup>

### *Hibernoma*

Hibernoma is a rare, slowly growing benign neoplasm that resembles the glandular, brown fat that is found in hibernating animals. The literature consists primarily of case reports, and in most of these the tumor arises within the thorax.<sup>116</sup> Lesions of the trunk, retroperitoneum, or extremities also are reported. Excision is generally curative.

### *Lipoblastoma and Lipoblastomatosis*

Lipoblastoma and lipoblastomatosis are peculiar variants of lipoma that occur almost exclusively in infancy and early childhood.<sup>117</sup> They differ from lipoma by their cellular immaturity and their close resemblance to the myxoid form of liposarcoma.

### *Liposarcoma*

Liposarcoma is primarily a tumor of adults with a peak incidence between age 50 and 65. Next to MFH, it is the most commonly diagnosed soft tissue sarcoma in adults. Liposarcoma may occur anywhere in the body, although the most common sites are the thigh and the retroperitoneum. As with other adult sarcomas, there are no characteristic clinical findings. Several types of liposarcoma are recognized and have different clinical outcomes.<sup>118</sup> Well-differentiated liposarcoma is a nonmetastasizing lesion. It is often difficult to distinguish well-differentiated liposarcoma from atypical lipoma, and the distinction may be irrelevant to the clinician. Sclerosing liposarcoma, also a low-grade lesion, typically occurs in the retroperitoneum.

Myxoid liposarcoma accounts for 40% to 50% of all liposarcomas. The tumor consists of proliferating lipoblasts within a delicate capillary network and has a myxoid matrix. The amount and distribution of the mucoid material may vary widely. Although previously considered a low-grade lesion, it is now clear that a myxoid matrix can be seen in many high-grade liposarcomas. As with other sarcomas, pathologic nomenclature can vary widely between pathologists. Myxoid liposarcoma typically has a t(12;16)(q13-14;p11) translocation.<sup>69</sup> Round cell (or lipoblastic) liposarcoma is characterized by excessive proliferation of small rounded cells. Round cell liposarcoma has the same translocation seen in myxoid liposarcoma,<sup>72</sup> suggesting that these liposarcomas are variants of the same pathogenetic process. Fibroblastic liposarcoma is composed of slender, fibroblast-like cells, and, like round cell liposarcoma, is of higher grade than myxoid liposarcoma. Pleomorphic liposarcoma, as the name implies, is a highly malignant lesion. Mitotic activity is high, and hemorrhage or necrosis is common.

It is not unusual for large liposarcomas to consist of multiple nodules, some of which contain only low-grade elements and others containing intermediate- or high-grade elements. The term *dedifferentiated liposarcoma*<sup>119</sup> has been used to refer to lesions that appear to begin as low-grade lesions, but progress to higher grade tumors and show evidence of nonlipogenic differentiation.<sup>120</sup> This lesion is seen most frequently in the retroperitoneum.

## TUMORS OF SMOOTH MUSCLE

### *Leiomyoma*

Benign smooth muscle tumors are quite common in the uterus and in the gastrointestinal tract. Rare cutaneous leiomyomas arise from the piloerector muscles of the skin. Some occur on a familial basis. These lesions are often multiple and may be quite painful.<sup>121,122</sup> Typically, these cutaneous leiomyomas develop in adolescence or early adult life as small discreet papules that eventually form nodules. The extensor surfaces of the extremities are most often affected, and the nodules may follow a dermatomal distribution. Although these tumors are histologically benign, recurrences after surgical incision are seen frequently, and often the lesions are so numerous that surgical incision is not possible. Leiomyoma may also occur deep within the extremities, abdominal cavity, or retroperitoneum.

Angiomyoma is a solitary form of leiomyoma. This lesion tends to occur on the extremity in people between the fourth and sixth decades of life. Women are more commonly afflicted than men.

Intravenous leiomyomatosis is a rare condition in which nodules of benign smooth muscle tissue grow within the veins of the myometrium and may extend into the uterine and hypogastric veins.<sup>123</sup> Rarely, these tumors extend up the inferior vena cava into the heart.<sup>124</sup> Diffuse peritoneal leiomyomatosis is also recognized, often occurring in association with pregnancy.<sup>125</sup> Leiomyomas in children have been associated with human immunodeficiency virus infection.

### *Leiomyosarcoma*

Leiomyosarcoma may arise in any location, but more than half are located in retroperitoneal or intraabdominal sites. These masses often reach quite large proportions, but present insidiously with nonspecific symptoms. In addition, most visceral sarcomas are leiomyosarcoma. Cutaneous leiomyosarcomas usually appear as small solitary extremity nodules.<sup>126</sup> Deep extremity leiomyosarcoma most frequently arises in the thigh and may arise in association with medium or large veins.<sup>127</sup> Although rare, leiomyosarcoma may arise in large vascular structures and present with symptoms of obstruction to the normal flow of blood. The most common arterial site is the pulmonary artery; patients present with symptoms of decreased pulmonary outflow. Leiomyosarcoma of the inferior vena cava, which may present with the

Budd-Chiari syndrome, is also described.

The typical cell of the leiomyosarcoma is elongated and has an abundant cytoplasm. Multinucleated giant cells are common. Epithelioid changes, in which the cells become rounded, with concomitant clear cell changes in the neoplasm, may occur in otherwise typical leiomyosarcomas. When the tumor is predominantly or exclusively epithelioid, the term *leiomyblastoma* has been used. The term *leiomyblastoma*, however, fails to convey any information with regard to clinical behavior.

Localization of muscle antigens by means of immunohistochemistry proves the diagnosis of leiomyosarcoma. Desmin and smooth muscle actin are the most common immunohistochemical stains. Grading of leiomyosarcoma, however, can be quite difficult, although mitotic activity appears to be the best indicator of prognosis.

## TUMORS OF SKELETAL MUSCLE

Benign tumors of striated muscle are rare. Several types of rhabdomyosarcoma are recognized. Embryonal rhabdomyosarcoma is a small cell tumor that usually arises in the orbit or genitourinary tract in children. The botryoid type of embryonal rhabdomyosarcoma, which frequently originates in mucosa-lined visceral organs such as the vagina and the urinary bladder, generally grows as a polypoid tumor. These tumors may disseminate widely, but are responsive to chemotherapy and radiation. Embryonal rhabdomyosarcomas occasionally arise in adults. Although regression of tumor in response to pediatric chemotherapy regimens usually occurs, age is an important prognostic factor for survival, with worse outcomes in older patients.<sup>128</sup> Extremity rhabdomyosarcoma in adolescents and young adults often has an alveolar histology. Alveolar rhabdomyosarcoma is composed of ill-defined aggregates of poorly differentiated round or oval cells that frequently show central loss of cellular cohesion and formation of irregular *alveolar* spaces. These tumors appear to have a worse prognosis than embryonal rhabdomyosarcoma in younger children, but not in adults. A specific translocation, t(2,13)(q37;q14) involving the PAX3 gene on chromosome 2 and the FKHR gene on chromosome 13, is seen in the majority of alveolar rhabdomyosarcomas.<sup>72</sup> In other patients, the translocated chromosome 2 locus is different.<sup>73</sup> Many pediatric studies include all types of rhabdomyosarcoma seen in the pediatric population.

In adults, pleomorphic rhabdomyosarcoma is the most common form of rhabdomyosarcoma. This high-grade lesion is not clinically distinguishable from other high-grade adult sarcomas.

## VASCULAR TUMORS

### *Hemangioma*

Hemangiomas are among the most common soft tissue tumors. Most hemangiomas are present at birth and regress spontaneously. Rapid growth with impingement on vital structures may occur, however, and treatment with intralesional injection of interferon has been life-saving.<sup>129</sup> Pulmonary hemangiomatosis, a rare disorder of diffuse microvascular proliferation in the lung, has been treated effectively with systemic interferon. Cavemous hemangioma refers to a benign lesion consisting of large dilated blood vessels with a flattened endothelium.

### *Lymphangiomyomatosis*

Pulmonary lymphangiomyomatosis is a disease of women of childbearing age. Patients present with cough, hemoptysis, and dyspnea. Grossly, the lungs demonstrate multiple small cystic lesions. On microscopic examination, there is proliferation of normal smooth muscle around the airways and the blood and lymphatic vessels. Tamoxifen does not appear to be useful, but responses to progestational agents have been seen.<sup>130</sup>

### *Epithelioid Hemangioendothelioma*

As its name implies, epithelioid hemangioendothelioma is a vascular tumor that has an epithelial appearance.<sup>131</sup> It has several forms. These lesions may appear as a solitary, slightly painful mass in either superficial or deep soft tissue. Metastases to lung, regional lymph nodes, liver, and bone are reported. Another pattern is that of a diffuse bronchoalveolar infiltrate or multiple small pulmonary nodules. This entity has also been called *IBVA7* (intravascular, bronchiolar, and alveolar tumor of the lung).<sup>132</sup> Patients may present with cough and hemoptysis. Epithelioid hemangioendothelioma can also arise in the liver, often presenting as an incidental finding, or as part of a workup for mild elevation of liver enzymes or vague abdominal pain. Multiple liver nodules are the rule. Although these lesions can metastasize, they usually run an indolent course. Liver transplantation has been performed, even in patients with metastatic disease.<sup>133</sup>

### *Kaposi's Sarcoma*

Classic Kaposi's sarcoma is an unusual vascular sarcoma that occurs in the skin of the lower extremities of elderly men of Mediterranean or Jewish extraction.<sup>134</sup> The disease is usually indolent, although it can spread to the lungs and the gastrointestinal tract. Cutaneous lesions can be palliated with radiation therapy when necessary. Another form of Kaposi's sarcoma occurs in Bantu men in Africa; it may also occur in African children in whom it runs a more aggressive course. Kaposi's sarcoma has arisen in renal allograft recipients who are receiving immunosuppressant therapy.<sup>135</sup> Epidemic Kaposi's sarcoma is a complication of human immunodeficiency virus infection (see [Chapter 50.1](#)).

### *Angiosarcoma*

Angiosarcomas may arise in either blood or lymphatic vessels. Cutaneous lymphangiosarcoma may develop in chronically lymphedematous extremities.<sup>136</sup> The classic presentation is the Stewart-Treves syndrome, lymphangiosarcoma in the chronically lymphedematous arms of women who have been treated for breast cancer with radical mastectomy, and, often, axillary irradiation.<sup>20</sup> Hemangiosarcomas are usually located in the skin or superficial soft tissue. Multicentric angiosarcomas occur on the scalp and face of elderly men, where unrelenting progression can cause severe ulceration and infection.<sup>137</sup> Angiosarcoma of the breast is usually an aggressive lesion that recurs locally and may metastasize, primarily to lung; histologic grade has been of prognostic value.<sup>138</sup> Angiosarcomas are known to occur in sites of prior irradiation without chronic lymphedema, in particular the pelvis of women who have received radiation therapy for gynecologic cancers.<sup>139</sup> Soft tissue angiosarcoma, often with epithelioid features, may arise on the extremities or within the abdomen.<sup>140</sup>

## PERIVASCULAR TUMORS

### *Glomus Tumor*

Glomus tumors mimic the modified smooth muscle cells of the glomus body, a special form of arteriovenous anastomosis that is located in the skin and participates in thermal regulation. The glomus tumor generally presents as small, blue-red nodule in subcutaneous tissue or in the subungual region of the finger.<sup>141</sup> These tumors are often associated with paroxysmal pain irradiating away from the tumor. Complete excision is the appropriate management.

### *Hemangiopericytoma*

The cells of these tumors resemble pericytes, cells that normally are arranged along capillaries and venules. These rare tumors usually arise in adults, although an infantile hemangiopericytoma is recognized. The adult form is most common in the lower extremity, but also occurs in the pelvis or retroperitoneum or other sites. The tumors tend to be well circumscribed and consist of tightly packed cells around thin-walled vascular channels of varying calibers. The cells of hemangiopericytoma stain immunohistochemically with factor XIIIa and HLA-DR antigen, but not with factor VIII-related antigen.<sup>142</sup> Many hemangiopericytomas have an indolent behavior, although some behave like other high-grade sarcomas.<sup>143</sup>

## TUMORS OF SYNOVIAL TISSUE

### *Nodular Tenosynovitis*

A variety of benign tumors and tumor-like lesions arise from the synovium. Nodular tenosynovitis (tenosynovial giant cell tumor) is a giant cell tumor that may occur at any age but is most commonly seen between the ages of 30 to 50. These tumors are somewhat more common in women. They occur with greatest frequency in the

hand, but are also seen in the ankles and knees, among other sites. These slow-growing tumors grow as circumscribed lobulated masses and are usually diagnosed when they are less than 5 cm in diameter. Because of their location, excision is often done with close margins and local recurrence is seen in 10% to 20% of patients. A diffuse form occurs in and around joints, most commonly around the knee or ankle. In contrast to most giant cell tumors, this neoplasm grows in expansive sheets without a mature capsule. Malignant giant cell tumors of the tendon sheath are also recognized.

### **Synovial Sarcoma**

Synovial sarcoma usually occurs in young adults.<sup>144</sup> The most common site is around the knee. As opposed to most other soft tissue sarcomas, these lesions occasionally are painful. This tumor is composed of two morphologically distinct types of cells that form a characteristic biphasic pattern. The biphasic synovial sarcoma includes epithelial cells with a surrounding spindle or fibrous component. Calcification, with or without ossification, is seen in up to 30% of tumors. The spindle cells stain positive for keratin and epithelial membrane antigen. Vimentin is demonstrable in spindle cells but absent in epithelial cells. S-100 may be positive as well. Monophasic synovial sarcoma of both fibrous and epithelial types are recognized, although monophasic epithelial synovial sarcoma is extremely rare. Synovial sarcomas contain a characteristic chromosomal translocation, t(X;18)(p11.2;q11.2); a hybrid transcript has been identified.<sup>68</sup>

## **TUMORS OF THE PERIPHERAL NERVES**

### **Neurofibroma**

Solitary neurofibromas are small, slow-growing cutaneous or subcutaneous nodules that usually arise during the third decade of life. By definition, these lesions are not associated with neurofibromatosis. Neurofibromatosis type 1 (NF1, peripheral neurofibromatosis, von Recklinghausen's disease) is one of the most common genetic disorders, affecting approximately 1 in 3000 live births.<sup>145</sup> An autosomal dominant mutation at the 17q11.2 locus has been identified.<sup>146</sup> The clinical features of NF1 include café au lait spots, Lisch nodules (pigmented hamartomas) of the iris, and neurofibromas of several types. Cutaneous neurofibromas, soft, fleshy growths, arise in the skin in all patients with NF1. These lesions may range in size from a few millimeters to 50 to 60 cm. Although some patients have only a few such lesions, others may have hundreds. Subcutaneous neurofibromas are firm and nodular and may be painful. Plexiform neurofibromas are large lesions that affect large segments of a nerve, thickening and distorting the nerve into a tortuous mass. They may cause severe dysesthetic pain.

### **Benign Schwannoma**

Also called *neurilemoma*, this benign lesion occurs most commonly in people aged 20 to 50 years. Common sites include the head and neck and the flexor surfaces of the extremities. It grows slowly and is usually smaller than 5 cm when the diagnosis is made. This encapsulated nerve sheath tumor is distinguished from neurofibroma in that schwannoma consists of two components: a highly ordered cellular region (Antoni A area), and a loose, myxoid component (Antoni B area).

### **Cellular Schwannoma**

This tumor is more cellular than classical schwannoma. It usually presents in patients during the seventh decade of life as a painless paravertebral mass.<sup>147</sup> Complete excision is curative in most patients.

### **Granular Cell Tumor**

The granular cell tumor (also called granular cell myoblastoma) is a rare tumor that probably is of neural origin. This tumor usually presents in adults as a small, poorly circumscribed subcutaneous nodule, although there are patients who have multiple lesions. This entity has a distinct histologic appearance and stains positive for S-100. Granular cell tumor usually runs a benign course, but metastases have been reported.

### **Malignant Peripheral Nerve Sheath Tumors**

MPNSTs have also been called malignant schwannoma, neurofibrosarcoma, or neurogenic sarcoma. The majority of MPNSTs are high grade and characteristically stain for the S-100 protein. The lower extremity and the retroperitoneum are the most common sites, but MPNSTs may arise anywhere in the body.<sup>148</sup> These tumors originate from the nerve sheath, rather than from the nerve itself. Although higher estimates appear in the literature, approximately 5% of patients with NF1 develop MPNSTs,<sup>10,11</sup> usually arising from a plexiform neurofibroma. The majority of patients with MPNST do not have neurofibromatosis, however. After accounting for size and grade, the prognosis of patients with MPNST in the setting of NF1 is not different from that of other patients. The malignant peripheral nerve tumor that develops in the patient with neurofibromatosis historically has been considered to have a poor prognosis compared with other extremity malignant sarcomas. However, when other factors of known risk for outcome such as grade and size are accounted for, malignant peripheral nerve tumors arising both sporadically and in the presence of neurofibromatosis tend to have a similar outcome to other poor prognosis peripheral sarcomas.<sup>149</sup> MPNSTs tend to present with a greater preponderance of large size and high grade than other soft tissue sarcomas, hence their reputation for aggressivity. The Triton tumor is a malignant peripheral nerve tumor with rhabdomyosarcomatous elements.<sup>149</sup>

Because of evolving concepts and nomenclature, the literature is confusing with regard to MPNST and primitive neuroectodermal tumor. The latter, a small cell tumor of children and young adults, is a variant of Ewing's sarcoma.

### **Gastrointestinal Autonomic Nerve Tumor**

GANT, also called plexosarcoma, presumably arises from the enteric plexus of the gastrointestinal tract. Clinically and microscopically, GANT resembles gastrointestinal leiomyosarcoma, but immunostaining is negative for markers of myogenic differentiation. Neurofilaments are seen by electron microscopy.<sup>90</sup> GANT is usually considered a subset of gastrointestinal stromal tumors (GISTs) and characteristically demonstrates expression of the oncogene c-kit (CD117).

## **EXTRASKELETAL CARTILAGINOUS AND OSSEOUS TUMORS**

### **Myositis Ossificans**

This benign lesion is a self-limiting process that usually is associated with trauma. Despite its name, myositis ossificans is not necessarily confined to the muscle nor is inflammation a prominent feature. The condition usually presents in athletic young adults as a tender, soft tissue mass. Over a period of weeks, the mass usually becomes firm or rock hard. Radiographs show calcification several weeks after the lesion appears. Histologically, the mass consists of fibroblastic tissue, often with prominent mitotic activity. Nonetheless, this process is benign and may be managed conservatively. Obviously, it is important to distinguish between myositis ossificans and sarcoma, especially extrasosseous osteogenic sarcoma.

### **Extraskeletal Chondrosarcoma**

Myxoid chondrosarcoma (also called chordoid sarcoma) occurs most commonly in patients over the age of 35. More than two-thirds occur in the extremity.<sup>150</sup> This tumor usually grows slowly, but late recurrence and metastasis is common. A nonrandom reciprocal translocation has been shown in these tumors.<sup>83,84</sup>

### **Extrasosseous Osteogenic Sarcoma**

Extrasosseous osteogenic sarcoma are rare, high-grade sarcomas defined by their production of malignant osteoid and bone.<sup>151,152</sup> By definition, they are not attached to the skeleton. Unlike typical osteogenic sarcoma of bone, these tumors rarely occur in patients under the age of 20, and most patients are over 50 years of age.<sup>153,154</sup> These high-grade tumors present like other soft tissue sarcomas. Most arise in the extremities, although osteosarcoma of other sites, including breast, retroperitoneum, urinary bladder, or other visceral organs have been reported. There is considerable heterogeneity in the histologic appearance. Spindle cell varieties may resemble MFH, MPNST, or fibrosarcoma, whereas others have a more epithelioid appearance. Giant cells are a common feature. Some lesions that may contain bone or cartilage are hard to distinguish from MFH, but bone in MFH is well differentiated. Nonetheless, extrasosseous osteogenic sarcoma resembles MFH in terms of

age, sites of distribution, and clinical behavior.

## TUMORS OF UNCERTAIN HISTOGENESIS

### **Myxoma**

Intramuscular myxoma is a rare tumor that occurs in adults, usually in the large muscles of the extremities. Myxomas consist of abundant mucoid material but few cells. Although these lesions often measure 5 to 10 cm, their clinical behavior is generally benign.<sup>155</sup> Multiple intramuscular myxomas occur in association with fibrous dysplasia.

Aggressive angiomyxoma<sup>156</sup> is a tumor that usually occurs in women, although male patients have been reported. The lesion generally presents as a mass in the perineal or pelvic area. Local recurrence can result in considerable morbidity given the location of these tumors, but distant metastases do not occur.

### **Mesenchymoma**

Malignant mesenchymoma is defined as a malignant tumor showing at least two types of malignant mesenchymal differentiation in addition to a poorly differentiated fibrosarcomatous element.<sup>157</sup> These rare tumors are generally thought to behave clinically in accordance with the predominant component, although one report suggests that their behavior is not as aggressive as might be expected.<sup>158</sup>

### **Alveolar Soft Part Tumor**

This rare tumor occurs most frequently in patients between 15 and 35 years of age. Women outnumber men, especially in patients less than 20 years of age.<sup>159</sup> Prognosis is better in those patients who present at a younger age. These tumors often present in the lower extremities as slow-growing painless masses. Grossly, alveolar soft part tumors are poorly circumscribed. They typically grow in an organoid or nest-like arrangement. The alveolar spaces actually are necrotic areas. Considerable controversy regarding histogenesis persists. Neural derivation has been suggested, but other data suggest a myogenic origin.<sup>160</sup> Lung, brain, and bone are the most common sites of metastasis. Although this tumor tends to grow slowly, the ultimate prognosis is quite poor. Patients may remain asymptomatic over years, however, even with metastatic disease.

### **Epithelioid Sarcoma**

Epithelioid sarcoma is another tumor of adolescents and young adults. This tumor usually presents as a small, firm nodule in the subcutaneous tissue of the distal extremities.<sup>161,162</sup> Multiple recurrences, which grow along tendons and fascial planes, are a characteristic feature. Unlike most other sarcomas, lymph node metastases are common, and the tumor may appear in the extremity in transit to the regional nodes.<sup>51,161</sup> Lung is the most common site of distant metastasis.

### **Clear Cell Sarcoma (Malignant Melanoma of Soft Parts)**

This tumor, also called *clear cell sarcoma of tendons and aponeuroses*, presents as a soft tissue mass. Because of the presence of intracellular melanin and the tendency for regional nodal metastasis, it has been suggested that this entity is better considered a melanoma than a soft tissue sarcoma. Despite these clinical features, clear cell sarcoma has a distinct chromosomal translocation, t(12;22)(q13;q13). Size is the most important prognostic factor. Treatment of the primary is similar to that of other sarcomas. There are few reported responses to chemotherapy.

### **Desmoplastic Small Cell Tumor**

This newly appreciated entity is a tumor of adolescents and young adults.<sup>163</sup> It usually presents in the abdomen, often with diffuse peritoneal implants. Because of its multifocal nature, complete resection is usually impossible. Chemotherapy regimens used in the treatment of Ewing's sarcoma have induced responses in patients with this disease, but are rarely curative. A specific translocation between chromosomes 11 and 22 that is different from the translocation of Ewing's sarcoma has been identified.<sup>164,165</sup>

### **Follicular Dendritic Cell Sarcoma**

This unusual lesion is thought to arise from lymphatic tissue<sup>166</sup> and commonly occur in the neck, but has been described in other sites.<sup>167</sup>

## CLINICAL PRESENTATION

The presence of soft tissue sarcoma almost invariably is suggested by the development of a mass. This mass is usually large, often painless, and may be associated by the patient with an episode of injury. The majority present at a size greater than 5 cm. The size distribution for 3541 cases admitted to Memorial Sloan-Kettering Cancer Center (MSKCC) is illustrated in [Figure 39.1-5](#). The focus of the clinical evaluation is to determine the likelihood of a benign or malignant soft tissue tumor, the involvement of muscular or neurovascular structures, and the ease with which biopsy or subsequent excision can be obtained. Size becomes an important feature (see [Prognostic Factors for Outcome](#), later in this chapter) and definitive diagnosis is dependent on biopsy and histologic confirmation.

**FIGURE 39.1-5.** Distribution by size of soft tissue sarcomas in 3541 patients aged 16 years or older admitted to Memorial Sloan-Kettering Cancer Center between July 1982 and July 1999.

## DIFFERENTIAL DIAGNOSIS

The major concern, when confronted with a soft tissue mass, is whether or not the lesion is benign or malignant. In most patients with small lesions, or even on occasion large lesions, the differentiation is from the most common soft tissue tumor, lipoma. This may be simple but becomes more difficult as the more aggressive and underappreciated inherently benign lesions are considered. Particularly difficult is myositis ossificans. The patient often has an antecedent history of trauma, and often presents with a large, firm to hard lesion that, on plain film, may have a telltale sign of intrinsic calcification. This does not preclude a malignant lesion. Tru-Cut (Travenol Laboratories, Deerfield, IL) needle biopsy or open biopsy is often accompanied by aggressive hemorrhage, suggesting a vascular neoplasm. In most cases, diagnosis can be made fairly accurately by either plain film ([Fig. 39.1-6](#)) or magnetic resonance imaging (MRI) ([Fig. 39.1-7](#)). Certainly, the diagnosis should be suspected when there is a significant history of trauma, the lesion is particularly hard, and there is inherent calcification.

**FIGURE 39.1-6.** Myositis ossificans suggested by calcification on a plain film.

**FIGURE 39.1-7.** Characteristic findings of myositis ossificans on magnetic resonance imaging, including diffuse tissue expansion.

Other difficult lesions are the angiomyolipoma and the rare angiomyxoma ([Fig. 39.1-8A](#) and [Fig. 39.1-8B](#)), which can also be vascular lesions, and the atypical schwannoma, which can be quite large and often is invasive ([Fig. 39.1-9](#)). They can often be quite destructive, causing ureteric obstruction and bone invasion. The management is as difficult as for any sarcoma. Conversely, unless absolutely imperative, multiple radical operations in inherently indolent lesions should be avoided.

**FIGURE 39.1-8.** Other similarly difficult lesions are angiomyxoma, here seen growing as a mass in the perineum **(A)** and pelvis **(B)** in a young woman.

**FIGURE 39.1-9.** Atypical schwannoma can be quite large and often invasive, as shown here in a man with a 20-year history of having undergone multiple resections for large invasive lesions.

## IMAGING STUDIES

Imaging studies for soft tissue sarcoma vary, depending to some extent on the site. They involve evaluation both of the primary lesion and the potential site of metastasis. Evaluation of the primary lesion in the extremity, and head and neck, predominantly is either by computed tomography (CT) scan, or magnetic resonance imaging (MRI), which provides some increased definition. In the hands of a knowledgeable radiologist, MRI can provide information over and above that provided by CT.<sup>168</sup> Nevertheless, a Radiology Diagnostic Oncology Group study comparing these modalities has shown no benefit of MRI over CT.<sup>169</sup> What is clear in this era of cost containment is that multiple modalities, all focusing on the same entity, are not required.

An important issue for the primary clinician is identification of the relationship of the sarcoma to neurovascular structures. Angiography is rarely of value. For the primary intraabdominal lesion we prefer CT scan ([Fig. 39.1-10](#)), which can identify both primary and potential metastasis, although in lesions known to involve the intestinal tract, MRI may add information.

**FIGURE 39.1-10.** Computed tomography of a massive intraabdominal liposarcoma.

### Positron Emission Tomographic Scan

While positron emission tomographic (PET) scan has been used as an investigational agent for several years, it has yet to gain universal acceptance. It does appear in some studies that grade can be distinguished by this modality. At present, it would appear that the role of PET is primarily in the identification of unsuspected sites of metastasis in patients with recurrent high-grade tumors.

### SITES OF METASTATIC DISEASE

As important as imaging studies of the primary lesion is evaluation of possible sites of metastasis. This knowledge is essential. An analysis of patients at MSKCC reveals the common sites of metastasis that can guide investigation (Fig. 39.1-11). Metastatic disease from soft tissue sarcoma is also site-specific. For patients with extremity lesions, most metastases (70%) go primarily to the lung.<sup>170</sup> For patients with retroperitoneal or visceral lesions, a much more common site for metastases would be the liver parenchyma, with lung only a secondary site. Nevertheless, no site is immune from soft tissue sarcoma metastasis, and other unique patterns can be identified (e.g., the unusual presentation of intraabdominal metastasis following an extremity liposarcoma).<sup>171</sup>

**FIGURE 39.1-11.** Common sites of metastasis that can guide investigation (from 1171 patients admitted to Memorial Sloan-Kettering Cancer Center between July 1982 and July 1999). The primary site of metastasis for extremity lesions is the lung.

Clearly, for small, superficial extremity lesions, either high or low grade, evaluation for sites of metastasis is less important and simple chest roentgenogram suffices. Conversely, with large high-grade lesions, where the risk of metastatic disease is significant, more extensive evaluation is required. For extremity lesions, the primary modality is a chest roentgenogram followed by a CT scan of the chest. For retroperitoneal, visceral, and intraabdominal lesions, then the site of metastasis that is most common (i.e., the liver) is evaluated with the modality that is used for evaluation of the primary lesion.

### BIOPSY

The primary thrust of biopsy is to obtain adequate tissue for definitive histopathologic confirmation, to evaluate grade, and to identify prognostic factors that would alter the approach to definitive treatment. In the main, for lesions that are less than 5 cm, particularly those that are superficial, excisional biopsy is the preferred approach.

### VALUE OF TRU-CUT BIOPSY

Several studies have examined this issue,<sup>172,173</sup> and a summary of the accuracy of Tru-Cut, incisional and frozen section biopsies is included in Table 39.1-6. In the main, the important issue is the adequacy of the sample. Sufficient viable tissue is required that is both representative of the lesion and available for all histopathologic evaluation, immunohistochemistry, and where necessary, electron microscopy. As molecular markers become a factor in prognosis, meticulous attention to the adequacy of biopsy, tissue preservation, and evaluation is paramount. Histopathologic interpretation varies from center to center and may be a major variable in decision making. As with other relatively rare lesions, it is essential that review of the histopathology be made by an experienced group. In a paper from a major center,<sup>174</sup> members of the Musculoskeletal Tumor Society were surveyed and the diagnostic accuracy of biopsies and the consequences of errors made in diagnosis were tabulated. More recent studies, however, show improved diagnostic accuracy and confluence of opinion at least for malignancy and grade.<sup>175</sup>

	Tru-Cut	Incisional	Frozen Section
Number	60	45	36
Adequate tissue (%)	95	100	94
Correct malignancy (%)	95	100	88
Correct grade (%)	88	96	62 <sup>a</sup>
Correct histology (%)	75	84	47 <sup>a</sup>

### FINE NEEDLE ASPIRATION CYTOLOGY

Fine needle aspiration cytology (FNA) has been examined by a number of authors<sup>175,176</sup> but is usually confined to the confirmation of recurrence, rather than for the primary diagnosis. In the hands of some, however, it has been a consistent tool. Kindblom<sup>176</sup> performed a study of 18 soft tissue tumors, 5 bone tumors, and 3

metastatic carcinomas thought to be primary soft tissue tumors to examine the relative advantages of a technique using both light and electron microscopy rather than conventional light microscopic aspiration cytology. In their hands FNA was a valuable adjunct used in this manner, but is rarely employed in most centers, other than to identify expected recurrent lesions.

Some authors have argued that biopsy itself is not justified if FNA is available. Rydholm<sup>177</sup> has suggested that no open biopsy is ever really indicated, the argument against its use suggesting the possibility of risking local tumor spread. The author is concerned that antecedent open biopsy increases both the magnitude of the subsequent operation and the need for adjuvant radiation therapy. The author argues that without biopsy, radiation therapy is not needed in the majority of cases and limits the need for more extensive resections. Using FNA, the surgeon proceeds directly to open operation. The author points out, however, that this requires referral before antecedent biopsy, a relatively uncontrollable event in the United States. In addition, other authors suggest that this results in ten patients with benign lesions referred for every sarcoma patient,<sup>178</sup> certainly an untenable situation under our present system.

In addition, this approach presupposes that all that is required is a malignant sarcoma diagnosis and the type or grade of sarcoma does not determine therapy. At MSKCC for extremity lesions we use brachytherapy (BRT) for high-grade lesions and external-beam radiation therapy for low-grade lesions, particularly of large size, that would preclude such an approach. The authors themselves conclude the difficulty if patients should be candidates for pretreatment neoadjuvant therapy to improve survival. However, they argue that immunohistochemistry, electron microscopy, DNA cytology, and chromosomal analysis, all of which can be performed on FNA, ensure the appropriateness of this approach.<sup>179</sup> We still favor adequate tissue from Tru-Cut, excisional, or incisional biopsy to begin such a procedure.

## FROZEN SECTION

In some institutions, frozen section is relied on as the diagnostic tool of choice. For many institutions, however, this is unavailable. Our results for frozen section are described in [Table 39.1-6](#). For diagnosis of malignancy, frozen section is accurate but for histopathologic subtypes and grade it is inferior to permanent sections of either Tru-Cut or incisional biopsy.

## STAGING

There have been significant changes in the staging of soft tissue sarcoma. The original 1992 staging system was based on a review published in 1977.<sup>180</sup> That staging system has since been considerably modified. The major difference was the inclusion in the original staging system of a subcategory grade [i.e., patients with small (less than 5 cm) lesions that were high grade, were considered as stage IIIA]. Several reviews, however, have suggested that such lesions (small, high grade) have a much more favorable prognosis than outlined in the original 1977 proposal. Reports from two separate institutions<sup>181,182</sup> suggest that survival of these patients is certainly better than 80% and in many patients, 90%. Consequently, size, which had been historically considered a subcategory of grade, was redefined. Clearly, however, size is a continuous variable and the decision to divide tumors into less than 5 cm or greater than 5 cm is clearly arbitrary.<sup>183</sup> An analysis of greater than 1000 patients with localized extremity sarcoma seen at MSKCC between 1982 and 1997 has been published.<sup>184</sup> The new staging system, however, now includes both size and depth. Our analysis of the present modified 1997 staging system makes it more clear that stages IB (low-grade, large superficial tumors) are uncommon as are stage IIC (high-grade, large, superficial tumors). They are in such a minority that the ability to use them meaningfully in a staging system must be questioned ([Table 39.1-7](#)). In addition, this would suggest that depth, although significant in multiple, overall analyses, is of less value when incorporated with other prognostic factors such as size. In addition, it is clear that size itself is a continuous variable as mentioned previously, and for the high-risk tumors (i.e., the large, less than 5-cm, deep tumors), they can be meaningfully divided into tumors of greater than 5 cm or greater than 10 cm. Using this approach then, distant metastasis-free survival can be quite clearly distinguished into four discriminating groups ([Table 39.1-8A](#), [Table 39.1-8 B](#), and [Table 39.1-8 C](#) and [Fig. 39.1-12](#)).

	Total (No.)	No (%)
Old staging system (1992)		
1A	140	2 (1)
1B	221	15 (6)
3A	272	47 (17)
3B	426	144 (34)
New staging system (1997)		
1A	140	2 (1)
1B	30	3 (10)
2A	191	16 (5)
2B	272	47 (17)
2C	23	4 (17)
3A	208	57 (27)
3B	195	83 (43)

Study	Log-Rank Test	Wilcoxon Test
Local recurrence	$P = .5$	$P = .25$
Disease-free survival	$P = .0001$	$P = .0001$
Overall survival	$P = .0001$	$P = .0001$

**TABLE 39.1-8C.** Statistical Test on Three Stages

**FIGURE 39.1-12.** Distant metastasis-free survival for patients with primary extremity soft tissue sarcoma ( $n = 1059$  patients admitted to Memorial Sloan-Kettering Cancer Center between July 1982 and January 1998) by stages, incorporating 1A/1B/2A versus 2B/2C versus 3A versus 3B. Significance describes the overall difference between the curves. (From ref. 183, with permission.)

Stage IV disease from lymph node metastasis, which as previously alluded to, is rare in the majority of adult soft tissue sarcomas, is equivalent to any other metastasis. For example, if one takes patients with lymph node metastasis only or lymph nodes plus other metastasis and contrasts those to other systemic metastasis, then the disease-specific survival is essentially the same ( Fig. 39.1-13). Finally, it is important to emphasize that prognostic factors can vary with time. For early recurrence, it would appear that grade is predominant, whereas for late recurrence, size assumes a progressively more important role. <sup>54,185</sup>

**FIGURE 39.1-13.** Disease-specific survival for patients with soft tissue sarcoma with metastases ( $n = 711$  patients admitted to Memorial Sloan-Kettering Cancer Center between July 1982 and July 1997); lymph node metastases alone versus lymph node metastases with other metastases versus all other metastases. (From ref. 183, with permission.)

Whether or not age should be a determinant in a staging system is as yet unclear. Certainly, when age is examined as an outcome for overall survival, the older patient has a shorter survival than the younger patient. This has usually been arbitrarily divided into less than 50 or greater than 50 years, with a patient over 50 having a worse prognosis. Conversely, a distinction into three groups can show some separation, which we thought were, in the main, disease-dependent rather than age-dependent ( Fig. 39.1-14). It certainly seems clear that patients under the age of 16 (i.e., the pediatric age group) have a far different prognosis and a far different response to treatment with sarcoma than do the adults, and this should not be included in the current adults' staging system. An analysis of the most common histopathologic type in children, rhabdomyosarcoma, suggested that the soft tissue sarcomas in children behave in a somewhat different manner than those in adults. It does appear that the early stage of disease and the late stage of disease are similar in both children and adults, but the intermediate stage lesions have a better prognosis in children, which does not appear solely due to their ability to tolerate extent of treatment. <sup>128</sup> Site is also a clear determinant of outcome. Patients with retroperitoneal and visceral sarcomas certainly do worse than patients with extremity lesions ( Fig. 39.1-15).

**FIGURE 39.1-14.** Overall survival for extremity soft tissue sarcoma by age group in 1813 patients aged 16 years or older admitted to Memorial Sloan-Kettering Cancer Center between July 1982 and July 1999 ( $P < .001$ ). Significance describes the overall difference between the curves.

**FIGURE 39.1-15.** Disease-specific survival by site of soft tissue sarcoma in 3968 patients aged 16 years or older admitted to Memorial Sloan-Kettering Cancer Center between July 1982 and July 1999 ( $P < .001$ ). Patients with retroperitoneal or visceral sarcomas did worse than patients with extremity lesions. Significance describes the overall difference between the curves.

Conversely, there are factors that affect our ability to treat specific sites such as difficulty of radical resections for head and neck tumors and the limitations of radiation therapy in intraabdominal sites.

It does appear that site is a significant factor in survival. However, it is difficult to separate site from adequacy of treatment. It is clear that patients with retroperitoneal sarcoma can and do die of local recurrence, an uncommon event in extremity lesions. The intraabdominal visceral leiomyosarcomas still maintain a high metastatic rate as the primary cause of death.

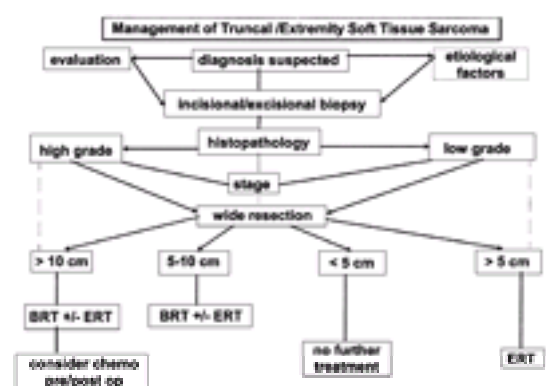

Bone invasion by soft tissue sarcoma with neurovascular invasion has historically been considered a bad prognostic feature. However, as bone invasion is relatively uncommon in soft tissue sarcoma, it has not been uniformly included in any staging system, but should certainly be considered as a poor prognostic factor.

As of the present time, the innumerable molecular markers that have been included and defined for soft tissue sarcoma, some with prognostic implications, have not been included in staging systems, but one that we would expect to become an increasingly important variable.

## MANAGEMENT OF EXTREMITY AND SUPERFICIAL TRUNCAL SOFT TISSUE SARCOMA

### Surgical Treatment

A suggested algorithm is shown in [Figure 39.1-16](#). Where appropriate, alternative approaches are discussed in the text (e.g., for patients with lesions less than 5 cm and positive microscopic margins not able to be resected without major morbidity, radiation therapy can be selectively used). The mainstay of treatment for all soft tissue sarcomas of the extremity and trunk is surgical excision. The issues of debate concern how extensive that surgical excision should be and whether it should be preceded or followed by adjuvant therapy.

**FIGURE 39.1-16.** Management algorithm for extremity and superficial truncal soft tissue sarcoma. BRT, brachytherapy; ERT, external-beam radiation therapy.

Wide *en bloc* resection is used most often. Historical attempts to resect all muscle bundles from origin to exertion have now been supplanted by an encompassing resection, aiming to obtain 2 cm of all uninvolved tissue in all directions. This is often unrealistic, however, because the limiting factor is usually neurovascular juxtaposition or, occasionally, bony juxtaposition. Because most soft tissue sarcomas tend not to invade bone directly, only rarely does bone need to be resected. Soft tissue sarcomas only uncommonly involve the skin, so major skin resection should be limited. In situations of primary or recurrent tumors where skin is involved, or the tumor is so extensive that skin is involved, then consideration of free flap or rotational flap closure becomes important, particularly in those patients who are candidates for subsequent adjuvant radiation therapy.

### EXTENT OF SURGICAL RESECTION

The most extensive resection is clearly amputation. This should be only rarely indicated in soft tissue sarcoma at the present time because limb-sparing operations are possible in at least 95% of patients. Experience over the last 25 years at MSKCC indicates that the 50% amputation rate in the late 1960s is now less than 5% ([Fig. 39.1-17](#)). Amputation should be reserved, in the main, for tumors not able to be resected by any other means, without evidence of metastatic disease and the propensity for good long-term functional rehabilitation. Often these are patients with large, low-grade tumors with considerable cosmetic and functional deformity, who can be rendered free of symptoms by a major amputation.

**FIGURE 39.1-17.** Limb-sparing surgery (LSS) versus amputation for all patients, primary and recurrent. Trends in management over time based on the experience at Memorial Sloan-Kettering Cancer Center from 1968 to 1998.

Major amputation has been contrasted to limb-sparing surgery combined with adjuvant radiation.<sup>186</sup> Local recurrence can occur after the limb-sparing operation, and follow-up data on this study confirm that this is almost invariably salvaged, but there is no effect on long-term survival.<sup>187</sup> The issue of amputation versus limb-sparing surgery for extremity lesions has been addressed by a prospective randomized trial at the National Cancer Institute (NCI). In patients entered into this trial, follow-up is now available for more than 10 years. Although local recurrence is greater in those undergoing limb-sparing operation plus irradiation compared with amputation (Fig. 39.1-18), survival overall is not different (Fig. 39.1-19).

**FIGURE 39.1-18.** Soft tissue sarcoma, local recurrence according to treatment. Limb-sparing surgery (LSS) plus irradiation (RT) compared with amputation (AMP) at the National Cancer Institute. (Courtesy of J. C. Yang and S. A. Rosenberg.)

**FIGURE 39.1-19.** Soft tissue sarcoma, disease-free survival according to treatment. Limb-sparing surgery (LSS) plus irradiation (RT) compared with amputation (AMP) at the National Cancer Institute. (Courtesy of J. C. Yang and S. A. Rosenberg.)

## SIZE

Because size is a prognostic factor for outcome both in terms of local recurrence and subsequent metastatic disease, the approach to these lesions can be varied. In patients with small approach to these lesions can be varied. In patients with small lesions less than 5 cm, complete surgical excision is usually sufficient, adjuvant therapy being reserved for only those with recurrent lesions. Given the high risk of recurrence and of systemic disease for lesions larger than 10 cm that are high grade, these patients are candidates for investigational approaches, especially neoadjuvant chemotherapy (see below, in Adjuvant Chemotherapy). All patients with lesions larger than 5 cm should be considered for adjuvant radiation therapy as a proven method of limiting local recurrence.<sup>181</sup>

## RADIATION THERAPY

Before discussing the role of radiation therapy in the management of soft tissue sarcoma, it is important to differentiate between radiosensitivity and radioresponsiveness. *Radiosensitivity* refers to the inherent response of cancer cells to radiation, and *radioresponsiveness* refers to how quickly a tumor regresses after radiation. These two parameters do not always correlate.

Unfortunately, the slow rate of regression of soft tissue sarcomas even after high doses of radiation, an example of poorly radioresponsive tumors, is often mistaken for radioresistance. This in turn has led to an extensive debate about the effectiveness of radiation therapy in soft tissue sarcomas. This debate was not settled until the recent past, even though the use of x-rays for the treatment of sarcoma was first proposed in 1902.<sup>188</sup> The fact that soft tissue sarcomas are radiosensitive tumors has not only been proven clinically, but it has also been shown in radiobiologic experiments. Radiation sensitivity of cell lines derived from sarcomas, measured *in vitro*, is not less than that of epithelial cancer cell lines.<sup>189,190 and 191</sup>

The discussion in this section is focused primarily on the role of radiation in the management of soft tissue sarcoma of the extremity and superficial trunk. The role of radiation in other sites is discussed separately in other sections of this chapter. Radiation therapy is mainly used as an adjuvant treatment to surgery in the form of BRT or external-beam radiation and rarely used alone for patients with unresectable disease.

## ADJUVANT RADIATION

The effectiveness of adjuvant radiation has been clearly shown not only through retrospective data but also through three prospective randomized trials that have compared surgery alone with surgery and radiation.<sup>187,192,193</sup> Therefore, the question that we should be asking is not whether radiation is useful, but rather which form of radiation is the most effective in terms of tumor control and function preservation.

## POSTOPERATIVE EXTERNAL-BEAM RADIOTHERAPY

The use of postoperative external-beam radiotherapy in soft tissue sarcoma of the extremities has served as an early model for function preserving approach in oncology.

Historically, amputation was considered the standard surgical treatment for soft tissue sarcoma of the extremity, but data that evaluated more conservative surgery followed by postoperative external-beam radiotherapy emerged as a reasonable alternative.<sup>194,195</sup> These encouraging results lead the NCI to perform a randomized prospective trial that compared amputation with wide local excision and postoperative radiation in patients with high-grade soft tissue sarcoma of the extremity. Twenty-seven patients were randomized to conservative surgery and radiotherapy, and 16 received amputation (2:1 randomization). There were four local recurrences in the limb-sparing group and none in the amputation group ( $P = .06$ ). However, there were no differences in disease-free survival rates (71% and 78% at 5 years;  $P = .75$ ) or overall survival rates (83% and 88% at 5 years;  $P = .99$ ) between the limb-sparing group and the amputation treatment groups.<sup>187</sup> In a subsequent trial, investigators at the NCI wanted to determine if adjuvant radiation was needed after wide local excision. Ninety-one patients with high-grade lesions were randomized; 47 to receive radiotherapy and 44 to not receive radiotherapy. With a median follow-up of 9.6 years, a highly significant decrease ( $P = .0028$ ) in the probability of local recurrence was seen with radiation, but no difference in overall survival was shown. Of 50 patients with low-grade lesions (24 randomized to resection alone and 26 to resection and postoperative radiotherapy), there was also lower probability of local recurrences ( $P = .016$ ) in patients receiving radiotherapy, again, without a difference in overall survival.<sup>193</sup>

The importance of technical aspects of postoperative radiation in soft tissue sarcoma of the extremity has been clearly emphasized in the literature. The volume at risk

has generally varied from including the whole compartment from origin to insertion, to giving a generous margin around the tumor bed, scar, and drainage sites.<sup>196,197</sup> and<sup>198</sup> However, whether such generous margins are always needed has been challenged. In particular, the results of adjuvant BRT suggest that radiation treatment directed to the tumor bed plus a 2-cm margin might be adequate.<sup>199</sup> In addition, some retrospective data showed no added benefit in terms of local control between field margins of 5.0 to 9.9 cm versus margins of greater than 10 cm or inclusion of the entire compartment.<sup>200,201</sup> During the design of the radiation field and irrespective of length of field, it is important to spare as much circumference of the limb as possible in order to avoid chronic edema.<sup>195,196</sup> The use of all preoperative images and CT-based treatment planning to ensure adequate coverage of the target volume with sparing of surrounding normal structures is important.

The optimal dose of radiation in the postoperative setting is also undergoing some debate. The traditional dose of postoperative external-beam radiotherapy is usually 60 to 66 Gy. A dose less than 63 Gy has been advocated by some authors,<sup>200,201</sup> but this remains controversial.

In summary, the effect of postoperative external-beam radiation on local control for soft tissue sarcoma of the extremity, whether it is high or low grade, has been shown in two prospective randomized trials. Most authors recommend that the tumor bed, including scar and drainage site plus at least 5 to 7 cm margins be included in the initial field of treatment. Then, one or two further reductions in the treatment volume should be done to allow maximum sparing of normal tissues. The total dose is usually 60 to 70 Gy depending on tumor grade, size, margin status, and location.

## ADJUVANT BRACHYTHERAPY

Although most of the initial experience with adjuvant radiation has revolved around external-beam radiation, BRT is becoming an attractive alternative. With BRT, patients usually leave the hospital having completed all their treatment in approximately 2 weeks compared with a 6- to 7-week course of external-beam radiation. The evaluation of the tumor bed at the time of the operation by both the surgeon and the radiation oncologist can far exceed any imaging modality in its accuracy, and the rapid dose fall off with BRT spares more normal tissue than external radiation. In addition, Janjan et al. reported savings of \$1000 per patient treated with BRT as compared with external irradiation.<sup>202</sup>

The initial experience with adjuvant BRT at MSKCC was reported by Hilaris et al. in 1982<sup>203</sup> and based on these encouraging results a prospective randomized trial was initiated at that time. The aim of this trial was to determine whether adjuvant BRT was needed after complete gross resection. One hundred sixty-four patients were enrolled in that trial; 78 patients were randomized to adjuvant BRT and 86 patients to no further therapy. With a median follow-up time of 76 months, the 5-year actuarial local control rates were 82% and 69% in the BRT and no BRT groups ( $P = .04$ ), respectively (Fig. 39.1-20). This improvement in local control, however, was limited to patients with high-grade histology (Fig. 39.1-21). For this group, local control for the BRT arm was 89% versus 66% for surgery alone ( $P = .0025$ ). There was no improvement in local control for patients with low-grade tumors. The 5-year freedom from distant recurrence rates were 83% and 76% in the BRT and no BRT groups ( $P = .6$ ), respectively. Analysis by histologic grade did not demonstrate an effect of BRT on the development of distant metastasis or survival.<sup>192</sup> Even though adjuvant BRT did not show an improvement in local control in patients with low-grade tumors, the local recurrence rates were 22% (no BRT) and 27% (BRT), indicating the need for adjuvant external radiation in those patients.<sup>204</sup>

**FIGURE 39.1-20.** Results of a prospective randomized trial at Memorial Sloan-Kettering Cancer Center of adjuvant brachytherapy (BRT) in patients undergoing limb-sparing surgery ( $n = 3968$  patients admitted to Memorial Sloan-Kettering Cancer Center between July 1982 and July 1992, follow-up to July 1999;  $P = .4$ ). Patients who received adjuvant BRT had a statistically significant improvement in local control. (Updated from ref. 192, with permission.)

**FIGURE 39.1-21.** Results of a prospective randomized trial at Memorial Sloan-Kettering Cancer Center of adjuvant brachytherapy (BRT) in patients undergoing limb-sparing surgery ( $n = 119$ , from July 1982 to July 1992, follow-up to July 1999;  $P = .002$ ). This local control advantage was limited to patients with high-grade lesions. (Updated from ref. 192, with permission.)

Other institutions have also reported encouraging results in their experience with BRT in soft tissue sarcoma.<sup>205,206</sup> In most of those cases, BRT was used as a boost in combination with external-beam irradiation, but whether this combination is needed in all patients is unclear. Alekhteyar et al. reported on 105 patients with primary or locally recurrent high-grade soft tissue sarcomas who were treated with wide local excision and BRT (87 patients) or BRT and external-beam irradiation (18 patients). With a median follow-up of 22 months, there was no statistically significant difference in the 2-year actuarial local control rates between the two groups; 86% in the BRT group compared with 90% in BRT plus external-beam irradiation group ( $P = .32$ ).<sup>207</sup> At MSKCC, external-beam irradiation is added to BRT only when the geometry of the implant is suboptimal or there is a positive surgical margin.

One of the most attractive aspects of BRT is the ability to deliver further radiation in previously irradiated patients who may otherwise need amputation in order to obtain good local control. Nori et al. and Pearlstone et al. reported a local control rate of 82.5% (33 of 40) and 65% (17 of 26), respectively, when using conservative surgery and reirradiation with BRT.<sup>208,209</sup> Catton et al., on the other hand, reported a local control of only 36% (4 of 11) for patients treated with conservative surgery and no further irradiation.<sup>210</sup>

The technical aspects of BRT are different from external-beam radiotherapy. At the time of the operation, the radiation oncologist and the surgeon jointly evaluate the tumor bed, and the radiation target area is determined by adding 2 cm margin longitudinally and 1.0 to 1.5 cm circumferentially. The radiation oncologist then implants this target area with an array of afterloading catheters, placed percutaneously and spaced 1 cm apart. The loading of the catheters takes place no sooner than the fifth postoperative day to allow enough time for wound healing.<sup>211</sup> Unlike with postoperative irradiation, no attempts are usually made to treat large margins or to include the scar and the drainage site. In patients treated with BRT alone, the dose is usually 45 Gy given over 4 to 6 days, and when given as boost the dose is usually 15 to 20 Gy plus 45 to 50 Gy with external-beam irradiation. The most common isotope used is the low-dose-rate iridium 192; however, high activity iodine 125 is occasionally used in young patients or to protect the gonads. More recently, high-dose-rate iridium 192 has been advocated by some authors to take advantage of its radiation safety aspects as well as its dose-optimization capabilities.<sup>212</sup> Further follow-up, however, is still needed to determine its long-term morbidity and overall

efficacy.

## PREOPERATIVE EXTERNAL-BEAM RADIOTHERAPY

Of the three types of adjuvant radiation, preoperative external-beam irradiation is the only modality that has not been tested against surgery in a randomized trial. There is, however, a great deal of interest and enthusiasm for this approach. Some of the potential advantages of preoperative external-beam radiation therapy include decreased intraoperative seeding of tumor cells, a smaller radiation target volume compared with postoperative irradiation, and tumor shrinkage that might facilitate later surgery. Suit et al. evaluated the relationship between tumor size and the sequencing of radiation and showed that preoperative radiation was superior to postoperative radiation in terms of local control for patients with tumors greater than 15 cm.<sup>213</sup> However, others have shown no difference.<sup>214</sup> Pollack et al. from M. D. Anderson Cancer Center compared the sequencing effect, not only according to size, but also according to presentation. For patients who presented to their institution with gross disease, the 10-year local control rate was 88% for preoperative radiation compared with 67% with postoperative radiation ( $P = .01$ ). In contrast, for those presenting after an excision elsewhere, the 10-year local control was better with postoperative radiation (88% versus 73%,  $P = .07$ ). It is important to note, however, that on multivariate analysis for predictors of local control for the entire population, the type of radiation was not a determinant of local control.<sup>215</sup> It is evident from this discussion that there are no conclusive data on which adjuvant radiation produces the best results in terms of local control; indeed the results are similar. Therefore, the only way to adequately answer this question would be through a randomized prospective trial. Such a trial was just concluded at the Princess Margaret Hospital in Toronto, Canada, where patients with extremity soft tissue sarcoma were randomized to preoperative versus postoperative radiation. With 1.9 years median follow-up, six cases manifested local relapse and metastatic outcome and survival were similar.<sup>216</sup> Outcome analysis must await longer follow-up.

The technical aspects of preoperative radiation for the large part are similar to postoperative irradiation. The typical margin around the target volume is 5 to 7 cm in the longitudinal axis and 1.5 to 2.0 cm circumferentially. The definition of the target volume is different in the preoperative setting since it only includes the gross tumor volume identified on imaging, preferably MRI. This volume usually receives 50 Gy in 5.0 to 5.5 weeks. Surgery is usually performed 2.5 weeks later. Most institutions that use the preoperative approach do not add a boost except in patients with positive margins, where an additional 15 Gy is given.<sup>198</sup>

## SPECIAL CONSIDERATIONS

### POSITIVE MARGINS OF RESECTION

Positive microscopic margin was found to be an independent adverse prognostic factor for local relapse in 1041 patients with localized soft tissue sarcoma of the extremity ( $P = .0001$ ).<sup>184</sup> Although adjuvant radiation has been shown to improve local control in soft tissue sarcoma of the extremity, its effect on patients with positive microscopic margin has not been clearly defined. Data from the Princess Margaret Hospital and Massachusetts General Hospital on patients treated with adjuvant radiation have shown a 10% to 16% increase in the 5-year local recurrence rates in patients with positive margins compared with those with negative margins despite the use of adjuvant irradiation.<sup>217,218</sup> In our trial of adjuvant BRT a total of 29 patients with positive margins were randomized: 15 to the BRT arm and 14 to the no BRT arm.<sup>192</sup> Five local failures were noted in each group ( $P = .99$ ). These findings then beg the following question, when compared with surgery alone; does adjuvant irradiation improve local control in patients with positive margins of resection? Alektiar et al. evaluated 110 patients with primary high-grade soft tissue sarcoma of the extremity who were treated at MSKCC with surgery alone (19 patients) or with surgery and radiation (91 patients). The 5-year actuarial local control for the whole group was 71%. In the group that received adjuvant radiation the 5-year local control rate was 75% compared with 56% in those treated with surgery alone ( $P = .01$ ). Adjuvant radiation also retained its significance as an independent prognostic factor for local control when multivariate analysis was performed ( $P = .01$ ).<sup>219</sup> Whether any radiation modality is better than another in those patients is debatable possibly due to the paucity of data. Alekhteyar et al.<sup>207</sup> demonstrated a trend toward improvement in local control if BRT was supplemented with external-beam radiotherapy in patients with positive margins (90% vs. 59%,  $P = .08$ ). However, others showed no difference in local control between external-beam irradiation and BRT boost.<sup>218</sup>

### SMALL SOFT TISSUE SARCOMAS

Despite the fact that two randomized trials that compared surgery alone with adjuvant radiation have shown an improvement in local control in all patients, there is still considerable debate in the literature on whether all patients need adjuvant irradiation. Two large-scale studies that have looked at prognostic factors in soft tissue sarcomas of the extremity have failed to show a correlation between local control and tumor size in multivariate analysis.<sup>184,220</sup>

Geer et al., on the other hand, reported on 174 patients with primary soft tissue sarcoma of the extremity measuring less than or equal to 5 cm. When only patients with negative margins of resection were analyzed (159 patients), the 5-year local control rate was 77% in those who received adjuvant radiation compared with 92% with surgery alone ( $P = .08$ ).<sup>181</sup> Therefore, the treatment policy at MSKCC has been to omit adjuvant irradiation in patients primarily treated at our institution with small tumors and adequate margins.

It is important, however, to consider other factors when deciding on whether to omit radiation. One such factor is the status of the surgical margin of resection. In the Geer study,<sup>181</sup> the effect of adjuvant radiation was only analyzed in the subset of patients with negative margins. In fact, patients with positive margins in that study had a 5-year local control rate of only 56% versus 88% in those with negative margins ( $P = .01$ ). Similar findings were reported by Fleming et al. from M. D. Anderson Cancer Center.<sup>182</sup> Therefore, it is also our policy to treat patients with positive margins even if the tumors were less than or equal to 5 cm. The other factor that should be considered is whether the patient has had a prior unplanned excision. Noria et al. found a significantly higher rate of local recurrence in patients who were treated after unplanned excision on the outside compared with patients who receive their treatment at their institution (22% vs. 7%,  $P = .03$ ).<sup>221</sup> It is important to remember that the previously mentioned scenario is common in the community settings when small soft tissue lesions are excised under the presumption that they are benign. Therefore, it is our policy to attempt a reexcision if at all feasible, otherwise patients are strongly considered for postoperative irradiation.

### SOFT TISSUE SARCOMAS OF THE HANDS AND FEET

Soft tissue sarcomas of the distal extremity deserve special consideration since they pose a formidable challenge to the treating oncologist. For a start, a true wide local excision is the exception rather than the rule in these sites due to the lack of muscular bulk and the proximity to neurovascular structures and bone. In addition, the overall prognosis has been shown to be inferior to other sites in the extremity. Brien et al. showed that even in patients with hand tumors that are less than or equal to 5 cm, the survival rate was significantly lower than other extremity sites ( $P = .0008$ ).<sup>222</sup>

In the past, the use of adjuvant irradiation was fraught with debate about the functional outcome in regions that have traditionally been considered poorly tolerant of radiation. However, more recently data to the contrary have been demonstrated. Talbert et al. treated 78 patients with nonmetastatic soft tissue sarcoma of the distal extremity with conservative surgery and radiation therapy. The 10-year local control rate was 74% and the salvage rate was 80% in patients who failed locally using this approach. The rate of amputation from complications was 8%.<sup>223</sup> Bray et al. also reported on 25 patients with soft tissue sarcoma of the hand and forearm. Twenty received adjuvant radiation and with a mean follow-up of 37 months, the local control rate was 88%. In addition, 88% of those who survived and did not require amputation were able to return to occupational and activities of daily living with minimal or no functional limitation.<sup>224</sup>

Therefore, conservative surgery and adjuvant radiation should be considered as an acceptable treatment modality for distal soft tissue sarcomas. Special attention, however, needs to be paid to radiation treatment technique in order to minimize complications and preserve function.

## DEFINITIVE RADIATION

Surgery remains the main treatment for patients with sarcoma of the extremity, and every effort should be made to attempt resection. However, in some patients with unresectable disease definitive radiation could be considered due to medical reasons or to achieve some palliation. Since sarcoma may be radiocurable in terms of cell killing but not radioresponsive in terms of shrinkage of the mass, this can be perplexing, as such masses could give the false impression that little has been accomplished, whereas in reality the mass is mainly made up of sterilized tumor cells and debris. Tepper and Suit reported on 51 patients treated with definitive photon beam irradiation to a total dose of 64 to 66 Gy. The 5-year local control and survival rate were 33% and 25%, respectively. Local control was better for tumors less than 5 cm (87.5%) than in tumors 5 to 10 cm (53%) or greater than 10 cm (30%).<sup>225</sup> Slater et al. showed similar findings in 57 patients treated with definitive photon irradiation to 44 to 88 Gy. The 5-year local control was 28%.<sup>226</sup>

More recently, hyperfractionated photon radiation was combined with intravenous iododeoxyuridine as a radiosensitizer. Goffman et al. reported on 36 patients

treated in this fashion, and with a median follow-up of 4 years the local control rate was 60%.<sup>227</sup>

Other investigators have looked at using neutron radiotherapy either alone or in combination with photon beam radiation. Schwarz et al. reviewed the European experience with such an approach and reported a local control rate of 50%, but the rate of severe complications ranged from 6.6% when neutron therapy was used as a boost to 50% when used alone.<sup>228</sup>

## ADJUVANT CHEMOTHERAPY

Surgery remains the mainstay of therapy for soft tissue sarcoma in the control of local disease. As discussed previously, radiation therapy also plays a role in the local control of soft tissue sarcomas. Nonetheless, as many as one-half of all patients with adequate local control of disease develop distant metastasis, usually to the lungs (extremity sarcomas) or liver (abdominal primary).<sup>229</sup> As has been demonstrated in other cancers such as breast and colorectal cancer and osteosarcoma, it was hoped that adjuvant chemotherapy would help decrease the frequency of distant metastases, thus increasing overall survival. At least 15 studies of adjuvant therapy for soft tissue sarcoma have been performed. Since anthracyclines are the most active agents in sarcoma therapy in the metastatic setting, they have been used in nearly all of the adjuvant trials, alone or in combination. Most of these studies are small, and therefore lack the statistical power to detect small changes in overall survival. Accordingly, metaanalyses have been performed on the randomized trials for adjuvant chemotherapy in soft tissue sarcoma. In the following section the data from the individual studies and metaanalyses are examined (Table 39.1-9). Single-agent chemotherapy trials are considered first, followed by studies with combination chemotherapy.

TABLE 39.1-9. Adjuvant Studies in Soft Tissue Sarcoma

### RANDOMIZED ADJUVANT STUDIES OF DOXORUBICIN ALONE

One of the earliest studies to accrue patients in a randomized trial of adjuvant chemotherapy was performed by the Gynecologic Oncology Group for patients with uterine sarcomas.<sup>230</sup> Two hundred twenty-five patients with stage I or II uterine sarcomas of any histopathologic subtype were treated surgically for local control. Radiation was added at the discretion of the physician for local control, then patients were randomized to doxorubicin, 60 mg/m<sup>2</sup> every 3 weeks for eight cycles, or to observation alone. Of 156 evaluable patients, disease-free survival was not different between the two groups, nor was there a statistically significant difference in overall survival (73.7 months in the treated arm versus 55.0 months in the control arm). The addition of radiation therapy did not affect survival, although there was a lower rate of vaginal relapse in the group treated with radiation.

Between 1978 and 1982, the Dana-Farber Cancer Institute, Brigham and Women's Hospital, and Massachusetts General Hospital enrolled AJCC stage IIB to IVA patients in a study in which local therapy consisted of radical surgery, or wide *en bloc* excision followed by radiation.<sup>231</sup> Forty-two patients were randomized to receive five doses of doxorubicin, 90 mg/m<sup>2</sup>, every 3 weeks, versus observation. The timing of chemotherapy varied between Dana-Farber Cancer Institute/Brigham and Women's Hospital and Massachusetts General Hospital, with former patients receiving both radiation and chemotherapy postoperatively, and the latter patients receiving radiation and two of the five cycles of chemotherapy before surgery. There was no significant difference in local control, relapse-free survival, or overall survival in this study, although there was a trend (not statistically significant) toward better overall survival of patients with extremity sarcomas who received chemotherapy compared with the patients who did not receive chemotherapy.

Similarly, the ECOG enrolled 47 AJCC stage IIB to IVA patients in a study in which local therapy consisted of radical surgery or wide *en bloc* excision followed by radiation.<sup>232</sup> Patients with local recurrence were permitted on the study as well. Thereafter, patients received doxorubicin, 70 mg/m<sup>2</sup> every 3 weeks for seven cycles. Thirty-two were eligible for analysis. There was no difference in local control, relapse-free survival, or overall survival in the treatment and control arms.

The Intergroup Sarcoma Study Group also examined AJCC stage IIB to IVA patients treated with surgery for local control. Seventy-eight eligible patients were randomized to observation or to doxorubicin at 35 mg/m<sup>2</sup> given as daily bolus doses on two consecutive days.<sup>233,234</sup> Six cycles of doxorubicin were given at 3-week intervals in the chemotherapy arm. There was no significant difference in local recurrence, disease-free survival, or overall survival in the chemotherapy arm compared with the control arm. A trend was noted toward improved disease-free survival for extremity lesions that was of borderline statistical significance ( $P = .06$ ). However, pooling the data from the Boston, ECOG, and Intergroup studies demonstrated no survival benefit for adjuvant doxorubicin.<sup>234</sup>

The Scandinavian Sarcoma Group performed the largest study of doxorubicin as an adjuvant to local therapy for soft tissue sarcomas.<sup>62</sup> Two hundred forty patients were treated with surgery with the option of adjuvant radiation for local control. Patients were then randomized to receive either doxorubicin, 60 mg/m<sup>2</sup>, every 4 weeks for nine cycles, or to no chemotherapy. Chemotherapy was started within 6 weeks of surgery when radiation was not used for local control, or within 10 weeks when radiation was used. One hundred eighty-one patients were evaluable; at a median follow-up of 40 months, there was no difference in local control, disease-free survival, or overall survival for the evaluable patients. Survival data was also assessed for the entire 240 patient cohort; again, there was no difference in disease-free survival or overall survival.

The Istituto Ortopedico Rizzoli examined a heterogeneous group of 77 patients with high-grade extremity sarcomas.<sup>235</sup> For local control some patients had radical surgery alone, surgery and preoperative radiation, or radiation and chemotherapy before surgical resection (the conservative surgery group). Thereafter patients were randomized to receive or not receive doxorubicin, 25 mg/m<sup>2</sup> given daily as boluses on 3 consecutive days in a 21-day cycle, for a total of six cycles. Relapse-free survival was improved in the chemotherapy arm (79% vs. 45%) at a median 28 months follow-up. In updated data from this study,<sup>236</sup> disease-free and overall survival were improved in the patients receiving chemotherapy. However, in a more recent update,<sup>237</sup> disease-free and overall survival benefit were not seen in the group treated with conservative surgery and chemotherapy versus conservative surgery alone. These data are difficult to analyze owing to the complex randomization scheme of the study as well as contamination of the control arm with patients receiving at least some chemotherapy (those receiving conservative surgery).

Investigators at the University of California, Los Angeles (UCLA) School of Medicine examined patients with high-grade extremity sarcoma, treating 119 patients with intraarterial doxorubicin for 3 days before radiation of the anatomic region and wide excision of the tumor.<sup>238</sup> Thereafter patients were randomized to observation alone versus five cycles of doxorubicin, 45 mg/m<sup>2</sup> daily as a bolus on 2 consecutive days, once a month. At a median follow-up time of 28 months, there was no improvement in either disease-free or overall survival in the chemotherapy arm. There was a statistically insignificant improvement in local control rates in the chemotherapy arm (3 of 21 patients vs. 9 of 27 patients in the control arm relapsed). The use of intraarterial preoperative doxorubicin in the control arm complicates comparison with the other doxorubicin adjuvant studies.

At Roswell Park Memorial Institute, 19 patients with stage I uterine sarcoma were randomized to surgery alone versus surgery plus adjuvant doxorubicin, 60 to 75 mg/m<sup>2</sup> every 4 weeks for six cycles.<sup>239</sup> No statistically significant difference in survival was noted. Six of the patients randomized to the chemotherapy arm refused randomization and were assessed as part of the control group, instead of using an intention-to-treat analysis.

## RANDOMIZED ADJUVANT STUDIES OF COMBINATION CHEMOTHERAPY

In 1983 the NCI published the first in a series of publications on adjuvant chemotherapy for soft tissue sarcoma of different anatomic sites. A pilot study examined 26 patients with extremity sarcoma grades II and III, treated for local control with amputation or limb-sparing surgery with radiation.<sup>240</sup> These patients were treated postoperatively with escalating doses of cyclophosphamide (500 to 700 mg/m<sup>2</sup>) and doxorubicin (50 to 70 mg/m<sup>2</sup>) every 28 days, with a maximum cumulative dose of 550 mg/m<sup>2</sup> of doxorubicin. This combination was followed by six cycles of intermediate dose methotrexate (50 to 250 mg/kg with dose escalation). Patients were randomized to receive chemotherapy with or without *C. parvum* adjuvant immunotherapy, and were compared with historic controls. There was no effect of the immunologic adjuvant, but the overall survival at 5 years was 73%, better than the 45% seen in the historic controls.

These initial data led to examination of adjuvant chemotherapy alone in a second cohort of patients with extremity sarcomas. Sixty-five patients underwent similar local control as described previously, then were randomized to observation or to the same cyclophosphamide, doxorubicin, and methotrexate regimen of the pilot study.<sup>240,241</sup> Initial data indicated that disease-free survival and overall survival were improved in the chemotherapy arm. With longer follow-up (median, 7.1 years), 5-year disease-free survival was still improved (75% vs. 54% in the control arm), but the difference in overall survival (83% vs. 60% in the control arm) was not statistically significant.<sup>242</sup> Local control was improved in the chemotherapy arm. In long-term follow-up there has been non-tumor-related mortality; there continues to be no survival advantage in either treatment arm (J. Yang, S. Rosenberg, unpublished results).

Fourteen of the 101 patients treated with the NCI regimen developed clinical congestive heart failure. Other patients had radioventriculograms performed confirming a subclinical decrease in cardiac ejection fraction at rest or with exercise. In all, there was an overall event rate of 46% clinical or subclinical cardiomyopathy in the 75 evaluated patients.<sup>243</sup> The high rate of cardiomyopathy led to a third trial examining the same cyclophosphamide, doxorubicin, and methotrexate combination versus a regimen without methotrexate and a doxorubicin ceiling cumulative dose of 350 mg/m<sup>2</sup>.<sup>242</sup> No difference in 5-year overall survival was observed (69% for low dose, 75% for high dose), nor was there a difference in 5-year disease-free survival. There was no clinical congestive heart failure documented in the low-dose arm, and the decrease in cardiac ejection fraction by nuclear medicine study was less pronounced than with the high-dose arm.

The NCI has also examined adjuvant chemotherapy for other sites in two other trials, using the same cyclophosphamide, doxorubicin, and methotrexate combination regimen.<sup>244,245</sup> In one study, some of the 37 patients with retroperitoneal sarcoma (15 of whom were prospectively randomized) were given adjuvant chemotherapy.<sup>245</sup> Patients given chemotherapy had a trend to poorer overall survival compared with the control group ( $P = .06$ ). Analysis of this study is difficult because of the small number of patients and lack of prospective randomization for all patients. A separate NCI study using the same chemotherapy regimen examined 31 patients with soft tissue sarcoma of the head and neck, breast, and trunk.<sup>244</sup> All patients had resection and postoperative radiation, then were randomized to receive chemotherapy or no further therapy. Six patients received *C. parvum* adjuvant immunotherapy. A trend toward improved disease-free survival was seen in the chemotherapy patients, but there was no statistically significant difference in overall survival.

The M. D. Anderson Cancer Center started one of the earliest adjuvant trials for soft tissue sarcoma.<sup>246,247</sup> Because of their high local relapse rate, patients with head and neck or abdominal sarcomas all received surgery, radiation, and chemotherapy in this study. Forty-three eligible patients with trunk and extremity sarcomas were treated with local therapy (surgery and radiation) with or without chemotherapy. The chemotherapy regimen consisted of vincristine, oral cyclophosphamide, and doxorubicin every 4 weeks. After seven cycles of doxorubicin-based therapy, actinomycin D was substituted for doxorubicin in a maintenance phase to complete 2 years of chemotherapy. The initial results demonstrated poorer disease-free survival in the chemotherapy arm (76% vs. 83% for the control arm,  $P$  value not significant) and double the rate of metastasis in the chemotherapy arm (but  $P > .3$ ), and the study was stopped. However, the original study stratified patients by histology, not by tumor grade. In a reanalysis of this data of the patients with truncal or extremity sarcomas, disease-free survival was improved in the chemotherapy arm (55% vs. 35% at 10 years,  $P = .05$ ), although there was no difference in overall survival in the two groups.<sup>247</sup>

Another early study of combination chemotherapy was reported by the Mayo Clinic.<sup>248</sup> Sixty-one patients with sarcomas of the trunk or extremities were treated with surgery alone for local control, then randomized to no further therapy or to chemotherapy. The chemotherapy alternated between cycles of vincristine, actinomycin D, and cyclophosphamide and cycles of vincristine, doxorubicin, and dacarbazine, given at 6-week intervals for eight courses. Thirteen patients (randomly selected from either group) were given bacilles Calmette-Guérin methanol extraction residue as nonspecific immunotherapy, but this was discontinued owing to ulceration at the injection site. There was no benefit in overall survival in the chemotherapy arm, and there was a high local recurrence rate, likely due to the omission of radiation in the local control phase of therapy. The chemotherapy regimen used in this study had low dose intensity by today's standards.

The largest single study of adjuvant combination chemotherapy in soft tissue sarcoma was performed by the EORTC.<sup>249</sup> Four hundred sixty-eight patients (excluding only very low grade sarcomas) were treated with surgery for their primary sarcoma, and with adjuvant radiation used for margins less than 1 cm. Patients were randomized to receive or not receive combination chemotherapy with cyclophosphamide, vincristine, doxorubicin, and dacarbazine (CyVADIC; Table 39.1-10), given every 28 days for eight cycles. Disease-free survival and local control were both better in the chemotherapy arm, but overall survival was not significantly different between the two arms. Improvement in local recurrence rates was limited to patients with head, neck, and trunk sarcomas and was not observed for patients with extremity sarcomas. Some criticism has been raised as to the long accrual time of the study (11 years), inability of nearly half of patients to complete all eight cycles of chemotherapy, and the relatively large number of patients ineligible for analysis, which most commonly was due to inappropriate radiation therapy.

Regimen	Dose	Comments
Doxorubicin	50-70 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Bolton	1 g/m <sup>2</sup>	With or without actinomycin D
High dose	1-2 g/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
AD	50 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Doxorubicin	50 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Cyclophosphamide	500-700 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
AD	50 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Doxorubicin	50 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Methotrexate with leucovorin	10-25 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Dacarbazine	500-700 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
AD or ADL	50 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Doxorubicin	50 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Dacarbazine with leucovorin	10-25 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
AD	50 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Methotrexate	10 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Doxorubicin	50 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Cyclophosphamide	500 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
CyVADIC	50 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Cyclophosphamide	500 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Vincristine	1 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Doxorubicin	50 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w
Dacarbazine	500 mg/m <sup>2</sup>	Relax or PEG over 3-4 d q1w

TABLE 39.1-10. Combination Chemotherapy for Sarcoma: A Comparison of Formulations

A smaller study from the Fondation Bergonié also examined the CyVADIC regimen as adjuvant therapy.<sup>250</sup> Following local therapy with surgery and radiation, 59 eligible patients with AJCC stage IIB to IVA tumors were randomized to receive no chemotherapy or CyVADIC chemotherapy, in doses similar to the EORTC study. In comparison with the EORTC trial, patients were treated with chemotherapy sooner after surgery, and on 21-day cycles, as opposed to 28-day cycles in the EORTC study. More patients with extremity sarcomas were in the chemotherapy group, and the histology of the treated groups was different (e.g., more MFH and no undifferentiated sarcoma in the chemotherapy arm). In contrast to the EORTC trial, local control, distant metastasis-free survival ( $P = .003$ ), and overall survival ( $P = .002$ ) were better in the chemotherapy arm than the control arm. However, in comparison with the EORTC study, the chemotherapy arm fared better (5-year survival 85% vs. 68% for the EORTC study), and the control group performed more poorly (5-year survival under 37%, compared with 63% in the EORTC trial).

The Italian Sarcoma Study Group reported in abstract form the only trial to date to examine an anthracycline plus ifosfamide as adjuvant therapy for extremity sarcoma.<sup>251</sup> After surgery with or without local radiation, 104 patients were randomized to receive no chemotherapy or to receive ifosfamide (1.8 g/m<sup>2</sup> on 5 consecutive days) with epirubicin (60 mg/m<sup>2</sup> on 2 consecutive days), with filgrastim support. Interim analysis in 1996 led to early conclusion of the trial. At a median follow-up of 36 months, overall survival in the chemotherapy arm was 72% compared with 55% for the control arm ( $P = .002$ ). This investigation is promising for its use of the two most active agents against sarcoma in an appropriate cohort of patients. Review of the final data will be necessary to assess patient selection and follow-up before conclusions can be drawn concerning this data.

## CONCLUSIONS FROM INDIVIDUAL ADJUVANT CHEMOTHERAPY STUDIES

Clearly, the small size of these trials makes interpretation on an individual basis difficult, since such studies have no statistical power to detect small (e.g., 10% to 20%) changes in overall survival. In many of the studies, a significant proportion of patients was ineligible for analysis, raising the question of selection bias. A second example of selection bias arises from the fact that patients who are enrolled on clinical trials are healthier overall than nonrandomized patients, and survive longer, as demonstrated in the Mayo study.<sup>248</sup> Historic controls are inadequate for comparison as there continue to be advances in diagnosis, specific therapy, and supportive care that could affect outcome.<sup>240</sup>

Beyond general problems with randomized studies, staging and dose intensity also affect our ability to draw conclusions about individual studies. A number of patients with low-grade or small tumors are included in the trials described previously. Patients with high-grade sarcomas do well as long as the primary disease is small (less than 5 cm). The improved outcome with small, high-grade tumors has been incorporated into the most recent staging system for sarcoma.<sup>252</sup> Future studies must focus on patients with large tumors at high risk of relapse. Furthermore, dose intensity of doxorubicin is low to moderate in many studies of adjuvant chemotherapy to date, and largely did not have growth factors such as filgrastim available. It is reasonably clear that doxorubicin and ifosfamide show dose-dependent responses,<sup>253,254,255,256,257</sup> and with better supportive care more intensive therapy may lead to improved survival. It is hoped that the first studies evaluating the use of adjuvant chemotherapy using an anthracycline combined with ifosfamide with growth factors<sup>251</sup> will give further direction to future studies in the adjuvant therapy of sarcomas.

## METAANALYSES OF RANDOMIZED TRIALS OF ADJUVANT CHEMOTHERAPY FOR SARCOMA

Given the lack of statistical power of the existing randomized trials, it was hoped that combining the data from individual studies of adjuvant chemotherapy for sarcoma would reveal improvement in overall survival that could not be detected in smaller studies. For example, to detect a 10% difference between control group and treatment group with a power of 0.90 would require approximately 1000 patients to be enrolled in a randomized study.

Antman and colleagues<sup>234</sup> pooled the data for three randomized studies (ECOG, Dana-Farber Cancer Institute/Massachusetts General Hospital, and the Intergroup studies). The 168 eligible patients examined in this study make up a smaller group than the EORTC adjuvant trial, but were followed for up to 11 years in some cases. Patients with extremity lesions fared better than those with other sites of disease ( $P = .02$ ), but there was no difference in overall survival in those receiving chemotherapy versus control patients.

Zalupski et al.<sup>259</sup> examined overall and disease-free survival in patients with extremity sarcoma obtained from ten of the adjuvant studies mentioned previously. Data was extracted from the text and tables of each study. The combined data indicated a 10% absolute improvement in overall survival (from 71% to 81%,  $P = .0005$ ) and 15% improvement in disease-free survival (53% vs. 68%,  $P < .00001$ ). Criticism of this metaanalysis includes the fact that potentially inappropriate patients were included (e.g., those from the Rizzoli and UCLA studies who received preoperative chemotherapy). In addition, some of the data were relatively immature as well, such as the EORTC and Bergonié studies.

Tierney and colleagues assessed 15 published studies 2 years later and converted the survival data into the odds of recurrence based on the latest available publication from each trial.<sup>260</sup> Standardization was performed to account for different lengths of follow-up. In all, 1546 patients were included in the study, which showed improved survival at 2 years and at 5 years in the 13 and 11 studies eligible for analysis at each time point, respectively. In contrast to the previous metaanalysis from Zalupski et al.,<sup>259</sup> the Rizzoli data were included in this study, but not the data from UCLA.

The most rigorous metaanalysis was published in 1997.<sup>261</sup> In this study, 23 potential studies were considered, and 14 ultimately included; only 31 potential patients were omitted due to unavailability of data, giving a cohort of 1568 patients to examine. Patient accrual had to be complete by the end of 1992, which excluded one trial. Histology for each patient was recorded, but pathology review was not centralized. Median follow-up was 9.4 years. Analyses were stratified by trial, and hazard ratios were calculated for each trial and combined, allowing for an assessment of the risk of death or recurrence in comparison with control patients. Disease-free survival at 10 years was found to be improved from 45% to 55% and was statistically significant ( $P = .0001$ ). Local disease-free survival at 10 years also favored the chemotherapy arm, improving from 75% to 81% ( $P = .016$ ). However, overall survival, while improving at 10 years from 50% to 54%, was not statistically significant ( $P = .12$ ). The largest difference in overall survival was found in subgroup analysis of the 886 patients with extremity sarcomas, in which absolute overall survival was shown to increase 7% in the group receiving chemotherapy ( $P = .029$ ).

## CONCLUSIONS: ADJUVANT CHEMOTHERAPY FOR SOFT TISSUE SARCOMAS

The data from the metaanalyses described previously must be examined with caution. Although the most recent metaanalysis is a useful tool, it still combines studies with different designs, diverse criteria for enrollment, variations in pathologic assessment such as grading, different chemotherapeutic regimens, and different end points. In particular, only one-fourth of the specimens from the 1997 metaanalysis underwent review of tumor grade; approximately 60% were reviewed for histologic subtype. Of 15 published adjuvant studies, only two, the Rizzoli and Bergonié studies, show improved overall survival in the chemotherapy arm. Only one small study included in the 1997 metaanalysis used ifosfamide, another active agent in sarcoma.

If there is a benefit for the adjuvant use of chemotherapy, it appears modest, based on the previously mentioned data. Given no statistically significant benefit in a population of patients typically healthier than patients not enrolled on protocols, the data do not support the routine use of adjuvant chemotherapy for soft tissue sarcoma outside of the setting of a clinical trial. However, moderate to large extremity lesions represent one situation in which adjuvant chemotherapy may be considered on a case-by-case basis. The subset analysis of extremity data from the 1997 metaanalysis indicates this is one situation in which adjuvant chemotherapy can be considered. However, subset analyses are used to generate hypotheses and do not necessarily give definitive results. Publication of the more recent Italian study of epirubicin and ifosfamide as adjuvant therapy for extremity sarcomas may clarify this situation further. With clear definition of a population at high risk for metastatic disease, identification of relatively sensitive histologic subtypes of sarcoma, and use of combinations of active agents, it is hoped that future studies will delineate which clinical situations merit use of adjuvant chemotherapy.

## PREOPERATIVE CHEMOTHERAPY

Preoperative chemotherapy has been successful in the management of predominantly pediatric sarcomas such as Ewing's sarcoma and osteosarcoma. With this success, the concept was extended to use in adult soft tissue sarcomas. Preoperative neoadjuvant chemotherapy can make subsequent surgery easier and potentially treats micrometastatic disease earlier before acquisition of resistance. Treating with chemotherapy before surgery also leaves primary vasculature intact for drug delivery. In addition, preoperative chemotherapy can guide postoperative treatment based on pathologic review of the tissue after chemotherapy. In experimental models, preoperative chemotherapy eliminates a postoperative surge in growth of metastases noted after resection of primary tumors.<sup>262,263</sup>

There is relatively little evidence concerning the use of neoadjuvant chemotherapy in the treatment of soft tissue sarcomas. Rouesse et al. retrospectively examined a group of 34 patients with locally advanced sarcomas for whom only amputation or mutilating surgery was feasible.<sup>264</sup> Patients received doxorubicin-based chemotherapy for two to seven cycles before resection. Postoperative radiation was offered to some patients. Partial or complete responses were noted in over one-third of patients; not surprisingly, those patients who had a complete response by any means had a better overall survival than those who did not respond completely. Local recurrence was common in the responding group, as well.

A retrospective trial of 46 patients from M. D. Anderson Cancer Center examined preoperative chemotherapy using cyclophosphamide, doxorubicin, and dacarbazine.<sup>265</sup> Forty percent of patients demonstrated complete, partial, or minor responses to chemotherapy and had better rates of survival than the patients who did not have an objective clinical response to chemotherapy.

A prospective trial was performed at MSKCC in which 29 patients with large, high-grade, primary or recurrent metastases were given two cycles of combination chemotherapy before definitive therapy with surgery and radiation.<sup>266</sup> Clinical and radiologic studies were performed before chemotherapy, and the specimen was assessed for response after surgical resection. Only 1 of 29 patients demonstrated a clinical partial response, although liquefaction, cystic necrosis, and hemorrhage into the tumor were noted regularly in the resected specimen, with three tumors showing greater than 90% necrosis. Most patients did not elect to receive postoperative chemotherapy after surgery, and survival results from this study did not differ significantly from studies of adjuvant doxorubicin or of no chemotherapy.

Assessing the response to preoperative chemotherapy in primary soft tissue sarcomas is difficult. Some softening or liquefaction can be noted clinically without significant change in tumor size, but in the trial from MSKCC neither CT nor MRI provided information that predicted long-term outcome. It appears that there are

significantly fewer cases of complete response compared with preoperative adjuvant chemotherapy for sarcoma of bone (osteosarcoma or Ewing's sarcoma), and it is difficult to objectively evaluate responses grossly or microscopically after chemotherapy. Other imaging modalities may demonstrate changes consistent with chemotherapy effect (MRI spectroscopy, PET, gallium scan, thallium scan),<sup>267,268,269,270 and 271</sup> but these modalities remain investigational.

In sum, preoperative chemotherapy is given to some patients with potentially sensitive sarcoma subtypes such as synovial sarcoma or other high-grade lesions. It is clear from the present AJCC staging system that larger, deep, high-grade lesions have a high risk of metastasis.<sup>252</sup> Thus, it is conceivable that local control could improve with adjuvant chemotherapy, without significantly changing overall survival. Nonetheless, preoperative chemotherapy may be considered during an attempt to maintain function of an extremity, with the possibility that more aggressive surgery could be performed later if needed. Selected patients have had responses that allow for a more conservative resection, avoid an amputation, or both.

## INTRAARTERIAL CHEMOTHERAPY

There have been many studies examining the role of intraarterial chemotherapy, with doxorubicin, cisplatin, or both; in some situations other drugs have been used as well. This infusional approach is to be differentiated from local limb perfusion, discussed later in the section [Hyperthermia and Limb Perfusion](#). Intraarterial chemotherapy has the potential benefit of providing higher doses of chemotherapy to the limb in a first-pass effect. However, pharmacokinetic data have not shown an advantage over intravenous chemotherapy.<sup>272</sup>

Intraarterial chemotherapy has been used in conjunction with radiation as well. Mention has already been made of the UCLA adjuvant study in which patients received 3 days of intraarterial doxorubicin before administration of 35 Gy of external-beam radiation over 10 days, or 17.5 Gy administered over 5 days.<sup>273</sup> Patients were then randomized to receive postoperative doxorubicin intravenously or no further chemotherapy. No difference in survival or local control was noted in this study. Thereafter, a randomized trial by the same group examined preoperative intravenous versus intraarterial chemotherapy before radiation (28 Gy given over 8 days) followed by wide excision. There was no difference in local recurrence or survival between the 45 patients receiving intraarterial doxorubicin and the 54 patients receiving intravenous doxorubicin.<sup>274</sup>

A number of studies have examined intraarterial chemotherapy before radiation and surgery,<sup>275,276</sup> doxorubicin alone,<sup>273,277</sup> or in combination with other drugs such as cisplatin,<sup>275,278,279</sup> single agent intraarterial cisplatin,<sup>280</sup> or intraarterial doxorubicin in combination with intravenous doxorubicin or other agents.<sup>281</sup> Doxorubicin with simultaneous radiation has also been examined.<sup>282,283</sup> In these studies, some patients have been able to avoid amputation. Infusional chemotherapy has its attendant complications as well, including arterial thromboembolism, infection, gangrene, and problems with wound healing, itself requiring amputation. Pathologic fractures have been reported in patients receiving chemotherapy and relatively large doses of radiation. One study<sup>283</sup> reported ten major complications in 13 patients treated intraarterial chemotherapy with simultaneous radiation, emphasizing the investigational nature of this approach. Although there are situations in which such therapy should be considered, intraarterial chemotherapy at present has a limited role in the treatment of extremity sarcomas.

## HYPERTHERMIA AND LIMB PERFUSION

In contrast to systemic intraarterial chemotherapy infusion, perfusion of limbs requires isolation of the arterial and venous system of the limb by means of a tourniquet and obtaining access to arteries and veins supplying the limb. The arterial and venous supply of the limb is connected to an extracorporeal circulation system to isolate the limb from the rest of the body. Recirculation of the blood from the limb is performed by a heart-lung machine to reoxygenate the blood. Care is taken after isolation of the limb to ensure no leakage of the circuit into the systemic circulation; technetium-labeled albumin is injected into the circuit and a probe is used over the heart to ensure isolation of the bypass circuit. Since mild hyperthermia may make chemotherapy more effective in some clinical settings (as mentioned in this section), the blood of the circuit is often warmed to 39° to 40°C.

A number of chemotherapeutic agents have been used for limb perfusion, such as melphalan, nitrogen mustard, actinomycin D, and doxorubicin. The most effective agents to date have been melphalan when given with tumor necrosis factor (TNF). The greatest experience with this technique comes from Eggermont et al.<sup>284,285</sup> Two hundred forty-six patients with primary or recurrent sarcomas that would otherwise require amputation or marked loss of function were treated with one and occasionally two isolated limb perfusion sessions. After isolation of the extremity, melphalan (10 to 13 mg/L limb volume) was perfused into the limb with a dose of TNF ten times the lethal dose for humans, under mild hyperthermic conditions. In early studies interferon- $\alpha$  was included in the regimen, but was later dropped, as it did not appear to improve results over melphalan and TNF alone. Both components of the regimen appeared important; the omission of TNF led to a decrease in tissue dose of melphalan, probably from its effects on the tumor vasculature. Surgery to remove residual tumor was performed 2 to 4 months after limb perfusion. With a median follow-up of 3 years, 71% of patients had successful limb salvage.

It is difficult to compare this approach with standard chemotherapy, given the heterogeneity of patients between the two types of studies. In aggregate, the response rate does appear higher in the perfusion studies than in the infusion studies. However, isolated limb perfusion requires substantial expertise and specialized dedicated equipment. Complications of this technique include shock (from systemic leak of TNF); infection; chronic damage to skin, muscles, and nerve; persistent edema; and arterial or venous thrombosis. Experience has led to a decrease in the incidence and severity of complications. Isolated limb perfusion does appear to hold promise for at least a subset of patients who would otherwise require amputation for local control and has been approved for such patients in Europe. Studies are underway to examine the utility of regional limb infusion, which would not require bypass machines, as a simplified means of treating otherwise unresectable extremity sarcomas.

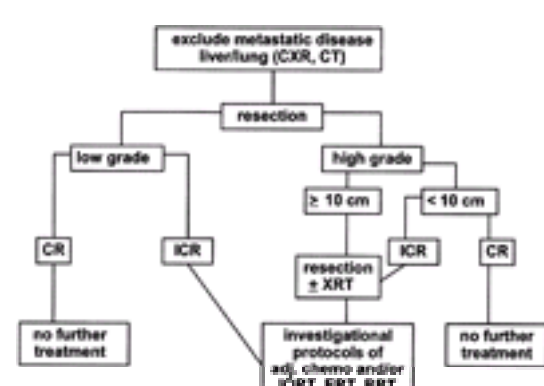

Hyperthermia has been used in other ways to enhance the effects of chemotherapy in patients with locally advanced disease. Whole body hyperthermia using extracorporeal heating of blood has been combined with ifosfamide and carboplatin intravenous chemotherapy, and responses have been seen in patients with otherwise refractory small cell sarcomas.<sup>286</sup> Regional hyperthermia provided through an external magnetic field (phased array) has been examined in combination with ifosfamide and etoposide.<sup>287</sup> Similarly, hyperthermia achieved with an external electromagnetic field has been combined with ifosfamide, etoposide, and doxorubicin.<sup>288</sup> In both studies, partial and complete responses in patients with locally advanced sarcoma have been observed. The hyperthermia used in these protocols is more aggressive than that used with limb perfusion; higher temperatures have led to a higher rate of local complications. Isolated limb perfusion has not been compared directly with simultaneous hyperthermia and chemotherapy. In sum, isolated limb perfusion and hyperthermia-enhanced chemotherapy represent novel ways of attempting to preserve function of limbs in what otherwise would be situations in which amputation would be necessary. In the United States, such procedures remain investigational at present.

## SPECIAL FEATURES OF THE MANAGEMENT OF SARCOMAS OF NONEXTREMITY SITES

### MANAGEMENT OF VISCERAL/RETROPERITONEAL SARCOMA

#### Clinical Presentation

Most patients present with an asymptomatic abdominal mass ([Fig. 39.1-22](#)). On occasion pain is present and, less commonly, gastrointestinal bleeding, incomplete obstruction, or neurologic symptoms relating to retroperitoneal invasion or pressure on neurovascular structures are present. Weight loss is uncommon and incidental diagnosis is often the norm. In one report,<sup>289</sup> neurologic symptoms related primarily to an expanding retroperitoneal mass were identified in 27% of patients.

**FIGURE 39.1-22.** Algorithm for the management of retroperitoneal or visceral sarcoma. BRT, brachytherapy; CR, complete resection; CT, computed tomography; CXR, chest radiography; ERT, external-beam radiation therapy; ICR, incomplete resection; IORT, intraoperative radiation therapy; x-ray therapy.

On physical examination, a large abdominal mass is often present. Important issues of differential diagnosis, particularly in the young, are the presence of a germ cell tumor or a primary retroperitoneal tumor arising from the adrenal. Most of such lesions, however, are tumors of mesenchymal origin, either benign or malignant.

**USE OF IMAGING STUDIES.** In the main, CT remains the primary modality for evaluation of retroperitoneal and visceral sarcomas. Because the most likely site of visceral metastasis is the liver, a CT scan of the abdomen and pelvis usually encompasses description not only of the primary lesion, but also of the most likely source of metastasis. For retroperitoneal lesions, the incidence of metastatic disease to the liver is possible but still low.

Of the histopathologic types, leiomyosarcoma and liposarcoma predominate (see Fig. 39.1-4), whereas other types seen in the extremity, such as MFH, are very uncommon. Most retroperitoneal tumors are high-grade lesions because of the predominance of leiomyosarcoma in the visceral lesions. The retroperitoneal liposarcoma is often predominantly low grade and overall the more common tumor. Nevertheless, with increasing frequency we note the mixed cellularity and grade of some retroperitoneal sarcomas.

Primary surgical resection is the dominant therapeutic modality. Preoperative bowel preparation is important, not because of tumor invasion, but often because of the technical difficulty of resection without encompassing the intestine. Because many tumors involve the retroperitoneum, evaluation of renal function, particularly the establishment of contralateral adequate renal function, is important, to allow nephrectomy where appropriate.

Although resection of adjacent organs is common<sup>289</sup> proof that a more extensive resection of adjacent organs has an effect on long-term survival seems limited. It is clear that complete surgical resection is the primary factor in outcome ( Fig. 39.1-23). Once complete resection is accounted for, the predominant factor in outcome is the grade of the lesion.

**FIGURE 39.1-23.** Survival following resection of primary retroperitoneal sarcoma according to resection status in 155 patients aged 16 years or older admitted to Memorial Sloan-Kettering Cancer Center between July 1982 and July 1999 ( $P < .001$ ).

**TECHNICAL ISSUES.** The major issue in resection of such lesions is adequate exposure. Thoracoabdominal incisions, rectus-dividing incisions, incisions extending through the inguinal ligament into the thigh, the availability of venovenous bypass, adequate and appropriate anesthetic, and blood replacement therapy are all important issues for many of these large lesions. Resectability rates vary widely, but seem independent of histologic type, grade, or size.<sup>289</sup>

These factors should not preclude attempts at resection. Complete resection is usually possible in 60% to 70% of patients presenting with a second or subsequent recurrence. In our reviews,<sup>289,290</sup> although nephrectomy was commonly performed (in 46% of cases), the kidney itself was rarely involved. In the report by Jaques and coworkers<sup>289</sup> only 2 of 30 nephrectomies showed true parenchymal invasion. Nevertheless, the encompassment of the kidney and the involvement of the hilar renal vasculature all make the resection of the kidney on occasions technically necessary.

The overriding principle is not to be reticent about resection of adjacent organs should they be involved by tumor. Conversely, one should not resect uninvolved organs if they are not the limiting factor in the margins. For example, the resection of a kidney, when the vena cava is the closest margin, makes little oncologic sense. Overall, the use of debulking for recurrent lesions is rarely of significant value in terms of long-term survival. More extended resections do not seem to improve local recurrence or survival. It is often difficult to decide how much can be palliated by incomplete removal of tumor. The concept, however, should be that unless palliation can be achieved, operation should be reserved for those patients for whom complete resection is at least possible, if not probable. The basis for unresectability is usually the presence of peritoneal implants or extensive vascular involvement.

Retroperitoneal sarcomas remain a major clinical challenge. Most of these tumors are large, making it difficult to obtain adequate margins of resection. Compounding the problem, the presence of normal organ such as small bowel, large bowel, kidney, and liver make delivery of therapeutic doses of radiation therapy either difficult or impossible.

Jaques and coworkers<sup>289</sup> reported the experience at MSKCC from 1982 to 1987. One-half of the patients presented with liposarcoma, whereas 29% had leiomyosarcoma. Sixty-five percent of primary sarcomas underwent a complete resection, whereas approximately one-half the patients with recurrent retroperitoneal sarcomas could have a complete resection. Despite complete resection, local recurrence developed in approximately 40% to 50% of cases. There is a clear need for adjuvant local therapy. Importantly, local recurrence is a problem for both high-grade and low-grade lesions: The local recurrence rate is similar, but the time to recurrence differs significantly. The median time for recurrence was 15 months for high-grade and 42 months for low-grade sarcomas. Fifty-three percent of patients required adjacent organ resection, and 40% of patients required more than one adjacent organ resection, in order to accomplish complete removal of disease.

Adjuvant external-beam irradiation is limited because of the low tolerance of surrounding normal organs. However, there are data to suggest some improvement in local control with moderate doses of external-beam irradiation.<sup>291,292</sup> Tepper and associates<sup>293</sup> reviewed a cohort of 23 patients with retroperitoneal sarcomas treated with surgery and radiation therapy. For patients who underwent a complete resection, local control was 71%. Radiation dose appeared to influence tumor control, with only 30% of patients locally controlled at doses less than 5000 cGy and 83% of patients controlled with doses greater than 6000 cGy. Obviously, the total dose of radiation that is possible varies with the size and location of that lesion.

With the need to deliver higher doses of radiation to the tumor and lower doses to surrounding tissue, there has been an interest in using intraoperative radiation therapy (IORT).<sup>294,295</sup> Petersen et al. from the Mayo Clinic reported on 87 patients who were treated with IORT that was supplemented by external-beam radiation in 80/87. With a median follow-up of 3 years, the 5-year local control and survival rates were 58% and 50%, respectively.<sup>296</sup> Sindelar and coworkers<sup>297</sup> reported a prospective, randomized clinical trial utilizing intraoperative radiation therapy at the NCI. Thirty-five patients with surgically resected sarcomas of the retroperitoneum were randomized to receive IORT (20 Gy) followed by low-dose external-beam irradiation (35 to 40 Gy) versus external-beam radiation therapy alone (50 to 55 Gy). The study revealed a significant improvement in local control for those who received IORT. There was no effect on survival. Patients who received IORT also received misonidazole, and they had a higher incidence of peripheral neuropathy than those who received external-beam radiation alone. On the other hand, those who received higher dose external-beam radiation alone, without IORT, had a higher incidence of radiation enteritis.

To build on the NCI data, we have begun to examine IORT at MSKCC. Instead of using electron beam IORT, we have used a technique that involves high-dose-rate remote afterloading. All patients had a maximal tumor resection. At the time of surgery, a dose of 12 to 15 Gy was delivered with IORT. Postoperative external irradiation of 45 Gy was added. No misonidazole was given. The concept is that this dose of IORT without misonidazole should result in a significantly lower incidence

of neuropathy than the experience of the NCI, and this dose of external-beam irradiation should result in lower risk of radiation enteritis. Alektiar et al. reported on 32 patients treated with such an approach.<sup>298</sup> With a median follow-up of 33 months, the 5-year actuarial local control and overall survival rates were 62% and 45%, respectively. The rate of peripheral neuropathy was 6% and the rate of gastrointestinal toxicity was 19%.

## MANAGEMENT OF HEAD AND NECK SARCOMA

Soft tissue sarcomas of the head and neck in adults are rare. They represent approximately 1% of all head and neck malignancies and 10% of all soft tissue sarcomas. Most of these tumors present as a painless subcutaneous or submucosal mass. Any histologic type of soft tissue sarcoma could originate in the head and neck area, but there is preponderance of angiosarcoma in this site. Multimodality approach is the cornerstone for most soft tissue sarcomas of the head and neck. Surgery is the main treatment for these tumors, and every attempt should be made to obtain at least gross total resection, otherwise the results are usually poor. However, unlike extremity sarcomas, head and neck sarcomas are not amenable to wide local excision with generous margin of normal tissue due to anatomic constraints. Therefore, the use of adjuvant radiation is more liberal in this site because local recurrence could be the cause of death in a substantial proportion of patients.

Eeles et al. reported on 103 patients with soft tissue sarcoma of the head and neck area treated by surgery with or without radiation. The 5-year survival rate was 50% and the local control rate was 47%. The only independent prognostic factor for survival was surgery other than biopsy ( $P = .003$ ). For local control the combined use of surgery and radiation as opposed to single modality was also an independent prognostic factor ( $P = .002$ ). In addition, local tumor was the cause of death in 63% of cases.<sup>299</sup> Willers et al. reported on 46 patients with soft tissue sarcoma excluding angiosarcoma who were treated by radiation with or without surgery. The 5-year survival and local control rates were 74% and 69%, respectively. On multivariate analysis survival correlated with low grade, recurrent presentation, and lack of direct extension ( $P = .001, .01, .03$ , respectively). For local control the only independent prognostic factor was the T stage ( $P = .05$ ). There was also a 15-fold increased risk of dying for patients whose tumor had recurred locoregionally, compared with controlled sarcomas ( $P = .004$ ).<sup>300</sup>

Le et al. reported on 65 patients treated by surgery with or without radiation and found the 5-year survival and local control rates to be 56% and 66%, respectively. On multivariate analysis the independent predictors of improved survival were age less than 55 ( $P = .009$ ), low grade ( $P = .0002$ ), extent of resection ( $P = .008$ ), and negative margin ( $P = .0009$ ). For local control smaller tumor size ( $P = .004$ ) and grade 1 to 2 ( $P = .01$ ) were independent predictors.<sup>301</sup>

Angiosarcoma of the head and neck deserve special consideration due to their poor prognosis compared with other sarcomas in that region.<sup>300,302</sup> Some of the difficulties in managing this disease have to do with its notorious propensity to infiltrate throughout the dermis beyond what is clinically apparent, making wide local excision with negative margins difficult to achieve. In addition, they display a higher incidence of regional lymph node metastasis than other sarcomas with a reported rate of 10% to 15%.<sup>303</sup>

Morrison et al. reported on 14 patients with angiosarcoma of the head and neck treated by radiation with or without surgery. The 5-year overall and distant metastasis-free survival rates were 29% and 37%, respectively. The 5-year above clavicle local control rates were 24% for definitive radiation compared with 40% with adjuvant radiation ( $P = .03$ ).<sup>304</sup> Similar findings were reported by Willers et al. on 11 patients with 5-year overall, distant metastasis-free, and local recurrence-free survival rates of 31%, 42%, and 24%, respectively.<sup>300</sup>

## MANAGEMENT OF BREAST SARCOMA

Primary soft tissue sarcomas of the breast are rare, representing approximately 1% of all breast malignancies. They usually present as a painless mass with no distinctive findings on mammography. The main treatment is surgery and the extent of resection is debatable, but most authors believe that wide excision with generous negative margin is adequate.<sup>305</sup> North et al. reported on 25 patients treated by surgery with or without radiation. The 5-year overall survival rate was 61%, which did not vary significantly between those treated with wide excision compared with those who underwent mastectomy ( $P = .9$ ). Five patients received adjuvant radiation and none of them developed local recurrence.<sup>306</sup>

Gutman et al. showed similar findings in 60 cases of breast sarcoma treated by surgery with or without radiation.<sup>307</sup> Johnstone et al. reported on 10 patients treated with mastectomy and adjuvant radiation. The 5-year survival rate was 66% with no local or regional failures.<sup>308</sup>

## SERIOUS COMPLICATIONS OF PRIMARY TREATMENT

### WOUND COMPLICATIONS

It is well established that radiation and chemotherapy inhibit wound healing. Early studies defined the effects of doxorubicin and x-ray treatment on wound healing in animal models.<sup>309</sup> The authors demonstrated that the timing and the combination of multiple antineoplastic agents were critical to inhibiting wound healing. They suggested that radiation or antineoplastic drugs delivered more than 7 days on either side of the wound were accompanied by minimal inhibition of wound healing. Conversely, the application of radiation or chemotherapy just before, or in close juxtaposition to, the time of wounding, resulted in significant impairment of wound healing as demonstrated by wound-breaking strength. This appeared to be due to inhibition of newly synthesized collagen as determined by hydroxyproline assays.

A comprehensive review of the effect of chemotherapeutic agents on wound healing<sup>310</sup> emphasized the importance of the agents used and the timing of delivery.

In our studies of adjuvant BRT and wound complications, we also demonstrated that when particular attention is paid to the timing of delivery of radiation via afterloading catheters to beyond the fifth postoperative day, the major wound complication rate approaches that with surgery alone.<sup>211</sup>

More recently, wound complications (wound infection or the need for further operative intervention) were analyzed in the randomized BRT trial at MSKCC.<sup>310a</sup> The overall rate was 24% in the BRT arm compared with 14% in the control arm ( $P = .13$ ). However, the rate of reoperation was higher in the BRT group, 10% versus 0% ( $P = .006$ ). The other covariable that contributed to wound reoperation was the width of the excised skin. If the width was greater than 4 cm the rate was 10%, but if the width was less than or equal to 4 cm the rate was 1% ( $P = .02$ ). These types of complications are not unique to BRT but have been shown with external-beam irradiation as well.<sup>311,312 and 313</sup> In a randomized trial from Princess Margaret Hospital comparing preoperative and postoperative irradiation, wound complication was a primary end point of the study. Wound complications were defined as secondary wound surgery, hospital admission for wound care, and deep packing or prolonged dressings within 120 days following tumor resection. The investigators found that preoperative radiation had a significantly higher rate of wound complications (35% vs. 17%,  $P = .01$ ).<sup>314</sup>

In situations in which wound complications may be anticipated because of the magnitude of the wound, extent of the resection, prior radiation, and so forth, serious consideration should be given to bringing fresh vascularized tissue in the form of either transpositional or free grafts into the area to cover the defect before the placement or delivery of radiation therapy. With this approach, postoperative morbidity can be markedly diminished.

### OTHER COMPLICATIONS

The effect of adjuvant radiation and chemotherapy on the development of bony fracture has been reported in the literature but the data are scant. Stinson et al. reported on 145 patients with soft tissue sarcoma who underwent limb-sparing surgery and postoperative radiation with or without chemotherapy and found a 6% fracture rate.<sup>315</sup> For patients treated with adjuvant BRT in the MSKCC randomized trial, the rate of fracture was 4% compared with 0% in the control arm. This difference, however, was not statistically significant ( $P = .2$ ).<sup>310a</sup> Brant et al. reported a 7.6% rate of pathologic fracture in patients treated with preoperative radiation.<sup>316</sup>

Lin et al. evaluated 205 patients with soft tissue sarcomas of the thigh to determine the contributing factors to pathologic fracture of the femur in patients treated with adjuvant radiation. The 5-year actuarial risk was 8.6%, which on univariate analysis correlated with periosteal stripping ( $P = .0001$ ), location in the anterior compartment ( $P = .008$ ), female sex ( $P = .01$ ), the use of chemotherapy ( $P = .02$ ), age greater than or equal to 50 ( $P = .03$ ), and the use of external-beam radiation instead of BRT ( $P = .04$ ). On multivariate analysis only periosteal stripping retained significance ( $P = .01$ ).<sup>317</sup>

The other type of complication encountered with adjuvant radiation is peripheral nerve damage. In the control arm of the MSKCC randomized trial the rate was 7% compared with 9% in the BRT arm ( $P = .8$ ).<sup>310a</sup> LePechoux et al. reported a rate of 1.6% of peripheral nerve damage in 62 patients treated with postoperative radiation.<sup>318</sup> Brant et al. reported a 3.4% rate for patients treated with preoperative radiation.<sup>316</sup>

## PROGNOSTIC FACTORS FOR OUTCOME

As more sophisticated approaches to the analysis of outcome become more widely employed, it becomes clear that the variables being investigated provide different information. Prognostic factors for local recurrence, metastasis, disease-specific survival, and overall survival may all be fine gradations of differing factors, all of which provide considerably different information.

An analysis of long-term follow-up for over 1000 patients with localized soft tissue sarcoma of the extremity has been provided from our group.<sup>184</sup> From prospective data collected from 1041 patients over the age of 16, we have determined the clinical pathologic factors that influence local recurrence, distant recurrence, and disease-specific and overall survival. The 5-year survival rate was 76%, with a median follow-up of 4 years. Factors that increased the risk of local recurrence were age greater than 50 years, recurrent disease at the time of presentation, positive histologic primary margins, histologic subtypes of fibrosarcoma (including desmoid), and malignant peripheral nerve tumors (Table 39.1-11).

	Local Recurrence (P)	Distant Recurrence (P)	Disease-Free Survival (P)
Age	1.6 (.001)	—	—
Recurrent presentation	2.0 (.001)	1.5 (.02)	1.5 (.033)
Fibrosarcoma	2.5 (.006)	—	—
Malignant peripheral nerve tumor	1.8 (.001)	—	1.9 (.008)
Size >5 cm	—	1.9 (.0001)	2.1 (.0001)
Margin positive	1.8 (.0001)	—	1.7 (.011)
Depth	—	2.5 (.0007)	2.8 (.0002)
High grade	—	4.8 (.0001)	4.0 (.0001)
Leiomyosarcoma	—	1.7 (.024)	1.9 (.012)

\*Multivariate number = 1041.  
(From ref. 184, with permission.)

**TABLE 39.1-11.** Relative Risk Influence on Recurrence of Localized Extremity Soft Tissue Sarcoma<sup>a</sup>

Factors that increased distant recurrence rates were tumor size greater than 5 cm, high histologic grade, deep location, recurrent disease at the time of presentation, and histologic subtype leiomyosarcoma. Histology of liposarcoma was favorable for decreased distant recurrence rate when compared with other histologies.

For disease-specific mortality, large tumor size, high histologic grade, deep location, recurrent disease at presentation, positive histologic margins at the time of resection of the primary, lower extremity site, and the histologic types of leiomyosarcoma and malignant peripheral nerve tumor were all factors.

Postmetastasis survival for most patients is independent of factors involved in the primary presentation, although large tumor size has been associated. The determination of recurrence rates and survival rates can depend on which factor is examined. For example, high-grade lesions have a much greater cumulative hazard rate of developing a distant metastasis in the first 30 months. Low-grade lesions, however, have a continued slow but inexorable progression to a continuing long-term rate of metastasis. This raises the interesting biologic question of whether lack of recognition of the metastatic potential of low-grade sarcomas is caused by inherent sampling error in low-grade lesions, where small foci of potentially metastatic cells are not appreciated. Alternatively, all soft tissue sarcomas may be inherently imbued with metastatic potential. One thing is clear: 5-year survival does not guarantee cure. An analysis of patients who were disease-free 5 years after the diagnosis and treatment of extremity lesions showed 9% would go on to have a further recurrence in the next 5 years (Fig. 39.1-24).<sup>185</sup>

**FIGURE 39.1-24.** Survival in patients with extremity soft tissue sarcoma who were metastasis-free at 5 years. (From ref. 527, with permission.)

## QUALITY OF LIFE AND FUNCTIONAL OUTCOME

Quality of life assessment has gained so much importance in recent years that many randomized trials in the field of oncology are evaluating that issue either as the primary end point or secondary to outcome. This issue is obviously of great significance in patients with soft tissue sarcoma of the extremity who are being treated with conservative surgery and adjuvant therapy in order to preserve function and potentially improve the overall quality of life.

However, in order to determine the effect of adjuvant therapy it is important to look at other potential contributing factors as well. One such factor is the extent of surgical resection. Sugarbaker et al. found no evidence of improved quality of life in patients treated with conservative surgery and adjuvant radiation compared with amputation,<sup>319</sup> but more recently Davis et al. showed a significantly higher level of handicap in amputated patients compared with those treated with conservative surgery.<sup>320</sup> In patients treated with conservative surgery, the effect of the extent of surgery on functional outcome is not clearly defined. Robinson et al. reported on 54 patients who were disease-free 2 or more years after limb-conserving treatment for soft tissue sarcoma of the leg or pelvic girdle.<sup>324</sup> The extent of surgery was not an independent prognostic factor for limb function, although univariate analysis suggested an association with range of movement ( $P < .025$ ).<sup>81</sup> On the other hand, Bell et al. showed that neural sacrifice performed at the time of wide local excision was associated with poorer outcome on univariate ( $P = .002$ ) and multivariate analysis ( $P = .019$ ).<sup>321</sup> Conventional chemotherapy has not been shown to affect the functional outcome of patients with extremity sarcomas.

The effect of adjuvant radiation and some of its parameters on functional outcome have been studied more extensively. Yang et al. reported that adjuvant postoperative external-beam radiation compared with surgery alone resulted in significantly worse limb strength and edema and range of motion, but these deficits were often transient and had few measurable effects on activities of daily life or global quality of life.<sup>193</sup> Schupak et al. reported on a group of patients who underwent rigorous psychofunctional testing and were part of the BRT randomized trial at MSKCC. There were no significant differences in the functional outcome between the BRT group and the no BRT group. The psychofunctional scores, however, revealed a higher level of anxiety, depression, and appreciation of illness in patients who received adjuvant BRT.<sup>322</sup> Karasek et al. evaluated 41 patients who were treated with surgery and radiation and showed that 83% of them had good or excellent functional outcome. But there was a correlation between volume irradiated to greater than or equal to 55 Gy and poorer functional score, strength, fibrosis, and skin changes.<sup>323</sup> Robinson et al. also found that doses in excess of 60 Gy resulted in increased fibrosis and a worse functional outcome.<sup>324</sup>

## TREATMENT OF LOCAL RECURRENCE

The treatment of locally recurrent soft tissue sarcoma in almost any site that is amenable to low morbidity surgical resection is resection. Local recurrence, however, remains a significant factor in long-term morbidity and mortality. In cases in which surgical resection can be achieved, then adjuvant radiation therapy should be considered in the vast majority of patients with recurrent disease. In patients undergoing systemic recurrence, again surgical resection should be considered.

Analyses of patients undergoing local resection of intraabdominal lesions have been extensively reviewed.<sup>289,290</sup> It is clear that when complete gross resection can be achieved, operation for local recurrence should be attempted along with investigational approaches such as IORT (see [Technical Issues](#), earlier in this chapter). Intraperitoneal chemotherapy following debulking of peritoneal metastases has been advocated,<sup>325</sup> but remains an investigational approach.

## MANAGEMENT OF ADVANCED DISEASE

Control of the primary site can be achieved in the vast majority of patients with soft tissue sarcoma, but ultimately close to one-half of patients succumb to metastatic or locally advanced disease. Unfortunately, the most active chemotherapeutic options are of limited value and are associated with serious and potentially life-threatening toxicity. Median survival from the time metastases are recognized is 8 to 12 months, although 20% to 25% of patients with metastatic sarcoma are alive 2 years after diagnosis. Patients with metastatic sarcoma often feel well at the time that a radiograph or CT reveals metastases and may remain free of symptoms for months, or even years. Thus, alleviation of symptoms is not an immediate concern in many patients, although progressive sarcoma is inevitable. Surgical resection can provide selected patients with prolonged periods of freedom from disease, and radiation therapy provides palliation for individual patients who have localized symptomatic metastases. Optimal treatment of patients with unresectable or metastatic soft tissue sarcoma requires an appreciation for the natural history of the disease, close attention to the individual patient, and an understanding of the benefits and limitations of the therapeutic options.

## RESECTION OF METASTATIC DISEASE

Approximately 20% of patients with a soft tissue sarcoma of an extremity or the trunk develop pulmonary metastases, and in the majority, the lung remains the only clinically evident site of metastasis. In retrospective series, 20% to 30% of patients who undergo metastasectomy are alive 5 years later.<sup>326,327,328,329,330 and 331</sup>

Of 716 patients with primary extremity sarcoma who were treated at Memorial over a period of 6 years, pulmonary-only metastases occurred in 19%, or 135. Of these 135 patients, 58% underwent thoracotomy and 83% of those had a complete resection of their tumor. In the 65 patients who had a complete resection of their tumor, 69% recurred with pulmonary metastases as their only site of disease. Median survival from complete resection was 19 months, and 3-year survival was only 23% of those resected and 11% of those presenting with lung metastasis only. Patients who did not undergo thoracotomy all died within 3 years.<sup>170</sup> Chemotherapy had no obvious effect on survival in either the resected or unresected patients. Incomplete resection was no better than no operation ([Fig. 39.1-25](#)). At M. D. Anderson, in contrast to the experience with primary sarcoma, response to chemotherapy administered before pulmonary resection did not predict for improved outcome.<sup>332</sup> Again, there is a glaring need for effective approaches to reducing systemic recurrence in patients rendered free of disease by surgical resection.

**FIGURE 39.1-25.** Pulmonary resection of soft tissue sarcoma metastases from the extremity. Comparison of no resection, versus incomplete resection versus complete gross resection of all known metastases. (From ref. 528, with permission.)

In patients who have pulmonary only metastatic disease that is not amenable to resection, an innovative approach under study is isolated lung perfusion.<sup>333</sup> This technique or direct lung infusion can be used to administer chemotherapeutic drugs or biologic agents in a way that results in a high concentration of the agent in the lung, with no systemic exposure.

## SYSTEMIC THERAPY FOR ADVANCED DISEASE

The activity of individual commercially available chemotherapeutic agents in patients with soft tissue sarcoma is summarized in [Table 39.1-12](#). Doxorubicin has been the mainstay of chemotherapy for advanced sarcoma. Whereas early studies suggested overall response rates of 30%,<sup>254,334</sup> in more recent trials the response rate was closer to 20%.<sup>335,336</sup> Subset analysis of patients with soft tissue sarcoma from a large randomized phase II trial of different doses of doxorubicin demonstrated a dose-response relationship in patients with sarcoma.<sup>254</sup> These data have been confirmed in other trials of single-agent doxorubicin and trials with doxorubicin-containing combination therapy.<sup>255,256,257 and 258</sup> Some studies have begun to examine liposomal forms of doxorubicin, which may have fewer side effects than doxorubicin itself; response rates have been low, however.

Study	Agents	n	Response Rate (%)	Median Survival (months)	Reference
1	Doxorubicin	100	20	12	254
2	Doxorubicin	100	20	12	335
3	Doxorubicin	100	20	12	336
4	Doxorubicin	100	20	12	255
5	Doxorubicin	100	20	12	256
6	Doxorubicin	100	20	12	257
7	Doxorubicin	100	20	12	258

**TABLE 39.1-12.** Selected Studies of Single-Agent Chemotherapy for Advanced Disease<sup>a</sup>

Ifosfamide has approximately the same efficacy as doxorubicin. In the past, ifosfamide dosing was limited by severe urothelial toxicity (hemorrhagic cystitis). The uroprotective agent mesna has markedly changed the ability to give both ifosfamide and cyclophosphamide, and ifosfamide doses as large as 14 to 18 g/m<sup>2</sup> over several days are given in some studies. There has been a debate as to the relative efficacy of cyclophosphamide versus ifosfamide, in particular whether ifosfamide is truly a different drug or whether differences in dosing of the two drugs accounts for the difference in response. The best study addressing this question came from the EORTC, which performed a randomized phase II trial examining the response rates of ifosfamide, 5 g/m<sup>2</sup>, to cyclophosphamide, 1.5 g/m<sup>2</sup>. There was greater myelosuppression with cyclophosphamide, but response rates were 7.5% for cyclophosphamide and 18% with ifosfamide; although suggestive, this difference did not

achieve statistical significance. Additionally, there is some evidence to suggest a dose-response relationship for ifosfamide.<sup>253</sup> This is also borne out by the large number of phase II trials examining high-dose ifosfamide in metastatic soft tissue sarcoma (see [Table 39.1-12](#)); responses to higher doses of ifosfamide are occasionally seen in patients failing lower doses of alkylating agents. The similar response rates of ifosfamide and doxorubicin, even in doxorubicin-resistant patients, suggested a lack of cross-resistance in combination chemotherapy. It should be noted that synovial sarcoma appears relatively responsive to ifosfamide.<sup>337,338</sup>

The third drug with modest activity in sarcoma is dacarbazine. Its activity was recognized over 20 years ago,<sup>339</sup> and later confirmed.<sup>340</sup> Dacarbazine has frequently been used in combination chemotherapy with doxorubicin (see [Combination Chemotherapy for Advanced Soft Tissue Sarcoma](#), later in this chapter). Dacarbazine is given in a variety of schedules, from intravenous continuous infusion as part of the mesna, doxorubicin, ifosfamide, and dacarbazine (MAID) protocol<sup>341</sup> (see [Table 39.1-10](#)), to one large bolus. The major side effect of dacarbazine is nausea and vomiting, which is abrogated to some extent by dividing the dose over 2 to 4 days. In general, nausea and vomiting from dacarbazine have been substantially reduced with the use of serotonin antagonist antiemetics.

As for other single agents, cisplatin and carboplatin have given occasional responses in phase II trials. However, in contrast to pediatric sarcomas such as Ewing's sarcoma and rhabdomyosarcoma, other agents such as single-agent vincristine, etoposide, and actinomycin D appear to be inactive. The taxanes also show little activity; however, there are data that vinorelbine<sup>342</sup> and gemcitabine<sup>343,344</sup> have modest activity in at least some subtypes of soft tissue sarcoma.

The response rates of other largely investigational agents in soft tissue sarcomas are shown in [Table 39.1-13](#). Few of these drugs have demonstrated meaningful activity in soft tissue sarcoma.

**TABLE 39.1-13.** Selected Studies of Investigational Agents in Sarcoma Therapy<sup>a</sup>

Used in some of the earliest studies in sarcoma adjuvant chemotherapy, immunotherapy for sarcoma treatment is seeing renewed interest, without significant success to date. Cytokines alone appear to be ineffective in sarcoma ([Table 39.1-14](#)), as does nonspecific immunotherapy with bacterial cell wall components. A study underway at the NCI is examining vaccination of patients with peptides representing the fusion proteins observed in specific subtypes of sarcoma. Lymphocyte activated killer cell and other T-cell immunotherapy with cytokines was investigated in a small number of patients at the NCI without any observed responses. Dendritic cell vaccines as well as other forms of tumor-specific immunotherapy are undergoing investigation and may be of relevance to patients with soft tissue sarcoma.

**TABLE 39.1-14.** Biologic Agents in Sarcoma Therapy

Angiogenesis inhibition has emerged as a potential new therapy for solid tumors of all types, including sarcoma. To date, weak angiogenesis inhibitors such as the interferons have shown no efficacy in sarcoma (see [Table 39.1-14](#)). Stronger angiogenesis inhibitors such as TNP-470 (AGM-1470), or vascular endothelial growth factor (VEGF)-pathway inhibitor SU5416 have been examined in phase I trials,<sup>345</sup> but there have been only a handful of sarcoma patients treated with these more potent antiangiogenic agents.

Newer biologic agents are beginning to be assessed, based on the biology of specific sarcoma subsets, in particular liposarcoma. The antidiabetic drug troglitazone binds to the receptor PPAR-g (peroxisome proliferator-activated receptor-g). This receptor is present on the cell surface of some liposarcomas. When PPAR-g binds a ligand, it can induce differentiation of the liposarcoma toward an adipocyte, with abundant fat droplet accumulation and decreased S-phase fraction. This laboratory finding led to an ongoing trial of troglitazone in patients with advanced liposarcoma.<sup>346</sup> A subset of patients with liposarcoma demonstrates similar lipid accumulation *in vivo* to that noted *in vitro*. To date, there are no data on relapse-free or overall survival of these patients.

### COMBINATION CHEMOTHERAPY FOR ADVANCED SOFT TISSUE SARCOMA

A variety of combinations of chemotherapy have been developed and examined in phase II trials. The typical backbone of a combination regimen is doxorubicin (or its analogue epirubicin) with an alkylating agent, with or without other agents (see [Table 39.1-10](#)). One of the earliest combinations used was doxorubicin and dacarbazine, which has been well studied by the Southwest Oncology Group. Although initial responses noted a 41% major response rate,<sup>347</sup> subsequent study of either a bolus or continuous infusion of the same regimen yielded a 17% response rate.<sup>348</sup>

CyVADIC has been widely used for sarcoma therapy in the United States and Europe. Although single arm studies showed response rates as high as 71%,<sup>256,257,349</sup> a randomized trial showed no significant difference in overall survival between CyVADIC and doxorubicin as a single agent.<sup>335</sup> The two drug combinations of doxorubicin and ifosfamide<sup>335</sup> or epirubicin and ifosfamide<sup>350,351</sup> and <sup>352</sup> have consistently given response rates above 25%. Current studies are investigating higher doses of ifosfamide with fixed doxorubicin dose and growth factor support.

MAID was proven effective in metastatic soft tissue sarcoma in a large phase II trial from the Dana-Farber Cancer Institute.<sup>341</sup> This randomized trial took place before the routine use of growth factors for aggressive chemotherapeutic regimens and examined doxorubicin and dacarbazine versus MAID. The study showed an increased response rate in the MAID arm (32% vs. 17%,  $P < .002$ ).<sup>353</sup> Underscoring the increased toxicity of aggressive chemotherapy regimens, there were eight toxic deaths on the study, seven in the 170 patients treated with the 7.5 g/m<sup>2</sup> total dose of ifosfamide per cycle. This dose was decreased to 6 g/m<sup>2</sup> during the course of the study. All treatment deaths occurred in patients older than 50 years of age. In a univariate analysis, there was a survival advantage for the two-drug arm (13 months vs. 12 months for MAID); however, this difference was not significant in a multivariate analysis. As noted in the later section on [Dose Intensity](#), with the introduction of

growth factors, the dose intensity of this regimen has become better tolerated.

The response rates of metastatic sarcoma to cisplatin are low, and response rate to mitomycin C is zero in one small study.<sup>354</sup> However, the combination of the two drugs with doxorubicin (called MAP) yielded a 43% response rate in a study from the Mayo Clinic. The activity of the MAP regimen has been confirmed in an independent ECOG trial.<sup>336,355</sup>

A recent metaanalysis of all of the data from seven large EORTC provided a useful resource to assess response rates to combination chemotherapy in a multiinstitutional setting.<sup>356</sup> The 2185 patients with follow-up in this study were subjected to a univariate and multivariate analysis of survival based on a number of factors, including age, sex, performance status before chemotherapy, presence and site of metastatic disease, histologic subtype, histologic grade, and disease-free interval (time since initial diagnosis of sarcoma). The overall median survival time was 51 weeks. The predictors of overall survival included good performance status, lack of liver involvement, low histopathologic grade, long disease-free interval, and young age ( $P < .005$  for all these factors in a multivariate analysis). Although absence of liver involvement, young age, and high histopathologic grade also predicted for response to chemotherapy, so did liposarcoma histology ( $P < .01$  for all these factors in a multivariate analysis); leiomyosarcoma histology did not qualify as a factor for response to chemotherapy independent of liver metastasis. Although not stratified by site, these data provide some of the best evidence that response rate does not necessarily correlate with overall survival.

Is combination chemotherapy better than single-agent doxorubicin for overall survival? Again, the concept arises of response rates differing from rates of overall survival. There have been several phase III trials examining the issue of combination chemotherapy versus single agents for patients with metastatic disease (Table 39.1-15); two such trials examined this question in uterine sarcoma. There were improved response rates in several of the trials with combination chemotherapy, but there was no survival advantage over single-agent doxorubicin. Complete responses were rare during these studies and were not durable. These data argue that single agents are as effective as combination chemotherapy for patients with metastatic disease, in terms of overall survival. However, some patients may be eligible for palliative resection of metastatic disease. In these situations in which such aggressive therapy is contemplated, combination chemotherapy, which gives better response rates than single agents, can be considered.

TABLE 39.1-15. Selected Randomized Trials in Advanced Disease

## DOSE INTENSITY

It is a central tenet of oncology that response to chemotherapy is a function of dose and dose intensity.<sup>357</sup> A dose-response effect for doxorubicin and ifosfamide has been suggested in a variety of studies.<sup>253,358</sup> However, toxicity limits the amount of chemotherapy that can be given in any one cycle, as illustrated by the phase III trial of the MAID combination chemotherapy noted previously.<sup>353</sup> It is argued that if dose could be increased, better responses might be seen. Better supportive care can help increase dose intensity as outlined in this section.

The use of hematopoietic growth factors has allowed for the study of higher doses of chemotherapy in sarcoma. Some of the aggressive regimens for therapy of metastatic sarcoma satisfy the American Society of Clinical Oncology guidelines for use of growth factors given their high rate of febrile neutropenia.<sup>359</sup> Granulocyte-macrophage colony-stimulating factor (sargramostim), the first granulocyte growth factor used, decreased the myelosuppression seen with CyADIC<sup>360</sup> and MAID<sup>361</sup> chemotherapy, and allowed for increased dose intensity of high-dose ifosfamide.<sup>362</sup> Granulocyte-macrophage colony-stimulating factor allowed for escalation of the dose of doxorubicin when given in combination with 5 g/m<sup>2</sup> of ifosfamide, with improvement in response rate.<sup>363,364</sup> Granulocyte-macrophage colony-stimulating factor has also been shown to allow increased dose intensity of the MAP combination of chemotherapy, allowing addition of ifosfamide.<sup>365</sup>

Similarly, granulocyte colony-stimulating factor (filgrastim) has been widely used to increase dose intensity and decrease myelotoxicity of aggressive chemotherapeutic regimens such as MAID<sup>366</sup> or dose-escalated doxorubicin and ifosfamide.<sup>367</sup> However, with escalated doses (25% increase) in the MAID regimen, there appears to be no significant increased response rate despite use of growth factors.<sup>368</sup> There may be other ways to achieve dose intensity. A study of low-dose, long-term (approximately 2-week) ifosfamide showed responses in patients who failed other forms of chemotherapy for their sarcomas.<sup>369</sup> As was seen with previous studies, it may well be that responsiveness to a particular regimen may not translate into increased survival.

Unfortunately, the cardiac toxicity of doxorubicin and nephrotoxicity and central nervous system toxicity of ifosfamide prevent much greater dose escalation than performed in some studies today. The next logical step is to proceed to high-dose therapy with stem cell support, which is currently under study with pediatric sarcomas.<sup>370,371</sup> Such studies show long-term disease-free survival for a handful of patients with Ewing's sarcoma, osteosarcoma, or rhabdomyosarcoma. Even in these relatively chemotherapy-sensitive sarcomas, the majority of patients have relapsed rapidly. Given that complete responses (and therefore chemotherapy sensitivity) are rare in the metastatic setting of adult soft tissue sarcoma, it is not surprising that the few patients with soft tissue sarcoma who undergo high-dose therapy with stem cell rescue relapse quickly. High-dose therapy with stem cell rescue should not be considered for patients with metastatic sarcoma outside the setting of a clinical trial.<sup>372,373</sup> With poor results from high-dose therapy, the pursuit of agents with better activity against soft tissue sarcoma will remain a primary focus for therapy of relapsed disease.

## RESPONSE BY HISTOLOGIC SUBTYPE AND SITE

A major focus in critical reading of the literature concerning responses of soft tissue sarcoma to chemotherapy is the variety of patient sarcoma histology. Pediatric sarcomas are known for their relative sensitivity to chemotherapy (Ewing's sarcoma, osteosarcoma, and rhabdomyosarcoma). As for adult sarcomas, synovial sarcomas and fibrosarcomas are generally sensitive to chemotherapy. GISTs, alveolar sarcoma of soft parts, and low- to intermediate-grade chondrosarcomas are notorious for their resistance to chemotherapy. An imbalance in the subtypes of sarcomas in various groups of patients can markedly affect overall outcome for the study in question.

Site of disease is another important factor in determination of outcome for patients with soft tissue sarcoma. For example, patients with large low-grade liposarcoma of the extremity show lower relapse rates than patients with low-grade liposarcomas of the retroperitoneum; the latter are more difficult to control locally. Similarly, formerly called leiomyosarcomas of the gastrointestinal tract, both true leiomyosarcomas and gastrointestinal stromal tumors (GISTs), are less responsive to chemotherapy than leiomyosarcoma of other sites (see [Leiomyosarcoma](#), later in this chapter). Anatomy of metastatic disease can also affect overall response rates. For example, metastases to liver are less likely to respond to chemotherapy than metastases to another site<sup>356</sup>; however, this may represent the tendency of GISTs to metastasize to the liver. Variations in the site of disease or metastasis pattern may at least in part account for the different responses noted in randomized trials of chemotherapy for soft tissue sarcoma.

It is clear that specific subtypes of soft tissue sarcomas demonstrate unique biologic behavior. As diagnosis and classification of sarcomas improve, these unique features may become more evident. Examples of specific sites or subtypes of sarcoma and their characteristics are presented here.

## LEIOMYOSARCOMA

Leiomyosarcomas are one of the most common forms of soft tissue sarcoma. They are also relatively uniform in histologic appearance, and thus there is greater concordance of pathologists in the diagnosis of leiomyosarcoma than other forms of soft tissue sarcoma. Given their relative frequency and the consistency of diagnosis of leiomyosarcoma, it is useful to examine the sensitivity of this subset of sarcomas to standard chemotherapy.

The response rate of leiomyosarcoma in subset analysis of randomized trials is shown in [Table 39.1-16](#). Subset analyses cannot substitute for primary trials of chemotherapy, but still can be useful in generating hypotheses for further studies. Doxorubicin appears to be active in leiomyosarcomas, but ifosfamide appears to add little to the response rate of this subset of tumors. In one small study of uterine leiomyosarcomas, a modest response to ifosfamide was observed.<sup>374</sup> Ifosfamide, in contrast, appears to be effective in other subtypes of sarcoma.

**TABLE 39.1-16.** Response of Leiomyosarcoma to Various Chemotherapy Regimens

The primary site of leiomyosarcoma can have an equally important effect on survival. The difference in response rates for different sites of leiomyosarcoma is highlighted in the trials from ECOG and Southwest Oncology Group.<sup>336,353</sup> Although only 20% to 25% of uterine leiomyosarcomas responded to chemotherapy, uterine leiomyosarcoma was approximately twice as responsive to chemotherapy compared with leiomyosarcomas arising from the gastrointestinal tract (GISTs). These data are at odds with the cumulative EORTC metaanalysis of therapy for metastatic sarcomas<sup>356</sup>; however, in the EORTC study, leiomyosarcomas were not stratified with respect to site; poorly responding gastrointestinal stromal tumors were grouped together with better responding leiomyosarcomas of other sites. Given the poor response of gastrointestinal stromal tumors to any chemotherapy, patients with recurrent unresectable disease carrying this diagnosis should be considered candidates for phase I or phase II studies, even before routine chemotherapy with doxorubicin or ifosfamide. Attention to improved histopathologic diagnosis will play a part in the design of future studies of chemotherapy in the adjuvant or metastatic setting.

## SYNOVIAL SARCOMA

Synovial sarcoma demonstrates two histologies, a monophasic form and a biphasic form. Specific translocations in this subset of sarcoma between the SSX and SYT genes on chromosomes X and 18 may be prognostic factors for this subtype of sarcoma. Patients with biphasic histology demonstrated SYT-SSX1 gene fusions. These patients fared more poorly than patients with SYT-SSX2 positive tumors that were associated with the monophasic phenotype<sup>375</sup>; such molecular phenotyping represents an attractive method of predicting outcome to therapy and need for more or less intensive therapy.

Patients with synovial sarcoma tend to be younger than patients with other subtypes of soft tissue sarcoma. Patients with synovial sarcoma are therefore likely to have a better performance status than patients with other subtypes of sarcoma, a positive predictor for response to chemotherapy in the EORTC database.<sup>356</sup> The higher response rates in such patients may therefore be in part due to patient selection factors, not just histologic diagnosis.

In patients with advanced synovial sarcoma, ifosfamide (at a high dose of 14 to 18 g/m<sup>2</sup>) appears to be an active agent with a 100% response rate in one study of 13 patients.<sup>338</sup> The EORTC metaanalysis of 2185 sarcoma patients included 115 synovial sarcomas evaluable for response to chemotherapy<sup>356</sup>; the response rate was 31%, not significantly different than the overall response rate of 26%. The conflict between these results may be due to dose intensity, as well as the use of an inappropriate group for comparison; the EORTC data examined the response of metastatic sarcoma to anthracyclines and only a portion of patients received ifosfamide (at a maximum dose of 5 g/m<sup>2</sup>, a low dose by today's standards).

## PEDIATRIC SARCOMAS IN ADULT POPULATIONS

A number of pediatric sarcomas occur in the adults, including Ewing's sarcoma (in soft tissue or bone), rhabdomyosarcoma (usually embryonal), and osteosarcoma. These diseases differ from typical adult sarcomas in that they are considered systemic diseases despite their initial presentation. Ewing's sarcoma and rhabdomyosarcoma are typically much more sensitive to chemotherapy than adult soft tissue sarcomas.<sup>376</sup> In osteosarcoma, long-term survival has been achieved in pediatric patients with the use of adjuvant chemotherapy. Unfortunately, adults with osteosarcoma are generally more resistant to chemotherapy than children. Adjuvant (or neoadjuvant) chemotherapy is the standard of care for adults with a diagnosis of rhabdomyosarcoma or Ewing's sarcoma. In addition, adults with a typical osteosarcoma of bone should receive neoadjuvant or adjuvant chemotherapy in addition to therapy for local control of their tumor. However, in extraskeletal osteosarcoma, the use of chemotherapy as an adjuvant to surgical control of the primary disease remains controversial, largely due to the low response rates to chemotherapy seen in patients with metastatic soft tissue osteosarcoma.<sup>153,377</sup>

Typical regimens for small cell pediatric sarcomas, specifically rhabdomyosarcoma and Ewing's sarcoma, include the combination of vincristine, doxorubicin, and cyclophosphamide (occasionally with actinomycin D), and the combination of ifosfamide and etoposide.<sup>376,378,379</sup> The MAID regimen also shows activity in pediatric sarcomas.<sup>380</sup> There is debate as to whether adults do worse than pediatric patients with the same stage of disease. Adults are less likely than children to tolerate the aggressive regimens of chemotherapy used in these diseases. In addition, adults may present with advanced stage disease relative to children or adolescents. One retrospective study showed older patients with rhabdomyosarcoma tolerated chemotherapy as well as the pediatric population, but fared worse overall<sup>381</sup>; tumor size, site, and response to chemotherapy predicted outcome in another series.<sup>382</sup> In Ewing's sarcoma, the role of age in predicting outcome is controversial.<sup>383,384</sup> A high percentage of patients with pediatric sarcomas are enrolled on protocols examining new therapy in the setting of randomized trials. Adults with diagnosis of sarcoma usually seen in pediatric populations should be included on pediatric protocols whenever feasible to help determine appropriate care for patients with these rare diagnoses.

## UTERINE SARCOMAS

Uterine sarcomas are rare, accounting for 3% to 7% of all uterine malignancies. The uterus is a unique site in that at least three different sarcomatous entities may arise from this organ, including leiomyosarcoma, endometrial stromal sarcoma, and carcinosarcoma (also known as *malignant mixed Müllerian tumor*). The most common histopathologic type is Müllerian tumor.

For localized disease surgery is the main treatment. Whether adjuvant radiation is needed remains a controversial topic. Most studies showed some improvement in local control but not survival.<sup>385,386</sup> More recently, however, Ferrer et al. reviewed the experience of the Grup Oncologic Catala-Occita and found that the addition of radiation to surgery improved local control as well as survival in 103 patients with stage I to IVa.<sup>387</sup> It is hoped that the ongoing EORTC-55874 randomized trial will determine the exact effect of adjuvant radiation in this malignancy.

The Gynecologic Oncology Group performed a prospective randomized trial comparing adjuvant chemotherapy with no further therapy in patients with stage I to II

uterine sarcoma. No significant improvement was noted in progression-free interval or overall survival. <sup>230</sup>

In advanced disease, the Gynecologic Oncology Group also compared doxorubicin alone with doxorubicin and dacarbazine in a randomized trial. <sup>388</sup> Response rates and overall survival did not differ between the two arms; the response rate to doxorubicin of 28 women with leiomyosarcoma was 25%. Thereafter, doxorubicin was compared with doxorubicin plus cyclophosphamide; response rates in both arms were 19%, with a 13% response rate to doxorubicin for patients with leiomyosarcoma. <sup>389</sup> Uterine sarcoma overall showed a 22% to 25% response rate to chemotherapy as noted previously. <sup>336,348</sup>

A number of phase II studies have examined responses to various agents for various subtypes of uterine sarcoma. Patients with carcinosarcoma (one form of mixed Müllerian tumor) have been treated with cisplatin, <sup>390,391</sup> or with doxorubicin <sup>391</sup>; there were no responses in the small cohort of patients given doxorubicin. <sup>391</sup> When patients develop metastatic disease from carcinosarcoma, it is usually of the carcinomatous elements, indicating this is the more important characteristic of the tumor to treat. This may explain the responses of this sarcoma to therapy effective for epithelial tumors. Leiomyosarcoma is responsive to doxorubicin as noted previously, less sensitive to ifosfamide (see [Leiomyosarcoma](#), earlier in this chapter), and also relatively unresponsive to cisplatin. <sup>390</sup>

Endometrial stromal sarcomas express estrogen and progesterone receptors, <sup>392</sup> and anecdotal responses to progestins have been noted. <sup>393</sup> However, it is clear that frequency of positive estrogen or progesterone receptor staining is substantially greater than the response rate to hormonal therapy such as tamoxifen. In a prospective trial of tamoxifen in uterine sarcomas, only one patient (with a mixed Müllerian tumor) responded, out of a total 29 patients treated (19 with leiomyosarcoma). <sup>394</sup>

## DESMOIDS (AGGRESSIVE FIBROMATOSES)

Desmoid tumors belong to a family of myofibroblastic fibromatoses that are unusual in their bland histology and slow progression. Surgery remains the treatment of choice for these lesions, which cannot truly be called sarcomas because of their lack of metastatic potential.

The role of adjuvant radiation for completely resected primary desmoid tumor is controversial. Most authors agree that for patients with negative resection margins, postoperative radiation is not recommended. <sup>395,396</sup> However, for patients with positive microscopic margins the role of adjuvant radiation is more debatable. Spear et al. from Massachusetts General Hospital reported a local control rate of 61% for patients with primary tumors with positive microscopic margins treated with surgery alone. <sup>395</sup> Others, however, have reported lower local control rates. <sup>397</sup> The conclusion from these studies is that failure does not invariably occur if residual microscopic tumor from a primary lesion is left *in situ* as long as local progression would not cause significant morbidity. When adjuvant radiation is indicated for some primary lesion or in most recurrent tumors, the usual dose is approximately 50 Gy.

In advanced cases desmoids can still cause significant morbidity in proximal extremity lesions and can be fatal if they arise in the retroperitoneum, since such sites are difficult to resect completely.

Although the use of adjuvant radiation is becoming more restricted, the role of definitive radiation is emerging as a reasonable alternative to radical surgery. Ballo et al. reported a 5-year local control rate of 69% for patients treated with radiation for gross disease. <sup>396</sup> Others have shown similar findings. <sup>395,398</sup> The recommended dose for definitive radiation is usually 56 Gy in 2 Gy per fraction to 60 Gy given at 1.8 Gy per fraction.

Desmoids classically arise in pregnancy as an abdominal mass independent of the uterus. Desmoids have been examined for hormone receptors and have binding sites for estrogens and antiestrogens in some cases. <sup>399,400</sup> There are anecdotes of responses to hormonal manipulation such as tamoxifen, <sup>401,402</sup> and <sup>403</sup> testolactone, <sup>404</sup> toremifene, <sup>405</sup> goserelin, <sup>406</sup> and progestins. <sup>406,407</sup> There are well-documented responses of desmoids to sulindac <sup>404</sup> and other nonsteroidal antiinflammatory drugs, and reports of responses to vitamin K, vitamin C, and warfarin. <sup>404,408</sup> Responses can take months and continue for years.

Responses have been reported to single-agent doxorubicin chemotherapy <sup>409</sup> as well as to combination chemotherapy at either standard or relatively low doses. <sup>410,411</sup> and <sup>412</sup> As noted previously, responses can be slow, and therapy should not be abandoned for stable disease.

In summary, for easily resectable disease, surgery alone would appear to be the optimal approach especially in patients with negative microscopic margin. In advanced cases, a trial of nonsteroidal antiinflammatory drugs or hormonal therapy can be considered in most patients. A period of close observation is also reasonable, because some patients demonstrate regression without any therapy. However, if a patient is symptomatic and not a candidate for surgery, consideration should be given to radiation or chemotherapy to increase the chance of a response.

## RECOMMENDATIONS FOR PATIENTS WITH ADVANCED DISEASE

Low-grade tumors grow slowly and may be less responsive to chemotherapy than higher grade lesions. Accordingly, an asymptomatic patient with stable or only slowly progressive disease can be observed only. Resection of metastatic disease, in particular lung metastases, provides some patients with long-term survival and can be considered if the lungs are the only site of remaining disease. <sup>413</sup>

Randomized studies have shown that combination chemotherapy can provide a better probability of a response than single-agent doxorubicin. However, overall survival for any combination chemotherapy has not been proven superior to doxorubicin alone as a single agent. When a clinical response is needed, e.g., before potential surgery for metastases, combinations of agents such as doxorubicin and ifosfamide should be considered, especially for patients with good performance status. For patients with poor performance status, single-agent doxorubicin remains the standard of care, since no other therapy or combination of treatments has proven superior to it for overall survival. Single-agent ifosfamide or dacarbazine can be used as a second-line agent. Dacarbazine demonstrates modest activity in soft tissue sarcoma, and with doxorubicin is a well-studied and well-tolerated combination in metastatic disease. Patients with advanced disease are candidates for phase I and phase II studies of new therapy for sarcoma, since we have but few tools with which to treat such patients presently.

## FUTURE DIRECTIONS

Metastatic sarcoma, whether at time of disease presentation, or after local control of primary disease, remains an extremely difficult problem. The search for effective chemotherapeutic and biologic agents will be the focus of continuing research for patients with advanced disease. In the near future, results should be forthcoming of the study of the differentiation agent troglitazone for patients with metastatic or recurrent liposarcoma. Even more potent agonists of the PPAR- $\gamma$  receptor such as rosiglitazone and pioglitazone will be examined in the metastatic and adjuvant setting for patients with liposarcoma. The study of angiogenesis inhibition is just beginning. The examination of antagonists of the VEGF and other pathways of angiogenesis, may show promise in this class of tumors, using agents such as SU5416, angiostatin, and endostatin. In terms of novel chemotherapeutic agents, ecteinascidin 743 has demonstrated some promise in phase I studies and may provide the first new effective antisarcoma agent since ifosfamide.

In the longer term, it is hoped that new biologic agents for sarcoma therapy can be found that are as potent as TNF in murine models of sarcoma. TNF, interleukin-2, and cytokines appear to be toxic and largely inactive as sarcoma therapy when given systemically. Nonetheless, other biologic interventions may show promise, such as immunotherapy with targeted production of cytokines, or interference with cell-signaling pathways. Characteristic fusion proteins of sarcomas (or peptides thereof) will be tested in the near future for their effectiveness in the appropriate subtypes of sarcomas, such as many pediatric sarcomas. Vaccines incorporating dendritic cells appear to be effective immunogens in preclinical studies. Preparations of heat shock proteins or of immunogenic glycolipids found in sarcoma cell membranes may also provide interesting agents for therapy. Potent agents inhibiting cellular signaling pathways through ras, tyrosine kinases, and other regulators of cell division are just now entering clinical trials. The first tentative steps into the realm of gene therapy for cancer are just now being taken. It is hoped that the continued strides made in understanding molecular and cell biology, such as the mechanisms of sarcoma induction by fusion proteins encoded by specific chromosomal translocations seen in sarcomas, will lead to new therapies that will affect the therapy of this diverse family of tumors.

## INTRODUCTION

Malignant tumors arising from the skeletal system are rare, representing only 0.2% of all new cancers. Approximately 2600 new cases occur in the United States each year.<sup>1</sup> Osteosarcoma and Ewing's sarcoma, the two most common bone tumors, occur mainly during childhood and adolescence.<sup>2,3</sup> and <sup>4</sup> Other mesenchymal (spindle cell) neoplasms that characteristically arise after skeletal maturity—fibrosarcoma, chondrosarcoma, and malignant fibrous histiocytoma (MFH)—are less common.<sup>5,6,7,8,9,10,11,12,13,14,15,16,17</sup> and <sup>18</sup> The vast majority of experience reported in the management of bone neoplasms has been obtained in patients with osteosarcoma. As a result, the surgical, chemotherapeutic, and radiotherapeutic principles developed for treatment of osteosarcomas form the basis of the management strategy for most of the spindle cell neoplasms.

Since the late 1970s, an explosion of clinical knowledge and experience in the management of bone neoplasms has been seen.<sup>18,19,20,21,22,23,24,25,26,27,28</sup> and <sup>29</sup> The development of centers of specific interest in these tumors has played an important role in the advancement of biologic understanding and surgical management of these lesions and the development of multimodality treatment regimens.<sup>24,25,26,27</sup> and <sup>28</sup> A surgical staging system that permits standardized preoperative evaluation, analysis, and end-result reporting has been developed.<sup>29</sup>

Amputation has been the standard method of treatment for most bone sarcomas, but the 1990s was witness to the development of limb-sparing surgery for most

malignant bone tumors.<sup>30,31,32,33,34,35,36,37,38,39 and 40</sup> Advances in orthopedics, bioengineering, radiographic imaging, radiotherapy, and chemotherapy have contributed to safer, more reliable surgical procedures.<sup>41,42,43,44,45,46,47,48,49,50,51,52,53,54,55,56,57,58,59,60,61,62,63,64,65,66,67,68,69,70,71,72,73,74,75,76,77,78,79,80 and 81</sup> Computed tomography (CT), developed during the early 1980s, and, more recently, magnetic resonance imaging (MRI), permit extremely accurate evaluation of the local anatomy and enhance the possibility of safe resection.<sup>82,83,84,85,86,87,88 and 89</sup> Today, limb-sparing surgery is considered safe and routine for approximately 90% of patients with extremity osteosarcomas. An evaluation system has been developed to determine a patient's functional status.<sup>29</sup> This system, for the first time, permits evaluation and comparison of the various limb-sparing procedures and types of surgical reconstructions.

Paralleling these advances has been the demonstrated effectiveness of adjuvant chemotherapy in dramatically increasing overall survival; specifically, the bleak 15% to 20% survival rate associated with surgery alone before the 1970s rose to 55% to 80% with various adjuvant treatment regimens by the 1980s.<sup>50,51,52 and 53,90,91 and 92</sup> Multiple-drug regimens are now considered essential treatment. The timing, mode of delivery, and different combinations of these agents are being investigated at many centers. Preoperative chemotherapy regimens (termed *neoadjuvant* or *induction chemotherapy*) and postoperative regimens are being evaluated to determine their effect on the tumor and their impact on the choice of operative procedure and on overall survival.<sup>93,94,95,96,97,98,99 and 100</sup>

This chapter focuses only on malignant spindle cell tumors. Ewing's sarcoma is presented in detail in [Chapter 39.1](#). Benign tumors are described briefly, and their significance for the oncologist is described.<sup>2,3</sup> Emphasis is placed on natural history, surgical staging, tumor imaging, criteria of patient selection for amputation versus limb-sparing surgery, and technique of limb-sparing procedures. The development, role, timing, and mode of delivery of adjuvant chemotherapy and its relationship to stage of disease are discussed. The role of radiotherapy in specific clinical situations is presented.

## CLASSIFICATION AND TYPES OF BONE TUMORS

Bone consists of cartilaginous, osteoid, and fibrous tissue and bone marrow elements. Each tissue can give rise to benign or malignant spindle cell tumors.<sup>2,3 and 4</sup> Bone tumors are classified on the basis of cell type and recognized products of proliferating cells. The classification system, described by Lichtenstein<sup>3,56</sup> and modified by Dahlin,<sup>2</sup> is presented in [Table 39.2-1](#). Jaffe<sup>4</sup> recommends that each tumor be considered a separate clinicopathologic entity. Radiographic, histologic, and clinical data are necessary to form an accurate diagnosis and to determine the degree of activity and malignancy of each lesion.

Histologic Type*	Benign	Malignant
Metaplastic (41.4%)	—	Metaplasia
Chondrogenic (20.9%)	Osteochondroma	Atypical cartilage cell sarcoma
	Chondroma	Primary chondrosarcoma
	Chondroblastoma	Secondary chondrosarcoma
Osteogenic (19.9%)	Chondromyxoid fibroma	Dedifferentiated chondrosarcoma
	Osteoid osteoma	Mesenchymal chondrosarcoma
	Benign osteochondroma	Chondrosarcoma
Unknown origin (9.8%)	Giant cell tumor	Parosteal osteogenic sarcoma
	—	Ewing's tumor
	—	Malignant giant cell tumor
Fibrogenic (8.8%)	(Fibrous) histiocytoma	Adiposarcoma
	Fibroma	Fibrosarcoma
	Desmoplastic fibroma	—
Neurochondral (3.3%)	—	Chondroma
Vascular (3.0%)	Hemangioma	Hemangioendothelioma
	—	Hemangioepithelioma
Ligamentous (0.5%)	Ligament	—
Neurogenic (0.5%)	Neurofibroma	—

\*Distribution based on Mass Clinic experience (Adapted from ref. 2, with permission.)

**TABLE 39.2-1.** General Classification of Bone Tumors

Cartilage tumors are lesions in which cartilage is produced. They are the most common bone tumors. Osteochondroma is the most common benign cartilage tumor; some 1% to 2% of solitary osteochondromas become malignant.<sup>57 and 58</sup> Enchondroma is a benign cartilage tumor that occurs centrally; in adults, malignant transformation may occur. Chondrosarcoma, the most common malignant cartilage tumor, is either intramedullary or peripheral. Ten percent are secondary, arising from an underlying benign lesion.<sup>2</sup> Most chondrosarcomas are low grade, although 10% dedifferentiate into high-grade spindle cell sarcomas or, rarely, a mesenchymal chondrosarcoma.<sup>2,57</sup>

Osteoid tumors are lesions in which the stroma produce osteoid. The benign forms are osteoid osteoma and osteoblastoma. Osteoid osteomas are never malignant. Osteoblastomas rarely metastasize; when they do, it is only after multiple local recurrences.<sup>59</sup> Osteosarcomas are the most common primary malignant tumors of the bone. Histologically, they are composed of malignant spindle cells and osteoblasts that produce osteoid or immature bone. Several variants are now recognized.<sup>60</sup> Parosteal, periosteal, and low-grade intraosseous osteosarcoma are histologically and radiographically distinct from the "classic" central medullary osteosarcomas and have a more favorable prognosis.<sup>61,63</sup>

Fibrous tumors of bone are rare. Desmoplastic fibroma is a locally aggressive, nonmetastasizing tumor, analogous to fibromatosis of soft tissue.<sup>5,6</sup> Fibrosarcoma of bone appears histologically as its soft tissue counterpart. Multiple sections must be obtained to demonstrate the lack of osteoid production. If osteoid is present, the lesion is classified as an osteosarcoma. MFH, a rare lesion and the counterpart of soft tissue MFH, has been described in bone.<sup>7,8 and 9</sup> The pathophysiologic behavior of bone and soft tissue MFH is similar, consisting of a storiform pattern with a histiocytic component. Giant cell tumors of unknown origin were originally called benign but are now considered low-grade sarcomas. They have high rates of local recurrence and malignant transformation.<sup>64,65</sup>

Tumors presumably arising from bone marrow elements are the round cell sarcomas. The two most common are Ewing's sarcoma and the rarer non-Hodgkin's lymphoma.

## RADIOGRAPHIC EVALUATION AND DIAGNOSIS

Radiographic evaluation combined with the clinical history and histologic examination is necessary for accurate diagnosis. Bone scans, angiography, CT, and MRI are generally not helpful in determining a diagnosis but are important in delineating the extent of local involvement. A systematic approach to the radiographic evaluation of skeletal lesions has been described by Madewell and colleagues,<sup>66</sup> who studied and correlated several hundred radiographic and pathologic specimens. They considered the radiograph as the gross specimen from which a detailed histologic interpretation could be made and biologic activity accurately diagnosed. According to their system, a bone tumor is evaluated by five radiographic parameters:

1. Anatomic site. Specific anatomic sites of the bone give rise to specific groups of lesions. Johnson<sup>67</sup> explained this by a "field" theory, which hypothesizes that the most active cells of a certain area of bone give rise to tumors that are characteristic of that area. In general, spindle cell sarcomas are metaphyseal, whereas round cell sarcomas tend to be diaphyseal.
2. Borders. The border reflects the growth rate and the response of the adjacent normal bone to the tumor. Most tumors have a characteristic border. Benign lesions (e.g., nonossifying fibromas and unicameral bone cysts) have well-defined borders and a narrow transition area that is often associated with a reactive sclerosis. Aggressive or benign tumors [e.g., chondroblastoma and giant cell tumors (GCTs)] tend to have faint borders and wide zones of transition with very little sclerosis, reflecting a faster-growing lesion. Poorly delineated or absent margins indicate an aggressive or malignant lesion.
3. Bone destruction. Bone destruction is the hallmark of a bone tumor. Three patterns of bone destruction are described<sup>66</sup>: geographic, moth-eaten, and permeative. In general, these patterns are found in the tubular bone rather than in the flat bone and represent a combination of cortical and cancellous destruction. These patterns reflect a progressively increasing growth rate of the underlying tumor.
4. Matrix formation. Calcification of the matrix, or new bone formation, may produce an area of increased density within the lesion. Calcification typically appears as flocculent or stippled rings or clusters. The appearance of the new bone varies from dense sclerosis that obliterates all evidence of normal trabeculae, to small, irregular, circumscribed masses described as "wool" or "clouds." Calcification and ossification may appear in the same lesion. Neither type of matrix formation per se is diagnostic of malignancy.
5. Periosteal reaction. Periosteal reaction is indicative of malignancy but not pathognomonic of a particular tumor. A combination of periosteal changes is often noted. In malignant tumors, periosteal reaction is noncontinuous and thin, with multiple laminations. A parallel or a perpendicular pattern may be present.

The radiographic parameters of benign and malignant tumors are quite different. Benign tumors have round, smooth, well-circumscribed borders. No cortical destruction and, generally, no periosteal reaction are found. Malignant lesions have irregular, poorly defined margins. Evidence of bone destruction and a wide area of transition with periosteal reaction are noted. Soft tissue extension is common.

## NATURAL HISTORY

Tumors arising in bone have characteristic patterns of behavior and growth that distinguish them from other malignant lesions. <sup>68,89</sup> These patterns form the basis of a staging system and current treatment strategies. These principles and their relationship to management, as formulated by Enneking and colleagues, <sup>68,89</sup> are described here.

## BIOLOGY AND GROWTH

Spindle cell sarcomas form a solid lesion that grows centrifugally. The periphery is the least mature part of this lesion. In contradistinction to a true capsule, which surrounds a benign lesion and is composed of compressed normal cells, a malignant tumor is generally enclosed by a pseudocapsule and consists of compressed tumor cells and a fibrovascular zone of reactive tissue with an inflammatory component that interdigitates with the normal tissue adjacent to and beyond the lesion. The thickness of the reactive zone varies with the degree of malignancy and histogenic type. The histologic hallmark of sarcomas is their potential to break through the pseudocapsule to form satellite lesions of tumor cells. This characteristic distinguishes a nonmalignant mesenchymal tumor from a malignant one.

High-grade sarcomas have a poorly defined reactive zone that may be invaded and destroyed by the tumor. In addition, tumor nodules in tissue may appear to be normal and not continuous with the main tumor. These are termed *skip metastases*. Although low-grade sarcomas regularly demonstrate tumor interdigitation into the reactive zone, they rarely form tumor nodules beyond this area.

The three mechanisms of growth and extension of bone tumors are: (1) compression of normal tissue, (2) resorption of bone by reactive osteoclasts, and (3) direct destruction of normal tissue. Benign tumors grow and expand by the first two mechanisms, whereas direct tissue destruction is characteristic of malignant bone tumors. Sarcomas respect anatomic borders and remain within one compartment. Local anatomy influences tumor growth by setting the natural barriers to extension. In general, bone sarcomas take the path of least resistance. Most benign bone tumors are unicompartamental; they remain confined and may expand the bone in which they arose. Malignant bone tumors are bicompartamental; they destroy the overlying cortex and go directly into the adjacent soft tissue. The determination of anatomic compartment involvement has become more important with the advent of limb-preservation surgery.

On the basis of biologic considerations and natural history, Enneking and colleagues <sup>69,101</sup> classified bone tumors into five categories, each of which shares certain clinical characteristics and radiographic patterns and requires similar surgical procedures.

1. Benign/latent: lesions whose natural history is to grow slowly during normal growth of the individual and then to stop, with a tendency to heal spontaneously. They never become malignant and, if treated by simple curettage, heal rapidly. Surgery is not indicated unless they become symptomatic.
2. Benign/active: lesions whose natural history is one of progressive growth. Simple curettage leaves a reactive rim with some tumor. Curettage is associated with a high recurrence rate. Wide excision through normal bone results in local control in approximately 95% of all cases.
3. Benign/aggressive: lesions that are locally aggressive but do not metastasize. The tumor extends through the capsule into the reactive zone. Local control can be obtained only by removing the lesion with a margin of normal bone beyond the reactive zone.
4. Malignant/low grade: lesions that have a low potential to metastasize. Histologically, a pseudocapsule rather than a true capsule is found. Tumor nodules exist within the reactive zone but rarely beyond. Local control can be accomplished only by removal of all tumor and reactive tissue with a margin of normal bone. These lesions can be treated successfully by surgery alone.
5. Malignant/high grade: lesions whose natural history is to grow rapidly and metastasize early. Tumor nodules are often found within and beyond the reactive zone and at some distance in the normal tissue. Surgery is necessary for local control, and systemic therapy is warranted to prevent metastasis.

## METASTASIS

Bone tumors, unlike carcinomas, disseminate almost exclusively through the blood; bones lack a lymphatic system. Early lymphatic spread to regional nodes has only rarely been reported. <sup>18,102</sup> Lymphatic involvement, which has been noted in 10% of cases at autopsy, is a poor prognostic sign. <sup>70</sup> McKenna and associates <sup>71</sup> noted that 6 of 194 patients (3%) with osteosarcoma who underwent amputation demonstrated lymph node involvement. None of these patients survived 5 years. Hematogenous spread is manifested by pulmonary involvement in its early stage and secondarily by bone involvement. <sup>71,72,73,74,75</sup> and <sup>76</sup> Bone metastasis is occasionally the first sign of dissemination. With the use of adjuvant chemotherapy, the skeletal system has become a more common site of initial relapse. <sup>46,103,104</sup>

## SKIP METASTASIS

A skip metastasis, as previously defined, is a tumor nodule that is located within the same bone as the main tumor but not in continuity with it. Transarticular skip metastases are located in the joint adjacent to the main tumor. <sup>77</sup> Skip metastases are most often seen with high-grade sarcomas. A skip lesion develops by the embolization of tumor cells within the marrow sinusoids; in effect, they are local micrometastases that have not passed through the circulation. Transarticular skips are believed to occur via the periarticular venous anastomosis. The clinical incidence of skip metastases is less than 1%. <sup>78</sup> These lesions are a prognosticator of poor survival. <sup>77,78</sup>

## LOCAL RECURRENCE

Local recurrence of a benign or malignant lesion is due to inadequate removal. The aggressiveness of the tumor determines which surgical procedure is required for local control. Ninety-five percent of all local recurrences, regardless of histology, develop within 24 months of attempted removal. <sup>69,79,80</sup> Local recurrence of a high-grade sarcoma decreases overall survival prospects substantially. Local recurrence in patients who have undergone therapy is associated with an even poorer prognosis (Fig. 39.2-1). <sup>75</sup>

FIGURE 39.2-1. Survival rates over a 5-year period of patients with bone sarcoma according to stage of disease. (From ref. 19, with permission.)

## STAGING BONE TUMORS

### MUSCULOSKELETAL TUMOR SOCIETY CLASSIFICATION

In 1980, the Musculoskeletal Tumor Society (MSTS) adopted a surgical staging system for bone sarcomas ( [Table 39.2-2](#)).<sup>100</sup> The system is based on the fact that mesenchymal sarcomas of bone behave similarly, regardless of histogenic type. The surgical staging system, as described by Enneking and colleagues,<sup>101</sup> is based on the GTM classification: grade (G), location (T), and lymph node involvement and metastases (M).

Stage	Grade	Site
IA	Low (G1)	Intracompartmental (T1)
IB	Low (G1)	Extracompartmental (T2)
IIA	High (G2)	Intracompartmental (T1)
IIB	High (G2)	Extracompartmental (T2)
III	Any G	Any (T)
	Regional or distant metastasis (M1)	

G, grade; G1, any low-grade tumor; G2, any high-grade tumor; M, regional or distal metastases; M0, no metastases; M1, any metastases; T, site; T1, intracompartmental location of tumor; T2, extracompartmental location of tumor.  
(From ref. 19, with permission.)

**TABLE 39.2-2.** Surgical Staging of Bone Sarcomas

G represents the histologic grade of a lesion and other clinical data. Grade is further divided into two categories: G1 is low grade, and G2 is high grade.

T represents the site of the lesion, which may be intracompartmental (T1) or extracompartmental (T2). Compartment is defined as “an anatomic structure or space bounded by natural barriers or tumor extension.” The significance of T1 lesions is easier to define clinically, surgically, and radiographically than that of T2 lesions, and the chance is better for adequate removal of the former without amputation. In general, low-grade bone sarcomas are intracompartmental (T1), whereas high-grade ones are extracompartmental (T2).

Lymphatic spread is a sign of widespread dissemination. Regional lymphatic involvement is equated with distal metastases (M1). Absence of any metastasis is designated as M0.

The surgical staging system developed by Enneking and colleagues<sup>101</sup> for surgical planning and assessment of bone sarcomas is summarized thus:

Stage IA (G1,T1,M0): low-grade intracompartmental lesion, without metastasis

Stage IB (G1,T2,M0): low-grade extracompartmental lesion, without metastasis

Stage IIA (G2,T1,M0): high-grade intracompartmental lesion, without metastasis

Stage IIB (G2,T2,M0): high-grade extracompartmental lesion, without metastasis

Stage IIIA (G1 or G2,T1,M1): intracompartmental lesion, any grade, with metastasis

Stage IIIB (G1 or G2,T2,M1): extracompartmental lesion, any grade, with metastasis

#### AMERICAN JOINT COMMITTEE ON CANCER BONE TUMOR CLASSIFICATION

In 1983, the American Joint Committee on Cancer Bone Tumor Classification (AJCC) recommended a staging system for the malignant tumors of bone. This system has undergone minimal changes and remains unchanged in the fifth edition of the *AJCC Cancer Staging Manual*. This system is based on two indications: TNM designation [extent of the tumor (T), nodal status (N), and distant metastases (M)] and grade (G). This system is similar to the MSTS classification; however, the AJCC uses four stages instead of three. The four stages are designated I to IV and may be further modified with A or B. Stages I and II are defined by the histologic grade (grade I and II) and modified by tumor extent (i.e., cortical involvement; designated E1 to E6) ( [Table 39.2-3](#)). T(I) indicates that the tumor is confined within the cortex (similar to the MSTS classification A), and T(II) indicates that the tumor extends beyond the cortex (similar to the MSTS classification B). In the AJCC, stage III has remained undefined and stage IV is defined as the presence of metastases. Stage IV tumors are modified by A, which is equivalent to III M1 in the MSTS system (i.e., indicates a nodal metastasis), and B, which is equivalent to III M1 in the MSTS system (i.e., indicates distant metastases).<sup>105</sup>

Maximal Extent	Definition
E1	Tumor touches but does not elevate or penetrate the periosteum.
E2	Tumor elevates but does not penetrate the periosteum.
E3	Tumor penetrates into but not through the periosteum.
E4	Minimal extraperiosteal extension, not into a defined structure or space, seen as a nodule of tumor of 1 cm or smaller in fat just outside the periosteum, where muscle does not insert onto bone; the nodule often lies next to a small artery and may represent a small venous embolus that has destroyed the wall of the vein.
E5	Tumor invades any one of the following: tendon, ligament, periarticular structures (tumor is covered by synovial tissue), joint (tumor is intraarticular), muscle, bone, or space (e.g., the popliteal fossa or axilla).
E6	Tumor invades two structures or more.

(From Sparsier SS, Schuster JJ, Vander Griest RA. The effect of local extent of the tumor on prognosis in osteosarcoma. *J Bone Joint Surg Am* 1990;72:643, with permission.)

**TABLE 39.2-3.** Definitions of Anatomic Extent for Stage IIB Tumors

#### PREOPERATIVE EVALUATION

If the plain radiographs suggest an aggressive or malignant tumor, staging studies should be performed before biopsy. All radiographic studies are influenced by surgical manipulation of the lesion, making interpretation more difficult.<sup>40,69</sup> More important, the biopsy site may be in a location that is not optimal for subsequent *en bloc* removal or radiotherapy.<sup>24,110,111</sup> Bone scintigraphy, MRI, CT, angiography, or a combination of these is required to delineate local tumor extent, vascular displacement, and compartmental localization.<sup>43,44,45,46 and 47,69,79,83,84,85,86,87,88 and 89</sup>

#### BONE SCANS

Bone scintigraphy helps determine polyostotic involvement, metastatic disease, and intraosseous extension of tumor.<sup>43,44,46</sup> Malignant bone tumors, although solitary, may in rare cases present with skeletal metastasis.<sup>47</sup> Skip metastases are rarely detected by bone scan, because they are small and localized to the fatty marrow and do not excite cortical response.<sup>77,78</sup>

Appreciation of the intraosseous extension of a bone tumor is important in surgical planning. Removal of bone 3 to 4 cm beyond the area of scintigraphic abnormality

has been accepted as a safe margin for limb-sparing procedures after induction chemotherapy. <sup>33</sup>

## COMPUTED TOMOGRAPHY

CT allows accurate determination of intra- and extraosseous extension of skeletal neoplasms. <sup>41,42,43,44</sup> and <sup>45</sup> It accurately depicts the transverse relationship of a tumor. By varying window settings, one can study cortical bone, intramedullary space, adjacent muscles, and extraosseous soft tissue extension. CT should include the entire bone and the adjacent joint. Infusion of intravenous contrast material permits identification of the adjacent large vascular structures. CT evaluation must be individualized. To obtain the maximum benefits from image reconstruction, the surgeon should discuss with the radiologist what information is desired. Three-dimensional reconstruction may be useful. Today, CT and MRI are considered complementary studies for bone sarcomas. Both studies are recommended for most patients.

## MAGNETIC RESONANCE IMAGING AND STAGING

MRI has several advantages in the diagnoses of bone sarcomas. <sup>82,83,84,85,86,87,88</sup> and <sup>89</sup> It has better contrast discrimination than any other modality; furthermore, imaging can be performed in any plane. MRI is ideal for imaging the medullary marrow and thus for detection of tumor as well as the extraosseous component. It has proved especially helpful in several heretofore difficult clinical situations, such as detecting small lesions, evaluating a positive bone scan when the corresponding plain radiograph is negative, determining the extent of infiltrative tumors, and detecting skip metastases. <sup>87,88</sup> and <sup>89</sup>

Dynamic MRI is currently being evaluated as a more accurate method of determining intraosseous extension of tumor than conventional MRI. Iwasawa et al. <sup>106</sup> performed a microscopic evaluation of six macrospecimens after tumor resection and chemotherapy. They concluded that the calculation of the slope value of dynamic MRI discriminated regions of microscopic invasion from tumor-free marrow in patients with osteosarcoma after chemotherapy. The slope value of dynamic MRI was greater in the region of microscopic invasion than in the tumor-free marrow and less than in the area showing macroscopic tumor invasion. This technique may provide more accurate determination of intraosseous bony extent than traditional MRI.

## ANGIOGRAPHY

The technique of arteriography for bone lesions differs from that used for arterial disease. At least two views (biplane) are necessary to determine the relation of the major vessels to the tumor. <sup>107</sup> Because experience with limb-sparing procedures has increased, it has become essential to determine individual vascular patterns before resection. This is especially crucial for tumors of the proximal tibia, where vascular anomalies are common. <sup>108</sup> Angiography is the most reliable means of determining vascular anatomy and displacement, whereas MRI and CT better demonstrate extraosseous extension. Presently, magnetic resonance angiography is being evaluated in the treatment of bone sarcomas.

## THALLIUM SCANS

Thallium 201 scintigraphy has been shown to accumulate in musculoskeletal neoplasms <sup>109,110</sup>; however, it cannot distinguish benign from malignant tumors. Thallium scintigraphy is helpful in following the response to neoadjuvant treatment and detecting local recurrence when MRI cannot be used. <sup>109,110,111</sup> and <sup>112</sup>

## CHOOSING A METHOD OF RADIOGRAPHIC EVALUATION

All of the above studies are required in the preoperative evaluation of a bone sarcoma. Each study has unique benefits. Bloem et al. <sup>113</sup> performed a prospective study comparing results of CT, MRI, scintigraphy, and angiography with 56 resected specimens to determine the appropriate choice of procedures. MRI, the single best study, was most accurate for determining intraosseous extent of tumor; scintigraphy and CT were often misleading. Angiography was performed only if the primary tumor was in the vicinity of the major vascular structures. They also reported that CT and MRI were equally accurate in evaluating cortical changes. MRI was superior to CT for detecting muscle involvement in the knee, pelvis, and shoulder.

MRI and CT (transverse data), combined with bone scans and angiography, allow the physician to develop a three-dimensional construct of the local tumor area before surgery and thereby formulate a detailed surgical approach.

## BIOPSY TECHNIQUE AND TIMING

The biopsy of a suspected bone tumor must be performed with great care and skill. <sup>114,115</sup> This principle cannot be overemphasized. The consequences of a poorly executed biopsy are often the deciding factor in the choice between a limb-salvage procedure and amputation. Murray and coworkers <sup>114a</sup> from the M. D. Anderson Cancer Center judged that only 19% of patients referred to that institution for treatment of primary bone sarcomas had properly placed biopsies. All of these patients had open (incisional) biopsies, whereas 92% of such procedures performed at the M. D. Anderson Cancer Center over the same period were needle biopsies. Similarly, Mankin et al. <sup>115</sup> compared the results of biopsies performed at the referring institution with those performed at the treatment center. In this study, which involved 329 patients, a major error in diagnosis occurred in 60% of patients from referring hospitals. Importantly, 18.2% of the referred patients had to have less than optimal treatment owing to problems related to the biopsy, and for 8.5% of the total, the prognosis and outcome were thought to have been adversely affected by the biopsy. It is recommended that the biopsy be performed by the surgeon who will make the ultimate decision about the operative procedure. This entails referring some patients who are strongly suspected of having primary bone malignancies to a regional cancer center for biopsy.

Trephine or core biopsy is recommended and often obtains an adequate specimen for diagnosis. <sup>116,117</sup> and <sup>118</sup> Multiple samples can be obtained from the same puncture site by slightly changing the angle of approach. Radiographs should be obtained to document the position of the trocar. Core biopsy is preferred if a limb-sparing option exists, because it entails less local contamination than does open biopsy. Core biopsy is especially helpful in difficult areas, such as the spine, pelvis, and hips. If a core biopsy proves to be inadequate, a small incisional biopsy is performed.

Every precaution should be taken to avoid contamination when performing an open biopsy. A tourniquet is used if feasible. If a soft tissue component is present, there is no need to biopsy the underlying bone. To decrease subsequent hemorrhage, polymethylmethacrylate (PMMA) is used to plug a cortical window. Gelfoam is used for hemostasis in the soft tissue. The overlying pseudocapsule is carefully closed to ensure maximum hemostasis. If it is necessary to biopsy the underlying bone, it is essential to use a small, rounded cortical window, especially if the tumor requires primary radiotherapy. Large segments will not reossify, and they often fracture and require late amputations. Regardless of the technique used, tumor cells contaminate all tissue planes and compartments transversed. All biopsy sites must therefore be removed *en bloc* when the tumor is resected or irradiated.

## RESTAGING AFTER PREOPERATIVE CHEMOTHERAPY

With the advent of preoperative chemotherapy for osteosarcoma, a need has developed for serial evaluation of the clinical and radiographic response of the tumor before surgery. The staging and preoperative clinical studies previously described are used to evaluate tumor response. These studies have been summarized. <sup>119,120,121,122,123,124</sup> and <sup>125</sup> Complete restaging studies should be obtained after the completion of induction chemotherapy. MRI, CT, thallium scans, and angiography should be evaluated before making a final surgical decision.

## CLINICAL EVALUATION

Pain often decreases after induction chemotherapy. Alkaline phosphatase (AP) levels likewise decrease. The tumor shrinks, especially if significant matrix is not present. Conversely, increase of pain, elevated AP values, and increasing tumor size are signs of tumor progression.

## PLAIN RADIOGRAPHY

There is a good correlation between radiographic response and the amount of necrosis. <sup>121,124</sup> Smith and colleagues <sup>124</sup> described the radiographic responses seen on serial radiographs: increased ossification of tumor osteoid, marked thickening and new bone formation of the periosteum and tumor border (giving the tumor a more

“benign” appearance), and decreased soft tissue mass. The healing ossification is usually solid, homogeneous, and regular and is easily differentiated from tumor osteoid.<sup>121</sup> Less significant changes take place within the intramedullary component, which may include both increased sclerosis and lysis, presumably caused by necrosis and hemorrhage.

## ANGIOGRAPHY

After chemotherapy, vascularity decreases markedly.<sup>120,121</sup> Chuang et al.<sup>121</sup> evaluated 53 patients and reported that those with a complete angiographic response had more than 90% necrosis; among those with a partial response, necrosis ranged from 40% to 78%. They concluded that angiographic evaluation was as reliable as pathologic evaluation and that the angiographic features were the best clinical criteria for the evaluation of tumor response.

Carrasco and coworkers<sup>122</sup> from the M. D. Anderson Cancer Center reported on their extensive experience with intraarterial chemotherapy for osteosarcoma (81 patients) and evaluated the angiographic appearance and changes after two and four cycles of preoperative chemotherapy. They developed a simple radiographic system for angiographic changes. They evaluated the midarterial (tumor vascularity) and parenchymal (capillary) phases. They described three types of responses:

1. Angiographic response: complete disappearance of tumor vascularity and stain.
2. Total disappearance of tumor vascularity, with slight persistence of tumor stain (capillary phase).
3. No response: persistence of tumor vascularity and capillary stain.

They reported that 40% of the histologic responders (more than 90% tumor necrosis) and 91% of nonresponders were identified after two cycles. The number of courses was no different between the responders and nonresponders. They concluded that the disappearance of tumor vascularity after two courses of chemotherapy was highly suggestive of a good histologic response and was unlikely to occur in the histologic nonresponders.

## COMPUTED TOMOGRAPHY

The most consistent finding in patients who respond to therapy is a decrease in soft tissue mass and the development of a rim-like calcification similar to that seen on plain radiographs.<sup>119</sup> Changes in marrow are not helpful in evaluating response.

## BONE SCINTIGRAPHY

Bone scan changes are difficult to evaluate. A decrease in activity generally indicates a favorable response; however, reparative bone formation, signaled by increased activity, may be misleading. Dynamic (quantitative) bone scans, which are based on tumor blood flow and regional plasma clearance by bone and soft tissue, may allow more valid evaluations.<sup>125</sup> Regions that show a greater than 20% decrease in technetium 99m methylene diphosphonate plasma clearance are reported to be associated with necrotic tumor. To quantify bone scans, a tumor to nontumor ratio is obtained after bone scintigraphy. This ratio is then determined preoperatively and after induction chemotherapy on serial scans. A decrease in this ratio is an indication of a good response to chemotherapy.

## MAGNETIC RESONANCE IMAGING

Monitoring of neoadjuvant chemotherapy by MRI has become the focus of many studies.<sup>126,127</sup> and <sup>128</sup> Holscher and colleagues<sup>126</sup> evaluated 57 patients at the University Hospital of Leiden. T1- and T2-weighted images were obtained in longitudinal, coronal or sagittal, and axial planes. Factors evaluated were margins, homogeneity, hematoma, fibrosis, calcification liquefaction, edema, joint effusion, and fracture. The authors concluded that increased tumor volume or increased or unchanged peritumoral edema and inflammation indicated a poor response. Subjective criteria, such as improved tumor demarcation or an increase in size of area of low signal intensity (presumably necrotic tumor), were independent of tumor response. They concluded that subjective criteria could not predict the good responders.

Conventional MRI is not specific enough to distinguish viable tumor from chemotherapy-related inflammation. On routine T2-weighted images, the signals for tumor, hemorrhage, necrosis, and edema are similar. Tumor cannot be differentiated from inflammation on T1-weighted gadolinium-enhanced images.

## THALLIUM SCINTIGRAPHY

Several studies have demonstrated that serial thallium 201 scintigraphy is an accurate way to follow the response of osteosarcoma during the course of neoadjuvant treatment and to predict tumor responses.<sup>109,110,111</sup> and <sup>112</sup> Rosen and associates<sup>110</sup> used this technique to evaluate tumor necrosis after preoperative chemotherapy in 27 patients. They concluded that serial thallium scans can accurately predict a good histologic response and good prognosis. Furthermore, thallium scintigraphy can identify poor responders within the first 2 weeks after the initiation of treatment. They described a simple classification of response: type I, no response; type II, discernible lesion still present; type III, no detectable lesion. All patients with a type III classification and 67% of those with a type II classification were rated as good responders (types II and III constituted a total of nine patients).<sup>110</sup>

## POSITRON EMISSION TOMOGRAPHY

Positron emission tomographic scans are nuclear medicine scintigraphy techniques that use 2[<sup>18</sup>F]-fluoro-2-deoxy-D-glucose as the radiopharmaceutical. This technique is under investigation. It is hoped that it will be able to dynamically evaluate the tumor and the percentage of tumor necrosis after chemotherapy.<sup>129</sup>

## SURGICAL MANAGEMENT OF SKELETAL TUMORS

Surgical removal, including curettage, resection, and amputation, is the traditional method of managing skeletal neoplasms. Limb-sparing techniques were developed during the early 1970s.<sup>20,21</sup> and <sup>22,29,30,31,32,33,34,35,36,37,38,39</sup> and <sup>40</sup> Marcove and associates<sup>130,131</sup> and <sup>132</sup> have described cryosurgery for some bony tumors. Enneking and colleagues<sup>101</sup> have formulated means of classifying surgical procedures based on the surgical plane of dissection in relationship to the tumor ( [Table 39.2-4](#)) and the method of accomplishing the removal ( [Table 39.2-5](#)). The scheme summarized below affords meaningful comparisons of various operative procedures and gives surgeons a common language.<sup>69,79,101</sup>

Margin*	Local	Amputation
Intralesional	Curettage or debulking	Debulking amputation
Marginal	Marginal excision	Marginal amputation
Wide	Wide local excision	Wide through bone, amputation
Radical	Radical local resection	Radical disarticulation

\*Tumors are classified by the type of margin achieved and whether they are obtained by a local or ablative procedure.  
(From ref. 19, with permission.)

**TABLE 39.2-4.** Classification of Surgical Procedures for Bone Tumors

Type	Plane of Dissection	Result
Intralesional	Piecemeal debulking or curettage	Leaves macroscopic disease
Marginal	Shell out <i>en bloc</i> through pseudocapsule or reactive zone	May leave either satellite or skip lesions
Wide	Intracompartmental <i>en bloc</i> with cuff of normal tissue	May leave skip lesions
Radical	Extracompartmental <i>en bloc</i> , entire compartment	No residual

(From ref. 19, with permission.)

**TABLE 39.2-5.** Surgical Procedure, Plane of Dissection, and Residual Disease for Musculoskeletal Tumors

**Intralesional:** An intralesional procedure passes through the pseudocapsule of the neoplasm directly into the lesion. Macroscopic tumor remains, and the entire operative field is potentially contaminated. Curettage is an intralesional procedure.

**Marginal:** A marginal procedure is one in which the entire lesion is removed in a single piece. The plane of dissection passes through the pseudocapsule or reactive zone around the lesion. When performed for a sarcoma, it leaves macroscopic disease.

**Wide (intracompartmental):** A wide excision, commonly termed *en bloc resection*, includes the entire tumor, the reactive zone, and a cuff of normal tissue. The entire structure of origin of the tumor is not removed. In patients with high-grade sarcomas, this procedure may leave skip nodules.

**Radical (extracompartmental):** A radical procedure involves removal of the entire tumor and the structure of origin of the lesion. The plane of dissection is beyond the limiting fascial or bony borders.

It is important to note that any of these procedures may be accomplished either by a local (i.e., limb-sparing) procedure or by amputation. Thus, amputation may entail a marginal, wide, or radical excision, depending on the plane through which it passes. Amputation does not necessarily remove all cancer, but it can achieve a specific margin. The local anatomy determines how such a margin can be obtained. Therefore, the aim of preoperative staging is to assess local tumor extent and important local anatomy to enable the surgeon to decide how to achieve a desired margin (i.e., to evaluate the feasibility of one surgical procedure over another). This system allows meaningful comparisons of surgical procedures, end-result reporting, and analysis of combined data. In general, benign bone tumors may be treated adequately by an intralesional procedure (curettage) or a marginal excision. Malignant tumors require either a wide (intracompartmental) or radical (extracompartmental) removal, by an amputation or an *en bloc* procedure. Today, wide excision combined with adjuvant chemotherapy is the treatment for most high-grade bone sarcomas. Radical resections are rare.

## PRINCIPLES AND TECHNIQUES OF LIMB-SPARING SURGERY

Limb-salvage surgery is a safe operation for selected cases ( [Fig. 39.2-2](#)),<sup>23,24,25,26</sup> and [27,133,134](#) and [135](#). This technique may be used for all spindle cell sarcomas, regardless of histogenesis. Approximately 90% of osteosarcomas can be treated successfully with this technique.<sup>24,26,29,33,40,101</sup> Successful management of localized osteosarcomas and other sarcomas requires careful coordination and timing of staging studies, biopsy, surgery, and preoperative and postoperative chemotherapy or radiation therapy.

**FIGURE 39.2-2.** Patient survival after three different types of surgical procedures for osteosarcoma of the distal femur.

## PHASES OF OPERATION

Successful limb-sparing procedures consist of three surgical phases<sup>134</sup>:

1. Resection of tumor: Tumor resection follows strictly the principles of oncologic surgery. Avoiding local recurrence is the criterion of success and the main determinant of how much bone and soft tissue are to be removed.
2. Skeletal reconstruction: The average skeletal defect following adequate bone tumor resection measures 15 to 20 cm. Techniques of reconstruction vary and are independent of the resection, although the degree of resection may favor one technique over another.
3. Soft tissue and muscle transfers: Muscle transfers are performed to cover and close the resection site and to restore motor power. Adequate skin and muscle coverage is mandatory. Distal tissue transfers are not used because of the possibility of contamination.

## GUIDELINES FOR LIMB-SPARING RESECTION

The surgical guidelines and technique of limb-sparing surgery used by the senior author (MM) are as follows<sup>134</sup>:

1. No major neurovascular tumor involvement
2. Wide resection of the affected bone, with a normal muscle cuff in all directions
3. *En bloc* removal of all previous biopsy sites and potentially contaminated tissue
4. Resection of bone 3 to 4 cm beyond abnormal uptake, as determined by CT or MRI and bone scan
5. Resection of the adjacent joint and capsule
6. Adequate motor reconstruction, accomplished by regional muscle transfers
7. Adequate soft tissue coverage

## TYPES OF SKELETAL RECONSTRUCTION

Large skeletal defects are reconstructed after tumor resection by several different modalities. Osteoarticular defects are most often reconstructed by segmental, custom prostheses that are fixed to the remaining intramedullary bone by PMMA ( [Fig. 39.2-3](#)). The newer knee prostheses allow some rotation as well as flexion and extension, this mobility decreases the forces on the bone-cement interface and thus reduces the risk of loosening.

**FIGURE 39.2-3.** Prostheses used in selected patients for skeletal reconstruction: distal femoral prosthesis **(A)**, proximal tibial prosthesis **(B)**, proximal humeral prosthesis **(C)**, proximal femoral prosthesis **(D)**.

There has been increasing interest in applying a porous coating to the prosthesis in the hope of obtaining long-term, perhaps even permanent, fixation. [38,136,137](#) and [138](#) In addition, titanium, a new alloy with superior metallurgical properties, has been introduced. Modular endoprosthetic replacement systems that can be assembled in the operating room are now available and avoid the problem of long delays for custom manufacturing. [38,136](#) Alternative methods of segmental replacement include large autografts or allografts, used to obtain an arthrodesis, or osteoarticular allografts that may replace the affected joint. [34,136,138,139](#) Composite allograft (i.e., allograft placed over a prosthesis) has been used. In general, allografts have been used successfully for low-grade sarcomas and for GCTs of bone that do not require chemotherapy or radiotherapy.

Today, most surgeons prefer endoprosthetic replacements. The modular replacement systems can replace the most commonly affected bones: the proximal femur, proximal humerus, distal femur, and proximal tibia.

### CONTRAINDICATIONS TO LIMB-SPARING SURGERY

#### **Major Neurovascular Involvement**

Although vascular grafts may be used, the adjacent nerves are usually at risk, making successful resection less likely. In addition, the magnitude of resection in combination with vascular reconstruction is often prohibitive.

#### **Pathologic Fractures**

A fracture through a bone affected by a tumor spreads tumor cells via the hematoma beyond accurately determined limits. The risk of local recurrence increases under such circumstances. If a pathologic fracture heals after neoadjuvant chemotherapy, a limb-salvage procedure may be performed successfully. [140](#)

#### **Inappropriate Biopsy Sites**

An inappropriate or poorly planned biopsy jeopardizes local tumor control by contaminating normal tissue planes and compartments.

#### **Infection**

The risk of infection after implantation of a metallic device or an allograft in an infected area is prohibitive. Sepsis jeopardizes the effectiveness of adjuvant chemotherapy.

#### **Skeletal Immaturity**

The predicted leg-length discrepancy should not be greater than 6 to 8 cm, although expandable prostheses have been used with success in this situation. Upper extremity reconstruction is independent of skeletal maturity.

#### **Extensive Muscle Involvement**

Enough muscle must remain to reconstruct a functional extremity.

### RELATIONSHIP OF VARIOUS ASPECTS OF SURGICAL MANAGEMENT TO PROGNOSIS

Makley and coworkers<sup>[141](#)</sup> from the Children's Cancer Study Group reported a randomized study of 166 patients that examined the relationship of various aspects of surgical management to prognosis for disease-free survival. They found no advantage to the various aspects of surgical management, specifically, interval from first symptom to definitive surgery, interval from biopsy to definitive surgery, surgical sequence, type of surgery, or site of primary tumor.

### QUALITY-OF-LIFE CONSIDERATIONS: LIMB-SPARING SURGERY VERSUS AMPUTATION

During the 1990s, as the techniques of limb-sparing surgery were being developed, it had been assumed that such surgery was superior to amputation. Nonetheless, when complications occurred, many surgeons thought that an amputation might have been preferable. Despite the extensive literature on the various chemotherapy regimens, surgical techniques, and limb-sparing surgery, few studies have focused on the patients' evaluation of their overall quality of life. [142,143](#) and [144](#) Two studies that have been published are described here.

Greenberg<sup>[143](#)</sup> from Massachusetts General Hospital and the Children's Hospital/Dana Farber Cancer Center evaluated 62 osteosarcoma survivors at a mean of 12 years from diagnosis. Of 89 survivors contacted, 62 patients (42 women and 20 men) agreed to be interviewed. These patients responded to a comprehensive battery of psychological questions. In general, most survivors were in good mental and physical health. The results are summarized as follows:

1. The reported rates of psychopathology among amputees and those undergoing limb-sparing surgery did not differ significantly.
2. Fertility was not a problem. Twenty-three normal progeny were born after chemotherapy to eight women and the wives of five men. Only two women were considered infertile; both had undergone radiation therapy associated with other childhood cancers.
3. All responders who had undergone limb-sparing surgery believed the effort to save their limb was worthwhile. Twenty patients rated the effort of limb-salvage very worthwhile, (mean 4.5 out of 5). Those whom the attempt at limb-salvage failed rated the effort as 4.0 (not significantly different than the successful group). Those patients who were less satisfied with surgery had secondary amputations.
4. Pain was usually minimal, but when present, was associated only with lower extremity amputation. The pain pattern suggested deafferentation syndromes. No patients undergoing upper extremity limb-sparing procedures had pain as a sequela.
5. Among patients who did not do well, multiple symptoms, family problems, and socioeconomic problems were more common than among patients who fared well.

The authors concluded that attention to the management of depression, treatment of substance abuse, and help with financial difficulties could contribute to the quality of life of patients who underwent limb-sparing surgery or amputation. Pain management, physical and vocational rehabilitation, and sexual counseling may also be of benefit, as may psychotherapeutic counseling when required.

Christ and coworkers<sup>144</sup> evaluated the long-term psychosocial effects of limb-sparing surgery and primary amputation for coping capacity and the degree of psychopathology. The overall incidence of emotional disturbance in the entire osteosarcoma group was no different than the general population. Unlike patients in other studies, those in the group with initial amputations had substantial difficulty maintaining an optimal functioning level. Their difficulty was even greater than that of limb-salvage patients with a compromised outcome, including those with late amputation. Specifically:

1. An amputee was significantly less likely to have married than a limb-spared patient.
2. Coping mechanisms of those with primary amputations were less effective than those patients in the limb-salvage group. This deficit was still evident several years after surgery.
3. Patients who had limb-salvage without later complications were very pleased with their outcome.
4. Good work experience was an important compensation for physical loss.
5. Male dependency needs were often underestimated. Some men were left to manage their own adaptation tasks, whereas for females the opposite was true. Female patients tended to become excessively dependent.
6. Patients reported no difficulty in enjoying sexual activity. The first postsurgical sexual experience was described as no more traumatic than the first experience that required showing the leg (e.g., swimming).

Despite good social support scores, the amputees had higher psychopathology scores than patients who had undergone limb-sparing procedures. The authors concluded that patients undergoing primary amputation need more intensive support than those whose limbs are spared. They recommend an overall approach similar to that for posttraumatic stress disorder.

## AMPUTATIONS

An amputation provides definitive surgical treatment in patients in whom a limb-sparing resection is not a prudent option. A significant number of patients still require amputation, despite the advent of limb-sparing surgery. In contrast to amputations performed for noncancer causes, those for cancer tend to be at a more proximal anatomic level, to occur in younger people (reflecting the incidence of bone sarcomas<sup>145</sup>), and to be technically more difficult.<sup>145</sup> The resultant psychological and cosmetic losses are also more substantial. The amputation experience of the National Cancer Institute since the 1960s has been reviewed; 89% of these procedures were done for sarcomas.<sup>145</sup> Fifty-five percent of the lower extremity amputations were either hip disarticulations or hemipelvectomies. One-half of the upper extremity amputations were interscapulothoracic (forequarter) resections. Osteosarcoma accounted for one-third of all amputations. Large lesions around the pelvis or proximal femur still generally require an amputation, whereas most sarcomas of the shoulder girdle and knee can now be resected. Amputation techniques are well described in the literature.

## CRYOSURGERY

Cryosurgery is the use of liquid nitrogen (temperature,  $-196^{\circ}\text{C}$ ) after curettage of a tumor cavity to kill the remaining tumor cells.<sup>130,131</sup> and <sup>132</sup> Necrosis has been shown to occur between  $-20^{\circ}$  and  $-40^{\circ}\text{C}$ .<sup>145</sup> In general, a double freeze-thaw cycle is required. The aim of this technique is to enhance local tumor control after a careful curettage and thus avoid resection of the involved bone. Cryosurgery was initially developed by Marcove and colleagues<sup>130,132</sup> at Memorial Hospital for treatment of metastatic bone tumors. They have applied this technique to the treatment of aggressive benign tumors, specifically GCTs, and more recently to low-grade sarcomas as well as chordomas. The local recurrence rate after cryosurgery for these aggressive benign tumors has decreased from more than 30% to 40% to between 5% and 10%.<sup>130,131</sup> and <sup>132</sup> This technique is not used for high-grade sarcomas.

## CHEMOTHERAPY FOR BONE SARCOMAS

Before the advent of effective adjuvant chemotherapy, the outlook for patients with osteosarcoma was dismal. The overwhelming majority of patients who presented without evidence of metastases and were treated only with surgery ultimately developed metastases and died.<sup>72,146,147,148</sup> and <sup>149</sup> A review of the literature published in 1972 summarized experience with 1337 patients in 11 studies conducted between 1946 and 1971.<sup>149</sup> Approximately one-half of these patients developed metastatic disease—virtually always in the lung—within 6 months after surgery of the primary tumor, and more than 80% developed recurrent disease. Fewer than 20% of the patients survived 5 years. The inescapable conclusion from these studies is that 80% of patients presenting without overt metastases had microscopic subclinical metastases at the time of diagnosis. Thus, the expectation that fewer than 20% of patients would survive beyond 5 years appeared to be reasonable; this expectation served as the background for trials of adjuvant chemotherapy conducted in the 1970s and 1980s. By the late 1970s, the prognosis for patients with osteosarcoma was improving, largely due to the beneficial effects of adjuvant chemotherapy. However, investigators from the Mayo Clinic and elsewhere challenged the apparent contribution of adjuvant chemotherapy, reporting that the patients' prognoses, with or without adjuvant therapy, had apparently improved over time.<sup>150,151,152,153,154,155</sup> and <sup>156</sup>

Two randomized, controlled trials were conducted in the mid-1980s by investigators of the Multi-Institutional Osteosarcoma Study and from the University of California, Los Angeles to resolve the controversy over the role of adjuvant chemotherapy in osteosarcoma. Both studies included a control group treated only with surgery of the primary tumor and no postsurgical adjuvant chemotherapy. Preliminary and mature results of these studies<sup>157,158,159</sup> and <sup>160</sup> confirm the favorable impact of adjuvant chemotherapy in the treatment of osteosarcoma. Furthermore, life tables of event-free survival for patients in the control groups of these studies recapitulated the historical experience *before* 1970. Results of these trials confirm that the natural history of osteosarcoma has not changed since the 1970s; fewer than 20% of patients treated only with surgery of the primary tumor can be expected to survive relapse-free. The bleak historical experience that served as the background for many uncontrolled adjuvant trials in the 1970s appears to be equally valid as a control for studies in the 1980s, 1990s, and beyond. Microscopic, subclinical metastatic disease can be presumed to exist in virtually all patients at the time of diagnosis. Although the more favorable results from the Mayo Clinic for patients treated without adjuvant chemotherapy remain unexplained, it is apparent from the Multi-Institutional Osteosarcoma Study and University of California, Los Angeles studies that adjuvant chemotherapy has a significant favorable influence on outcome and should, therefore, be recommended for all patients with osteosarcoma.

## ADJUVANT CHEMOTHERAPY

The rationale for adjuvant chemotherapy of osteosarcoma is derived from experimental evidence that microscopic metastatic disease can be eradicated if the treatment is initiated when the total body burden of metastatic tumor is sufficiently low.<sup>161,162</sup> and <sup>163</sup> The strategy of adjuvant chemotherapy after surgical removal of the primary tumor has been applied successfully in the management of other childhood tumors. However, osteosarcoma is a relatively drug-resistant neoplasm, and results of studies of the activity of single agents and drugs in combination against macroscopic osteosarcoma have been disappointing. Few drugs have produced responses in more than 15% of patients, and most responses are partial. Notable exceptions are the responses observed in trials of doxyrubicin,<sup>164</sup> cisplatin,<sup>165,166,167</sup> and <sup>168</sup> high-dose methotrexate (HDMTX) with leucovorin rescue<sup>169,170</sup> and <sup>171</sup> and, more recently, ifosfamide.<sup>172</sup> Logic dictates that the application of agents with only modest activity against macroscopic osteosarcoma should not influence the natural history of this disease. Experimental evidence, however, suggests that eradication of microscopic metastases is possible, even with drugs that are marginally effective or even ineffective against gross macroscopic tumors.<sup>161,162</sup> and <sup>163,173</sup>

The hopeless prognosis for patients with osteosarcoma led to the enthusiastic application of the available agents, singly or in combination, as adjuvant therapy for patients with nonmetastatic osteosarcoma. An apparent improvement in outcome compared with the historical experience without chemotherapy was demonstrated in a number of these trials. Results of some of the important adjuvant chemotherapy trials of the 1970s and early 1980s are summarized in [Table 39.2-6](#). Concerns have been raised that adjuvant chemotherapy for osteosarcoma may delay, but not prevent, relapse. However, the results of many of the adjuvant studies reported in [Table 39.2-6](#), and more recent trials that include presurgical chemotherapy ([Table 39.2-7](#)), some with follow-up beyond 10 years, suggest that life tables of event-free survival have stable plateaus beyond 4 years and that relapses after 3 years are infrequent. The majority of patients surviving 3 years without evidence of recurrence are probably cured.

the contribution of ifosfamide have not yet been analyzed.

## PRESURGICAL CHEMOTHERAPY

Presurgical chemotherapy has been used with increasing frequency in the management of osteosarcoma. This strategy evolved concurrently with limb-sparing procedures. Initial attempts at limb salvage at the Memorial Sloan-Kettering Cancer Center in 1973 involved the fabrication of customized endoprostheses for select patients undergoing *en bloc* resection. While the prosthesis was being made (a process requiring up to 3 months), chemotherapy was administered to prevent tumor progression.<sup>54</sup> Retrospectively, it appeared that patients treated with presurgical chemotherapy fared better than did patients treated during the same period with immediate surgery and postoperative adjuvant therapy.<sup>50</sup>

In studies from the Memorial Sloan-Kettering Cancer Center, responsiveness of the primary tumor to preoperative chemotherapy, assessed by histologic evaluation, was found to be a powerful prognostic factor; unfavorable responders were likely to develop distant metastases despite continued use of chemotherapy with the same agents after surgery.<sup>188</sup> The prognostic significance of tumor response to preoperative chemotherapy has been confirmed in multiple studies,<sup>177,189,190,191,192</sup> and tumor responsiveness has emerged as one of the most powerful prognostic factors in patients with nonmetastatic extremity osteosarcoma.<sup>194</sup>

Although the initial impetus for presurgical chemotherapy was limb salvage, several theoretical advantages of presurgical chemotherapy apply to all patients with osteosarcoma<sup>50</sup> (Table 39.2-8). Because chemotherapy is administered very soon after biopsy and diagnosis, treatment of the micrometastases known to be present in the majority of patients can be instituted early. This offers a substantial advantage over the traditional adjuvant approach, in which the administration of systemic chemotherapy is delayed by 1 month or more for surgery and wound healing. Earlier administration of systemic treatment may reduce the emergence of drug-resistant cells in the micrometastases.<sup>195,196</sup> For the surgeon, presurgical chemotherapy offers some advantages, because it allows time for fabrication of prostheses and may effect a reduction of bulky tumors, thereby increasing the feasibility of limb-salvage surgery in selected patients.

Timing of Chemotherapy	Advantages	Disadvantages
Preoperative	<ul style="list-style-type: none"> <li>Early initiation of systemic therapy against micrometastases</li> <li>Reduced chance of spontaneous emergence of drug-resistant clones in micrometastases</li> <li>Reduction in tumor size, increasing the chance of limb salvage</li> <li>Provides time for fabrication of customized endoprostheses</li> <li>Low chance of viable tumor being present at the time of surgery</li> <li>Individual response to chemotherapy allows selection of different risk groups</li> </ul>	<ul style="list-style-type: none"> <li>High tumor burden less optimal for therapeutic benefit</li> <li>Increased probability in the selection of drug-resistant cells in primary tumor, which may metastasize</li> <li>Delay in definitive control of bulk disease, increased chance for systemic dissemination</li> <li>Psychological trauma of awaiting tumor</li> <li>Risk of local tumor progression with loss of a limb-sparing option</li> </ul>
Postoperative	<ul style="list-style-type: none"> <li>Reduced amount of bulk tumor decreases tumor burden and increases growth rate of residual disease, reducing 5-year-specific survival</li> <li>Some active and quiescent conditions for metastatic foci</li> <li>Decreased probability of achieving a long remission time in the postoperative tumor</li> </ul>	<ul style="list-style-type: none"> <li>Delay of systemic therapy for micrometastases</li> <li>No progression to increase of systemic response</li> <li>Possible spread of viable tumor by surgical manipulation</li> </ul>

TABLE 39.2-8. Considerations for Presurgical and Postsurgical Chemotherapy

## ASSESSMENT OF TUMOR RESPONSE

Assessment of the response of primary tumors has been based on clinical and radiographic data (see [Restaging after Preoperative Chemotherapy](#), earlier in this chapter); however, the histologic appearance of the resected tumor specimen after presurgical chemotherapy has emerged as the standard for measuring response.<sup>98,188,192,197,198</sup> Several systems for grading the effect of preoperative chemotherapy have been proposed, all of which are based on the degree of cellularity and necrosis in the resected specimen. Grading systems are necessarily imprecise and subject to sampling errors; however, with scrupulous attention to adequate sectioning from many sites of the surgical specimen, the degree of response can be reliably and reproducibly assessed. The grading system designed at Memorial Sloan-Kettering Cancer Center by Huvos and colleagues<sup>98,188</sup> has been used widely (Table 39.2-9). Grade III and IV responses, indicating extensive to complete response in the primary tumor, are considered favorable. Grade I and II responses, indicating minimal destruction of the tumor, are unfavorable. In studies using the Huvos grading system, patients with favorable response (grade III or IV) fare extremely well, whereas those with an unfavorable histologic response to preoperative chemotherapy (grade I or II) are likely to develop distant metastases. Thus, patients at high risk for recurrent disease can apparently be identified early in treatment on the basis of poor response to presurgical chemotherapy. The Huvos grading system has served as a model for other systems for grading tumor response.

Grade	Effect
I	Little or no effect identified
II	Area of acellular tumor osteoid, necrotic, or fibrotic material attributable to the effect of chemotherapy, with other areas of histologically viable tumor
III	Predominant areas of acellular tumor osteoid, necrotic, or fibrotic material attributable to the effect of chemotherapy with only scattered foci of histologically viable tumor cells identified
IV	No histologic evidence of viable tumor identified within the entire specimen

(From ref. 98, with permission.)

TABLE 39.2-9. Histologic Grading of the Effect of Preoperative Chemotherapy on Primary Osteosarcoma

Although the predictive value of tumor response to presurgical chemotherapy is now indisputable, a number of problems have surfaced in the application of such response grading to patient management. Different criteria for the definition of favorable and unfavorable response are used in different grading systems, making comparisons among studies difficult. The grading system formerly used by the German Society of Pediatric Oncology (GPO) identifies six categories of response.<sup>197</sup> In the Germany-Austria-Swiss Cooperative Osteosarcoma Study (COSS 80) study conducted by the GPO, favorable response was defined as more than 50% tumor destruction after presurgical chemotherapy; however, in more recent GPO studies, 90% destruction is required. The grading system favored by investigators at the M. D. Anderson Cancer Center divides response into three categories: (1) no effect or doubtful effect with less than 40% tumor destruction; (2) partial effect with 40% to 60% tumor destruction; and (3) definite effect, in which more than 60% of the tumor is destroyed and fibrovascular regeneration is present.<sup>198</sup>

Of particular concern is that an update of the Memorial Sloan-Kettering experience with presurgical chemotherapy suggests that a modification of the Huvos system is in order because the implications of “favorable” and “unfavorable” response to presurgical chemotherapy have changed somewhat. It is apparent that grade IV response is predictive of favorable outcome; however, the outcome of patients with grade III response is not significantly superior to that of patients with grade II response.<sup>199</sup> Thus, only patients who experience a grade IV response to presurgical chemotherapy might be considered as being in the most favorable prognostic group.

Perhaps most problematic are the differences among studies conducted to date in the timing of surgery relative to the initiation of chemotherapy, and especially the variable duration of exposure to chemotherapy *before* definitive surgery and histologic evaluation of the response of the primary tumor. It appears that presurgical chemotherapy regimens of longer duration are associated with a higher proportion of “favorable” responders.<sup>199,200</sup> However, as the duration of presurgical chemotherapy increases, the predictive value of response for outcome may be lost; longer, more intensive presurgical regimens may achieve a greater proportion of favorable responders, but the favorable responses achieved with such regimens may not translate into more favorable outcomes. An analysis from the Memorial Sloan-Kettering Cancer Center suggests that this is indeed the case.<sup>199</sup>

## TAILORING THERAPY

One of the most compelling rationales for presurgical chemotherapy is its use as an *in vivo* drug trial to determine the sensitivity of an individual tumor and to customize postoperative chemotherapy. As noted above, results of studies from the Memorial Sloan-Kettering Cancer Center and elsewhere suggest that patients whose tumors are responsive to presurgical therapy are destined to do well when the same therapy is continued postoperatively. Patients whose tumors are unresponsive to the presurgical regimen have a much less favorable outlook and might benefit from a change in chemotherapeutic agents. This strategy was pioneered at Memorial Sloan-Kettering in the T-10 protocol<sup>51,98</sup> (see Fig. 39.2-4A). Patients were treated preoperatively with HDMTX, the BCD combination, and doxorubicin. Those with favorable (grades III and IV) histologic responses continued to receive the same agents postoperatively (T-10B regimen). Patients demonstrating unfavorable (grades I and II) histologic responses were treated on regimen T-10A, consisting of doxorubicin and cisplatin along with the BCD combination (without HDMTX) postoperatively (see Fig. 39.2-4B). Although only 39% of patients achieved a favorable histologic response to presurgical chemotherapy (51% if only patients younger than 21 years were analyzed), virtually all of the favorable responders were projected to survive free of recurrence.<sup>51,98</sup> The patients whose primary tumors demonstrated an unfavorable histologic response were switched to the cisplatin-containing regimen, and almost 85% were initially projected to remain relapse-free at 3 years. Overall, in preliminary reports, 90% of patients treated on the T-10 regimen with tailored therapy were projected to remain disease-free at 3 years. Moreover, a significant difference in outcome could no longer be detected between those who did and did not respond to presurgical chemotherapy, supporting the contention that poor responders were “salvaged” by the administration of alternative chemotherapy postoperatively. Because of these very favorable preliminary results, the T-10 protocol served as a model for many of the osteosarcoma treatment studies launched in the 1980s and 1990s, virtually all of which featured presurgical chemotherapy and tailoring of treatment on the basis of responsiveness of the primary tumor.

## NEOADJUVANT CHEMOTHERAPY

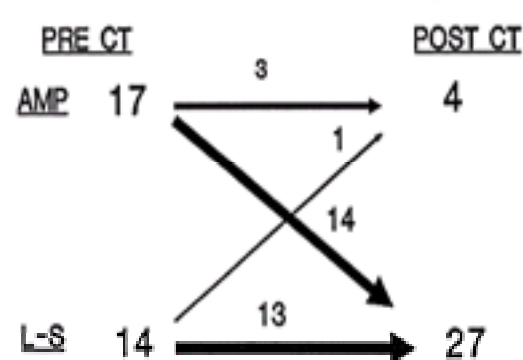

Results reported from representative trials using presurgical chemotherapy are summarized in Table 39.2-7. Responses in the primary tumor have been variable, with favorable responses observed in 30% to 85% of patients. The overall results are excellent but are comparable to adjuvant studies that used regimens of equal intensity without any preoperative chemotherapy (see Table 39.2-6). Furthermore, the importance of custom tailoring of therapy in this strategy remains to be defined. Several trials are pertinent in this regard. The CCG attempted to duplicate the T-10 regimen in a multiinstitutional setting (CCG 782).<sup>192</sup> Results were not as favorable as those initially reported from Memorial Sloan-Kettering Cancer Center; only 28% of the patients demonstrated favorable responses in the primary tumor. These patients fared extremely well (projected 5-year event-free survival, 87%). The remaining poor-responding patients did not benefit from a change in therapy postoperatively and had a less favorable outcome (projected 5-year event-free survival, 49%). Overall, only 56% of patients in the CCG study were projected to remain free of recurrent disease at 5 years—a disappointing result when compared with the initial results reported from Memorial Sloan-Kettering. The COSS 82 trial of the GPO<sup>191</sup> also tested the strategy of tailoring treatment. As in the CCG trial, results suggest that patients demonstrating poor response of the primary tumor are destined to do poorly and that treatment of poor responders with “salvage regimens” (as in the T-10 protocol) does not improve their prognosis. Investigators of the GPO concluded that active agents should not be withheld from the initial therapy of newly diagnosed patients. At the Rizzoli Institute,<sup>177,201</sup> overall results have improved over time, concurrent with the adoption of the strategy of presurgical chemotherapy. However, the Rizzoli investigators conclude that the improvement in prognosis more likely reflects increased effectiveness of the agents used rather than the use of presurgical chemotherapy *per se*, because a group of patients treated concurrently at the same institution without the benefits of presurgical chemotherapy fared just as well as patients treated with presurgical chemotherapy.<sup>201</sup> As in most trials of presurgical chemotherapy, an early trial of presurgical chemotherapy reported from the Rizzoli Institute demonstrated that favorable responders had a better overall outcome; change in the postoperative chemotherapy for poor responders did not alter their unfavorable prognosis. However, in a more recent Rizzoli trial<sup>202</sup> conducted between 1986 and 1990, patients were treated initially with HDMTX, doxorubicin, and intraarterial cisplatin preoperatively. Favorable responders (more than 90% necrosis in their primary tumors) were treated postoperatively with 21 additional weeks of the same agents, whereas unfavorable responders received 30 weeks of chemotherapy, including ifosfamide and etoposide in addition to doxorubicin, cisplatin, and HDMTX. Seventy-one percent of patients in this study achieved a favorable response to presurgical chemotherapy, and 71% of these patients were projected to be disease-free survivors at 5 years. Of note, the poorly responding patients had a projected disease-free survival equal to that of good responders if only patients receiving adequate therapy were considered. This is one of the few studies in which the strategy of salvage chemotherapy for poorly responding patients has been shown to be of benefit.

Perhaps of greatest significance, an update of results of the Memorial Sloan-Kettering Cancer Center studies<sup>199,203</sup> indicates that the very promising preliminary results have eroded with further follow-up. Moreover, no difference in overall disease-free survival is apparent, regardless of whether patients received presurgical chemotherapy. Although histologic response to preoperative chemotherapy strongly predicted subsequent disease-free survival and overall survival, with longer follow-up the Memorial Sloan-Kettering investigators were unable to demonstrate an improvement in disease-free survival for poor responders who received a modification of their postoperative chemotherapy compared with a similar group of patients treated without such tailoring of treatment.<sup>199</sup> In support of these findings, members of the Pediatric Oncology Group reported preliminary results of a randomized trial designed to test the impact of presurgical chemotherapy on outcome of patients with extremity osteosarcoma.<sup>204</sup> The overall event-free survival was identical whether patients were treated with chemotherapy *before* definitive surgery of the primary tumor. Moreover, the overall results of this study were identical to those achieved in a predecessor study (Multi-Institutional Osteosarcoma Study) in which all patients were treated with immediate surgery followed by conventional adjuvant chemotherapy. Thus, it does not appear that the administration of presurgical chemotherapy (with or without individualizing of therapy based on tumor response) *per se* has led to an improvement in the outcome of children with osteosarcoma, at least in terms of rate of cure. Rather, improvements in outcome probably reflect the increasing intensity of the chemotherapy regimens used.

Although responsiveness of the primary tumor to presurgical chemotherapy is a powerful predictor of outcome, the likelihood that an individual patient will respond favorably cannot be predicted at the time of diagnosis. Because a majority of poor responders relapse and modifications of postsurgical chemotherapy do not have an impact on this unfavorable outcome, strategies are needed to predict favorably and poorly responding patients *before* the initiation of therapy, and markers that predict poor overall prognosis independent of response to chemotherapy, so that more aggressive approaches can be used for poor-prognosis patients earlier in treatment. Analysis of tumor DNA content,<sup>205</sup> tumor expression of P glycoprotein [product of the multidrug-resistant (MDR) gene<sup>206</sup>], and other resistance-related proteins<sup>207</sup>; expression of mutant p53<sup>208</sup>; and loss of heterozygosity of the retinoblastoma gene<sup>209</sup> in primary tumors before therapy have been examined as prognostic factors, but results have been inconclusive. Tumor expression of high levels of HER2/erbB-2 has been associated with unfavorable histologic response to chemotherapy and inferior event-free survival.<sup>208,210</sup> If confirmed, these findings suggest a possible intervention with anti-HER2 monoclonal antibodies (Herceptin) for patients whose tumors express high levels of this unfavorable molecular marker.

## INTRAARTERIAL CHEMOTHERAPY

Presurgical chemotherapy may be administered directly into the arterial supply of the tumor to maximize drug delivery to the tumor vasculature ( Fig. 39.2-5).<sup>120,177,193,198,211</sup> Doxorubicin and cisplatin, in particular, have been delivered by prolonged intraarterial infusion to the extremities, and high local drug concentrations have been achieved.<sup>120</sup> However, the rationale for the use of intraarterial therapy is not self-evident for several reasons. Even in the prechemotherapy era, control of the primary tumor in patients with extremity primaries was rarely a problem. Rather, micrometastatic disease present in the lung ultimately killed the patient. Improvements in the outcome of patients with osteosarcoma have resulted directly from improvements of systemic chemotherapy for micrometastatic disease rather than from better local control measures. Thus, strategies that improve drug delivery to the primary tumor at the expense of drug delivery to micrometastatic disease are counterintuitive. Little evidence suggests that responses to intraarterial administration of chemotherapy are superior to those seen with systemic intravenous administration of the same agents, nor has intraarterial chemotherapy improved the proportion of patients suitable for limb-sparing surgery. Finally, the administration of intraarterial chemotherapy in resectable osteosarcoma has waned, and the strategy cannot be recommended for most patients.

**FIGURE 39.2-5.** The impact of neoadjuvant chemotherapy on the choice of surgical procedure: surgical decisions made before receiving chemotherapy (PRE CT) compared with actual surgical procedure [amputation (AMP) vs. limb-sparing surgery (L-S)] performed after induction with intraarterial chemotherapy (POST CT). Initially, 17 of 31 patients (55%) would have required amputation, compared with only 4 of 31 amputations (13%) actually performed (limb salvage rate of 87%). Notice that 14 of 17 patients (82%) were converted from an amputative decision to a limb-sparing procedure. (From Malawer MM, Buch R, Reaman G, et al. Impact of two cycles of preoperative chemotherapy with intraarterial cisplatin and intravenous doxorubicin on the choice of surgical procedure for high-grade bone sarcomas of the extremities. *Clin Orthop* 1991;270:214, with permission.)

## RADIOTHERAPY FOR BONE TUMORS

In keeping with the multidisciplinary, multimodality approach to the treatment of bone tumors, all patients should be evaluated by a radiation oncologist and by an orthopedic and medical (or pediatric) oncologist before decisions are made concerning therapy. Close communication between members of the care team is crucial. Tumors of the axial skeleton and facial bones are treated by a combination of limited surgery and radiotherapy. Ewing's sarcoma and peripheral primitive neuroectodermal tumors of bone may be managed by definitive radiation treatment, complete surgical excision, or combined surgical and radiotherapy approaches and are discussed in [Chapter 39.1](#). In general, radiation therapy is not used in the primary treatment of osteosarcoma. Radiation therapy is used for patients who have refused definitive surgery, require palliation, or have lesions in axial locations.

### TREATMENT PLANNING

Optimal radiotherapy of bone tumors requires careful planning ([Table 39.2-10](#)). Such planning begins with tumor localization and accurate definition of the clinical and radiographic extent of tumor as well as of all tissue at risk for microscopic involvement. Precise, three-dimensional definition is required. This evaluation is identical to that done for surgical evaluation (see [Preoperative Evaluation](#), earlier in this chapter). Using these composite studies, the maximal tumor dimensions are established.

---

Tumor localization
Simulation
Patient immobilization
Megavoltage irradiation
High radiation dose
Large treatment fields, with use of shrinking and cone-downed fields
Beam-shaping devices
Beam modifiers—compensators, wedges
Multiple fields treated each day

---

**TABLE 39.2-10.** Guidelines for Optimal Radiation Therapy in the Treatment of Bone Sarcomas

With the clinical physicist, decisions are then made concerning the optimal choice of radiation beam (e.g., photon, electron), technique (external beam, brachytherapy, intraoperative therapy), beam modifiers (compensators, wedge filters), and immobilization system. All patients should undergo simulation and be treated with megavoltage therapy units. No role for orthovoltage (low-kilovoltage x-ray) exists in the management of primary tumors of bone.

Patient immobilization is essential to optimal radiotherapy. The patient should be placed in a comfortable position on the treatment table. The precise patient set-up should be planned using three points for reproducibility. <sup>212</sup> Immobilization devices, such as casts, shells, vacuum pillows, and sandbags, are frequently necessary. <sup>213</sup> Molding techniques that require a cast of the anatomic site to be treated are generally preferred when treatment fields are complex and the radiation course is lengthy.

### DOSE AND VOLUME CONSIDERATIONS

Large treatment volumes that include the entire clinical and radiographic extent of tumor plus a generous margin for microscopic or subclinical extension of disease are needed. For tumors that tend to spread along the medullary canal (lymphoma, Ewing's sarcoma), the standard radiation field in the past included the entire bone, with a boost of radiation to the area of bulky disease. However, current practice suggests that radiation confined to the involved area may be sufficient for small round cell bone tumors that have responded to induction chemotherapy. If large fields are needed, it is desirable to use an extended source-to-skin distance to enable the entire radiation field to fit into one portal. If extended distances are not possible and two radiation fields must abut, the abutment must pass through areas of microscopic, rather than gross, disease. Match lines should be routinely moved every 10 Gy.

The irradiated field should encompass at least the volume of tissue that would be resected, plus an allowance of approximately 2 cm for patient movement and dose fall-off at the margin of the field. Extremity fields should be planned with a strip of tissue deliberately out of the beam to allow for lymphatic and venous return and to decrease morbidity. This nonirradiated strip should overlie the lymphatic drainage, which is located medially in the extremity.

Because large doses often are necessary for treatment of malignant bone tumors, a shrinking field technique is recommended, which allows treatment to a large volume of tissue involved by subclinical disease with a moderate radiation dosage, whereas the area of gross tumor is treated with a larger, sterilizing dose.

Additional principles involve using multiple beam-shaping devices so that shaped fields can be designed to conform to individual tumor volume and anatomy. Multiple fields should be used to optimize the radiation dosage, and all fields must be treated every day. Beam modifiers, including compensating filters and wedge filters, should be used to account for individual variations in patient thickness. Three-dimensional conformal radiation techniques using multiple fields, multileaf collimation, and intensity-modulated beams are useful aids to optimize the homogeneity of the dose within the target volume while sparing adjacent, critical normal structures. When chemotherapy, such as Adriamycin and dactinomycin, and radiotherapy are used, it is important to avoid concomitant administration of drugs that may act as radiation sensitizers to normal tissue.

### COMPLICATIONS OF RADIATION

The complications of radiation are related directly to treatment dose and volume. Reactions that occur during the early stages of treatment usually are reversible and not of major significance. These include erythema, dry desquamation of the skin, and epilation. More serious late reactions may include fibrosis, contracture, atrophy, impaired growth, secondary fracture, and radiation-induced neoplasm. When pelvic treatment is necessary in young women, it is important to consider ovarian transposition whenever possible. Techniques to move the small bowel out of the pelvis are useful, as is avoiding treatment of the entire bladder if cyclophosphamide or ifosfamide is also being used. Fibrosis and contracture can be minimized—or possibly avoided—by embarking on an active physical therapy program during radiation therapy; such a program should be continued in the postradiation therapy follow-up period. Whenever possible, treating across a joint space and treating an open epiphysis should be avoided. For tumors of weight-bearing bones, partial weight bearing and protective bracing are important until reossification occurs.

## BENIGN BONE TUMORS

### SOLITARY AND MULTIPLE OSTEOCHONDROMAS (EXOSTOSIS)

Osteochondroma is the most common benign bone tumor. The tumors characteristically are sessile or pedunculated, arising from the cortex of a long tubular bone adjacent to the epiphyseal plate. Osteochondromas are usually solitary, except in multiple hereditary exostosis. Plain radiographs are usually diagnostic, and no

further tests are required. Sessile osteochondromas are difficult to diagnose, especially when they occur in unusual sites, such as the distal posterior femur, where they must be differentiated from a parosteal osteosarcoma. Bone scintigraphy and CT are helpful in distinguishing between the two.

Osteochondromas grow with the individual until skeletal maturity is reached. Growth of an osteochondroma during adolescence does not, therefore, signify malignancy. Pain is not a sign of malignancy in childhood or adolescence, although in adulthood it is a significant warning sign. Pain in a child may be due to local bursitis, mechanical irritation of adjacent muscles, or pathologic fracture.

Between 1% and 2% of solitary osteochondromas undergo malignant transformation; patients with multiple hereditary exostosis are at higher risk. <sup>2,4,57,58</sup> Malignant tumors arising from a benign osteochondroma are usually low-grade chondrosarcomas. Proximal osteochondromas are more likely than distal ones to undergo malignant transformation. In general, surgical removal is recommended only for symptomatic osteochondromas and for those arising along the axial skeleton or pelvic or shoulder girdle.

### SOLITARY AND MULTIPLE ENCHONDROMAS

Enchondromas are composed of mature hyaline cartilage that arises within a bone. They may be solitary or multiple (Ollier's disease) and have been reported in most bones.<sup>3,4</sup> Their biologic potential is often over- or underestimated. In general, pathologic interpretation of cartilage tumors is more difficult than that of other bone tumors; it is particularly difficult to differentiate a benign enchondroma from a grade I chondrosarcoma. <sup>10,11,214</sup> Malignant transformations do occur, but the rate is difficult to determine. <sup>215</sup> Lesions of the pelvis, femur, and ribs are generally at higher risk for malignant transformation than are lesions at more distal sites.

Pain is a sign of local aggressiveness and possible malignancy. Enchondromas of the hands and feet are benign, irrespective of pathology, <sup>3</sup> whereas cartilage tumors of the pelvic or shoulder girdle are often malignant, even though the histology appearance is benign. Plain radiographs may be helpful in making this distinction. Radiographic scalloping is a sign of local aggressiveness. Bone scintigraphy is not helpful in differentiating a low-grade chondrosarcoma from an active enchondroma. Patient age is an important indicator of possible malignancy; enchondromas rarely undergo malignant transformation *before* skeletal maturity. Painful, histologically benign-looking proximal enchondromas in adults are often malignant, despite their histology. Thus, correlation of symptoms, plain radiographic findings, and histology is crucial.

### CHONDROBLASTOMA, OSTEOLASTOMA, AND OSTEIOD OSTEOMA

Chondroblastoma and osteoblastoma are characterized by immature but benign chondroid or osteoid production, respectively. Both may undergo malignant transformation in rare cases. <sup>59,216</sup> Osteoid osteomas are smaller than 1 cm, painful, bone-forming tumors that are always benign. It is essential that the oncologist be aware of these entities and be able to differentiate them from their malignant counterparts, chondrosarcoma and osteosarcoma. Chondroblastomas appear radiographically in the epiphysis of a child; conversely, primary chondrosarcomas are rarely epiphyseal and occur in adults. Although osteoblastomas may be found in any bone, one-half of them are in the spine and skull. Osteoblastomas must be differentiated from osteosarcomas and osteoid osteoma.

Both chondroblastomas and osteoblastomas are considered aggressive, benign lesions with a high recurrence rate after simple curettage. <sup>2,3</sup> and <sup>4,216</sup> Local control can be achieved by primary resection; however, routine resection cannot be recommended for tumors adjacent to a joint. Marcove et al. <sup>131</sup> report a 5% to 10% local recurrence rate when curettage is combined with cryosurgery. This method has obviated resection and extensive reconstruction in select patients. Osteoid osteoma is treated by simple excision. In a few cases, nonsteroidal antiinflammatory drugs have proven curative when continued for a minimum of 1 year. Because surgical removal is the treatment of choice for these benign bone lesions, the role of radiotherapy is limited. For nonresectable tumors, radiotherapy has been associated with long-term control ([Table 39.2-11](#)), but most radiation oncologists do not believe that radiation plays a role in the management of these conditions. <sup>214,217</sup>

Tumor	Radiation Dose	Comments
Osteoblastoma/osteoid osteoma	30 Gy	Role of radiation is limited and controversial.
Aneurysmal bone cyst	30-36 Gy	Megavoltage radiation in conventional fractionation and low total dose is effective in reducing recurrence and stability is associated with long-term complication.
Langerhans' cell histiocytosis	6-10 Gy in 10-15 Gy fractions	Low doses of radiation have a high likelihood of local control if measured and not time limited.
Cordoma/mucous osteoma	40-60 Gy	A rare vascular abnormality that may be managed by surgery or radiotherapy.

**TABLE 39.2-11.** Radiation Guidelines for Benign Bone Lesions

### ANEURYSMAL BONE CYSTS

Aneurysmal bone cysts (ABCs) are benign tumors of childhood, occurring typically *before* skeletal maturity. <sup>2,3</sup> and <sup>4</sup> They never become malignant. They often involve the metaphyseal regions of the long bones or the vertebrae. Radiographically, ABCs are eccentric, lytic, and expansile, characterized by cortical destruction and periosteal elevation. They can grow rapidly and appear extremely aggressive, and distinguishing them from a primary malignancy may be difficult. Differential diagnosis includes GCT and telangiectatic osteosarcoma. ABCs contain some osteoid; however, careful examination reveals this to be reactive and not neoplastic. Approximately one-third arise in conjunction with another bony neoplasm. <sup>216,218</sup> The classic treatment is simple curettage and bone graft, which has a recurrence rate of 20% to 35%. <sup>4</sup> Wide curettage may decrease the recurrence rate to approximately 10%. Marcove and colleagues <sup>130,131</sup> and <sup>132</sup> recommend curettage and cryosurgery as the primary treatment. Primary resection of tumors involving weight-bearing bones is not warranted. Expandable bones, especially the ribs and fibula, may be treated by primary resection. The Mayo Clinic reviewed its experience of 238 patients with ABCs. <sup>219</sup> Eighty percent of those lesions involved long bones. The investigators noted that CT and MRI may show characteristic septations or fluid-fluid levels. Of 153 patients treated, 19% had recurrence after curettage. The high-risk period for local recurrence was the first 2 years. The most significant clinical problem is deciding whether a lesion is an ABC or a telangiectatic osteosarcoma.

Radiation therapy is recommended in surgically inaccessible sites. <sup>3,217,218</sup> Megavoltage doses (25 to 30 Gy in 18 to 24 days) have been associated with a decrease in local recurrence from 32% to 8% and are generally recommended. <sup>98,214,218,220,221</sup> and <sup>222</sup>

### DESMOPLASTIC FIBROMA

Desmoplastic fibroma is an extremely rare bone tumor; only 80 cases have been reported. <sup>216</sup> It is characterized by abundant collagen formation and a fibrous stroma without evidence of mitosis or pleomorphism. It presents radiographically as an osteolytic lesion with well-defined margins. Most important in differential diagnosis is primary fibrosarcoma of bone. Treatment is *en bloc* resection; curettage has a significant rate of local recurrence. Radiation therapy has been suggested when surgery is not a reasonable option, but dose-response data are not available. <sup>223</sup>

### LANGERHANS' CELL HISTIOCYTOSIS

*Langerhans' cell histiocytosis* is a more descriptive and recently accepted term to describe the disease commonly referred to as *histiocytosis X*. The solitary or multifocal osseous lesions (Greenberger stage IA and B) were formerly referred to as *eosinophilic granuloma*.<sup>224</sup> This condition can be difficult to diagnose and may mimic radiographically a primary bone malignancy.

Almost any bone can be involved. Radiographically, the lesions appear as lytic, destructive defects, with ill-defined margins. Periosteal elevation occurs in one-half of

all cases. This combination of characteristics strongly resembles that of Ewing's sarcoma or osteomyelitis. When the disease arises in a flat bone, specifically the pelvis, there may be a large soft tissue component. Solitary lesions are treated by surgical curettage.

## MALIGNANT BONE TUMORS

### CLASSIC OSTEOSARCOMA

Osteosarcoma is a high-grade, malignant spindle cell tumor that arises within a bone. Its distinguishing characteristic is the production of "tumor" osteoid or immature bone directly from a malignant spindle cell stroma.<sup>2,3,60,225</sup>

#### Clinical Characteristics

Osteosarcoma typically occurs during childhood and adolescence. An epidemiologic study from the Swedish Cancer Institute documented that the mean and median age of patients with osteosarcoma has increased since 1971.<sup>226</sup> Investigators evaluated 227 patients from 1971 to 1984 and reported the peak incidence to be between 10 and 19 years of age but noted the mean and median values to be 29 and 20 years, respectively. The overall incidence—2.1 cases per million people per year—has not changed. When osteosarcoma occurs in patients older than 40 years, it is usually associated with a preexisting condition, such as Paget's disease, irradiated bones, multiple hereditary exostosis, or polyostotic fibrous dysplasia.<sup>2,225,226,227,228,229</sup> and <sup>230</sup> Bones of knee joint and the proximal humerus are the most common sites, accounting for 50% and 25%, respectively, of all osteosarcomas.<sup>216</sup> In general, 80% to 90% of osteosarcomas occur in the long tubular bones<sup>2,4,57,227,231,232</sup> and <sup>233</sup>; the axial skeleton is rarely affected. Fewer than 1% are found in the hands and feet.<sup>2</sup>

With the exception of serum AP levels, which are elevated in 45% to 50% of patients, laboratory findings are usually not helpful.<sup>231</sup> Furthermore, elevated AP per se is not diagnostic, because it is also found in association with other skeletal disease. Pain is the most common complaint. Physical examination demonstrates a firm, soft tissue mass fixed to the underlying bone with slight tenderness. No effusion is noted in the adjacent joint, and motion is normal. Incidence of pathologic fracture is less than 1%. Systemic symptoms are rare.

#### Radiographic Characteristics

Typical findings are increased intramedullary radiodensity (due to tumor bone or calcified cartilage), an area of radiolucency (due to nonossified tumor), a pattern of permeative destruction with poorly defined borders, cortical destruction, periosteal elevation, and extraosseous extension with soft tissue ossification.<sup>231,232</sup> and <sup>233</sup> This combination of characteristics is not seen in any other lesion. Wilner classified 600 radiographs of osteosarcoma seen at the Memorial-Sloan Kettering Cancer Center into three broad categories<sup>233</sup>: sclerotic (32%), osteolytic (22%), and mixed (46%). Although no statistically significant difference was found in overall survival rates among these types, the patterns are important to recognize. The sclerotic and mixed types offer few diagnostic problems. Errors of diagnosis most often occur with pure osteolytic tumors. The differential diagnosis of osteolytic osteosarcoma includes GCT, ABC, fibrosarcoma, and MFH.<sup>234</sup> In a series of 305 osteosarcoma cases, DeSantos and Edeiken<sup>234</sup> reported that 42 (13.5%) were purely lytic. Most commonly, they presented as ill-defined lesions with a moderate to large soft tissue component. Nine of the lesions had benign radiographic features.

#### Clinical and Prognostic Considerations

Before the era of adjuvant chemotherapy, treatment consisted of amputation. Metastasis to lungs and other bones generally occurred within 24 months. A large number of series shows an overall survival of 5% to 20% at 2 years<sup>72,73,74</sup> and <sup>75</sup> (Fig. 39.2-6). This pattern has been altered by adjuvant chemotherapy and aggressive thoracotomy for pulmonary disease.<sup>46,103,235</sup> Metastases may now appear at less common sites, and disease-free intervals are longer.<sup>235</sup> In 1968, Lockshin and Higgins<sup>236</sup> reviewed the experience of 100 authors over 50 years and concluded that there was no significant difference between survival rates of patients with the three histogenic subtypes (osteoblastic, chondroblastic, and fibroblastic) or between patients whose lesions had a different radiographic appearance (sclerotic, osteolytic, or mixed).<sup>236</sup> Likewise, tumor size, patient age, and degree of malignancy did not correlate with survival. The most significant variable was anatomic site. Patients with pelvic and axial lesions had a lower survival rate than those with tumors of the extremities, probably due to surgical inaccessibility and incomplete removal. Patients with tumors of the tibia had a significantly higher survival rate than those with tumors of the distal femur (35% vs. 16%). Larsson and colleagues,<sup>237</sup> using a multifactorial analysis of all patients from the Swedish Cancer Registry between 1958 and 1968, similarly concluded that patients with tibial lesions had a better survival rate than those with femoral lesions (38.1% vs. 15.1%), due to the fact that the former were less advanced at the time of treatment.

**FIGURE 39.2-6.** The historical survival curve for 145 patients with osteosarcoma treated by surgery alone at Memorial Sloan-Kettering Cancer Center as reported by Marcove and associates. (From Marcove RC, Mike V, Hajek JV, et al. Osteogenic sarcoma under the age of 21. *J Bone Joint Surg Am* 1966;48:1, with permission.)

Marcove et al.,<sup>72</sup> reviewing 145 patients younger than 21 years of age who underwent surgery without adjuvant chemotherapy at Memorial Sloan-Kettering, noted no statistically significant differences with regard to race, gender, or duration of symptoms (see Fig. 39.2-6). Younger patients developed metastases sooner, but this made no difference in overall survival. Location had no impact on the 5-year survival rate. Brostrom and coworkers<sup>238</sup> evaluated 52 patients treated by surgery alone. They studied tumor size and site and reported that patients with distal lesions measuring smaller than 10 cm had a significantly higher survival ( $P < .01$ ) than those with proximal lesions larger than 10 cm (43% vs. 12%, respectively). More recently, Hudson and associates<sup>239</sup> reported on 98 patients treated at the M. D. Anderson Cancer Center with three different protocols. Tumor size ( $P = .04$ ) and the percentage of tumor necrosis induced by induction therapy ( $P = .01$ ) were the most important prognostic factors.

Baldini et al.<sup>240</sup> from the Rizzoli Institute have reviewed the prognostic factors of osteosarcoma patients treated with preoperative chemotherapy. This is one of the more recent studies that attempts to determine prognostic factors when chemotherapy is administered, in contrast to older studies, which evaluated prognostic factors before chemotherapy. Baldini et al. evaluated 160 patients with stage II high-grade osteosarcomas at a single institution. One hundred forty-two patients were treated by a limb-sparing procedure, and 18 underwent amputation. Tumor size was not found to be associated with a histologic response to chemotherapy. One-hundred fifteen patients had a good response (more than 90% necrosis), and 40 had a poor response. Larger tumors were not found to be associated with a lower likelihood of response to chemotherapy. No association was found between the size of the tumor and the event-free survival of the patients, as determined by univariate and multivariate analysis.

#### Changing Pattern of Metastasis

The classic pattern and time frame of metastatic dissemination of osteosarcoma has been somewhat modified by the use of adjuvant chemotherapy and thoracotomy. Bacci and coworkers<sup>241</sup> evaluated the pattern of metastatic spread of osteosarcoma in 193 patients at the Rizzoli Institute. Thirty patients who were treated with surgery alone were compared to 163 patients who underwent adjuvant chemotherapy. No difference was found in sites of first relapse; approximately 90% of cases in both groups occurred in the lungs. After chemotherapy, extrapulmonary spread occurred in 10% of cases, usually to bony sites. Simultaneous bone and lung

metastases occurred in approximately 2%. The time to metastases differed (surgery alone was 13 months vs. adjuvant chemotherapy at 8 months), and the number of metastatic nodules were reduced. In general, lung metastases appeared later and were fewer in number after adjuvant chemotherapy but with variable difference on extrapulmonary or bony spread. The authors of this study concluded that the alteration of metastatic spread permitted surgical resection of pulmonary metastases in a larger number of patients (51% vs. 29%).

### Alkaline Phosphatase

Serum AP level is an important biologic marker of tumor activity in patients with osteosarcoma.<sup>242,243</sup> The early studies of the relationship of AP activity and survival were evaluated in several studies *before* the introduction of adjuvant chemotherapy (i.e., in patients treated with surgery alone).

The prognostic significance of AP has more recently been evaluated in conjunction with neoadjuvant chemotherapy. Bacci and coworkers evaluated patients treated for osteosarcoma between 1972 and 1989.<sup>244</sup> The study demonstrated that for patients with osteosarcoma of the extremities, presurgical serum AP levels are useful prognostic markers in patients treated with adjuvant or neoadjuvant chemotherapy. Specifically, the study demonstrated that patients presenting with nonmetastatic osteosarcoma and an elevated serum AP level had a worse prognosis than those with normal values (55% of relapses versus 26%). Among those patients determined to have elevated pretreatment serum AP levels, there was a correlation showing that the higher the serum levels of AP, the greater the risk was for relapse. Patients with elevated pretreatment serum AP who experienced relapse or recurrence had a poorer disease-free survival when compared with individuals who relapsed and had normal pretreatment serum AP levels.

### Surgical Resection of Localized Extremity Osteosarcoma

Before the early 1980s, treatment for localized osteosarcoma was amputation one joint above the tumor-containing bone or, occasionally, transmedullary amputation.<sup>2,3,72,73</sup> and <sup>74</sup> Since the early 1980s, parallel developments in radiology, orthopedics, and oncology have made limb-sparing procedures an option in 50% to 80% of patients.<sup>20,21,22,23,24,25,26,27,28,29,30,31,32,33</sup> and <sup>34</sup> A significant impetus for these developments was the introduction of effective chemotherapeutic agents in the early 1970s.<sup>48,49,50,51,52</sup> and <sup>53</sup>

Springfield and coworkers<sup>245</sup> from the University of Florida compared limb-sparing surgery with amputation in 53 patients with stage IIB osteosarcoma. For ethical reasons, the patients were not randomized. No difference in survival was found between amputation and resection or between radical resection and a wide surgical margin. Three local recurrences were reported. The investigators concluded that a wide surgical resection was adequate for local control. In general, they recommended amputation if the major neurovascular bundle was involved. They concluded that local recurrence was due to an extremely aggressive tumor or to skip metastases.

Rougraff and colleagues<sup>142</sup> updated a combined study from the Musculoskeletal Tumor Society of 227 patients from 26 institutions treated for osteosarcoma of the distal femur. One hundred nine patients (48%) were alive at an average of 11 years after surgery. No differences in local recurrence, overall survival, or duration of disease-free survival were noted between amputation and limb-sparing groups. The local recurrence rate (10%) was identical for above-knee amputation and limb-sparing surgery. The most common causes of failed limb-sparing procedures were infection and local recurrence. Rougraff et al. concluded that the type of surgery did not affect outcomes. No difference was noted among patients treated with endoprostheses, allografts, composites, rotationplasties, and arthrodesis; however, the numbers of patients in those categories were small.

### Local Recurrence, Tumor Necrosis, and Surgical Margins

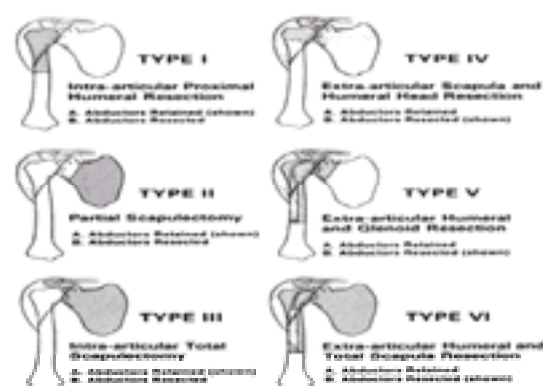

During the 1990s, many surgeons intuitively believed that a patient with a good response to neoadjuvant chemotherapy was more likely to undergo a limb-sparing procedure safely than a patient with a poor response. A relationship appears to exist between the safety of limb-sparing resection and the surgical margins achieved with neoadjuvant chemotherapy. Patients whose lesions respond well to chemotherapy are less likely to develop local recurrence than those whose lesions respond poorly.<sup>246</sup> Picci and coworkers<sup>246</sup> from the Rizzoli Institute analyzed the relationship between local recurrence after neoadjuvant chemotherapy, surgical margin obtained, and tumor response as demonstrated by percentage of tumor necrosis. Of 355 patients, 7% developed local recurrences. The mean time to local recurrence was 13 months from diagnosis (range, 2 to 56 months). Eighty-nine percent of the local recurrences developed within 18 months of the diagnosis. Of 237 patients in the group who had undergone a limb-sparing procedure, 23 (10%) developed a local recurrence. The types of surgical margins obtained and their respective local recurrence rates were as follows: wide margin, 3%; marginal margin, 29%; intralesional margin, 36%; contaminated margin, 15%.

When the type of surgical margin and the response to chemotherapy were analyzed together, differences in outcome were dramatic. The patients with poor necrosis (<60%) and wide margins had ten times the risk of local recurrence. The worst combination was poor necrosis and less than wide margins.

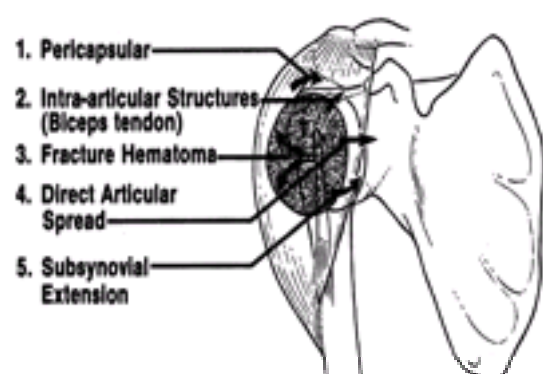

### Treatment by Anatomic Site

The unique features of evaluation, management, and resection of tumors of the most common anatomic areas, the shoulder and knee, are described and illustrated in this section.

**SHOULDER GIRDLE.** A surgical classification for shoulder girdle resections has been described and is shown schematically in [Figure 39.2-7](#).<sup>247,248</sup> This classification is useful for all limb-sparing procedures of the shoulder girdle. It is recommended that osteosarcomas arising from the proximal humerus be treated by a type VB resection (see [Fig. 39.2-7](#)). [Figure 39.2-8](#) illustrates the various means by which a sarcoma may involve the shoulder joint.

**FIGURE 39.2-7.** Schematic of proposed surgical classification of shoulder girdle resections. In general, types I to III are for benign or low-grade tumors, and types IV to VI are for high-grade tumors. A and B denote the status of the abductor mechanism: A is intact, and B is partially or completely excised. Types I to III and types IV to VI are intraarticular and extraarticular resections, respectively.

**FIGURE 39.2-8.** Mechanisms of local tumor spread for sarcomas of the shoulder. (From Malawer MM, Buch R, Reaman G, et al. Impact of two cycles of preoperative chemotherapy with intraarterial cisplatin and intravenous doxorubicin on the choice of surgical procedure for high-grade bone sarcomas of the extremities. *Clin Orthop* 1991;270:214, with permission.)

**PROXIMAL HUMERUS.** Adequate resection of the proximal humerus requires removal of 15 to 20 cm of the humerus and shoulder joint with the deltoid, rotator cuff, and portions of the biceps and triceps muscles<sup>249</sup> (Fig. 39.2-9). The procedure involves suspension of the arm, motor reconstruction, and provision of adequate soft tissue coverage.

**FIGURE 39.2-9.** Osteosarcoma of the proximal humerus. This patient was placed in a shoulder splint and given three cycles of chemotherapy in the hope of avoiding a forequarter amputation. Due to the good clinical and radiographic response, this patient underwent a limb-sparing resection (type V).

Proximal humeral lesions should not be biopsied through the deltopectoral interval. Biopsy under fluoroscopy through the anterior one-third of the deltoid by a trocar is preferred. Angiography is the most useful preoperative study. If the neurovascular bundle is clear, resection is feasible.

Extraarticular resection of the glenohumeral joint by medial scapulosteotomy is safer than intraarticular resection. A custom prosthesis is used for reconstruction. Soft tissue reconstruction and suspension are essential to avoid postoperative pain, instability, and fatigability.<sup>249</sup> Suspension by Dacron tape and muscle transfer is effective. Hand and wrist function is normal after resection. Shoulder motion is minimal, but stable, and scapulothoracic motion provides some internal and external rotation. Cosmesis is acceptable and can be enhanced with use of a shoulder pad.

Alternatively, resection of the proximal humerus for osteosarcomas can be performed by an intraarticular resection that preserves the glenoid and the adjacent deltoid muscle. The problems associated with this procedure include significant local recurrence rates and instability of the reconstructed prosthesis or allograft. When the glenoid and deltoid are preserved in this procedure, minimum margins are obtained along the shoulder joint, the deltoid muscle, and the axillary nerve. Because of this serious inherent drawback, this technique is not recommended by the senior author (M. M.).

**DISTAL FEMUR.** Adequate *en bloc* resection includes 15 to 20 cm of the distal femur and proximal tibia and portions of the adjacent quadriceps.<sup>134</sup> Biplane angiography is crucial to determine popliteal vessel involvement. Biopsy must avoid the sartorial canal and the knee joint. Contraindications to resection are popliteal vessel involvement, massive soft tissue contamination from previous biopsy, and fracture. Large tumors requiring removal of the entire quadriceps or hamstrings can be adequately reconstructed by an arthrodesis.

#### **PROXIMAL TIBIA.**

Today, limb-sparing procedures often are feasible for tumors of the proximal tibia after induction chemotherapy.<sup>250</sup> It is more difficult to obtain an adequate margin of resection and a good functional result with lesions of the proximal tibia, which tend to have a higher incidence of local complications than do distal femoral tumors. These problems are directly related to the anatomic constraints: minimal adjacent soft tissue and the normal subcutaneous location of the medial tibial border. It is extremely important that the biopsy be small and that it avoid the knee joint. A core biopsy of medial flare is preferred to avoid contamination of the anterior musculature and peroneal nerve.

The popliteus muscle adjacent to the posterior aspect of the tibia prevents direct tumor involvement of the neurovascular bundle.<sup>250,251</sup> Lateral angiography is essential to demonstrate this interval. Tumor extension often involves the tibiofibular capsule.<sup>250</sup> Extraarticular resection of the proximal tibiofibular joint *en bloc* with the tibia is required to obtain a safe margin. The average resection length is 15 to 18 cm. Reconstruction is achieved by prosthetic replacement, arthrodesis, or allograft. The medial gastrocnemius is routinely transferred to provide soft tissue coverage of the reconstructed area.<sup>252</sup> Postoperative management consists of a long leg cast for 2 to 4 weeks to allow the extensor muscles to heal. Rehabilitation emphasizes knee extension, but not flexion, for a maximum of 2 to 3 months.<sup>250</sup>

#### **PROXIMAL FIBULA.**

Tumors of the proximal fibula require the same evaluation as do proximal tibial lesions.<sup>253</sup> Unique considerations are early soft tissue extension, proximity to the lateral tibial condyle, necessity of ligation of the anterior and peroneal arteries, sacrifice of the peroneal nerve, and tumor infiltration of the tibiofibular joint capsule. Contraindications to resection are direct tibial involvement, an anomalously absent posterior tibial artery, and intraarticular knee joint extension. Adequate resection includes the fibula, the tibiofibular joint, the anterior and lateral muscle compartments, and a portion of the lateral gastrocnemius muscle. After surgery, the only functional deficit is footdrop, which is treated by an orthosis. Knee function is normal.<sup>253</sup>

### **OSTEOSARCOMA OF THE PELVIS AND PROXIMAL FEMUR**

Osteosarcomas of the pelvis and proximal femur are less common than those occurring at other anatomic areas. They account for 10% and 5%, respectively, of all osteosarcomas.<sup>216</sup> Tumors arising from these structures are often large, involve important structures, and are difficult to resect. Hemipelvectomy often is required for pelvic tumors, whereas modified hemipelvectomy is used for tumors of the proximal femur.<sup>145</sup> The limb-sparing options, when feasible, are all functionally superior to amputation at this level.<sup>254,255</sup> A poorly planned biopsy often contaminates the extrapelvic structures, typically making a hemipelvectomy the only safe option. Detailed anatomic and surgical considerations are discussed in the section on chondrosarcomas (see [Chondrosarcoma](#), later in this chapter), which often arise in these sites.

Fahey and Spanier<sup>256</sup> reviewed 25 patients with osteosarcoma of the pelvis treated at the University of Florida between 1967 and 1990 and described their biologic behavior, growth, and histologic and vascular findings. Common problems included delay in diagnosis, widespread invasion into major pelvic veins, microscopic foci of tumor in otherwise normal tissue, and extension into adjacent (and other) pelvic structures. They noted marked differences in obtaining tumor-free margins with surgery. Eighteen patients underwent surgery (ten hemipelvectomies and eight limb-sparing resections). Only two of ten hemipelvectomy patients obtained wide margins, and only two of the eight limb-sparing patients obtained negative margins. Major intraoperative complications occurred in 11 patients. Intraoperative blood loss exceeded 10 L in six patients. An unexpected intraoperative finding was obvious tumor invasion into the large veins in nine patients: the iliac veins in two patients, the inferior vena cava in three patients, and unnamed veins in four patients.

The high incidence of venous invasion requires that the iliac vessels be evaluated preoperatively and intraoperatively. Radiographic staging studies should include a thorough evaluation of the iliac vessels. This can best be performed by CT, MRI with contrast, and pelvic venography. Survival for patients with pelvic osteosarcoma is dismal. Only 1 of 25 patients remained disease-free. The five patients that lived the longest were all treated with chemotherapy. Innovative treatment strategies are

needed for pelvic osteosarcomas.

### **Clinical Analysis of Limb-Sparing Surgery**

The most recent comparison of the results of limb-sparing surgery and amputation were reported by Sluga and colleagues<sup>257</sup> from the University of Vienna. They evaluated 130 consecutive patients younger than 21 years of age treated for osteosarcoma of the extremity. Ninety percent (116 patients) were treated by a limb-sparing procedure. Fourteen amputations, 32 rotationplasties, and 84 resections with subsequent reconstruction were performed. The 5-year metastasis-free survival rate was 60% for patients treated by amputation or rotationplasty and 71% for patients treated by limb-sparing surgery. The surgical margins were classified as wide in 109 cases and radical in ten cases. The overall local recurrence rate was 2.3%: 4.3% for amputation and/or rotationplasty and 1.2% for limb-sparing surgery. The overall survival rate was significantly influenced by tumor volume ( $P = .0018$ ), response to chemotherapy ( $P = .039$ ), and presence of metastases at the time of diagnosis ( $P = .0001$ ). The authors emphasize that there was no selection bias by tumor volume for the type of surgical procedure performed. The authors warn that limb-sparing is not suitable for every patient; patients with large tumors and close margins may require amputation. They emphasize the importance of wide margins to a successful limb-sparing procedure. This study, as well as previous studies, showed no difference in patient survival or local recurrence in patients treated by a limb-sparing procedure and those undergoing an amputation.

Rougraff and colleagues<sup>142</sup> evaluated 227 patients with nonmetastatic osteosarcoma of the distal femur treated at 26 institutions. They reported eight (11%) local recurrences in 73 patients with a limb salvage procedure, and nine (8%) local recurrences in 115 patients who had an above-knee amputation. No local recurrences were reported in the 39 patients who had a hip disarticulation.

Bacci et al.<sup>258</sup> retrospectively evaluated 540 patients treated over 10 years in three multicenter studies with 63 participating institutions. The rate of local recurrence was 8% for patients with a poor histologic response and 3% for those with a good histologic response. A limb-sparing procedure was performed on 84% of the 540 cases evaluated, with a local recurrence rate of 6%. The most important determinant of local recurrence was the type of surgical margin and the response to chemotherapy. Of the 540 patients, 31 had a local recurrence. The overall outcome of this group was extremely poor. All local recurrences were accompanied by metastases, and despite treatment, only one patient remains alive (3%). Local recurrence did not correlate with patient age, gender, histologic type, site and volume, pathologic fracture incidence, chemotherapy, or type of surgical procedure.

It appears, in summary, that the safety and efficacy of limb-sparing procedures for high-grade bone sarcomas have been well answered during the 1990s.<sup>259</sup> The senior author (M. M.) would like to emphasize that these procedures are demanding and must be performed by surgeons experienced in limb-sparing procedures.

### **Allograft Replacement**

Allograft (cadaver bone) replacement was popular in the 1970s and mid-1980s, which were the early days of limb-sparing surgery. Allograft was used for replacement of large bony segments after limb-sparing surgery. When used in patients in conjunction with chemotherapy, allografts have a significant complication rate, including infection, fracture, nonunion, and local recurrence, which may lead to secondary amputation.<sup>260</sup>

The most recent authors to evaluate the use of allografts for reconstruction of the distal femur (the most common site for osteosarcoma) were Powell et al.<sup>261</sup> They evaluated their experience over a 13-year period. A total of 37 osteoarticular allografts were used to reconstruct the distal femur of 34 patients who underwent tumor resection. Twenty-one patients with sarcoma received chemotherapy. Average follow-up was 86 months. Eighty-five percent of patients had postoperative complications, and 21 of 33 patients (73%) required further surgery. The most common complications were joint instability (55%), degenerative joint disease (44%), nonunion (36%), allograft fracture (28%), and infection (17%). Only 13 of the 36 of the allografts (36%) remained intact. A steady decline in actuarial survivorship of the reconstruction was noted over time: 83.2% at 2 years, 42.3% at 5 years, and 14.3% at 10 years.

Allograft replacement remains popular at some institutions but is reserved for low-grade tumors that do not require chemotherapy. The use of allografts has become less common with the development of reliable prosthetic replacements, especially the modular replacement systems.

### **Prosthesis Survival and Complications**

Prosthetic replacement is commonly used for reconstruction after resection of the proximal humerus, proximal femur, distal femur (Fig. 39.2-10), and proximal tibia. Several studies have evaluated the long-term results, prosthetic survivorship, and complications associated with prosthetic replacement.<sup>262,263,264</sup> and<sup>265</sup> Ruggieri and associates<sup>264</sup> reported on 133 cases of nonmetastatic osteosarcoma of the extremities treated with neoadjuvant chemotherapy and limb-sparing surgery. Sixty-three percent of the patients had one or more complications. Twenty-eight complications were considered minor (i.e., no surgery was required), and 77 complications were major. The infection rate was 6.2%. Mechanical problems occurred in seven patients (5%). The average number of complications per patient was 1.3. The authors thought that the most serious problems resulting from a complication were those that required the delay of chemotherapy or deviation from the recommended dose, either of which could jeopardize survival. Such consequences were not, however, demonstrable statistically.

**FIGURE 39.2-10.** Osteosarcoma of the distal femur treated by limb-sparing resection. **A:** Plain radiograph of a distal femoral osteosarcoma. **B:** Intraoperative photograph shows a modular distal femoral prosthesis.

Campagna and colleagues<sup>265</sup> from the Rizzoli Institute reported on 95 distal femoral resections performed between 1983 and 1989 (average follow-up, 51 months). The overall complication and infection rates were 55% and 5%, respectively. The most common complication was failure of the polyethylene bushings used with the knee component, which occurred at an average of 5.3 years after the procedure. They reported an overall local recurrence rate of 5% (average, 15 months). Mechanical stem breakage was rare (6%) and was associated with two factors—the use of a narrow stem and extensive quadriceps excision. The results were not related to patient age or length of resection. The tibia component caused no problems. All revisions done for infections were unsatisfactory. The incidence of infection correlated with the extent of soft tissue resection of the quadriceps. No revisions were needed because of loosening.

Malawer and Chou<sup>262</sup> evaluated the prosthetic survivorship of large-segment prostheses in 89 patients with high-grade bone sarcomas. The overall limb survival and infection rates were 90% and 7%, respectively. The infection rate resulting in amputation was 7%. The 5- and 10-year prosthetic survival rates (no need for revision or amputation) were 83% and 67%, respectively. Age, gender, and diagnosis were not related to prosthetic survival. The authors of this study suggested that infection was related to periods of bacteremia and neutropenia associated with postoperative chemotherapy and to episodes of line sepsis.

In 1999, Henshaw et al.<sup>266</sup> reported the long-term prosthetic survival analysis of the 100 patients treated with the American-designed modular replacement system (Howmedica and Osteonics, Inc., Allendale, NJ). The minimum follow-up period was 2 years. *Prosthetic failure* was defined as removal of the implant for any reason. Kaplan-Meier survival analysis was performed for all implants and for each site of reconstruction. The authors reported no mechanical failures of the stem, body, or taper components. No clinically significant prosthetic loosening was reported. The infection rate was 8% (four in distal femurs, three in proximal tibias, and one in proximal humerus), leading to six amputations and one prosthetic removal. The amputation rate was 7% (six infections and one local recurrence). The Kaplan-Meier

survival analysis (Fig. 39.2-11) for all sites was 88% at 10 years, with a median follow-up of 64.4 months. The estimates of 10-year survival for the distal femur, proximal humerus, proximal femur, and proximal tibia were 90%, 98%, 100%, and 78%, respectively. Today, modular prostheses are forged by several manufacturers and are the standard prostheses used for most limb-sparing procedures.<sup>266</sup>

**FIGURE 39.2-11.** Kaplan-Meier curve showing the survival of prosthetic replacements according to anatomic site in 100 patients treated by limb-sparing surgery for high-grade bone sarcomas. The anatomic site was the most significant predictor of survival of the prosthesis. Distal Femur, distal or mid-part of the femur; Prox Humerus, proximal part of the humerus; Prox Femur, proximal portion of the femur; Prox Tibia, proximal portion of the tibia. (From ref. 266, with permission.)

### Revision of Limb-Sparing Surgery (Prosthesis)

The growing popularity of limb-sparing surgery has led to a need for revision of a limb-sparing endoprosthesis. The early causes of prosthetic failure were postoperative infection, secondary infection due to transient bacteremia during postoperative chemotherapy, and local recurrence. These events usually occur within the first 2 years after surgery. Long-term survival of the prosthesis depends on the mechanical properties of the prosthesis and on the host response to the polyethylene, methylmethacrylate, and metallic components. The most common causes of late failure of a prosthesis necessitating revision (i.e., removal and replacement of the prosthesis) are aseptic loosening of the prosthesis, mechanical breakage, or polyethylene component failure.

Renard et al.<sup>267</sup> evaluated 26 revision procedures. The most common reasons for a revision were polyethylene wear (nine cases) and aseptic loosening (eight cases). The follow-up after the last revision ranged from 6 months to 12 years, with a median of 3 years. All patients retained their extremity, and approximately 75% incurred no functional loss after prosthetic revision.

### Cost of Limb-Sparing Surgery versus Amputation

The question of the cost effectiveness of limb-salvage surgery for bone tumors has arisen in the face of managed care, especially within the United States. The only published report on this subject is by Grimer et al.,<sup>268</sup> who compared the cost of a limb-sparing procedure in lieu of an amputation. They developed a formula for the cost of the limb-salvage procedure versus an above-knee amputation with subsequent prosthetic replacement over the predicted life of the patient. This was calculated for tumors around the knee. They excluded tumors of the proximal humerus and of the proximal femur, because, whatever difference in cost there might be, there was a tremendous advantage of replacing the proximal femur rather than performing a hemipelvectomy or hip disarticulation. Similarly, there is a tremendous advantage in preserving the upper extremity and a functioning hand in lieu of a forequarter amputation for a proximal humeral sarcoma. Their study is based on large experience of amputations and limb-sparing procedures at the Royal Orthopedic Hospital in Birmingham, England. The formula is  $E + 2Fy + sSy + rRy + 3R(rRy)$ , where E is the cost of the original procedure, y is the number of years since the original operation, F is the cost of follow-up attendance, s is the risk of a service procedure in any year, S is the cost of a servicing procedure in any year, r is the risk of a revision procedure being needed, and R is the cost of revision procedure.

They concluded the savings for an average patient undergoing a limb-sparing surgery over a 20-year period to be approximately 70,000 British pounds (at 1977 prices), which is approximately six times the cost of the original limb-sparing procedure. They concluded that the equation can be used for any method of limb-salvage procedure. This study was performed with distal femoral resections that used a simple hinge prosthesis, which is now out of date. The modern rotating hinged-knee prosthesis, with an improved surface and a collar coated with porous beads, provides a much longer rate of survival. These features should provide a significantly lower rate of wear and failure, thus increasing cost-effectiveness.

The surprising feature of these findings is the considerable cost of amputation. Most active young people would demand and use a sophisticated artificial limb. These individuals frequently have stump problems and require multiple replacements of the socket and prosthesis. They often require a spare prosthesis as well. Many request and use a sports limb and a limb designed for swimming. A new prosthesis is required at regular intervals. With the increasing complexity of artificial limbs, it is likely that the maintenance cost of the amputated extremity will increase.<sup>268</sup>

### Limb-Sparing Surgery and Pathologic Fracture

Traditionally, a fracture through an osteosarcoma was treated by amputation. As experience with induction chemotherapy and limb-sparing surgery has increased, however, several centers have attempted limb-sparing surgery in this high-risk patient population. The assumption has been that if the fracture can be immobilized during the induction period and the tumor shows clear signs of necrosis and secondary fracture healing, an amputation may be avoided. The earlier strategy, immediate amputation, was based on the presumed high risk of local recurrence after a limb-sparing procedure. A limb-sparing procedure may now be safely performed if the response to induction chemotherapy is good, as evidenced by fracture healing.

Steadman et al.<sup>269</sup> evaluated their experience with patients with osteosarcoma-induced pathologic fractures between 1970 and 1995. Nine primary instances of limb salvage in patients with preoperative chemotherapy and eight primary cases of amputation with postoperative chemotherapy were studied. No significant difference in survival was found. One local recurrence occurred in the limb-salvage group, and none in the amputation group. This retrospective analysis, combined with other reported results, makes a convincing case that a pathologic fracture does not indicate the need for an immediate amputation. The strategy today is to immobilize the extremity and proceed with induction chemotherapy. If the fracture heals and the tumor appears to respond to chemotherapy, a limb-sparing operation is warranted. Repeat staging studies after induction chemotherapy and close serial observation during the induction period are essential.

## CLINICAL PRESENTATIONS OF OSTEOSARCOMA AND TREATMENT CONSIDERATIONS

### Treatment Considerations

**LOCALIZED EXTREMITY DISEASE.** Management of osteosarcoma requires the expertise of a multidisciplinary team familiar with the various management options. Patients with a suspected diagnosis of osteosarcoma (based on radiographic findings) should be referred to centers with treatment programs before biopsy. The biopsy should be performed by an orthopedic surgeon familiar with the management of malignant bone tumors and experienced in the required techniques.<sup>270</sup> Whenever possible, this individual should be the surgeon who will ultimately perform the definitive surgical procedure, because the biopsy must be planned carefully with a consideration of subsequent definitive surgery. A poorly conceived and poorly placed biopsy may jeopardize the subsequent treatment, especially a subsequent limb-salvage procedure.

The patient with a primary tumor of the extremity without evidence of metastases requires surgery to control the primary tumor and chemotherapy to control micrometastatic disease. The choice between amputation and limb-sparing resection must be made by an experienced orthopedic oncologist, taking into account tumor location, size, or extramedullary extent; the presence or absence of distant metastatic disease; and patient factors such as age, skeletal development, and lifestyle preference. Routine amputations are no longer performed; all patients should be evaluated for limb-sparing options. Intensive, multiagent chemotherapeutic regimens have provided the best results to date (see Table 39.2-6 and Table 39.2-7). Patients who are judged unsuitable for limb-sparing options may be candidates for presurgical chemotherapy; those with a good response may then become suitable candidates for limb-sparing operations. The management of these patients

mandates close cooperation between the medical oncologist and surgeon.

**PELVIC TUMORS AND UNRESECTABLE DISEASE.** In some pelvic and most vertebral primary tumors, complete resection often is not possible. Most pelvic osteosarcomas can be treated by hemipelvectomy; more centrally located pelvic tumors, especially those involving the sacrum, are unresectable. Only a few pelvic osteosarcomas can be treated by limb-sparing resection (internal hemipelvectomy). Contraindications to resection are unusually large extraosseous extensions with sacral plexus or major vascular involvement. On rare occasions, vertebral and sacral resections have been attempted.<sup>271,272</sup> and <sup>273</sup> In general, these tumors cannot be resected with negative margins and are best treated by radiotherapy and chemotherapy. Some success has been achieved with systemic or intraarterial chemotherapy, which is administered to convert apparently inoperable tumors into lesions that can be ablated surgically.<sup>89,90</sup> Patients with primary tumors of the axial skeleton have had a poor outcome, because local control was rare. The prognosis for these patients may improve with a more aggressive surgical approach and more effective chemotherapy.<sup>274</sup> Patients whose tumors can be completely resected should be approached with curative intent; radiotherapy provides significant palliation in patients with unresectable primary tumors.

**METASTATIC PULMONARY DISEASE AT DIAGNOSIS.** Metastatic disease detected at initial diagnosis does not preclude a curative treatment strategy, although the presence of extrathoracic metastases makes cure extremely unlikely. In general, the surgical principles outlined for the treatment of relapsing patients apply equally to the patient presenting with macroscopic metastases. Newly diagnosed patients have not been exposed to chemotherapy and are, thus, less likely to have drug-resistant tumors. Therefore, several options are available to them.

For the patient presenting with resectable disease (i.e., usually fewer than 15 pulmonary nodules and a primary tumor of the extremity), the traditional approach has been resection of all evidence of macroscopic disease by median sternotomy and limb amputation or resection, followed by intensive adjuvant chemotherapy. The tumor burden is thereby reduced to a minimum before the application of adjuvant therapy. Some investigators have favored treatment with chemotherapy, followed weeks or months later by definitive surgery for residual macroscopic disease in primary and metastatic sites.<sup>92,93</sup> Arguments advanced to justify this approach are similar to those used to support preoperative chemotherapy in general, and the theoretical advantages and disadvantages of this strategy as discussed for patients with nonmetastatic osteosarcoma apply here as well. The risk for the patient with metastases is that growth of tumor nodules in the face of chemotherapy may render small, operable metastases unresectable and prevent cure. Although the timing of the surgery of the primary tumor and metastatic sites has been variable, most modern approaches entail alternating chemotherapy and surgery. The initial treatment is usually a course of chemotherapy, followed by surgical resection of the primary tumor, followed by a second course of chemotherapy and surgical ablation of metastatic sites, followed by the remaining courses of chemotherapy. Patients with tumors that respond to presurgical chemotherapy are more likely to be cured. In patients with inoperable metastases, primary treatment with chemotherapy is probably appropriate; metastases may respond sufficiently to allow complete resection. Because these patients usually require surgery for the primary tumor as a palliative procedure, early surgery may be recommended, despite unresectable pulmonary disease. Although improving, the outlook for patients presenting with metastatic disease remains poor.<sup>275,276</sup>

**RECURRENT DISEASE AFTER CURATIVE ATTEMPT.** Historically, patients developing recurrent disease had a poor prognosis and were treated palliatively; most died within 1 year of the development of metastatic disease. Because more than 85% of metastases occur in the lung, surgical resection of tumor nodules can be readily accomplished. With the advent of thoracic CT scanning, metastatic nodules can be detected when quite small and more easily resectable, although in most cases the surgeon discovers more lesions at thoracotomy than anticipated on the basis of the CT scan.<sup>277,278</sup> and <sup>279</sup> In many patients, the lungs are likely to be the only site of metastasis, especially in cases in which recurrences appear more than 1 year after diagnosis and in which the metastatic lesion is solitary. In such cases, the recurrent tumors are likely to behave more indolently and may not further metastasize. These patients have been cured by thoracotomy alone.

Surgical resection of all overt metastatic disease is a prerequisite for long-term salvage after relapse.<sup>278,279,280</sup> and <sup>281</sup> Patients not treated by thoracotomy have little hope for cure, because complete responses of macroscopic metastases to chemotherapy are rare.<sup>279,280</sup> and <sup>281</sup> The completeness of surgical resection is an important determinant of outcome, because patients left with measurable or microscopic disease at the resection margins are unlikely to be cured.<sup>279</sup>

Many investigators have recommended adjuvant chemotherapy after thoracotomy for the management of metastatic osteosarcoma to destroy residual microscopic tumor deposits.<sup>92,102,103</sup> For patients who develop recurrent disease within 1 year of initial surgery, the possibility of additional microscopic metastatic disease is quite high, and further chemotherapy is indicated. Long-term survival has been reported for some patients with recurrent osteosarcoma who were treated only with surgery.<sup>98,99</sup> and <sup>100</sup> These survivors were more likely to be patients experiencing late relapses with solitary pulmonary nodules.

If overt metastatic disease is discovered, a thorough search for all metastatic lesions is essential. The discovery of unresectable extrathoracic metastases or unresectable pulmonary disease is a contraindication to aggressive thoracotomy, and the patient should be treated palliatively. Radiotherapy may be particularly useful in this context. In some patients with unresectable disease, an aggressive approach with curative intent may still be indicated. Chemotherapy, with or without radiotherapy, rarely eradicates all metastatic disease; nonetheless, some patients with inoperable metastases may respond sufficiently to allow for complete resection of disease at a later date. Occasionally, patients with unresectable pulmonary metastases are cured with chemotherapy or high-dose radiotherapy alone.

Patients with resectable lung disease should undergo thoracotomy to remove all evidence of disease. Bilateral disease may be approached by staged bilateral thoracotomies or a median sternotomy. The role of adjuvant chemotherapy after thoracotomy should be studied; it is probably indicated for patients with more than three lesions appearing 6 months to 1 year after initial surgery, for patients whose metastatic disease has not been completely resected, or for those with evidence of pleural disruption by tumor. Repeat thoracotomies may be required for subsequent recurrence and should be performed if all disease can be resected.

Survival after relapse has undeniably been enhanced by approaches designed with curative intent that incorporate repeated aggressive surgery to remove overt disease. With such treatment, 30% to 40% of patients have been reported to survive beyond 5 years after relapse,<sup>92,98,100,101,282,283,284</sup> and <sup>285</sup> although not all of these patients are ultimately cured. Such considerations emphasize the value of close follow-up, with frequent chest radiographs and thoracic CT scans, to detect recurrent disease when it is still resectable. Thus, for the patient with osteosarcoma, the development of metastases is not a hopeless situation; aggressive systematic treatment offers prolonged survival for many patients and the possibility of cure for a significant fraction. Ironically, as adjuvant regimens used in front-line therapy of patients are intensified and the number of patients surviving without ever developing recurrence increases, the proportion who are likely to be salvageable after relapse may decrease, because relapsing patients are more likely to have drug-resistant recurrences.

### **Radiation Therapy in the Treatment of Osteosarcoma**

**BACKGROUND.** Significant experience with primary radiotherapy for osteosarcomas was obtained in the 1950s and early 1960s. Primary radiotherapy with delayed amputation gained acceptance in 1955, when Cade<sup>286</sup> advocated initial therapy with radiation and delayed amputation for patients in whom there was no evidence of metastasis 4 to 6 months after radiotherapy. This approach was designed to circumvent amputation in the majority of patients who were destined to develop an early relapse. Radiation doses were 7000 to 8000 cGy administered over 7 to 9 weeks at 1000 cGy/week. A few patients in Cade's series who were not subjected to delayed amputation were controlled with irradiation alone, and amputation was eventually performed. The 5-year survival rate was 21.8%. Other investigators followed a similar regime, using various radiation doses and schemes (Table 39.2-12). Subsequent surgical specimens of many of the patients managed in this fashion were found to have no histologic evidence of tumor. The ability of high radiation doses to sterilize some tumors, however, was associated with significant necrosis of normal tissue.<sup>287,288,289,290,291</sup> and <sup>292</sup>

Number of Patients	Dose	Modality	Survival (%)
13	7000-8000 cGy in 7-9 wk, 1000 cGy/wk	RT	21.8
13	10,000 cGy in 10-12 fractions	Chest RT or RT	98
12	8000-9000 cGy in 10-12 fractions		21.8
16	7000-10,000 cGy in 10-12 fractions	Orthotopography and RT	75 (3-35 follow-up)
54	Variable	Variable	21.5
25	7000-10,000 cGy in 7-9 wk	Orthotopography and RT	26
17	8000-9000 cGy in 10-12 fractions		1
17	8000-9000 cGy in 10-12 fractions	Orthotopography and RT	25

**TABLE 39.2-12.** Series of Primary Radiation Followed by Delayed Surgery for Osteosarcoma

Results of preoperative radiation were subsequently evaluated. Overall success with preoperative radiation followed by ablative surgery was, in general, suboptimal; most patients relapsed shortly after treatment. This led Jenkin et al.<sup>260</sup> at Princess Margaret Hospital to recommend limiting radiation to patients who had unresectable tumors or who were being treated for palliation only. Beck et al.<sup>293</sup> observed no survival advantage for preoperative radiation followed by surgery over surgery alone; furthermore, only 43% of their patients obtained any palliative benefit from radiotherapy.

Radiotherapy has, however, been shown to be successful in several distinct clinical situations—facial lesions, palliation and, possibly, as a postoperative adjuvant. High-dose combination photon and proton radiation using three-dimensional treatment planning may improve long-term local control. Guidelines for the use of radiotherapy for osteosarcoma and other malignant bone tumors are shown in [Table 39.2-12](#) and [Table 39.2-13](#).

Tumor	Radiation Dose	Comments
Osteosarcoma	70-80 Gy	See Table 39.2-12
Chondrosarcoma	50-70 Gy	Radiation indicated for unresectable or inoperable tumors
Giant cell tumor (osteoclast)	50-60 Gy	Sarcomatous transformation occurs in 3% of cases
Enchondroma	50-60 Gy	-
Chondroma	70-75 Gy	Most cases are benign
Lipoma	60-80 Gy	High local control with chemotherapy. Radiation may be useful in palliative patients

*Gy, cobalt Co equivalent.*

**TABLE 39.2-13.** Radiation Guidelines for Malignant Bone Lesions

**PALLIATION.** Radiation therapy is extremely beneficial in patients requiring palliation of metastatic bony sarcomas; tumors at axial sites, which are unresectable; and advanced, inoperable lesions of the pelvis or extremities. A novel approach using high-dose-per-fraction radiation and intraarterial 5'-bromodeoxyuridine (BUdR) as a radiosensitizer was undertaken by the Stanford Group.<sup>294</sup> Pulsed 48-hour BUdR infusions were performed before each 600-cGy radiation fraction, with a total radiation dose to the primary site of 4200 to 4800 cGy in 5 weeks (seven to eight fractions). Infusions of methotrexate-leucovorin were administered simultaneously. Local control was achieved in seven of the nine patients (78%) treated.<sup>295</sup> However, local tissue toxicity was excessive and included subcutaneous fibrosis, nonhealing traumatic fractures, peroneal neuropathy, and atrophy. Because the patients were treated with an unusual fractionation scheme using large fractions as well as intravenous chemotherapy, the specific role of the BUdR in both the local control and the excessive toxicity was not established.

Kinsella and Glatstein<sup>296</sup> have used intravenous radiosensitizers of BUdR, iododeoxyuridine, or misonidazole with high-dose radiotherapy, with various fractionation schemes and usually with chemotherapy, in patients with large, unresectable primary or metastatic sarcomas. Twenty-one of 29 patients (75%) achieved local control, which was defined as freedom from symptoms and absence of growth.

These studies demonstrated the efficacy of radiation therapy in obtaining long-term local control and palliation. They lend support to further clinical investigations using radiation sensitizers with high-dose radiotherapy.

### VARIANTS OF CLASSIC OSTEOSARCOMA

Dahlin and Unni<sup>60</sup> have identified 11 variants of the classic osteosarcoma. These accounted for 268 of 1021 (28%) cases reviewed at the Mayo Clinic. Osteosarcoma arising in the jawbone, the most common variant, is characterized by well-differentiated cells with a low metastatic potential.<sup>60</sup> Excluding tumors arising secondary to Paget's disease, irradiation, or dedifferentiation of a chondrosarcoma, parosteal and periosteal osteosarcomas are the most common variants of classic osteosarcoma arising in the extremities. In contrast to classic osteosarcoma, which arises within a bone, both parosteal and periosteal osteosarcomas arise on the surface of the bone (juxtacortical).

The three types of surface osteosarcomas are parosteal osteosarcoma, periosteal osteosarcoma, and high-grade surface osteosarcoma. The Mayo Clinic reported 518 surface osteosarcomas seen between 1926 and 1996. The incidence was 335 parosteal osteosarcomas (64.7%), 137 periosteal osteosarcomas (26.4%), and 46 high-grade surface osteosarcomas (8.9%). These 518 surface osteosarcomas were from a pool of 4365 osteosarcoma tumors (i.e., a ratio of 1:8.4 cases).<sup>297</sup>

#### Parosteal Osteosarcoma

Parosteal osteosarcoma is a distinct variant of conventional osteosarcoma that accounts for 4% of all osteosarcoma.<sup>60</sup> It arises from the cortex of a bone and generally occurs in older individuals. It has a better prognosis than classical osteosarcoma.

**CLINICAL CHARACTERISTICS.** There is a slight predominance of parosteal osteosarcoma in women. The distal posterior femur is involved in 72% of all cases; the proximal humerus and proximal tibia are the next most frequent sites. Parosteal osteosarcoma metastasizes slowly and has an overall survival rate of 75% to 85%.<sup>60,298</sup> Unni and colleagues<sup>62</sup> noted that all patients who died of tumor lived longer than 5 years. The natural history of parosteal osteosarcoma is progressive enlargement and late metastasis. Parosteal osteosarcoma presents a mass and occasionally is associated with pain. In contrast to conventional osteosarcoma, duration of symptoms varies from months to years. Unni et al.<sup>298</sup> reported that 50 of 79 patients had complaints of longer than 1 year, and one-third of this group had pain for more than 5 years. Tumor size, location, and duration of symptoms did not correlate with survival.<sup>60</sup>

**RADIOGRAPHIC FINDINGS.** Roentgenograms characteristically show a large, dense, lobulated mass broadly attached to the underlying bone without involvement of the medullary canal. If old enough, the tumor may encircle the entire bone. The periphery of the lesion is characteristically less mature than the base. Ahuja and coworkers<sup>61</sup> emphasized that intramedullary extension is difficult to determine from plain radiographs. Unni et al.<sup>298</sup> emphasized that high-grade foci did not usually alter the roentgenographic appearance of these tumors.

**PATHOLOGY AND GRADING.** Parosteal osteosarcoma is characterized by well-formed lamellar or woven bone with a mature spindle cell stroma with few signs of malignancy. The cellularity of the spindle cell components varies; generally, it is not anaplastic, with few mitoses.<sup>2,3,4,59,60</sup> The differential diagnosis is osteochondroma, myositis ossificans, and conventional osteosarcoma. Cortical tumors of the posterior femur should always be suspected of malignancy; this is a rare location for a benign osteochondroma. In contrast to sarcoma, myositis ossificans is rarely attached to the underlying bone. In addition, the periphery is more mature, both radiographically and histologically. Ahuja and colleagues<sup>60</sup> reviewed all cases of parosteal osteosarcoma at Memorial Sloan-Kettering Cancer Center from 1934 to 1975 and described three grades: grade I (low grade), grade II (intermediate), and grade III (high grade). They emphasized the importance of evaluating the fibroblastic, cartilaginous, and osseous components independently. Of 24 patients, eight were grade I, ten grade II, and six grade III. Unni et al.<sup>298</sup> reviewed 79 patients and reported that 18 were grade II (23%), and seven had high-grade foci (9%). Neither group of researchers could distinguish the three grades on plain radiographs. The survival rate of patients with grade III tumors is similar to that of patients with conventional osteosarcoma.

Jelinek et al.<sup>299</sup> reviewed the records of the Armed Forces Institute of Pathology and evaluated 60 patients with parosteal osteosarcomas for tumor size, location, and presence of cleavage plane; intramedullary extension; soft tissue mass; and the presence and pattern of ossification. Tumors were classified as low grade or high grade. The average maximal length for low- and high-grade tumors was 7.7 and 15.0 cm, respectively. A cleavage plane was present in 20 low-grade (62%) and 19

high-grade (68%) lesions. On cross-sectional imaging, intramedullary extension was present in 13 low-grade (41%) and 14 high-grade (50%) lesions. They concluded that a poorly defined soft tissue component distinct from the ossified matrix is the most distinctive feature of high-grade parosteal osteosarcoma and may be the optimal site to perform a biopsy.

Intramedullary involvement does not necessarily imply a worse prognosis, although this may be the case in patients with high-grade lesions. <sup>60</sup> Eleven of 24 patients (46%) reviewed by Ahuja<sup>61</sup> had medullary involvement; moreover, the patients with medullary involvement who had a local resection all had a local recurrence.

Okada and associates<sup>297</sup> has updated the experience of the Mayo Clinic. They reviewed the records of 226 patients. Dedifferentiation was more common (16% of patients) than previously reported. They emphasized the usefulness of cross-sectional imaging in planning surgical resection. The tumor often had extensive intramedullary, extraosseous, and adjacent soft tissue components. Medullary involvement was present in 22% of the patients, and extraosseous, unmineralized soft tissue peripheral to the mineralized cortical mass was noted in 51% of the patients. Adjacent soft tissue extension occurred in 46% of patients. In contrast to their previous studies, intramedullary involvement was not a poor prognostic factor. The authors stressed the need for long-term follow-up. Eleven of the 67 patients managed at their institution died at an average of 14 years (range, 2 to 41 years). Ten of the 11 patients died from a dedifferentiated tumor.

**treatment.** Wide excision of the tumor is the treatment of choice. This may be accomplished either by an amputation or a limb-sparing procedure. No experience with preoperative chemotherapy or radiotherapy has been reported. Parosteal osteosarcomas are often amenable to limb preservation due to their distal location, low grade, and lack of local invasiveness. If the adjacent neurovascular bundle is free of tumor, resection is feasible. Vascular displacement is not a contraindication for resection. The major surgical decision usually is whether to remove the entire end of the bone and the adjacent joint or to preserve the joint. Small lesions can be resected with joint preservation. If the medullary canal is involved, the joint usually cannot be preserved. A second factor mitigating against joint preservation is extensive cortical involvement. Techniques of resection and reconstruction are similar to those described for conventional osteosarcoma. The major difference is that only a small amount of soft tissue usually must be resected; consequently, a good functional result is obtained. Grade III parosteal lesions warrant systemic therapy because of the risk of metastasis.

### Periosteal Osteosarcoma

Periosteal osteosarcoma is a rare cortical variant of osteosarcoma that arises superficially on the cortex, most often on the tibia shaft. <sup>61</sup> Radiographically, it is a small, radiolucent lesion with some evidence of bone spiculation. The cortex is characteristically intact, with a scooped-out appearance and a Codman's triangle ( [Fig. 39.2-12](#)). Histologically, periosteal osteosarcomas are relatively high-grade chondroblastic osteosarcoma composed of a malignant cartilage with areas of anaplastic spindle cells and osteoid production. Unni and colleagues, <sup>60</sup> in a report of 23 cases, found periosteal osteosarcomas to be one-third as frequent as the parosteal variant. The largest tumor measured 2.5 x 3.5 cm. Four of the 23 patients died of metastatic disease.

**FIGURE 39.2-12.** Periosteal osteosarcoma. **A:** Typical radiograph of a periosteal osteosarcoma of the humerus. Notice the cortical location with a scooped-out defect of the lateral aspect of the shaft and the diaphyseal location. **B:** Longitudinal section of the gross specimen after a limb-sparing resection. The tumor seems to arise on the outer cortex without any evidence of cortical involvement. **C:** Postoperative radiograph. A custom prosthesis was used to reconstruct the defect. (From Hall RB, Robinson LH, Malawar MM, Dunham WK. Periosteal osteosarcoma. *Cancer* 1985;55:165, with permission.)

One of the largest reported series was by Okada et al. <sup>297</sup> from the Mayo Clinic. They evaluated 46 patients and described their radiographic, clinical, and pathologic evaluation. All the tumors were broad based and attached to the underlying cortex. Nineteen of the 46 tumors (41%) showed infiltration into the cortex of the underlying bone. Medullary involvement was documented on gross or radiologic examination in 13 tumors and by microscopic examination only in six tumors. They attempted to evaluate the effectiveness of chemotherapy in this very rare subtype of osteosarcoma. Fifteen of the 21 patients receiving systemic treatment showed no response to chemotherapy. Among those 15 patients, only one patient remains alive. All six patients who showed a good response to chemotherapy are alive. Medullary involvement did not affect prognosis. The survival rate was 57.5% at 3 years and 46.1% at 5 years.

Treatment is similar to that of other high-grade lesions. *En bloc* resection should be performed when feasible; amputation is rarely indicated. [Table 39.2-12](#) compares the significant characteristics of periosteal tumors with those of conventional osteosarcoma.

### Paget's Sarcoma

Approximately 1% of patients with Paget's disease will develop a primary bone sarcoma. <sup>229,230</sup> Greditzer and colleagues<sup>230</sup> reported 41 sarcomas among 4415 patients with Paget's disease followed at the Mayo Clinic; 35 were osteosarcomas and six were fibrosarcomas. The average patient age was 64 years old, and the most common sites were the pelvis, femur, and humerus. One-half of these lesions were osteolytic; the remainder had a mixed pattern. Cortical destruction and a soft tissue component were the most common signs noted; periosteal elevation was rare. Most patients with this condition present with pain; thus, a patient with known Paget's disease who complains of increasing pain, especially when it is well localized, should be evaluated radiographically. The diagnosis is usually made by plain radiography and confirmed by biopsy. Traditionally, fewer than 8% of patients survive, and most deaths occur within 2 years. <sup>230</sup> Treatment is similar to that recommended for adolescent patients with osteosarcoma without metastatic disease.

### High-Grade Surface Osteosarcoma

High-grade surface osteosarcoma (peripheral conventional osteosarcoma) is the rarest variant of surface osteosarcoma. <sup>300</sup> The parosteal and periosteal osteosarcomas have a better prognosis, whereas the high-grade surface variant has the same prognosis as the conventional, intramedullary lesion. This variant was previously called *type III parosteal osteosarcoma*. Schajowicz and coworkers<sup>300</sup> studied the different surface osteosarcomas. They reported that only 7 of 80 surface osteosarcomas (9%) were considered to be the high-grade variant. Clinically, the median age was 13.5 years (younger than that of patients with other surface lesions), and almost all were located in the diaphyseal region of the bone. The femur was the most common site. These tumors may show extensive intramedullary involvement. Radiographically, it appears as a small or moderate-size lesion with slight to heavy calcification. The broad base of the lesion abuts the cortex. The radiographic features often are misleading and may suggest the periosteal variant; thus, the preoperative diagnosis may be difficult. But the young age, diaphyseal location and, most important, the highly malignant histologic features indicate the correct diagnosis. Wide excision with limb preservation has been reported. Adjuvant chemotherapy is warranted due to the high rate of metastases.

### Small Cell Osteosarcoma

The small cell osteosarcoma, a rare variant of osteosarcomas, resembles a Ewing's sarcoma and is often classified as an "atypical" Ewing's sarcoma. <sup>301,302</sup> Characteristically, areas of osteoid and, on occasion, chondroid formation are present. The differential diagnosis includes Ewing's sarcoma, atypical Ewing's sarcoma, primitive neuroectodermal tumor, mesenchymal chondrosarcoma, lymphoma, and Askin's tumor. Differentiation from Ewing's sarcoma and the typical osteosarcoma is important, because the response of small cell osteosarcoma to treatment is poorly defined.

Devaney and colleagues<sup>303</sup> from the Bone Branch of the Armed Forces Institute of Pathology evaluated 79 round cell tumors of bone with immunohistochemistry in an attempt to distinguish small cell osteosarcoma from the other round cell tumors of bone. They noted that none reacted with cytokeratin, epithelial membrane antigen, factor VIII-related antigen, synaptophysins, or Leu-M1-positive. Thus, a strong positivity of any of these studies should rule out small cell osteosarcoma. Vimentin was seen in the majority of the various tumor types. They concluded that immunohistochemical stains alone could not make the diagnosis.

Sim et al.<sup>301</sup> recommend surgery, whereas at the Pediatric Branch of the National Cancer Institute, these tumors, like other pediatric round cell tumors, are treated by a combination of radiation therapy and chemotherapy.

### **Radiation-Induced Osteosarcoma**

Radiation-induced osteosarcomas arise in a previously irradiated field and meet the general criteria of a radiation-induced sarcoma [i.e., they appear after a latent period of 5 to 20 years, are documented to be secondary (different from the original one), and occur in a documented irradiated field]. Amendola and coworkers<sup>304</sup> from the University of Michigan reviewed 22,306 patients treated with radiation between 1934 and 1983 and reported 23 patients with radiation-associated sarcoma (prevalence, 0.1%). The median latent period was 13 years (range, 3 to 34 years). The radiation doses ranged from 25 to 72 Gy. The data suggest that intensive chemotherapy may have shortened the latency period.

In two nested case-control studies of 3-year cancer survivors from France and the United Kingdom, the risk of osteosarcoma was found to be a linear function of radiation dose and alkylating agent chemotherapy.<sup>305,306</sup> The 20-year risk of osteosarcoma among survivors of retinoblastoma (7.2%), Ewing's sarcoma (5.4%), and other bone tumors (2.2%) suggests a genetic influence in the induction of secondary osteosarcoma. However, the risk of developing bone sarcoma within 20 years for the majority of survivors of childhood cancer is less than 0.9%.

The treatment of radiation-associated osteosarcoma is wide resection, when possible, combined with adjuvant chemotherapy.<sup>307</sup> A previously irradiated field presents a unique challenge for the surgeon—choosing the best local option. The likelihood of local complications is greater in such cases.

## **CHONDROSARCOMA**

Chondrosarcoma is the second most common primary malignant spindle cell tumor of bone.<sup>2</sup> Chondrosarcomas form a heterogeneous group of tumors whose basic neoplastic tissue is cartilaginous without evidence of direct osteoid formation.<sup>329</sup> Occasionally, bone formation occurs from differentiation of cartilage. If evidence is found of direct osteoid or bone production, the lesion is classified as an osteosarcoma. The five types of chondrosarcomas are central, peripheral, mesenchymal, differentiated, and clear cell.<sup>2,3</sup> and <sup>4,10</sup> The classic chondrosarcomas are central (arising within a bone) or peripheral (arising from the surface of a bone). The other three are variants and have distinct histologic and clinical characteristics.

Both central and peripheral chondrosarcomas can arise as primary tumors or secondary to underlying neoplasm. Seventy-six percent of primary chondrosarcomas arise centrally.<sup>2,10,11</sup> and <sup>12,308</sup> Secondary chondrosarcomas most often arise from benign cartilage tumors. The multiple forms of benign osteochondromas or enchondromas have a higher rate of malignant transformation than the corresponding solitary lesions.<sup>11,12,58,215</sup>

### **Central and Peripheral Chondrosarcomas**

**CLINICAL CHARACTERISTICS.** One-half of all chondrosarcomas occur in persons older than 40 years of age.<sup>2,216</sup> Only 3.8% occur in those younger than 20 years.<sup>2</sup> The most common sites are the pelvis (31%), femur (21%), and shoulder girdle (13%).<sup>11,12,215,216</sup> Chondrosarcomas are the most common malignant tumors of the sternum and scapula. The clinical presentation varies. Peripheral chondrosarcomas may become large without causing pain, and local symptoms develop only because of mechanical irritation. Pelvic chondrosarcomas are often large and present with referred pain to the back or thigh, sciatica secondary to sacral plexus irritation, urinary symptoms from bladder neck involvement, unilateral edema due to iliac vein obstruction, or as a painless abdominal mass. Conversely, central chondrosarcomas present with dull pain; a mass is rare. Pain, which indicates active growth, is an ominous sign of a central cartilage lesion. This cannot be overemphasized. An adult with a plain radiograph suggestive of a "benign" cartilage tumor but associated with pain most likely has a chondrosarcoma.

**HISTOLOGY AND GRADING.** Chondrosarcomas are categorized as grade I, II, or III. The majority of chondrosarcomas are either grade I or II.<sup>1,10,11</sup> and <sup>12,215,216,308</sup> The metastatic rate of moderate-grade lesions is 15% to 40%; in high-grade lesions, it is 75%.<sup>1,10,11,12,86,215</sup> Grade III lesions have the same metastatic potential as osteosarcomas.<sup>11,308</sup>

Because cartilage tumors are difficult to grade histologically,<sup>10,215,216</sup> some investigators have attempted to apply cytologic, histochemical, and biochemical analysis to evaluate these lesions.<sup>215,309,310</sup> Sanerkin<sup>215</sup> described a combination of cytologic and histologic criteria. He emphasized that cytologic analysis evaluates nuclear abnormalities better than conventional histologic sections, whereas histologic evaluation of bone-tumor interface is the best predictor of local aggressiveness. Krocberg and colleagues<sup>311</sup> performed a retrospective study of DNA content of 45 chondrosarcomas as an indicator of malignancy by evaluating diploid (normal DNA content) and hyperploid (abnormal increase in DNA) cells and correlating the findings to 10-year survival. Regardless of tumor grade, size, and location, patients with diploid cells had a better prognosis than those with hyperploid cells. A preliminary report assessing the malignancy of cartilage tumor by flow cytometry to determine the percentage of diploid, tetraploid, and aneuploid cells indicates that it may be a promising method of grading chondrosarcomas.<sup>311</sup>

**RADIOGRAPHIC DIAGNOSIS AND EVALUATION.** Central chondrosarcomas have two distinct radiologic patterns.<sup>312</sup> One is a small, well-defined lytic lesion with a narrow zone of transition and surrounding sclerosis with faint calcification. This is the most common malignant bone tumor that may appear radiographically benign. The second type has no sclerotic border and is difficult to localize. The key sign of malignancy is endosteal scalloping. It is difficult to diagnose on plain radiographs and may go undetected for a long period. In contrast, peripheral chondrosarcoma is recognized easily as a large, calcified mass protruding from a bone. Its differential diagnosis includes large benign osteochondroma, parosteal osteosarcoma, and juxtacortical myositis ossificans. Correlation of clinical, radiographic, and histologic data is essential for accurate diagnosis and evaluation of the aggressiveness of cartilage tumor. Proximal or axial location, skeletal maturity, and pain point toward malignancy, even though the cartilage may appear benign.

**prognosis.** Metastatic potential tends to correlate with the histologic grade of the lesions.<sup>10,11,12,308</sup> Marcove et al.<sup>308</sup> reported on long-term follow up of 113 chondrosarcomas of the proximal femur and the pelvis. The survival rates in patients with grade I, II, or III lesions were 47%, 38%, and 15%, respectively; the overall survival rate was 52%. No significant difference was noted between grades I and II; however, the mortality rate for grade III was significantly higher ( $P < .02$ ) than for the other two. Eleven of 59 deaths occurred after 5 years. The authors emphasized that the meaningful survival interval should be considered 10 or 15 years. No relationship between grade, age, gender, or location was found, and there was no statistical difference between primary and secondary chondrosarcomas. Adequacy of surgical removal was the main determinant of recurrence. In general, chondrosarcomas occurring during childhood have a worse prognosis than those of adult onset.<sup>313</sup>

In a review of 125 chondrosarcomas at the Rizzoli Institute, Gitellis and colleagues<sup>13</sup> reported that adequacy of treatment was the main determinant of local recurrence, length of survival, and length of disease-free interval. Patients adequately treated had a 6% local recurrence rate, whereas the recurrence rate among those inadequately treated was 69%. The 10-year survival rates were 78% (adequately treated) versus 61% (inadequately treated). No relation between local recurrence and grade was determined.

In the largest reported series of chondrosarcomas from one institution, Bjornsson et al.<sup>314</sup> from the Mayo Clinic reported the experience and the clinical pathologic profiles of 344 patients with chondrosarcomas over 80 years. They analyzed the anatomic site, clinical history, and overall survival. Survival analysis was limited to 233 patients whose primary tumors were treated at the Mayo Clinic. The minimum follow-up was 5 years. The overall 5-year survival rate was 77%. Local recurrence developed in 19.7% of patients, and metastatic lesions in 13.7%. The recurrence rate was higher for tumors of the shoulder and pelvis than for tumors of long bones. Histologic tumor grade was an important predictor of local recurrence and metastases.

In general, peripheral chondrosarcomas have a lower grade than central lesions. Gitellis et al.<sup>13</sup> reported that 43% of peripheral lesions, compared with 13% of central lesions, were grade I. The 10-year survival rate among those with peripheral lesions was 77%, and among those with central lesions was 32%. Secondary

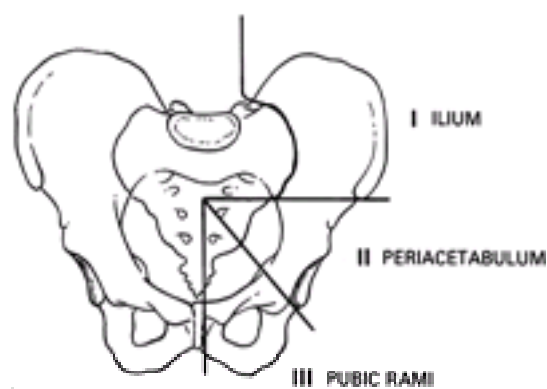

chondrosarcomas arising from osteochondromas also have a low malignant potential. Eighty-five percent are grade I. Garrison and associates <sup>58</sup> reported that only 3% of 75 patients with secondary chondrosarcomas from an osteochondroma developed metastases, although 12% died of local recurrence.

**TREATMENT.** The treatment of chondrosarcomas is surgical removal. <sup>10,12,308,313,315</sup> No reports of effective adjuvant chemotherapy have been published. Resection guidelines for high-grade chondrosarcomas are similar to those for osteosarcoma. The shoulder and pelvic girdle are the most common sites for chondrosarcomas. This, combined with the fact that chondrosarcomas tend to be low grade, make them amenable to limb-sparing procedures. Lesions of the ribs and sternum are treated by wide excision. Cryosurgery, a technique using liquid nitrogen after thorough curettage of the lesion, has been used for central, low-grade chondrosarcomas. <sup>131,132</sup> There have been a few reports of effective radiation therapy for axial chondrosarcomas and, more recently, encouraging reports using fractionated proton radiation therapy for the low-grade chondrosarcomas arising at the base of the skull. <sup>316</sup> The Massachusetts General Hospital group report a 5-year local control rate of 82% and a 10-year local control rate of 58% among 28 patients with low-grade base-of-skull chondrosarcomas treated to approximately 69 CGE (cobalt Gy equivalent) using the proton beam. <sup>317</sup> High-grade chondrosarcomas warrant consideration of adjuvant chemotherapy.

#### **Limb-Sparing Procedures: Specific Anatomic Sites**

The four most common sites of chondrosarcomas are the pelvis, proximal femur, shoulder girdle, and diaphyseal portions of long bones. The unique characteristics of each are described in the following sections.

**PELVIS.** The pelvis consists of three areas: ilium, periacetabulum, and pubic rami ( Fig. 39.2-13). Each site may be resected independent of the others. <sup>30,316</sup> Resections are classified as type I (iliac wing), type II (acetabulum), or type III (pubic rami, pelvic floor). Bone scan most accurately determines specific bony involvement, whereas CT and MRI delineate the extraosseous component. Contraindications to resection are vascular (iliac artery and vein), peritoneal, and sacroiliac joint and/or sarcoplasmic involvement.

**FIGURE 39.2-13.** Segmental resection for pelvic tumors.

The retroperitoneal space is explored first to determine resectability. Type I resection is performed by a supraacetabular osteotomy and disarticulation of the sacroiliac joint. Type II resection may require removal of the femoral head; intraarticular involvement of the hip joint by tumor is evaluated by arthrotomy before finalizing the surgical plan. Type II and III resections require mobilization of the iliac vessels and femoral nerve. Care must be taken to protect these structures. Type III procedure requires mobilization of the bladder and urethra before resection. Bilateral pelvic floor resection may be used for chondrosarcomas arising from the midline of the symphysis pubis, in which case urethral resection and reconstruction may be required. Partial cystectomy may be necessary.

Long-term results of these procedures have been published by Enneking and Dunham, <sup>30</sup> who reported that local recurrence was only 4% if adequate margins were obtained. Function was nearly normal if the hip joint was preserved. If the hip joint was removed and fusion was obtained, results were good. A saddle prosthesis ( Fig. 39.2-14) has been developed, permitting reconstruction after periacetabular resections with minimal morbidity. <sup>318</sup>

**FIGURE 39.2-14.** Limb-sparing resection for a large periacetabular chondrosarcoma involving the pelvic floor. **A:** Computed tomography shows acetabular destruction by a large tumor mass (arrows) with involvement of the pubic rami. **B:** The patient was treated by an internal hemipelvectomy (type II and III resection). **C:** A custom-made saddle prosthesis was used for the reconstruction. This is a new type of pelvic prosthesis that has made pelvic reconstruction more reliable with less morbidity than other techniques.

Treatment of malignant tumors of the pelvis is one of the greatest challenges in musculoskeletal oncology. Kawai and coworkers <sup>319</sup> reviewed 102 patients with localized pelvic sarcomas who underwent surgical excision at Memorial Sloan-Kettering Cancer Center. Chondrosarcoma was the most common diagnosis. They evaluated the prognostic factors for local recurrence, metastasis, and survival. The 5-year survival rate for sarcomas of pelvic chondrosarcomas was 65%. An inadequate surgical margin was the only independent prognostic factor for local recurrence. For distant metastases, surgical stage (i.e., histologic grade and site) is an independent prognostic factor.

**PROXIMAL FEMUR.** Chondrosarcoma of the proximal femur can often be treated successfully by resection and prosthetic replacement. A lateral trephine biopsy is recommended. Care must be taken to avoid intraarticular contamination. A posterior approach should be avoided because of potential contamination of the posterior flap in the event a hemipelvectomy is required.

**SHOULDER.** The technique of resection of chondrosarcomas of the proximal humerus and scapula is similar to that described for osteosarcomas. In low-grade, intracompartmental (stage IA) tumors, preservation of the deltoid, rotator cuff musculature, and glenoid is possible, and alternatives for reconstruction are more variable. Endoprostheses, fibula autografts, and allografts all have a high rate of success. <sup>35,36,37,38,39 and 40,139,140 and 141,254,255</sup>

**DIAPHYSEAL SEGMENTS OF THE TIBIA, FEMUR, AND HUMERUS.** Central diaphyseal chondrosarcomas can be adequately treated by segmental resection without sacrificing the adjacent joint. Because the ends of the bones are not involved, function is excellent. Reconstruction is performed by allografts or autografts combined with internal fixation.

**CRYOSURGERY.** Marcove et al. <sup>130,131 and 132</sup> pioneered the technique of cryosurgery for bone tumors. This method involves thorough curettage and cryotherapy of the cavity with liquid nitrogen. With increasing experience, the indications were expanded to low-grade intramedullary cartilage tumors as well as to some high-grade lesions. With these indications, they have treated 30 chondrosarcomas with only one local recurrence. The major advantages of cryosurgery are preservation of bone

stock and the avoidance of resection.

Schreuder et al.<sup>320</sup> reported the experience of 26 benign and low-grade intramedullary chondrosarcomas treated with curettage and cryosurgery. Fourteen enchondromas and nine grade I chondrosarcomas were treated with curettage, cryosurgery, and bone grafting. After a follow-up of 26 months, no recurrences were observed. The most common complication was postoperative fracture (two cases). All bone grafts had incorporated, resulting in full weight-bearing capacity and excellent functional results. These authors emphasized that the preoperative assessment of these lesions is essential and that only low-grade cartilage tumors should be treated with a cryosurgical technique.

### **Variants of Chondrosarcoma**

**CLEAR CELL CHONDROSARCOMA.** Clear cell chondrosarcoma, the rarest form of chondrosarcoma, is a slow-growing, locally recurrent tumor resembling a chondroblastoma but with some malignant potential.<sup>321</sup> It generally occurs in adults. The most difficult clinical problem of this entity is early recognition. It is often confused with chondroblastoma. Metastases occur only after multiple local recurrences. Primary treatment is wide excision. Systemic therapy is not required.

**MESENCHYMAL CHONDROSARCOMA.** Mesenchymal chondrosarcoma is a rare, aggressive variant of chondrosarcoma characterized by a biphasic histologic pattern (i.e., small, compact cells intermixed with islands of cartilaginous matrix).<sup>322,323</sup> and <sup>324</sup> It has a predilection for flat bones; long, tubular bones are rarely affected.<sup>216</sup> It tends to occur in younger individuals and has high rates of metastatic potential. Harwood and colleagues<sup>322</sup> reported that 8 of 17 patients died within 1 year of diagnosis. The 10-year survival rate is 28%.<sup>322</sup> This entity responds favorably to radiotherapy. It is hypothesized that the round cell component, similar to other round cell sarcomas, is relatively radiosensitive. Treatment is surgical removal combined with adjuvant chemotherapy. Radiotherapy is recommended if the tumor cannot be completely removed.<sup>324</sup>

Approximately 10% of chondrosarcomas may be dedifferentiated into a fibrosarcoma or osteosarcoma.<sup>2,10,11,57</sup> This occurs in older individuals and is highly fatal. Surgical treatment is similar to that described for other high-grade sarcomas. Adjuvant therapy is warranted.

### **Radiation Therapy in the Treatment of Chondrosarcoma**

Unresectable or inoperable chondrosarcomas arising within the axial skeleton and pelvic and/or shoulder girdle can be controlled, and in some cases cured, by radiation therapy. A unique situation is chondrosarcomas of the facial bones and skull, in which a combination of radiotherapy and surgery has been shown to be successful.

Although chondrosarcomas have generally been considered radioresistant, data exist to show that some are radiocurable.<sup>324</sup> Among 38 patients undergoing radical irradiation, with or without concurrent chemotherapy, at the Princess Margaret Hospital, 5- and 10-year actuarial survival rates of 41% and 36%, respectively, were achieved. Median survival was 46 months.<sup>324</sup> The best results, a 48% 5-year actuarial survival rate, were obtained in the group with favorable (well and moderately differentiated) histology. Conversely, for those with unfavorable (mesenchymal and poorly differentiated) histology, the 5-year survival rate was only 22%. Radical radiotherapy was defined as a minimum of 40 Gy in 4 or more weeks of megavoltage therapy. Of the 38 patients treated, 17 developed local recurrence. The authors recommend 50 Gy in 4 weeks with treatment to the whole bone if possible and, if not, at least a 5-cm margin of normal bone. These authors noted tumor regression continued slowly for 2 to 3 years after therapy.

McNaney et al.,<sup>325</sup> from the M. D. Anderson Cancer Center, reported 20 patients with chondrosarcoma treated with photons and/or neutrons, with or without chemotherapy. The doses of radiation administered ranged from 4000 to 7000 cGy. Thirteen of 20 (65%) were surviving at 30 months' median follow-up. Among the 11 patients treated with radiotherapy alone, six survived (54%). Six patients, all of whom had received photon therapy alone, developed local failure. No local failures were reported among the four patients treated with a mixed beam of photons and neutrons. Similarly, Hug et al.<sup>326</sup> reported 100% local control and disease-free status for six patients with axial skeleton chondrosarcoma treated with a mean target dose of 73.9 CGE delivered using a 160 MeV proton beam and 23 MV megavoltage beam.

After radical irradiation, clinical regression of tumor is slow and may take months to complete. Radiographically, the affected bone never returns to normal. The combination of extremely slow regression of tumor with a persistent radiologic defect makes follow-up and assessment of response difficult. No rebiopsy data are available to document long-term sterilization of these tumors. Radiotherapy for chondrosarcoma can provide palliation. In such cases, high doses (in the range of 5000 cGy in 4 to 5 weeks, or its equivalent) are necessary; low doses for symptomatic relief are ineffective.<sup>327</sup>

Ryall et al.<sup>328</sup> used radiation and the radiosensitizer razoxane (ICRF 159) in eight patients with 12 chondrosarcomas. Seven tumors in five patients achieved complete or partial remission after 4500 to 6000 cGy. Two of the responders were disease-free 2.5 years after treatment.

### **GIANT CELL TUMOR OF BONE**

GCT is an aggressive, locally recurrent tumor with a low metastatic potential.<sup>14,15</sup> and <sup>16,64</sup> and <sup>65,216,336</sup> It consists of spindle-shaped and ovoid cells uniformly interspersed with multinucleated giant cells. *Giant cell sarcoma of bone* is a term that refers to the *de novo*, malignant GCT, not the tumor that arises from the transformation of a GCT previously thought to be benign. These two lesions are separate clinical entities.

#### **Clinical Characteristics**

GCTs occur slightly more often in females than in males. Pain, mass, local tenderness, and decreased motion in the adjacent joint are the most common clinical symptoms. Eighty percent of GCTs in the long bones occur after skeletal maturity, and 75% of these develop around the knee joint.<sup>3,63</sup> An effusion or pathologic fracture, uncommon with other sarcomas, is common with GCTs. GCTs occasionally occur in the vertebrae (2% to 5%) and the sacrum (10%).<sup>2,3</sup> and <sup>4</sup>

#### **Grading and Pathologic Characteristics**

Jaffe<sup>4</sup> attempted to grade GCTs as grade I (completely benign), grade II (borderline), and grade III (frankly sarcomatous). In general, grades I and II do not correlate well with biologic behavior. There is also a poor correlation between the histologic pattern and the tendency for recurrence or malignant transformation.<sup>14,15,64,216</sup> Nineteen percent to 25% of GCTs have some osteoid production.<sup>216</sup> When osteoid formation is noted, care must be exercised in differentiating a GCT from an osteosarcoma. Conversely, an osteosarcoma with giant cells may be misinterpreted as a benign GCT. No correlation has been found between osteoid formation and increased risk of recurrence or metastasis. Necrosis or hemorrhage is often noted. Neither has a relationship to malignant potential or local recurrence rate.<sup>64</sup>

#### **Natural History**

Although GCTs are rarely malignant *de novo* (2% to 8%),<sup>14,330</sup> they may undergo transformation and demonstrate malignant potential histologically and clinically after multiple local recurrences.<sup>14,15</sup> and <sup>16</sup> Between 8.6% and 22% of known GCTs become malignant after local recurrence.<sup>14,15</sup> and <sup>16,216,330</sup> This rate decreases to less than 10% if patients who have undergone radiotherapy are excluded from the series. Hutter noted that 40% of malignant GCTs were malignant at the first recurrence<sup>15</sup>; the remainder had become malignant by the second or third recurrence. Thus, each recurrence increases the risk of malignant transformation of typical GCT, especially if the transformation occurs after radiation therapy. Local recurrence of a GCT is determined by the adequacy of surgical removal rather than histologic grade.

#### **Radiographic and Clinical Evaluation**

Giant cell tumors are eccentric lytic lesions without matrix production. They have poorly defined borders with a wide area of transition. They are juxtaepiphyseal with a metaphyseal component. Although the cortex is expanded and appears destroyed at surgery, it is usually found to be attenuated but intact. Periosteal elevation is rare; soft tissue extension is common.

## Treatment

Treatment of GCT of bone is surgical removal. Resection is curative in 90% of these tumors,<sup>14,15</sup> whereas curettage, with or without bone grafts, has a recurrence rate of 40% to 75%.<sup>14,15</sup> and <sup>16,64,331</sup> Johnson and Dahlin<sup>16</sup> reported a recurrence rate of 29% within 1 year of curettage and of 54.1% within 5 years. O'Donnell and colleagues<sup>332</sup> reviewed the literature from 1970 to 1990 and reported an overall recurrence rate of approximately 40%.

Although *en bloc* excision offers a reliable cure, routine resection is not recommended.<sup>331,332</sup> and <sup>333</sup> Primary resection of a joint has a significant morbidity. It is recommended for GCT of the proximal radius and fibula, distal ulna, tubular bones of the hand and foot, coccyx, sacrum, and pelvic bones. Under certain situations, a curettage is reasonable. If the lesion heals, resection is avoided. In general, curettage does not rule out a later curative resection. Today, the technique of curettage is more extensive than previously performed. Curettage is accomplished through a large cortical window, equal to the length of the bony defect, using both mechanical curettage and a mechanical burr. This extensive technique has been termed *curettage/resection* and has decreased the rate of local recurrence to approximately 15% to 25%. Bone graft and PMMA are used to reconstruct the surgical defect.

O'Donnell et al.<sup>332</sup> reviewed the experience at the Massachusetts General Hospital of 60 patients with GCTs treated by curettage and packing with PMMA. The overall rate of local recurrence was 25% (15 of 60 patients) occurring at an average of 4 years. Risk factors for local recurrence were pathologic fracture, stage III disease, anatomic site, and the use of adjuvant treatment. The distal radius and the proximal tibia had the highest rate of local recurrence: 50% (five of ten patients) and 28% (7 of 25 patients), respectively. These authors emphasized that adjuvant treatment with a high-speed burr or PMMA, or both, after curettage decreased the local recurrence rate from 42% (8 of 19 patients) to 17% (7 of 41 patients). They concluded that PMMA alone did not reduce the rate of local recurrence, but that the use of a wide curettage combined with additional curettage with a high-speed burr is necessary.

Malawer et al.,<sup>334</sup> in a multicenter study of 100 cases of GCTs of the extremities (treated with wide curettage, high-speed burr, and either a single or double cycle of cryosurgery with liquid nitrogen), reported a local recurrence rate of 9% (9 of 100 patients). They used the direct-pour technique as described by Marcove.<sup>131,132</sup> Reconstruction of the surgical defect was performed with PMMA (combined with internal fixation in most cases). The secondary fracture rate was 5%. Only two patients required a secondary resection and prosthetic replacement. These authors recommend liquid nitrogen adjuvant after curettage in the treatment of GCTs.

Amputation is reserved for massive recurrence, malignant transformation, or infection. Because of the biologic propensity for malignant transformation, radiation is reserved for specific lesions, usually lesions of the spine, that cause bone destruction in a confined area and can lead to spinal cord compression and severe deformity.<sup>335</sup> Thus, treatment of GCT of the vertebrae and sacrum must be individualized. A combination of surgical excision and cryosurgery or radiotherapy is required to eradicate the tumor and prevent neurologic impairment.<sup>117</sup>

## Cryosurgery

Cryosurgery has been used more successfully for GCTs than for any other type of bone tumor.<sup>130,131</sup> and <sup>132,334</sup> Marcove<sup>131,132</sup> developed the technique of cryosurgery because of the high recurrence rates after curettage and the significant risk of sarcomatous degeneration in GCTs treated by irradiation. He found cryosurgery effective in eradicating the tumor while preserving joint motion and avoiding resection or amputation. He reported a 17-year experience of 100 GCTs treated by thorough curettage and cryosurgery.<sup>131</sup> He noted a recurrence rate of 16% in the first 50 cases and 2% in the following 50 cases. The major complications of cryosurgery are necrosis of the adjacent bones, which are liable to develop a late pathologic fracture, and delayed union. The rate of secondary pathologic fracture has been decreased by a combination of PMMA, augmentation, bone graft, internal fixation of the cavity, and postoperative use of a long-leg brace with a quadrilateral socket.<sup>336,337</sup> Persson and Wouters<sup>338</sup> have reported curettage with PMMA augmentation of the bony defect with bony necrosis due to the heat of polymerization. This technique may provide better local control than curettage alone.

Bickels and colleagues<sup>333</sup> reported 102 patients treated by curettage and cryosurgery at two institutions between 1983 and 1993. The surgical stage was I in 15 cases, II in 47 cases, and III in 40 cases. Sixteen percent of the patients had presented with local recurrences. The local recurrence rate among 86 patients treated primarily with cryosurgery was 2.3%. There were six local recurrences among 16 patients who were referred with recurrent disease. The overall recurrence rate was 7.9%. The most common complication was pathologic fracture (5.9%). No pathologic fractures occurred when internal fixation was used along with PMMA. This study emphasized that the overall function was good to excellent in 92% of the patients. All 102 patients were free of disease at final follow-up.

Cryosurgery is a powerful physical adjunct to curettage in the treatment of GCTs of bone. Bickels and colleagues<sup>333</sup> recommend routine use of cryosurgery for all GCTs of long bones.

## Giant Cell Tumors of the Sacrum

Giant cell tumors of the sacrum are difficult to treat. Patients often present with back pain, neurologic deficits, and rectal symptoms. The diagnosis is often delayed. CT, MRI, and bone scintigraphy are required for accurate local anatomic staging. Turcotte et al.<sup>339</sup> reviewed the treatment of 26 patients treated at the Mayo Clinic between 1960 and 1986 with an average follow-up of 7.8 years. Neurologic deficit was present in 88%. The local recurrence rate for patients treated by curettage was 33%. Twenty-one patients had radiation therapy; malignant transformation occurred in three. They suggested initial treatment is complete curettage. Radiation therapy is recommended for incomplete resection and local recurrence. Resection of the sacrum should be reserved for extensive recurrences. The technique of surgical resection of the sacrum is similar to the combined anterior and posterior approach described for chordomas.

**RADIATION THERAPY.** The specific indications for radiation include inoperable and incompletely resected lesions, and lesions that occur locally despite definitive surgery. These situations are most likely to occur in the spine.<sup>335</sup> Doses of 35 to 50 Gy in 4 to 5.5 weeks using megavoltage equipment is recommended.

Although concern has been raised about malignant transformation after radiotherapy,<sup>340,341,342,343,344,345,346,347,348</sup> and <sup>349</sup> transformation also occurs independent of radiation, most often after multiple local recurrences, suggesting that this observation is best explained by the natural history of the disease.<sup>350</sup>

Giant cell tumor is not radioresistant, as was once believed. Local control rates range from 75% to 85% in more recent series.<sup>339,342,343</sup> and <sup>344</sup> The Princess Margaret Hospital group has reported that local control was achieved in 13 of 14 patients with GCT treated with one course of megavoltage radiation. The disease in 12 patients was controlled for longer than 5 years.<sup>342</sup> The researchers observed no instance of malignant transformation. Larsson and colleagues<sup>335</sup> reported three patients with GCT of the spine and sacrum treated by moderate doses of radiotherapy; all have done well. Similarly, the Gainesville group reports 12 of 16 tumors (75%) controlled locally with 35 to 54 Gy, with no untoward complications or secondary sarcomas.<sup>343</sup> Several authors now suggest curettage, followed by planned megavoltage radiation, as a good alternative to complex and difficult surgery.

## MALIGNANT FIBROUS HISTIOCYTOMA

### Clinical Characteristics

MFH is a high-grade bone tumor histologically similar to its soft tissue counterpart.<sup>7,8</sup> and <sup>9</sup> It is a disease of adulthood. The most common sites are the metaphyseal ends of long bones, especially around the knee. AP values are normal. Pathologic fracture is common. Huvos<sup>9</sup> emphasized that a lytic metaphyseal lesion with a pathologic fracture in an adult with a normal serum AP level suggests a primary MFH rather than an osteosarcoma or fibrosarcoma. MFH disseminates rapidly. Spanier and colleagues<sup>7</sup> reported that 9 of 11 patients died of the tumor. The average disease-free survival was 6 months. One-third of patients (three of nine) with pulmonary metastasis had lymph node dissemination. The author hypothesized that lymphatic spread was due to the histiocytic component of the tumor.

### Radiographic Characteristics

MFH is an osteolytic lesion associated with marked cortical disruption, minimal cortical or periosteal reaction, and no evidence of matrix formation.<sup>9</sup> The extent of the tumor routinely exceeds plain radiographic signs. McCarthy et al.,<sup>8</sup> reporting on 35 patients with MFH, noted that four tumors were multicentric and four were

associated with bone infarcts.

### **Treatment**

Today, MFH and osteosarcoma of bone are treated in much the same way. Data demonstrate that results of limb-sparing surgery for MFH of bone, as well as responses to chemotherapy among MFH patients, are very similar to those of patients with primary osteosarcoma. Picci et al.,<sup>351</sup> in the largest review to date, evaluated the effects of neoadjuvant chemotherapy of MFH of bone and extremity osteosarcomas. They reported 51 patients treated with high-grade MFH of bone and 390 patients with high-grade osteosarcoma treated with identical regimens of neoadjuvant chemotherapy at the Rizzoli Institute between 1982 and 1994. All tumors were located in the limbs. Preoperative chemotherapy was performed according to three successively activated regimens consisting of methotrexate and *cis*-diamminedichloroplatinum II (CDP): MTX/CDP intraarterially, MTX/CDP plus Adriamycin, and MTX/CDP plus Adriamycin and ifosfamide). Rates of limb salvage were approximately the same for MFH (92%) and osteosarcoma (85%). Although MFH showed a statistically significantly lower rate of good histologic response, the rate of tumor necrosis for MFH was 90% or more [27% vs. 67% for osteosarcoma ( $P < .001$ )] for all three regimens. Despite this low chemosensitivity, the disease-free survival rates for the two neoplasms were similar (67% vs. 65%). Nevertheless, the two tumors had similar prognoses when treated with chemotherapy regimens based on methotrexate, cisplatin, Adriamycin, and ifosfamide. The surgical procedures were both similar limb-sparing procedures. This study emphasized that induction chemotherapy, followed by limb-sparing surgery and subsequent postoperative chemotherapy, was just as effective for MFH of bone as for the osteosarcomas.<sup>339</sup>

Bacci et al.,<sup>352,353</sup> also from the Rizzoli Institute, reported on 65 patients treated with MFH of bone in the extremities with neoadjuvant chemotherapy. The limb-salvage rate was 89% (58 patients) and amputation rate was 11% in seven patients. The histologic response to preoperative chemotherapy was good (90% or more tumor necrosis) in 16 patients (25%) and poor in 49 patients (75%). At a median follow-up of 7 years, 40 patients (69%) remained free of disease and 20 patients experienced relapse (18 metastases and two local recurrences followed by metastases). The rate of disease-free survival was significantly higher for patients who had a good response than for those who had a poor response (94% vs. 61%). Similarly, these authors concluded that a high percentage of patients with MFH of the extremities can be cured with neoadjuvant chemotherapy and that it is usually possible to avoid amputation. Similarly, Nishida and colleagues<sup>354</sup> from the Mayo Clinic reviewed their experience with MFH of the extremities and reported that the overall prognosis for patients with MFH was not significantly different from that of patients with osteosarcoma. The primary approach to the treatment of MFH of bone is similar to that of osteosarcoma—wide surgical resection (usually limb-sparing surgery) combined with pre- and postoperative chemotherapy. Similar chemotherapeutic regimens are recommended.

## **FIBROSARCOMA OF BONE**

### **Clinical Characteristics**

Fibrosarcoma of bone is a rare entity characterized by interlacing bundles of collagen fibers (herringbone pattern) without any evidence of tumor bone or osteoid formation.<sup>5</sup> Fibrosarcoma occurs in middle age. The long bones are most affected. Fifteen percent of tumors are found in the bones of the head and neck.<sup>216</sup> Fibrosarcomas occasionally arise in conjunction with an underlying disease, such as fibrous dysplasia, Paget's disease, bone infarcts, osteomyelitis, and postirradiation bone and GCT.<sup>5</sup> Fibrosarcoma may be either central or cortical (periosteal). The histologic grade is a good prognosticator of metastatic potential. Huvos and Higinbotham<sup>5</sup> reported overall survival rates of 27% and 52% for central and peripheral lesions, respectively. Late metastases do occur, and 10- and 15-year survival rates vary. In general, periosteal tumors have a better prognosis than central lesions.

### **Radiographic Features**

Fibrosarcoma is a radiolucent lesion that shows minimal periosteal and cortical reaction. The radiographic appearance closely correlates with the histologic grade of the tumor.<sup>5</sup> Low-grade tumors are well-defined, whereas high-grade lesions demonstrate indistinct margins and bone destruction similar to that of osteolytic osteosarcoma. In general, plain radiographs underestimate the extent of the lesion. Pathologic fracture is common (30%) owing to the lack of matrix formation. Differential diagnosis includes GCT, ABC, MFH, and osteolytic osteosarcoma.<sup>5,6</sup>

Fibrosarcoma of bone is primarily managed surgically. Irradiation is recommended for inoperable tumors, for patients with postsurgical residual disease, and for palliation.

## **MALIGNANT HEMANGIOENDOTHELIOMA OF BONE**

Malignant hemangioendothelioma of bone (also referred to as *epithelioid hemangioepithelioid sarcoma* or *histiocytoid hemangioma*) comprises only 0.5% to 1.0% of primary malignant bone tumors.<sup>355,356,357</sup> and <sup>358</sup> More than one-third of these lesions arise in the long, tubular bones, especially those of the lower extremity.<sup>356,358</sup> Incidence peaks in the third decade of life, but the tumor can present at any age. Multicentric lesions are common. The treatment of choice has been surgery, often in combination with radiotherapy.<sup>358</sup> In rare cases, radiotherapy has been the sole modality of treatment.<sup>355,357,358</sup> Radiation doses in the range of 50 to 60 Gy are associated with long-term local control. Chemotherapy plays no significant role in treatment.

## **CHORDOMA**

Chordoma is a rare neoplasm arising from notochordal remnants in the midline of the neural axis and involving the adjacent bone. The ends of the spine are the most common sites. The sacrococcygeal and the base of the skull (35%) near the sphenoid-occipital area are most commonly involved, accounting for 50% and 35%, respectively, of all chordomas.<sup>216</sup> Histologically, the physaliferous cell is pathognomonic. Large areas of syncytial strands of cells lying in a mass of mucus are typically present. Myxoid chondrosarcoma and metastatic carcinoma must be differentiated. This tumor is highly fatal because of the high rate of local recurrence and local complications.<sup>359,360,361</sup> and <sup>362</sup> Death is most commonly due to local disease.<sup>359</sup> Gray and colleagues<sup>362</sup> reviewed 222 cases from the literature and noted that only two patients were disease-free at 10 years. Average survival was 5.7 years. Mindell<sup>359</sup> emphasized that the main malignant potential of chordomas resides in their critical locations adjacent to important structures, their locally aggressive nature, and their extremely high rate of recurrence. Chordomas at the base of the skull are often described as *chondroid chordomas*. Patients with these lesions at this site tend to survive longer than those with the sacrococcygeal tumors.

The most common complaint of patients with sacrococcygeal tumors is dull pain; constipation is an occasional symptom. Bladder and sensory loss are late complaints. Clinical suspicion is the key to early diagnosis. Rectal examination characteristically reveals a large presacral mass. Sphenoid-occipital tumors present with signs of cranial nerve or pituitary dysfunction, or both. CT and MRI are essential for accurate evaluation. Myelography is used to determine intraspinal extension. A transrectal biopsy should not be performed because of potential contamination. A small midline posterior incision or trocar biopsy is recommended.

### **Treatment**

The first surgical procedure has the best chance of cure.<sup>361,362</sup> Inadequate surgery results in local recurrence, with little chance of subsequent surgical removal. Sacrococcygeal tumors are best removed by a combined abdominosacral approach, as described by Localio and colleagues.<sup>360,361</sup> They emphasized wide excision of the sacrum one level higher than the lesion. A lateral position is used. The rectum can be mobilized and the iliac vessels controlled anteriorly. The rectum may be removed with the sacrum if necessary. Guterberg et al.<sup>364</sup> reported that if only one-half of the first sacral vertebra remains bilaterally, the pelvic girdle is still stable enough to allow immediate mobilization. DeVries and associates<sup>363</sup> reported two long-term survivors (7 years and 10 years) after cryosurgery of sacral chordomas.

### **Radiation Therapy**

Because local recurrence is common with chordomas, radiation therapy is an integral treatment modality, particularly for tumors of the base of skull and sphenoid-occipital region. Results of conventional radiation therapy have been disappointing. Heffelfinger et al.<sup>365</sup> reported on 36 patients with nonchondroid varieties of chordomas of the base of skull, none of whom were rendered free of disease by surgery, radiation, or a combination thereof. However, the chondroid variant is more sensitive; of 19 patients with chondroid chordomas, seven were alive and six were disease-free.

Amendola et al.,<sup>366</sup> reported on 21 patients with a 5-year survival rate of 50% but a disappointing 10-year survival rate of only 20%. This is not surprising, because chordomas are relatively slow-growing. In fact, long-term survival free of tumor regrowth over 10 years is relatively rare. Amendola et al. emphasized the importance

of using CT in planning the radiation field, administration of high radiation doses (i.e., 5500 to 7000 cGy with megavoltage equipment), and use of irradiation immediately after surgery to prolong local control, rather than reserving it until recurrence. The Massachusetts General Hospital experience of 48 patients is similar to that reported by others; 50% of the patients survived years or more.<sup>367</sup> Radiation doses varied from 4500 to 8040 cGy, but even with high doses, a 45% incidence of local recurrence was reported. The Princess Margaret Hospital group investigated various fraction schedules in an effort to impact local control. They used conventionally fractionated radiation at a median dose of 50 Gy in 25 fractions over 5 weeks, and a hyperfractionated course of 1 Gy over 4 hours four times per day, with a median dose of 40 Gy in 44 fractions over 14 days. No difference was found between the conventional or hyperfractionated regimen with respect to symptomatic response or progression-free interval. With a median survival of 65 months, the authors concluded that external-beam radiation provided useful palliation but was rarely curative.<sup>368,369</sup>

Investigators now advocate using precision heavy-charged particle irradiation, particularly for chordoma of the basisphenoid region and cervical spine. The Massachusetts General Hospital experience now includes 68 patients, 40 with chordomas and 28 with low-grade chondrosarcomas of the basisphenoid region and cervical spine, who have been treated with proton-beam radiation therapy at a median tumor dose of 69 CGE. The actuarial 5-year disease-free survival rate is 76%, whereas the local control rate is 82%.<sup>370,371</sup> No difference was found in local control between those patients with low-grade chondrosarcoma and those with either chondroid or nonchondroid chordoma.<sup>370</sup> Hug and the Massachusetts General Hospital investigators<sup>326</sup> have reported axial skeleton chordoma treated with a myxoid proton and photon beam (mean dose of 73.9 CGE). Five of 14 patients (36%) had local recurrence, and two of the five developed distant metastases. The 5-year actuarial local control and overall survival rates were 53% and 50%, respectively, for the chordoma patients. Other groups also report local control and reversal of neurologic symptoms and signs using 75.5 Gy proton therapy for chordoma of the clivus.<sup>372</sup> Proton therapy should be considered after initial surgical removal for inoperable clivus chordoma.

Stereotactic radiosurgery has been tried for skull-based tumors and is a potential means to provide symptomatic relief for small-volume (4 cm or smaller) tumors.<sup>373,374</sup>

## SMALL ROUND CELL SARCOMAS OF BONE

Round cell sarcomas of bone behave differently than spindle cell sarcomas and require different therapeutic management.<sup>375,376</sup> These tumors consist of poorly differentiated small cells without matrix production. They present radiographically as osteolytic lesions. These lesions are best treated with radiation and chemotherapy; surgery is reserved for special situations. Non-Hodgkin's lymphoma and Ewing's sarcoma are the two most common small cell sarcomas. The differential diagnosis of all round cell sarcomas includes metastatic neuroblastoma, metastatic undifferentiated carcinoma, histiocytosis, small cell osteosarcoma, osteomyelitis, and multiple myeloma.

## LYMPHOMAS OF BONE (DIFFUSE LARGE CELL LYMPHOMA)

Lymphoma of bone (previously called *reticulum cell sarcoma of bone*) accounts for only 5% of the primary bone tumors. In general, lymphoma presenting in bone is a sign of disseminated (stage IV) disease; occasionally, it may be a true solitary lesion defined as "involvement of single extralymphatic organ or site" (stage IE).<sup>375,376</sup> Reimer and coworkers<sup>375</sup> at the National Cancer Institute reported that only 1 of 12 patients presenting with bone lymphomas had a true solitary lesion. Sweet and colleagues<sup>376</sup> from the University of Chicago reported that 50% of so-called "solitary" lesions were associated with disease elsewhere. Sweet et al. presented a useful algorithm for the evaluation and treatment of bone lymphomas. They emphasized that all patients with a presumed solitary lymphoma of bone should undergo a thorough evaluation for other involvement.<sup>376</sup>

Treatment is based on extent of disease. Stage IE lesions have traditionally been treated with radiotherapy, with a reported 90% cure rate.<sup>375</sup> The role of surgery is limited to obtaining adequate tissue for diagnosis and treatment of pathologic fracture. The technique of biopsy is important to avoid secondary fracture through potentially irradiated bone. Biopsy for a suspected round cell tumor should always include a frozen section and additional material for electron microscopy, tissue culture, and immunophenotyping. Patients presenting with pathologic fractures require fixation. To prevent late fractures, all patients treated with radiotherapy should be protected with a brace until reossification occurs.

### Radiation Therapy

Local control of the primary tumor with retention of good function of the affected part is commonly achieved after radiation therapy. Radiation therapy is administered to the entire bone and soft tissue extent with a dose of 4000 cGy and a boost to the original tumor area of 500 cGy. Regional lymph nodes should be included in the radiation port if they are adjacent to the area treated or if clinically involved. Mendenhall et al.<sup>377</sup> from the University of Florida achieved local and regional control in all irradiated sites among 21 patients with primary bone lymphomas. Two patients relapsed in apparently uninvolved regional lymph node sites that had not been included in the primary treatment portal.

Patients with lymphoma of the bone should be considered to have systemic disease; accordingly, they require chemotherapy. Patients treated with radiation and Adriamycin-based chemotherapy have long-term survival in the 90% to 100% range. The Dana Farber Cancer Center reported 90% lymphoma-free survival at 8 years, with radiation and the Adriamycin, prednisone, and Oncovin combination regimen.<sup>378</sup> Similarly, the Bone Tumor Center in Bologna, Italy, reports 88% disease-free survival at 7.5 years with radiation and Adriamycin, vincristine, and cyclophosphamide.<sup>379</sup> Patients presenting with monostotic disease have a better outcome than those with polyostotic disease.<sup>380,381</sup> Although a randomized controlled clinical trial testing radiation therapy and chemotherapy versus radiation therapy alone has not been performed, combined modality is commonly used in adults with primary and non-Hodgkin's lymphoma of the bone.<sup>383,384</sup> The international index parameters of age 60 years or younger, normal lactate dehydrogenase, and Eastern Cooperative Oncology Group performance status of 0 are prognostic factors for good outcome.<sup>382</sup> The Dana Farber investigators reported second bone tumors 5 and 7.5 years after combined modality therapy. Because of this concern and the success of intensive combination chemotherapy, investigators have begun to question the need for primary radiation therapy among children responding to multiagent chemotherapy.<sup>385,386</sup> The Pediatric Oncology Study Group<sup>387</sup> studied the impact of localized bone radiotherapy in children with early-stage primary non-Hodgkin's lymphoma, all of whom received multiagent chemotherapy. Thirty of 31 were disease-free and all survived, thus leading these investigators to recommend a 9-week chemotherapy regimen of modest intensity without radiation therapy as definitive treatment of children with localized primary lymphoma of the bone.

#### INTRODUCTION

Malignant mesotheliomas (MMs) are highly aggressive neoplasms that arise primarily from the surface serosal cells of the pleural, peritoneal, and pericardial cavities. Epidemiologic studies have established that exposure to asbestos fibers is the primary cause of MM, <sup>1</sup> and more recent investigations have implicated simian virus 40 (SV40) in the etiology of some MMs. <sup>2,3</sup> and <sup>4</sup> MM is characterized by a long latency from the time of exposure to asbestos to the onset of disease, suggesting that multiple somatic genetic events are required for tumorigenic conversion of a normal mesothelial cell. Early evidence in support of this notion was provided by karyotypic analyses, which revealed multiple clonal cytogenetic alterations in most human MMs. <sup>5</sup> Although a specific chromosomal change is not shared by all MMs, several prominent sites of chromosome loss have been identified in this malignancy. Tumor suppressor genes (TSGs) residing in these deleted chromosome regions may be responsible for the tumorigenic conversion of mesothelial cells, and studies have begun to identify the specific TSGs that contribute to the development and progression of MM. In this chapter, we provide an overview of recurrent chromosome deletions and molecular genetic alterations characteristic of MM. We also review the mechanistic role of asbestos and SV40 in this malignancy.

#### MECHANISM OF ASBESTOS-INDUCED ONCOGENESIS

Presently, it is not known whether asbestos fibers act directly on mesothelial cells or if they act indirectly via formation of reactive oxygen species (ROS) and growth factors. <sup>6,7</sup> In tissue culture, asbestos can physically interact with the mitotic spindle apparatus, which can result in aneuploidy and other forms of chromosome damage. <sup>8</sup> *In vivo*, iron-rich crocidolite asbestos fibers may lead to the release of ROS when hydrogen peroxide and superoxide react to form hydroxyl radicals. Asbestos has been shown to induce the expression and enzymatic activity of the mammalian DNA repair enzyme, apurinic/aprimidinic (AP) endonuclease, suggesting that ROS generated by asbestos may induce DNA damage. <sup>9</sup> Furthermore, the inflammatory response to asbestos leads to the generation of several cytokines that are responsible for the well-known local and systemic immunosuppressive activity of asbestos. <sup>10</sup> Asbestos can also induce autophosphorylation of the epidermal growth factor (EGF) receptor, leading to increased expression of the protooncogenes *c-fos* and *c-jun*, which encode transcription factors that activate various genes critical in the initiation of DNA synthesis. <sup>6</sup> Persistent induction of these transcription activators by asbestos may enhance cellular proliferation and could render cells more susceptible to subsequent mutations in TSGs. Such enhanced expression of protooncogenes and inactivation of TSGs may cooperate in a multistep process that leads to MM.

#### CYTOGENETIC ASSESSMENT OF MALIGNANT MESOTHELIOMAS

Chromosome banding analyses have revealed that most MMs have complex karyotypes. <sup>5</sup> Among 20 MMs karyotyped by one of us (J. R. T.), all but one displayed more than ten clonal chromosome alterations. <sup>11</sup> Deletions of specific regions in the short (p) arms of chromosomes 1, 3, and 9 and long (q) arm of 6 were repeatedly observed in these tumors. Loss of a copy of chromosome 22 is the single most consistent numerical change seen in MMs. In the series by Taguchi et al., <sup>11</sup> deletions and unbalanced rearrangements accounted for overlapping losses from the chromosome region 1p21-22 in 17 of 20 cases (85%). Thirteen of 20 MMs (65%) had interstitial deletions or other rearrangements that resulted in losses from 3p21. Ten cases (50%) showed losses from 6q, with a shortest region of overlap (SRO) at 6q15-21. Losses involving 9p were observed in 16 cases (80%), with the SRO being 9p21-p22. Monosomy 22 was documented in 13 cases (65%). These recurrent losses of 1p, 3p, 6q, 9p, and 22q frequently occurred in combination in a given tumor. All five of these aberrations were found in 5 of our 20 MMs. Losses of 1p, 3p, 9p, and 22q coexisted in another three cases, and various combinations of three of these four abnormalities were seen in seven other cases. It is not known if this multistep cascade evolves slowly during the course of tumor formation or in rapid succession at some critical stage of the disease. In any case, the accumulated loss of DNA sequences from chromosomes 1p, 3p, 6q, 9p, and 22q appears to play a critical role in the pathogenesis of MM.

More recent molecular cytogenetic studies, using comparative genomic hybridization (CGH), also have documented recurrent genomic imbalances in MM. CGH is a fluorescence *in situ* hybridization technique that permits the identification of chromosome gains and losses in the entire tumor genome in a single experiment. Balsara et al. <sup>12</sup> performed CGH analyses on 24 MM cell lines derived from patients seen in the United States; each of these cell lines exhibited multiple (6 to 25) genomic imbalances. Losses involving 22q, documented in 14 of 24 cell lines (58%), was the most prominent alteration. Also in agreement with earlier karyologic findings, losses of 1p, 3p, 6q, and 9p were common, with each being observed in approximately 30% to 40% of cell lines. In addition, CGH analysis uncovered other recurrent chromosome losses not highlighted in previous karyotypic studies. In particular, 13 of 24 MMs (54%) showed losses of part or all of 15q, with the SRO being 15q11.1-21. In addition, losses involving 14q24.2-qter and 13q12-14 were each observed in 42% of the cell lines. The most frequently overrepresented chromosomal arm was 5p (54% of cases), suggesting the involvement of a putative oncogene(s) at this location.

Many of the recurrent genomic imbalances identified in U.S. cases were also detected in MM specimens examined by Finnish investigators. <sup>13</sup> However, three prominent imbalances in the series from the United States (i.e., losses of 15q11.1-21.1, 8p21-pter, and 3p21) were each observed in only 1 of 42 cases from Finland. Discrepancies between the data from Finland and the United States could reflect dissimilarities in the type of asbestos exposure or genetic differences in the study populations. Alternatively, they may be related to the presence of SV40 in MMs from the United States and the absence of SV40 in MMs from Finland. <sup>14</sup>

#### DELETION MAPPING

The recurrent genomic losses just described are consistent with a recessive mechanism of oncogenesis and can be viewed as indicators of the locations of putative TSGs important in the development and progression of MM. As a prelude to the isolation of these genes, the critically deleted regions in 1p, 3p, 6q, 9p, and 15q defined by cytogenetic studies of MM have been mapped at the molecular genetic level by loss of heterozygosity (LOH) analysis using polymorphic DNA markers. Results of these investigations have been reviewed in detail elsewhere, <sup>5</sup> but are briefly summarized here.

#### CHROMOSOME 1p22

To map the critically deleted region of 1p, Lee et al. <sup>15</sup> performed LOH analyses of 50 MMs using a large panel of DNA markers located throughout the entire short arm of chromosome 1. Allelic losses at 1p21-22 were observed in 36 cases (72%), and we were able to localize the SRO of deletions to a 4-centimorgan segment within 1p22. Currently, candidate TSGs mapped to this region are being assayed for possible mutations and altered expression in MMs.

## CHROMOSOME 3p21

Research groups led by two of us (J. R. T., H. I. P.) have independently demonstrated that 3p is a common site of allelic loss in MM. In one of these investigations, for example, 15 of 24 cases (62.5%) exhibited losses from 3p, with the highest frequency being at 3p21.3. Losses from this region also have been reported in many other malignancies, particularly lung cancers, suggesting that perturbation of a TSG(s) located in this region may play a role in the development of multiple tumor types.

## CHROMOSOME 6q

LOH analysis of 6q has revealed a complex pattern of allelic loss. LOH at 6q occurs in approximately 60% of MMs, and deletions fall into several discrete regions involving markers mapped within 6q14-21, 6q16.6-21, 6q21-23.2, and 6q25. Multiple nonoverlapping regions of 6q loss also have been described in other types of malignancy, such as non-Hodgkin's lymphoma.

## CHROMOSOME 9p21

To map the minimal region of 9p deletion in MMs, one of us (J. R. T.) initially performed gene dosage studies on a series of MM cell lines, 83% of which showed homozygous or hemizygous deletions involving an approximately 1-megabase segment located between the interferon gene cluster and the marker D9S171 in 9p21. The *CDKN2A* locus, which encodes the alternative TSG products p16 and p14<sup>ARF</sup> is located within this region. The cellular function of p16 and p14<sup>ARF</sup> and their potential role in MM are discussed in the following section, [Alterations of Tumor Suppressor Genes in Mesothelioma](#).

## CHROMOSOME 15q11.1-15

CGH analyses performed by Balsara et al.<sup>12</sup> revealed losses from 15q in 13 of 24 MM cell lines (54%) examined, and subsequent LOH analyses showed allelic losses from one or more 15q loci in 10 of these 13 lines. The extent of overlap of 15q deletions was used to define a minimal region of chromosome loss within 15q11.1-15. Losses overlapping this region also have been observed in several other types of malignancy, such as metastatic tumors of the breast, lung, and colon, suggesting that this region harbors a TSG that may contribute to the progression of diverse cancer types.

## ALTERATIONS OF TUMOR SUPPRESSOR GENES IN MESOTHELIOMA

One of the protein products of the *CDKN2A* locus, p16, is capable of binding to the cyclin-dependent kinase CDK4, thereby inhibiting the catalytic activity of the CDK4/cyclin D enzymes. Several months after its initial cloning, the *p16* gene was identified as the 9p21 putative TSG by using a positional cloning approach, and homozygous deletions of *p16* were detected at high frequencies in cell lines derived from many different kinds of cancer.<sup>16</sup>

Because of its location within the region we previously determined as the SRO of 9p deletions in MMs and because of its involvement in many other cancer types, *p16* emerged as the prime candidate for the 9p TSG in MM. Among 40 MM cell lines studied by Cheng et al.,<sup>17</sup> 34 (85%) had homozygous deletions of one or more *p16* exons and another had a point mutation in *p16*. Down-regulation of *p16* was observed in four of the remaining cell lines. Homozygous deletions of *p16* were identified in 5 of 23 MM specimens (22%). The finding of a much higher incidence of *p16* alterations in MM cell lines than in tumor tissues may be associated with a selective growth advantage provided by *p16* deletion during the culturing process. On the other hand, MM samples often contain a significant amount of contaminating normal stroma, which can mask the existence of a homozygous deletion in the malignant cell population. Down-regulation of *p16* in MM cells may result from 5' CpG island hypermethylation, as has been demonstrated in other types of cancer.<sup>18</sup> At the protein level, Kratzke et al.<sup>19</sup> reported abnormal expression of p16 in 12 of 12 MM specimens and 15 of 15 MM-derived cell lines examined by immunohistochemistry. Moreover, in xenograft experiments, reexpression of p16 in MM cells resulted in cell-cycle arrest and cell death, as well as inhibition of tumor formation or diminished tumor size.<sup>20</sup>

It is important to note that homozygous deletions of the *CDKN2A* locus would in many cases also lead to the inactivation of another putative TSG, *p14<sup>ARF</sup>* (the mouse homologue is *p19<sup>ARF</sup>*), because *p16* and *p14<sup>ARF</sup>* share exons 2 and 3, although their reading frames differ. *p14<sup>ARF</sup>* is essential for the activation of p53 in response to the action of oncogenes such as Ras.<sup>21</sup> On the other hand, p16 induces a G<sub>1</sub> cell-cycle arrest by inhibiting the phosphorylation of the retinoblastoma protein, pRb. Thus, homozygous loss of *p14<sup>ARF</sup>* and *p16* would collectively affect both p53- and pRb-dependent growth regulatory pathways. However, there is evidence that retention of exon 1b, which encodes the active domain of *p14<sup>ARF</sup>*, may produce a peptide containing a functional, or partly functional, protein.<sup>21</sup> Moreover, unlike the response to oncogenic Ras, *p14<sup>ARF</sup>* is not required for activation of p53 in response to DNA damage by agents such as asbestos, suggesting that *p16* could be the critical TSG targeted by 9p21 deletions in MM.

Extensive LOH analysis of chromosome 22 losses in MM has not been performed because an entire copy of chromosome 22 is lost in most cases. Although the neurofibromatosis type 2 TSG, *NF2*, predisposes affected individuals primarily to tumors of neuroectodermal origin, somatic mutations of *NF2* have occasionally been identified in seemingly unrelated malignancies.<sup>22</sup> Thus, two groups independently embarked on mutational studies of *NF2* in MM. Bianchi et al.<sup>22</sup> identified nucleotide mutations in 8 of 15 MM cell lines (53%). The mutations, which included deletions and insertions and one nonsense mutation, predicted truncated forms of the NF2 protein, known as *merlin* or *schwannomin*. Similar results were also reported by Sekido et al.,<sup>23</sup> who detected somatic mutations in one MM specimen and in 7 of 17 MM cell lines (41%). In the study by Bianchi et al.,<sup>22</sup> the mutations observed in complementary DNAs from MM cell lines were confirmed in genomic DNA from six matched primary tumor specimens. It is intriguing that the two complementary DNA alterations that could not be confirmed by genomic analysis were both splicing-related—that is, deletion of exon 10 in one cell line and a 43-base-pair insertion between exons 13 and 14 in the other. This finding suggests that aberrant splicing, either by mutations of cis elements or by changes in the splicing machinery regulating the processing of *NF2* transcripts, may constitute an additional mechanism for *NF2* inactivation in MM.

In a subsequent report, mutations in the *NF2* coding region were detected in 12 of 23 new MM cell lines.<sup>24</sup> Western blot analyses revealed high levels of NF2 in 11 MM cell lines lacking *NF2* mutations, whereas NF2 protein was not detectable in the 12 cell lines that exhibited alterations of the *NF2* gene. In addition, two cell lines with *NF2* mutations reported in an earlier study were also examined, and both of these cell lines showed no NF2 expression. LOH analyses were performed on the entire 25 MM cell lines using two polymorphic DNA markers residing at or near the *NF2* locus in chromosome 22q12. Eighteen of the 25 cell lines (72%) showed losses at one or both of these loci. All cases exhibiting mutation or aberrant expression of *NF2* showed allelic losses, implying that inactivation of *NF2* in MM occurs via a two-hit mechanism.

## SIMIAN VIRUS 40

SV40 is a DNA tumor virus that has been associated with MM. Although SV40 is endogenous to the rhesus monkey, the virus infected the human population through contaminated polio- and adenovaccines, both attenuated and killed, between 1955 and 1963.<sup>2,3 and 14</sup> Poliovaccines were prepared in cell cultures grown as monolayers of infected rhesus monkey kidney cells. Because the virus produces no cytopathic effects in these cells, their infection went unrecognized until 1960, when high titers of the virus were found in some lots of the vaccine. As a result of this contamination, it is estimated that up to 96 million adults and children in the United States alone may have been injected with poliovaccines containing SV40. After 1963, slow-replicating strains of SV40, which are difficult to detect using cytopathic tests, may have infected humans exposed to products produced with monkey cells.<sup>25</sup> This hypothesis is supported by the observation that individuals born after 1962 with minimal risk of exposure to contaminated vaccines had an approximately 10% positive rate for SV40-neutralizing antibodies.<sup>3</sup> In addition, horizontal transmission is also possible because SV40 sequences have been detected in sperm, in circulating mononuclear phagocytes, and in cells obtained from the milk of a healthy woman.<sup>2,3 and 4</sup> Regardless of its method of introduction into humans, SV40 appears to be presently transmitted among humans similarly to other papovaviruses.

A link between SV40 and tumor development was first recognized in hamsters, when, in 1960, Bernice Eddy found that subcutaneous injection of rhesus monkey kidney cells into newborn hamsters led to the formation of sarcomas at the injection site. In 1991, it was found that 60% of hamsters injected intracardially with SV40 developed pleural MMs.<sup>4</sup> When SV40 was injected into the pleural spaces of these animals, 100% developed pleural MMs in 3 to 6 months.<sup>4</sup> Interestingly, in hamsters, SV40 is a much more potent carcinogen in the induction of MMs than asbestos. For example, in a study by Smith and Hubert,<sup>26</sup> hamsters were injected intrapleurally with varying doses of chrysotile, amosite, and tremolite. Of 50 hamsters, 13 developed MMs on injection with chrysotile. In a separate group of 50 animals, four developed MMs when injected with amosite. No tumors were observed in those injected with tremolite. Among all tumors that developed, the earliest was observed after 151 days in a hamster injected intrapleurally with 25 mg of chrysotile. In contrast, MMs developed in 100% of hamsters injected intrapleurally with

SV40 in only 3 to 6 months.<sup>4</sup>

The discovery that SV40 produced MMs in hamsters subsequently led to the polymerase chain reaction analysis of human MM specimens for the presence of the virus.<sup>27</sup> It was found that 29 of 48 human MMs (60%) contained and expressed SV40 DNA. Sequence analysis revealed that these DNA sequences were homologous to SV40. These results were confirmed by many laboratories<sup>3,4</sup> and by an independent multilaboratory study organized by the International Mesothelioma Interest Group.<sup>28</sup> This study found that 83% of the MMs tested contained SV40 DNA sequences.<sup>28</sup> More recently, using a microdissection technique, Schivapurkar et al. demonstrated that SV40 is specifically present in neoplastic MM cells and not in the surrounding reactive stromal cells or in lung cancer cells.<sup>29</sup> It should be noted, however, that Finnish MM specimens consistently tested negative for SV40.<sup>14</sup> This finding, together with the observation of a different incidence of SV40 in bone tumors from different regions of the world, suggest geographic differences for SV40 in human tumors.<sup>2,3 and 4</sup> It has been hypothesized that these differences may be related either to the use of contaminated poliovaccines (because Finnish poliovaccines were not contaminated by SV40) or to other factors presently unknown.<sup>14</sup>

The ability of SV40 to transform human cells *in vitro* is well established. The SV40 genome is a double-stranded circular DNA molecule containing 5243 base pairs, which can be divided into two regions, early and late, according to the order in which they are transcribed.<sup>2,3 and 4</sup> The early region encodes three proteins—large T antigen (Tag), small t antigen (tag), and 17kT—and is responsible for the transforming ability of the virus. The late region encodes viral coat proteins. Only the early region is necessary for transformation to occur, so immortalization experiments have been done with both the whole viral genome and the early-region DNA alone.<sup>2,3 and 4</sup> Tag binds to viral and cellular DNA, inducing their replication, and has mutagenic and clastogenic function, as it can cause chromosome rearrangements, point mutations, and aneuploidy. Tag is also capable of binding and inactivating the products of several TSGs, including p53, pRb, pRb2/p130, p107, p400, and p300, which are necessary to prevent cells with DNA damage from cycling.<sup>2,3 and 4</sup> In addition, through inhibition of p53, Tag inactivates an essential cell checkpoint at which DNA alterations are repaired before the cell is allowed to continue into the S phase of the cell cycle. If the cell does not repair the mutations, normally apoptosis occurs. Tag inhibition of p53 allows the cell to undergo mitosis even in the presence of mutations. Whether continuous expression of Tag is necessary to maintain the transformed phenotype is currently unclear.<sup>2,3 and 4</sup> Experiments in hamsters indicate that continuous expression of Tag is necessary to induce and maintain transformation. In contrast, more recent experiments in SV40 transgenic mice and human cells *in vitro*<sup>2,4</sup> and in rats<sup>30</sup> suggest that continuous expression of Tag is not always needed for maintenance of the transformed phenotype.

A 19-kD protein, tag is found predominantly in the cytoplasm of infected or transformed cells and performs several functions to increase the transforming potential of Tag.<sup>2,3 and 4</sup> It increases production of Tag, causes mitosis in quiescent cells through stimulation of mitogen-activated protein (MAP) kinase and AP-1, and contributes to the complete inactivation of p53 by stimulating cellular phosphatase 2A (PP2A) to indirectly alter the phosphorylation state of p53.

After infection with SV40, some human cells die and others are transformed. Many of the transformed cells eventually reach crisis and die, but a few become immortal.<sup>31</sup> Although human cells immortalized by SV40 do not produce tumors in nude mice, these same cells may become oncogenic if they are transfected with an oncogene, mutated by carcinogens, or if they are passed enough times to allow a significant number of mutations to accrue.<sup>2,3 and 4,31</sup>

Through the actions of Tag and tag, human mesothelial cells, fibroblasts, bronchial epithelium, and breast epithelium have been transformed *in vitro*.<sup>31</sup> Human cells transformed by SV40 in tissue culture, when injected into human volunteers, have induced subcutaneous tumors.<sup>4</sup> Analysis of p53 and retinoblastoma family members demonstrated that Tag complexes and inactivates these gene products in human MM.<sup>32,33</sup> p53, pRb, p107, and pRb2/p130 are present in detectable quantities in human mesothelial cells, and their expression is also significantly associated with Tag expression.<sup>32,33</sup> Their absence of mutations, their unusually high level of expression in tumor cells, and the ability of Tag to co-precipitate with each of these tumor suppressors supports the assertion that SV40 Tag binds, stabilizes, and inactivates p53 and retinoblastoma proteins, which may allow for MM development.<sup>32,33</sup> This hypothesis has been supported by experiments in which transfection of antisense SV40 inhibited Tag expression, restored the p53-p21 pathway, and caused growth arrest and apoptosis of SV40-positive human MM cell lines.<sup>34</sup> These findings suggest that antisense SV40 strategies may be useful in the treatment of SV40-positive MM patients.<sup>34</sup>

## CONCLUSIONS

Multiple genetic alterations are involved in the development of most malignancies. Many MM patients who expressed SV40-Tag contained asbestos in their lungs.<sup>8,35</sup> Both SV40 and asbestos cause genetic damage. Thus, SV40 may act with asbestos to cause MM. Cells of patients with preexisting genetic alterations have been found to be more susceptible to SV40 transformation than normal control cells.<sup>2,3 and 4</sup> For instance, the transformation frequency by SV40 of fibroblasts from a lung cancer patient with Klinefelter's syndrome was three to ten times higher than that of fibroblasts from normal individuals with no history of cancer. Furthermore, fibroblasts from individuals with Down syndrome and Fanconi's anemia also have increased susceptibility to transformation by SV40 *in vitro*. Thus, it is possible that because cells with preexisting genetic alterations are more easily transformed by SV40, cells harboring DNA alterations caused by asbestos would also be more prone to SV40 transformation.

In a normal cell, mitosis is controlled through a delicate balance of phosphorylation and dephosphorylation events. Increased levels of AP-1 are ultimately responsible for cell division, and the activity of AP-1 is normally regulated through phosphorylation and dephosphorylation events ( Fig. 40.1-1). Autophosphorylation of the EGF receptor, or activation of ras and others, leads to phosphorylation of MEK1 kinase, which in turn phosphorylates the MAP kinases, also known as *extracellular-regulated kinases* (ERK). The activation of these kinases causes activation of other intermediaries, such as elk-1, and this in turn stimulates c-fos and c-jun and other members of the AP-1 family, inducing cell division.<sup>6</sup> Down-regulation of AP-1 activity is achieved through PP2A, which dephosphorylates MAP kinases. Asbestos and SV40 Tag, working through this mechanism, may actually induce tumor formation. Asbestos is capable of inducing both DNA damage and autophosphorylation of the EGF-receptor, which eventually leads to increased c-fos and c-jun expression, AP-1 expression, and cell division.<sup>36</sup> When Tag is concurrently expressed, it binds and inhibits p53 and pRb and causes DNA alterations. In addition, tag can bind and inactivate PP2A, allowing increased activity of MAP kinases, AP-1 and, ultimately, cell division. Tag inactivation of p53 does not allow repair of the mutations caused by asbestos and/or Tag at the G<sub>1</sub>/S checkpoint mediated by p53 through p21. Thus, these two carcinogens would allow the cell to divide unchecked and accumulate further somatic genetic changes.<sup>2,3 and 4</sup> Whereas DNA alterations are either of no significance or lead to cell death in the majority of the cases, a few cells could potentially develop perturbations of key cell-cycle regulatory genes<sup>5</sup> and become immortalized, transformed, and tumorigenic. Therefore, we propose that the combined effects of asbestos and SV40 overwhelm cell-cycle regulatory mechanisms, result in unchecked cell division, and occasionally allow transformation and MM development. Evidence in support of this assertion comes from experiments with p53-deficient mice.<sup>37</sup> These studies demonstrate that p53-deficient animals are more susceptible to the induction of MM on exposure to asbestos. Similarly, human mesothelial cells positive for SV40 have Tag-mediated inhibition of p53<sup>33</sup> and may be more susceptible to asbestos carcinogenicity. The finding that, in MM cells, restoration of the p53 pathway with antisense Tag causes growth arrest and apoptosis supports this scenario.<sup>34</sup> It should be noted that SV40 is a very strong immunogen and that cells expressing SV40 viral antigens are usually efficiently recognized and killed by the host immune system.<sup>2,3 and 4</sup> In other words, SV40 is a very potent carcinogen, capable of fully transforming human cells in tissue culture.<sup>2,3 and 4</sup> At the same time, SV40 is a strong immunogen; therefore, SV40-transformed cells should be killed by the immune system. It is possible that the local and systemic immunosuppressive activity of asbestos<sup>10</sup> may favor the growth of cells expressing SV40 antigens and may partly explain the strong association of SV40 with MM.

**FIGURE 40.1-1.** Diagram illustrating mesothelioma pathogenesis. Increased levels of activator protein 1 (AP-1) stimulate cell division.<sup>36</sup> The activity of AP-1 is regulated through a delicate balance between phosphorylation and dephosphorylation. Autophosphorylation of the epidermal growth factor receptor (EGF-R), or activation of ras and others, leads to phosphorylation of MEK1 kinase, which in turn phosphorylates the mitogen-activated protein (MAP) kinases also known as *extracellular-regulated kinases* (ERK). The activation of these kinases leads through other intermediaries, such as elk-1 (Elk1), to the activation of c- fos, c- jun, and

other members of the AP-1 family (not shown), which through their transcriptional activity stimulate cell division.<sup>36</sup> Phosphatase 2A (PP2A) down-regulates AP-1 activity by dephosphorylating the MAP kinases; therefore, PP2A plays an important role in preventing asbestos-mediated cancerogenesis. Crocidolite asbestos induces both DNA mutations and autophosphorylation of the EGF-R, which leads to increased levels of *c-fos* and *c-jun* expression, AP-1 activation, and cell division.<sup>36</sup> When simian virus 40 (SV40) large T antigen (Tag) is expressed in this system, it binds and inhibits p53 and the retinoblastoma protein pRb, and it contributes to the development of DNA alterations.<sup>32,33</sup> In addition, Tag is known to be directly and indirectly (through p53 inactivation) mutagenic.<sup>2,4</sup> When SV40 small t antigen (tag) is also expressed in this system, it binds and inactivates PP2A and contributes to cellular transformation. This leads to increased activity of the MAP kinases, increased activity of AP-1, and cell division.<sup>36</sup> In this scenario, crocidolite may increase the amount of *c-fos* and *c-jun* and, to some extent, their activity, whereas tag, by removing PP2A, further increases their activity. If the dividing cells have developed DNA alterations (such as *p16* and *p14<sup>ARF</sup>*) through the mutagenic effects of asbestos—mediated through the production of reactive oxygen species (ROS) created by alveolar macrophages during phagocytosis of asbestos fibers<sup>5,36</sup>—and/or Tag, these mutations may not be repaired because of the Tag inactivation of the G<sub>1</sub>/S checkpoint mediated by p53 through p21.<sup>32,33</sup> and<sup>34</sup> In this scenario, the cell may complete division and possibly continue to divide.<sup>34</sup> Cells with unrepaired DNA damage are prone to develop additional DNA alterations that usually result in cell death but occasionally may result in immortalization, which may be followed by transformation and tumor development. Therefore, the combined effects of asbestos and SV40 may overwhelm the cell-cycle regulatory mechanisms and result in cell division and occasionally in cellular transformation, which may lead to mesothelioma development. Because asbestos depresses both the local and systemic immune responses,<sup>10</sup> asbestos may help mesothelial cells expressing SV40 antigens to escape immune surveillance. Arrowheads indicate a stimulatory effect, and crossed bars indicate an inhibitory effect. The circle indicates nonintegrated SV40; in some tumors, however, SV40 has been found integrated in the host cell DNA. NF2, neurofibromatosis type 2; TSG, tumor suppressor genes.

## SUMMARY

A large body of experimental and epidemiologic data support the notion that asbestos, or at least amphibole asbestos, causes MM. The same data also support the notion that exposure to asbestos is usually not sufficient for MM development and that other factors, including radiation, genetic predisposition, and SV40, may render some individuals more susceptible to asbestos carcinogenicity. At this time, the involvement of radiation and genetic predisposition in MM development is speculative. On the other hand, SV40 is present in most human MMs. In these neoplasms, SV40 interferes with key cell-cycle regulatory genes and may contribute with asbestos or alone (in non-asbestos-associated tumors) to the development of molecular genetic alterations that ultimately lead to a malignant phenotype. The local and systemic immunosuppressive activity of asbestos may also interfere with the ability of the immune system to eliminate cells expressing SV40 antigens and thus favor tumor progression.

## EPIDEMIOLOGY

Asbestos is the predominant cause of pleural, peritoneal, and probably epididymal mesothelioma in humans. The resistance of asbestos to heat and combustion was recognized by ancient civilizations. Although Pliny had observed that asbestos miners were less healthy than other slaves, the health hazards of asbestos exposure were generally not recognized until this century.<sup>1</sup>

The Industrial Revolution greatly expanded demand for asbestos as insulating and packing material for machines and power generators. In 1898, pulmonary scarring and eventual death from respiratory failure was noted in asbestos workers from French and English asbestos textile mills.<sup>2</sup> However, the cause of the pulmonary fibrosis remained uncertain because tuberculosis and other respiratory infections were often epidemic among poor laborers. The two World Wars further increased the use of asbestos in ships and other equipment of combat and transport. The availability, durability, and low cost of asbestos additionally expanded its range of uses in industrial and consumer products. In 1930, the causal association between asbestos and asbestosis was firmly established by Merewether and Price at the London Chest Hospital.<sup>3</sup> When limits were set on allowable industrial levels of asbestos exposure in England, many thought the asbestos problem had been solved.<sup>4</sup> However, case reports of lung cancer in patients with asbestosis appeared as early as 1935.<sup>4,5</sup>

In 1955, Doll<sup>6</sup> reported a case-control study that established the association between asbestos and lung cancer. The attitudes and opinions of scientists between 1935 and 1965 reveal early agreement on the carcinogenesis of asbestos by 1943 in Germany, but rejection of German scientific thought during and after World War II and the lack of epidemiologic and experimental evidence delayed a consensus elsewhere.<sup>7</sup>

Up to 8 million living persons in the United States have been occupationally exposed to asbestos over the last five decades during mining and milling of asbestos and in diverse manufacturing processes that use the material. Today, many public and private buildings contain asbestos, including 10% to 15% of schools in the United States that were insulated or sprayed on interior surfaces with asbestos between 1946 and 1972. The public health significance of exposure in such buildings and the cost-effectiveness of asbestos removal are controversial.<sup>8</sup> However, one study suggested risk from such incidental exposures. For 9 of 12 schoolteachers with mesothelioma, the only potential asbestos exposure was that derived from asbestos-containing building materials in schools.<sup>9</sup>

## ASBESTOS-ASSOCIATED MESOTHELIOMA

The existence of mesothelioma as a distinct pathologic entity was debated by pathologists before 1960.<sup>10</sup> In the late 1940s, case reports of mesotheliomas in patients with asbestosis began to appear. In 1960, Wagner et al.<sup>11</sup> in South Africa reported 33 cases of mesothelioma diagnosed between ages 31 and 68 years in a South African crocidolite mining community. An additional 14 cases were added in an addendum to the paper. A substantial proportion of these patients were exposed in childhood through living in the vicinity of asbestos mills and mines; a few had occupational contact. This study was followed by reports of mesotheliomas in asbestos workers in other parts of the world.

### *Mechanisms of Asbestos Carcinogenicity*

Two major forms of asbestos exist: curly pliable serpentine asbestos (chrysotile) and rod-like amphiboles (crocidolite, amosite, anthophyllite, tremolite, and actinolite). The first three of these are mined for their commercial utility; the latter three are usually contaminants. Asbestos fibers tend to separate readily and form numerous individual strands, which often are less than 1  $\mu\text{m}$  in diameter.

Carcinogenic effects of asbestos appear to result from its physical properties, rather than chemical structure.<sup>12</sup> In one animal experiment, other fiber types produced mesothelioma more efficiently than amosite asbestos.<sup>13</sup> Long rod-like fibers of narrow diameter are more likely to induce tumors in laboratory animals.<sup>14</sup> Although serpentine asbestos (chrysotile) is generally considered less carcinogenic than the rod-like amphiboles (crocidolite, amosite, anthophyllite, tremolite, and actinolite), debate continues over whether cases associated with chrysotile asbestos are actually caused by amphibole contamination<sup>15</sup> or are caused by chrysotile itself.<sup>16</sup> Long, needle-like amphibole fibers lodge more readily in the distal respiratory area, where they persist longer and are transported to the pleura and peritoneum.<sup>14</sup>

After inhalation most asbestos is expectorated or swallowed and subsequently excreted in the feces. The remainder can be cleared from the tracheal and bronchial tree via multiple mechanisms, including ciliary action in the trachea, ingestion by macrophages, or penetration through the endothelial lining into interstitial tissues.<sup>17</sup> Short fibers are cleared more readily than long fibers. Fibers that remain preferentially accumulate in the lower third of the lungs adjacent to the visceral pleura. Fibers can be counted visually or using electron microscopy and correlate with asbestos exposure,<sup>18</sup> although visual counting provides substantially lower estimates of fibers per gram of lung.<sup>19</sup>

Asbestos results in an inflammatory and fibrotic process, mediated in part by cytokines released by activated alveolar macrophages.<sup>20</sup> At a molecular level, protooncogenes such as c-sis (platelet-derived growth factor- $\beta$  chain) are up-regulated in alveolar macrophages from fibrotic lungs, a factor that enhances mesothelial cell proliferation. In addition, asbestos can transfect DNA into cells.<sup>20</sup> Epidermal growth factor–positive cells have been found in 68% of mesotheliomas examined and correlate with improved survival.<sup>21</sup> Chrysotile fiber has been shown to be a strong mutagen in mammalian cells.<sup>22</sup> Asbestos fibers can cause persistent expression of early response genes, such as c-fos and c-jun in tissue culture.<sup>23</sup> The oxidative stress response gene product, heme oxygenase, can be induced by asbestos fibers.<sup>24</sup> These findings suggest that reactive oxygen species produced by asbestos fibers are responsible for the expression of cytotoxicity, DNA damage, mutation, gene expression, or carcinogenesis. Asbestos fibers have also been shown to enhance gamma ray–induced oncogenicity in mammalian cells.<sup>22</sup>

### **Risk Rates**

The annual incidence of mesothelioma is not known with certainty.<sup>25</sup> The neoplasm can be difficult to diagnose, even by expert pathologists. Data from death certificates are unreliable for estimating disease frequency despite the usually rapidly fatal outcome of malignant mesothelioma. Cancer deaths are not coded by morphology (mesothelioma). Rather, the cause of mortality is assigned by primary site of the neoplasm (primary neoplasms of pleura and peritoneum). In a study of the Surveillance, Epidemiology, and End Results program of the National Cancer Institute, only 274 of 1130 white decedents with mesothelioma (approximately 95% diagnosed by microscopy) were recorded as having died of a primary neoplasm of pleura or peritoneum.<sup>26</sup> The majority of these mesothelioma cases were coded as having malignant neoplasm of the lung or unknown site.

A reasonable estimate is that 2200 new cases of mesothelioma occur annually in the United States (range, 1000 to more than 3000 cases)<sup>26,27</sup> or approximately 12.1 per million white men. In the United States, mesothelioma is approximately threefold more common in men than in women.<sup>25,26</sup> Incidence rises steadily with age and is approximately tenfold higher in men aged 60 to 64 years as compared with those aged 30 to 34.

Because of local asbestos industries, some locations in the United States have incidences as high as 636 male cases and 96 female cases per year per million population.<sup>28</sup> Whether risk in such communities extends to the population at large who are not employed in the asbestos industry remains controversial. The standardized incidence of mesothelioma in Wittenoom, Australia, was 260 per million for both men and women once residents employed in the crocidolite industry were excluded.<sup>29</sup> Purely residential exposure accounted for only 3% of incident cases in Yorkshire, England,<sup>30</sup> but at least 18% of the cases in South Africa.<sup>31</sup>

The incidence of mesothelioma appears to be increasing perhaps by as much as 50% in the last decade.<sup>25,26</sup> Projections of future incidence for the United States suggest that the numbers of cases will peak at the turn of the twentieth century<sup>32</sup> or rise moderately in the twenty-first century,<sup>27</sup> and then decline as a result of legislation to reduce asbestos exposure in the workplace and the ambient environment. In the Netherlands, the peak in annual male mesothelioma deaths is expected later, in approximately the year 2018. Pleural mesothelioma may account for 0.87% of all deaths in the 1943 to 1947 birth cohort of Dutch men.<sup>33</sup> Peto et al. project that the risk of dying of mesothelioma in Western Europe will double over the next 20 years, with the highest risk of approximately 1 in 150 men in the 1945 to 1950 birth cohort.<sup>34</sup>

### **High-Risk Individuals**

Persons at high risk of mesothelioma can be identified by tracing the processing and commercial uses of asbestos. The mineral is mined, milled, and incorporated into a wide range of industrial and commercial products, including insulation, textiles, heat protectors, filters, and construction materials (spackling, roofing, siding, and floor and ceiling tiles).<sup>1,25</sup> Workers with high levels of asbestos exposure, therefore, are miners, millers, producers of asbestos products, and laborers who install plumbing, boilers, and heating equipment in ships, factories, and homes. The risk extends to workers who may not handle asbestos directly but are in proximity to the material, such as carpenters, electricians, and welders in shipyards.

The risk of mesothelioma associated with occupational exposure to asbestos has been examined in case-control studies and cohort studies. In case-control studies, up to 75% of cases had asbestos exposure, as compared with a small fraction of controls.<sup>25</sup> In cohort studies, up to 10% of asbestos workers have died of mesothelioma.<sup>35</sup> However, mesothelioma risk is difficult to quantitate for several reasons. First, ambient levels of asbestos in most workplaces have not been measured. A *high* level in one study might be called *moderate* or *low* in another. Duration of employment has been used as another surrogate measure of exposure. Second, the time from exposure to the development of mesothelioma is long, usually three to four decades in most reported studies. Mathematical modeling suggests that risk of mesothelioma increases exponentially by the third to fourth power of time from first exposure, but few cohorts have been followed to the end of life. Third, the composition of the inspired asbestos differed among exposed workers.

Despite the obstacles to quantifying risk of mesothelioma, several consistent observations have emerged from studies worldwide. Crocidolite is associated with high risk of mesothelioma in miners, manufacturers, and workers who install asbestos products.<sup>36</sup> Another amphibole, amosite, appears to carry an intermediate risk. Chrysotile, currently the major form of asbestos in production, shows the weakest association with mesothelioma.<sup>14</sup> Occupations with highest risk appear to be insulators, asbestos producers and manufacturers, and heating and construction tradespeople. The projected lifetime risk among these workers exposed from early adulthood ranges up to 20%. Working in proximity to these occupational groups in construction sites confers a relatively lower risk. In addition, some patients with mesothelioma have reported only isolated or brief occupational exposures to asbestos.

In a cohort study of 248 insulation workers in Sweden where exposure to asbestos had almost ended in the mid-1970s, 84 deaths occurred between 1970 and 1994 compared with 46 expected mainly due to an increased cancer mortality (approximately 50%). The morbidity was increased for lung cancer (11.0 cases vs. 2.5 expected), peritoneal mesothelioma (7 vs. 0), cancer in pancreas (5.0 vs. 0.7). No pleural mesotheliomas were found. The risk of lung cancer did not reach normal levels despite decreased asbestos exposure. Mesothelioma in insulation workers seems to be peritoneal more often than pleural.<sup>37</sup>

Malignant mesothelioma is rarely curable at present, so screening of asbestos workers for mesothelioma is inappropriate. However, smoking greatly increases the risk of lung cancer (but not mesothelioma) in asbestos workers and smoking cessation efforts are needed in this high-risk group.<sup>38</sup> Clinicians considering the diagnosis of malignant mesothelioma should take a detailed exposure history emphasizing the period 20 to 50 years before diagnosis and including possible household contact exposure. Brief exposures may be long forgotten.<sup>39</sup>

### **Exposure in the Home**

Mesothelioma in wives and children of asbestos workers has prompted studies that show increased asbestos levels in their homes.<sup>40,41</sup> Presumably, asbestos was brought into the home on hair and on clothing to be washed in the family laundry. Asbestos workers have been required to shower and change clothing before leaving the workplace only since 1972. Asbestos-related neoplasms have been reported in multiple members of some families, but genetic predisposition to the neoplasm remains to be shown. The risk of mesothelioma in household contacts of asbestos workers has been estimated to be as high as 0.4 to 1.0%,<sup>38</sup> but clearly varies with the level of household contamination, and may be overestimated in the reported data. More than one-half of women with mesothelioma in one series were household contacts of asbestos workers.<sup>42</sup>

A high incidence of mesothelioma (22 per 10,000 persons of age greater than 25) observed in the Anatoli region of Turkey has been attributed to zeolite, a silicate ubiquitous in the soil and to tremolite<sup>43</sup> and sometimes sprayed onto homes. Erionite found in Karain, Turkey, is also associated with a high incidence of mesothelioma.<sup>44</sup> In a cohort of 162 Karain immigrants to Sweden, 18 cases of mesothelioma had occurred, accounting for 14 of the 18 deaths (78%).<sup>45</sup> Although human herpes virus (HHV) is associated with body cavity lymphomas, HHV-8 amplification products were absent by polymerase chain reaction in 13 diffuse malignant mesotheliomas.<sup>46</sup>

### **MESOTHELIOMAS WITHOUT A HISTORY OF ASBESTOS EXPOSURE**

No asbestos exposure can be documented in approximately 30% to 50% of cases of mesothelioma. Quantitation of asbestos fibers in some of these patients has documented background pulmonary fiber levels consistent with the absence of a substantial asbestos exposure.<sup>47</sup> Two cases of peritoneal mesothelioma were associated with familial Mediterranean fever.<sup>48</sup>

Approximately 25 published cases of pleural and peritoneal mesothelioma have developed following therapeutic radiation<sup>49,50</sup> or in two patients, arising adjacent to deposits of thorium dioxide (thorotrast) still visible on chest radiographs after extravasation during diagnostic procedures years earlier. Patients with a history of Hodgkin's disease may have an increased risk of developing mesothelioma. All five of the mesotheliomas in one series occurred in the field of prior radiation therapy with an average interval between radiation treatment and diagnosis of mesothelioma of 15 years.<sup>51</sup> Three of the five patients also received chemotherapy. No patients recalled exposure to asbestos or had evidence of asbestosis on chest radiography. In reported cases a median of 16 years (range, 7 to 36 years) had elapsed between radiation and detection of mesothelioma.

## BIOLOGY OF MESOTHELIOMA: PLOIDY STUDIES

Ploidy status and the percentage of cells actively synthesizing DNA have been analyzed by flow cytometry in almost 200 malignant mesotheliomas.<sup>52,53</sup> and<sup>54</sup> Ploidy and S-phase fraction seem to be consistent in different sections from the same tumor and were not associated with histologic subtype.<sup>53</sup> In the various studies, 60% to 78% were diploid and 27% were near diploid. In contrast, 85% to 88% of lung cancer are aneuploid.<sup>52</sup> Significantly shorter survival is associated with a high percentage of S-phase cells (but not aneuploidy).<sup>53,54</sup>

## DIAGNOSIS OF MESOTHELIOMA

Initial misdiagnosis is common. Pathologic opinion appears particularly diverse when litigation is involved. Because a substantial percentage of mesotheliomas develops in patients with no known asbestos exposure and other malignancies are common in asbestos workers, asbestos exposure should not influence the diagnosis of mesothelioma. Because of the poor current prognosis of pleural mesothelioma, a major role of establishing the diagnosis is to exclude the possibility of a more treatable illness. Accurate diagnosis is also important in the event of subsequent litigation and for epidemiologic and therapeutic studies.

## HUMORAL FACTORS

Hyaluronic acid has been reported to be useful in diagnosis or for following response but is relatively nonspecific.<sup>55</sup> The level of hyaluronic acid was studied in the pleural fluid of 19 patients with malignant mesothelioma, 27 with lung cancer, 1 with breast cancer, 1 with mediastinal tumor, and 51 with benign diseases. The pleural fluid concentration of hyaluronic acid was greater than 100 µg/mL in 37% of (7 of 19) mesotheliomas and 1.3% of (1 of 80) lung cancers and other malignant and benign diseases.<sup>56</sup> A markedly elevated serum or pleural fluid carcinoembryonic antigen, however, suggests a diagnosis other than mesothelioma.

Hematopoietic growth factors<sup>57,58</sup> and<sup>59</sup> and blood group antigens<sup>60,61</sup> have been produced by normal and malignant mesothelial cell lines. Serum levels of interleukin-6 (IL-6), C-reactive protein, α<sub>1</sub>-acid glycoprotein, and fibrinogen were significantly higher in 25 mesothelioma patients than in patients with lung adenocarcinoma with cytology-positive pleural effusions. Serum IL-6 levels correlated with the levels of the acute-phase proteins and significantly with platelet counts. The level of IL-6 in the pleural fluid of patients with mesothelioma was approximately 60 to 1400 times higher than in the serum. Even higher levels of IL-6 in the pleural fluid and of thrombocytosis were found in patients with tuberculous pleurisy. High cytokine levels were not specific to mesothelioma (similar profiles were found in patients with tuberculous pleurisy). However, the detection of a markedly increased level of IL-6 in pleural fluid argues against a diagnosis of adenocarcinoma.<sup>62</sup>

## PATHOLOGY

Benign inflammatory and reactive processes producing mesothelial hyperplasia or other malignant tumors may mimic mesothelioma<sup>63</sup> but do not invade normal tissues and lack cytologic atypia and hyperchromatism. Repeated cytologic examination or biopsy results may be negative despite active tumor. When tumor tissue is obtained, light microscopy often provides documentation of malignancy, but usually does not distinguish adenocarcinoma from mesothelioma. Electron microscopy of either needle biopsy or cytocentrifuge specimens from pleural fluid may establish the mesothelial origin of the malignant tumor. Sputum cytology and bronchoscopy may be helpful in documenting an occult bronchogenic adenocarcinoma. The Cancer Committee of the College of American Pathologists has established a checklist protocol for the examination of specimens from patients with malignant pleural mesothelioma.<sup>64</sup>

Adenocarcinomas from primary lung, breast, ovary, stomach, kidney, or prostate cancer frequently metastasize to the pleura and can be extremely difficult to distinguish from epithelial mesothelioma cytologically or histologically. Metastatic adenocarcinoma with extensive pleural involvement may grossly resemble mesothelioma and has been called *pseudomesothelioma*.<sup>65</sup>

Sarcomatous mesotheliomas must be distinguished from fibrosarcoma, malignant fibrous histiocytoma, malignant schwannoma, and hemangiopericytoma. Synovial sarcoma and carcinosarcomas, which may also have mixed sarcomatous and epithelial components, usually present as a localized mass in the lung.

Autopsy requires skilled performance and experienced interpretation to reliably exclude other occult primary carcinomas. Advanced malignant mesothelioma tends to form peripheral visceral masses mimicking primary carcinomas.<sup>66</sup> Asbestos counts and postmortem examinations may have legal as well as epidemiologic value.

### Cytology

In one study of 21 cases of epithelial malignant mesothelioma (15 pleural, 6 peritoneal) diagnosed by effusion cytology, 13 were of the cohesive cell type and 8 were of the noncohesive cell type. Because of its resemblance to florid reactive mesothelial hyperplasia and the general lack of awareness of the existence of the single-cell pattern of mesothelioma, the noncohesive cell type can often be missed.<sup>67</sup>

For 29 patients with at least one cytologic pleural fluid examination, cytology was positive for mesothelioma in 32%. The median time from initial symptoms to the diagnosis of mesothelioma was 8 weeks (4 weeks for patients with positive or suspicious cytology results, and 12 weeks for those with negative cytology results). Cytogenetic analysis of pleural fluid had a sensitivity of 56% and was positive in one case in which results of cytologic examination were negative. Patients in whom the time from presentation to diagnosis was greater than 1 year all had negative cytologic results followed by long periods without further workup, despite a history of exposure to asbestos. Because the sensitivity of cytologic examination for mesothelioma is so low, patients in whom mesothelioma is suspected should undergo immediate pleural biopsy if the pleural fluid cytology result is negative.<sup>68</sup>

### Fine-Needle Aspirations

Cytomorphologic features (amount of cytoplasm and the degree of nuclear pleomorphism and cellular cohesion) on fine-needle aspiration of primary mesothelioma and of metastatic lesions varies greatly among individual cases. However, numerous distinct, uniformly small intracytoplasmic vacuoles, believed to represent intracellular fat and glycogen, were consistently present in metastatic lesions.<sup>69</sup>

**GROSS DESCRIPTION.** Discrete nodules and plaques of firm, grayish tumor coalesce, eventually obliterating the parietal and visceral surfaces. A rind of up to 5 cm in thickness may encase and constrict the lung with only superficial invasion. The chest wall, pericardium, and diaphragm as well as the interlobar fissures are involved relatively early.<sup>66</sup> At autopsy, tumor invades thoracic lymph nodes in up to 70% of patients with occasional extension to cervical nodes.<sup>63</sup> Small hematogenous metastases are documented to liver and lung and less commonly to kidney, adrenal, and bone in 33% to 67% of cases.<sup>63,70</sup> Without careful postmortem examination, hematogenous metastases may be missed.

**MICROSCOPIC DESCRIPTION.** Extensive sampling of biopsy, laparotomy, pleurectomy, or pneumonectomy specimens is required. A *small* piece should be fixed in glutaraldehyde for electron microscopy and the remainder promptly fixed in neutral buffered formalin. There are three histologic variants: epithelial, sarcomatoid, and mixed.<sup>66,71</sup> Fifty percent to 60% are epithelial, characterized by tubular, papillary, solid, or vacuolated patterns. The sarcomatoid variant is composed of ovoid to spindle-shaped cells with cellularity and hyperchromatism similar to that of a fibrosarcoma. A biphasic pattern with mixed epithelial and sarcomatoid elements is virtually pathognomonic of malignant mesothelioma although extensive sampling may be required to demonstrate the minor component.

### Histochemical Methods

Three methods are in common use to distinguish metastatic adenocarcinomas from epithelial mesotheliomas. The periodic acid–Schiff stain used before and after diastase digestion, is the single most reliable histochemical method generally available.<sup>66</sup> *Neutral* mucopolysaccharides that are strongly positive for periodic acid–Schiff diastase are found in intracellular secretory vacuoles and in intracinar vacuoles in most adenocarcinomas, but are rarely found in mesotheliomas. Their presence is strong but not unequivocal evidence for a diagnosis of adenocarcinoma. Appropriate controls for diastase activity and to distinguish staining of vacuoles from stroma and other structures are essential. Alcian blue at pH 2.5 and colloidal iron stain acid mucopolysaccharides are present in mesothelioma and many adenocarcinomas.<sup>63</sup> Disappearance after digestion with hyaluronidase, which removes hyaluronic acid in intracellular and secretory vacuoles and intercellular lumens, is characteristic of mesothelioma. *Stroma* hyaluronic acid is a nonspecific finding in many tumors, however. Under most staining conditions, Mayer's mucicarmine method (which stains neutral and weakly acidic mucopolysaccharides in intracellular and intercellular secretory vacuoles pink or red) is strongly positive in many adenocarcinomas. Mesotheliomas are usually negative but occasionally may stain strongly in some laboratories possibly due to fixation or technical conditions. Thus, the method is not completely reliable.

### Immunohistochemistry

Immunoperoxidase stains using various antibodies may be effectively applied to paraffin-embedded tumor tissue. Monoclonal antibodies against keratin proteins are strongly reactive in mesothelioma with diffuse cytoplasmic staining,<sup>72</sup> and perinuclear accentuation with ring formation. Both epithelial and spindle-shaped tumor cells of mixed and sarcomatoid variants are often stained, reflecting transitional patterns of differentiation also observed on electron microscopy.<sup>73</sup> This reactivity is helpful in distinguishing mesothelioma from fibrosarcoma, malignant fibrous histiocytoma (MFH), and schwannoma; however, carcinosarcomas and synovial sarcomas, which also have biphasic histology, also express keratin proteins. Adenocarcinomas also stain positively, usually with localization to the periphery of the tumor cell. Immunoperoxidase staining for Leu M1 is usually absent in mesotheliomas but positive in most adenocarcinomas. Staining for carcinoembryonic antigen is moderate to strong in most adenocarcinomas, but often weak or absent in renal, prostate, and some ovarian and endometrial carcinomas as well as mesotheliomas.<sup>74,75</sup> and <sup>76</sup> Unfortunately, there is marked variability among available monoclonal and polyclonal antibodies.<sup>77</sup>

### Electron Microscopy

The epithelial variant is composed of polygonal cells with numerous long, slender branching surface microvilli, desmosomes, abundant tonofilaments, and intracellular lumen formation.<sup>73,78</sup> Primary lung, breast, and upper gastrointestinal tract adenocarcinomas have short stubby surface microvilli, fewer tonofilaments, and microvillous rootlets or lamellar bodies.<sup>79,80</sup> Ovarian and endometrial carcinomas lack intracytoplasmic lumens, but have few tonofilaments and may express features of intestinal metaplasia (abundant mucin droplets, numerous cilia, and dense core granules).<sup>79,80</sup> Elongated nuclei, and abundant rough endoplasmic reticulum are found in the sarcomatoid variant. Stromal cells separated by matrix containing collagen fibers appear spindle or ovoid with both sarcomatoid and epithelial features, characteristic of the biphasic nature of mesothelioma.<sup>73,78</sup>

### Prognostic Correlations

Serum concentrations of two cytokeratin markers, CYFRA 21-1 and tissue polypeptide antigen, were elevated in 26 (50%) and 30 (58%) of 52 patients, respectively, and were highly correlated ( $r = .98$ ). Univariate analysis of data from 51 patients showed a relation with survival for performance status ( $P = .010$ ), thoracic pain ( $P = .014$ ), platelet count ( $P = .027$ ), CYFRA 21-1 ( $P = .002$ ), and tissue polypeptide antigen ( $P = .003$ ). Multivariate analysis identified independent prognostic significance for performance status, platelet count, and CYFRA 21-1. In addition to performance status, the cytokeratin markers identified patients with good prognosis in a log rank test.<sup>81</sup>

Microvascular quantification by staining for the antigens CD34 and CD31 in 25 mesotheliomas counted manually or on a computerized image analysis system significantly correlated with each other and with shorter survival independent of patient age and histologic type or grade of mesothelioma. No association was noted with p53 immunorepression.<sup>82</sup>

## MALIGNANT PLEURAL MESOTHELIOMA

### PRESENTATION

Malignant pleural mesothelioma most commonly develops in the fifth to seventh decade (median age, 60 years), typically 20 to 50 or more years since first documented asbestos exposure. The risk has been estimated to be linearly proportional to the intensity and duration of exposure, and to the time since first exposure to a power of between 3 and 4. Latency periods between first exposure to asbestos and a diagnosis of mesothelioma may vary by occupation, with shorter latencies for insulators and dock workers and longer intervals for shipyard and maritime workers, as well as domestic exposures.<sup>83</sup> A significant proportion of patients with mesothelioma diagnosed between the ages of 20 and 40 report household or neighborhood exposure during childhood.<sup>11,84</sup> Children who present with the disease generally have no apparent asbestos exposure.<sup>85,86,87</sup> and <sup>88</sup>

A ratio of five men to one woman is affected. Dyspnea, nonpleuritic chest wall pain, or both bring 90% of patients to medical attention. Examination is generally remarkable for dullness at one base, and chest radiography reveals a large freely movable unilateral pleural effusion. Occasional patients are asymptomatic, an effusion found incidentally on chest radiography. Five patients in one series presented with spontaneous pneumothorax with the unsuspected diagnosis of mesothelioma made at pleurectomy.<sup>89</sup> Sixty percent have right-sided lesions, and less than 5% have bilateral involvement at the time of diagnosis.

Pulmonary function test results may document restrictive lung disease resulting from encasement of the lung and assess the potential tolerance for pneumonectomy. Obstructive spirometric changes are unrelated to mesothelioma or asbestosis. Laboratory evaluation is otherwise generally unremarkable except for an elevated platelet count and erythrocyte sedimentation rate.

### STAGING

As described by Rusch and Venkatraman, the five staging systems before the International Mesothelioma Interest Group (IMIG) Staging System have been “to some extent imprecise and incompletely validated.”<sup>90</sup> The Butchart classification (Table 40.2-1) suffers from an absence of tumor, node, metastasis (TNM) descriptors and vague statements regarding lymph node involvement and degrees of chest wall invasion.<sup>95</sup> Mattson's classification recognizes contralateral involvement as stage II rather than stage III and has largely been abandoned. Chahinian was the first to devise a TNM-based mesothelioma staging system, with an attempt to qualify the influence of such parameters as locoregional lymph node involvement as well as specific sites and extent of invasion.

TABLE 40.2-1. Two of the Five Published Staging Systems for Pleural Malignant Mesothelioma

The Union International Contra le Cancrum proposed a TNM staging system that evolved into the presently described International Mesothelioma Interest Group Staging System. The IMIG staging system has only been available for a short time, but it has been validated in two large surgical series of mesothelioma. <sup>91,92</sup> Sugarbaker et al. have proposed the alternative but complementary Brigham Staging System based on tumor, resectability, and nodal status. <sup>93</sup> In any evaluation for the patient with mesothelioma, careful attention must be paid to the diaphragmatic extent of the tumor with suspicious scans confirmed by laparoscopic evaluation for transdiaphragmatic extension. <sup>94</sup>

The most important preoperative prognostic indicator may be tumor status of the patients. Tumor volumes associated with malignant pleural mesothelioma patients who have no spread to lymph nodes are significantly smaller than in those patients with positive nodes. Moreover, progressively higher IMIG stage is associated with higher median preoperative solid volume of tumor. <sup>92</sup> Further studies verifying that preresection tumor volume is representative of tumor status in malignant pleural mesothelioma and can predict overall and progression-free survival, as well as postoperative IMIG stage, are needed to complement metabolic imaging studies.

### **Noninvasive Studies to Determine Stage**

The major role of noninvasive procedures is to determine isolated hemithorax disease. Despite a history of asbestos contact in 50% to 70% of patients, pleural plaques or interstitial fibrosis are apparent on chest radiography in only approximately 20%, but pleural calcifications are evident on almost one-half of computed tomographic (CT) scans <sup>95</sup> and in up to 87% at autopsy. Scoliosis with contracture of the ipsilateral hemithorax is visible even on chest radiography with advanced disease.

A CT scan or magnetic resonance imaging (MRI) of the primary tumor to assess the extent of disease is indicated if treatment is contemplated. Characteristic CT findings in almost 100 patients are pleural thickening in 92% (and of the intralobar fissures in 86%), effusions in 74%, and pleural calcifications in 20% to 50%. <sup>96,97</sup> CT scan is helpful in differentiating benign from malignant pleural thickening, but does not reliably distinguish primary from metastatic malignancy.

Coronal MRI is particularly helpful to evaluate the diaphragm. In a study of 26 mesothelioma patients evaluated with sequential paired CT and MRI scans, MRI showed tumor spread into the interlobar fissures, tumor invasion of and through the diaphragm, and invasion of bony structures better than CT. Invasion of the chest wall and mediastinal soft tissue and tumor growth into the lung parenchyma were equally well seen on both imaging methods. CT was better for detecting pleural calcifications. <sup>98</sup>

Twenty-eight consecutive patients referred for the evaluation of suspected malignant mesothelioma were evaluated by positron emission tomography (PET) with 2-fluoro-2-deoxy-D-glucose (FDG) imaging. Video-assisted thoracoscopy or surgical biopsies provided a malignant diagnosis in 24 patients (22 with mesothelioma) and benign processes in the remaining four. The uptake of FDG was significantly higher in malignant than in benign lesions ( $P = .0001$ ). FDG-PET images identified active tumor sites. Hypermetabolic lymph nodes were noted on FDG-PET images in 12 patients, 9 of which appeared normal on CT scans. Histologic examination in six patients confirmed malignant nodal disease in five cases and granulomatous lymphadenitis in one. Standardized uptake values were inversely correlated with duration of survival after the PET study ( $P = .05$ ). <sup>99</sup> These important data require verification in larger numbers of patients but could be useful in deciding which patient may be a candidate for an aggressive approach since a high FDG uptake in these tumors may indicate a shorter patient survival.

Mesotheliomas are reported to take up gallium 67. <sup>100</sup> Gallium 67 scans in seven cases obtained before resection were compared with pathology. When the involved pleural thickness was over 6 mm, gallium 67 uptake correlated with the macroscopic thickness of mesothelioma in resected specimens. Thickness of the pleura on CT images was only reliable for thick involvement. No definite correlation was found between gallium 67 uptake and the histologic type, extent of tumor parenchyma, interstitial volume, and tumor vascularity. <sup>101</sup>

Planar <sup>201</sup>Tl scintigraphy in a single mesothelioma patient revealed diffuse pleural tumor accumulation. Single photon emission CT demonstrated exact tumor location. <sup>102</sup>

Brain, bone, and liver metastases or extension into other serosal surfaces, although present in more than one-half of patients at autopsy, are sufficiently uncommon at presentation to obviate the need for extensive baseline studies in the absence of symptoms or laboratory abnormalities. However, such studies may identify an occult adenocarcinoma of the lung, a pattern of widespread metastases, or a markedly elevated serum or pleural fluid carcinoembryonic antigen suggesting a diagnosis other than mesothelioma. <sup>63,103</sup>

Although there are no definitive biomarkers for mesothelioma, future studies investigating serial serum levels of tissue polypeptide antigen <sup>104</sup> or thrombomodulin <sup>105</sup> may be of interest.

### **Diagnostic Surgery**

Although obtaining an accurate histologic confirmation of mesothelioma from pleural fluid cytology or needle biopsy specimens is often difficult, the diagnosis of mesothelioma has such a poor prognosis that an unequivocal tissue diagnosis is mandatory. Surgical intervention is usually required, either a thoracoscopy or thoracotomy, despite the risk of seeding the biopsy site or surgical scar with tumor. For patients who are not candidates for radical surgery, thoracoscopy usually obtains sufficient tissue for histochemical analysis. <sup>106</sup> The later development of chest wall masses from seeding of the biopsy site or surgical scar is an uncommon complication (approximately 10%) of any diagnostic procedure, but can usually be avoided by radiotherapy to the scar if appropriate (see [Surgery](#), later in this chapter). Tumor nodules seeded from fluids rich in tumor cells may develop in the subcutaneous tissue surrounding Denver shunts and intrapleural ports. <sup>107</sup>

If preoperative studies suggest stage I mesothelioma in good-risk patients with asbestos exposure, most surgeons combine the diagnostic and therapeutic surgical interventions in one stage. <sup>108</sup> Generous biopsies can be performed at the inception of the exploration, using frozen sections to differentiate mesothelioma from adenocarcinoma. A sample of uninvaded lung should be obtained for counting asbestos fibers. <sup>39</sup>

Bronchoscopy should be performed in all patients suspected of mesothelioma to rule out endobronchial disease, rare in mesothelioma. <sup>109</sup> The role of mediastinoscopy in patients with suspected mesothelioma is undefined. Some surgeons believe it is unnecessary because nodes can be removed with the lung. Other surgeons believe that, because positive nodes indicate stage III disease, surgery would be contraindicated. Nevertheless, if radical extrapleural pneumonectomy (EPP) is contemplated, mediastinoscopy is recommended, because 20% of patients with mesothelioma have mediastinal lymph node involvement. <sup>109</sup>

## **NATURAL HISTORY**

Shortness of breath and chest pain can be controlled initially by repeated thoracenteses and minor narcotics. Although chest tube drainage and sclerosis is generally unsuccessful, pleural fluid eventually becomes loculated as the tumor obliterates the pleural space. <sup>70</sup> With advanced disease, fatigue and dyspnea increase out of proportion to radiographic findings or pulmonary function values. Because hypoxia results from shunting of desaturated blood through a poorly aerated lung, therapeutic oxygen provides little symptomatic relief.

Mesothelioma tends to be locally invasive. Chest wall masses develop in approximately 10% of patients, generally over thoracentesis, chest tube drainage, or thoracotomy tracts. <sup>70,110</sup> Direct involvement of esophagus, ribs, vertebrae, nerves, and the superior vena cava cause dysphagia, pain, cord compression, brachial plexopathy, Horner's syndrome, or superior vena cava syndromes, respectively. <sup>111</sup> Fevers and sweats with no documented source of infection are common and often accompanied by significant weight loss, poor performance status, and an early death. Thrombocytosis and other clotting abnormalities occur in 10% to 20% (more frequently in peritoneal mesothelioma). <sup>112,113</sup> Disseminated intravascular coagulation, thrombophlebitis, pulmonary emboli, and Coombs' positive hemolytic anemia have been reported, <sup>114</sup> as well as hypercalcemia associated with elevated levels of a parathyroid hormone–like peptide. <sup>115</sup>

The median survival is 4 to 18 months in various series (range, weeks to 16 years). Patients generally die of respiratory failure or pneumonia. Small bowel obstruction from direct extension through the diaphragm develops in approximately one-third, and 10% die of pericardial or myocardial involvement. <sup>84,111</sup>

Prognostic variables at presentation are shown in [Table 40.2-2](#). Poor prognostic variables in 180 patients in one single institution series included chest pain, older

age, pleural site, and sarcomatous or mixed histology.<sup>116</sup>

---

Sarcomatous histology  
Poor performance  
Pleural primary  
Weight loss  
Lactate dehydrogenase level >500  
Older age  
Advanced stage  
Elevated platelet count  
Chest pain at diagnosis

**TABLE 40.2-2.** Poor Prognostic Variables at Presentation

In the European Organization for Research and Treatment of Cancer experience in 204 adults with malignant pleural mesothelioma on five consecutive phase II clinical trials, the median survival was 13 months from diagnosis and 8 months from trial entry. In the multivariate analysis, poor prognosis was associated with a poor performance status, a high white blood cell count, male gender, and the sarcomatous histologic subtype.<sup>117</sup>

Factors predictive of poorer survival among 337 patients with mesothelioma on Cancer and Leukemia Group B studies included poor performance status, chest pain, dyspnea, platelet count greater than 400,000/ $\mu$ L, weight loss, serum lactate dehydrogenase level greater than 500 IU/L, pleural involvement, low hemoglobin level, high white blood cell count, and increasing age over 75 years.

With decreasing risk ratio, a multivariate Cox analysis showed that pleural involvement, lactate dehydrogenase greater than 500 IU/L, poor performance, chest pain, platelets greater than 400,000/ $\mu$ L, nonepithelial histology, and increasing age older than 75 years jointly predict poor survival. Performance was the most important prognostic split in the regression tree.<sup>118</sup>

*Localized* malignant fibrous tumors of the pleura that may resemble sarcomatous mesotheliomas histologically have also been described. Of 82 malignant localized tumors, 45% were cured by simple excision.<sup>120</sup> If the nature of the lesion is ambiguous, involvement of the pleura on random biopsy would establish a diagnosis of diffuse (malignant) disease.

## **SURGICAL TREATMENT**

The role of surgery in managing diffuse pleural mesothelioma remains controversial, but there are an increasing number of thoracic oncologic surgeons who are operating for this disease. Nevertheless, overwhelming pessimism for *curative* surgical options continues in most centers that do not routinely deal with the disease since the combination of effusive disease and bulky tumor renders surgical eradication virtually impossible. The disappointing long-term overall survival results, the historically high morbidity and mortality, as well as the propensity for local recurrences have forced many centers to abandon radical operations except for the rare localized situation. The arguments regarding appropriate management of mesothelioma can have geographic differences. In a United Kingdom poll of chest physicians, only 46% of the physicians surveyed would consider referral to a thoracic surgeon for radical resection (E. G. Butchart, personal communication). The French approach to the disease has been a concentration on detection of early stage I disease that is treated with intrapleural therapy, including interferon-g with or without cisplatin.<sup>121</sup> Surgery is performed after this therapy only to improve local control, either by pleurectomy or EPP. In patients with stage II or III mesothelioma, Boutin et al. recommend surgery and postoperative radiation therapy. In the United States a cohort of specialized cancer centers have evolved that have maintained an interest in the surgical management of the disease. As a new cohort of aggressively trained, specialized thoracic oncologists enters practice, the necessity for such referrals may be diminished. At the present time, however, the evolution of the use of surgery with or without intraoperative, postoperative innovative adjuvant therapies is being defined by these centers. In general, innovative, multimodality protocols that incorporate surgery as part of the package are being explored in larger numbers of patients.

### **History of Surgical Management**

Eiselberg<sup>122</sup> is credited with the earliest resection of mesothelioma in a 46-year-old man in whom he removed chest wall and a portion of lung. Much of the original interest in *en bloc* resection for diffuse malignant mesothelioma originated in Germany between 1920 and 1960. With advances both in surgery and anesthetic management, a more extensive resection that included lung, pleura, and diaphragm became technically feasible.

### **Rationale**

Diffuse pleural mesotheliomas are rarely amenable to *en bloc* removal. A small proportion of tumors called *mesotheliomas* may present as an encapsulated mass, not associated with pleural effusion, and these may be amenable to surgical extirpation with negative margins of resection. The majority of diffuse malignant mesotheliomas, however, cannot be surgically removed *en bloc* with truly negative histologic margins because many of the patients have had a previous biopsy and there is invasion of the endothoracic fascia and intercostal muscles at that site, or pleural effusion, which, although cytologically negative, may be breached, or both leading to local permeation of tumor cells either into the residual cavity or into the abdomen. Nevertheless, in the largest series of EPP performed for mesothelioma from the Boston group, 66 of 183 patients were defined as having negative resection margins after EPP. Patients with this finding who had epithelial mesothelioma were found to have 2- and 5-year survival rates of 68% and 46%, if the node dissection did not reveal tumor.<sup>93</sup>

The operation of choice, especially for early pleural mesothelioma, has yet to be defined. There is no doubt that EPP is a more extensive dissection and may serve to remove more bulk disease than a pleurectomy, chiefly in the diaphragmatic and visceral pleural surfaces. Some surgeons, however, include diaphragmatic resection and pericardial resection with their pleurectomies to accomplish removal of "all gross disease." For EPP, it is almost a necessity to include pericardiectomy with or without resection, for the maneuver aids in the exposure of the vessels and allows intrapericardial control to prevent a surgical catastrophe. There are no real guidelines preoperatively that one can use to assure the patient which operation will accomplish tumor removal. The presence of irregular, bulky disease that on the CT infiltrates into the fissures probably dictates the necessity for EPP; a large effusion with minimal bulk disease may call for pleurectomy decortication. Moreover, the philosophy of the surgeon regarding the operation may affect his or her choice, because some surgeons reserve EPP for those patients with bulk disease that presents simple pleurectomy, whereas others believe that the greatest chance for complete gross excision is via EPP performed in the patient with minimal disease. This important factor, preoperative quantitative bulk of disease, may not only influence the choice of resection, but may be an important preoperative prognostic factor in any patient with malignant pleural mesothelioma.<sup>92</sup>

### **Indications for Surgical Management**

Surgery is involved in the management of pleural mesothelioma either for diagnosis, palliative therapy, or as part of a multimodal therapeutic plan. The operations involved in this management include thoracoscopy, pleurectomy and decortication, or EPP. The indications for each of these operations depend on the extent of disease, performance and functional status of the patient, and the philosophy of the treating institution. Basically, operative intervention in mesothelioma is for primary effusion control, cytoreduction before multimodal therapy, or to deliver and monitor innovative intrapleural therapies.

### **Functional Evaluation of the Patient Being Considered for Surgical Intervention**

The majority of patients seeking treatment for mesothelioma are middle-aged to older individuals with a long latency period between asbestos exposure and tumor development. If surgical intervention is to be considered, a detailed physiologic and functional workup directed chiefly at the cardiopulmonary axis must be performed.

**PULMONARY EVALUATION.** Poor underlying pulmonary function in patients with malignant mesothelioma usually reflects the burden of asbestos exposure, concomitant smoking history (up to 70% of the patients have had a heavy tobacco intake), degree of lung trapped by tumor or fluid, and patient age. Decreases in the forced vital capacity correlate with the degree of costophrenic angle involvement, width, and length of pleural fibrosis, and the presence of either circumscribed plaque or diffuse pleural thickening. The extent of fibrosis correlates with the amount of dyspnea on exertion, and the diffusion capacity of carbon dioxide is reduced in these patients. There is restriction of chest wall motion resulting in reduced lung volumes. Such changes may be bilateral and thus the extent of surgical therapy is influenced by the patient's respiratory functional reserve. Generally accepted criteria for tolerance of an EPP can be assessed by pulmonary function testing including the patients' response to bronchodilators. Patients with a forced expiratory volume in 1 second (FEV<sub>1</sub>) of greater than 2 L/second usually are able to withstand a pneumonectomy. In general, an FEV<sub>1</sub> of less than 1 L/second, a PO<sub>2</sub> less than 55, or a pCO<sub>2</sub> greater than 45 are relative contraindications to performance of EPP.<sup>93</sup> If the patient presents with an FEV<sub>1</sub> of less than 2 L/second, or if the predicted FEV<sub>1</sub> is less than 1.2 L/minute after pneumonectomy, quantitative ventilation-perfusion scanning should be performed.

**CARDIAC EVALUATION** Operations for malignant pleural mesothelioma are associated with profound blood loss and potentially significant cardiac demands. The patient should be carefully screened for a history of hypertension, angina, and previous myocardial infarction, and routine electrocardiography should reveal no signs of previous injury. Any patient sustaining a myocardial infarction within the past 3 months or having an arrhythmia requiring medication should not be considered for EPP. Patients without objective evidence of cardiac injury who have a history of chest pain compatible with angina or remote myocardial infarction should have dobutamine thallium screening to investigate reversible perfusion defects indicative of myocardium at risk. In general, patients with an ejection fraction of less than 45% are not considered to be candidates for EPP.<sup>93</sup> This may also affect their enrollment in innovative multimodality programs using potentially cardiotoxic drugs. These patients may then be considered for angioplasty before operative intervention for their disease, and indeed, may be better candidates if a multimodality approach is being contemplated.

#### Other Preoperative Evaluation

Preoperative medications must be carefully scrutinized, specifically any nonsteroidal antiinflammatory drugs that could affect platelet function. Patients should have complete extrathoracic staging evaluation including bone scan, abdominal CT, and head CT to rule out systemic involvement. If patients are to participate in multimodality programs that use drugs with potential renal toxicity (i.e., cisplatin), a preoperative creatinine clearance should be performed.

#### Effusion Control

In general, the indications for palliative surgery include the control or prevention of effusion that results in disabling dyspnea. The most efficacious and least invasive of the surgical procedures to accomplish effusion control is thoracoscopy with talc pleurodesis. Two to 5 g of asbestos-free, sterile talc can be insufflated over the lung and the parietal surfaces. Success rates in effusion control with talc, used either via thoracoscopy or via slurry, approach 90%. Failure of these techniques are usually associated with mesothelioma with entrapped lung, a large solid tumor mass, a long history of effusion with multiple thoracenteses leading to loculations, or age older than 70 years. This technique is widely used once the diagnosis of mesothelioma is made. Primary care physicians, however, should carefully deliberate before using sclerosants and consider the extent of visceral and parietal pleural disease. The use of talc or other sclerosants could affect the suitability for patients to enter innovative trials that incorporate either pleurectomy or EPP and could jeopardize the ability of the surgeon to spare a lung that may not have visceral pleural implants. [Table 40.2-3](#) reviews the results of videothoroscopic talc pleurodesis specifically for mesothelioma. Patients who were able to have a successful pleurodesis had a significantly longer survival than those who did not, and success depended on presence of trapped lung or degree of invasion of the pleura.

Author	No.	Success* (%)	Median Survival (mo)

\*Success defined as no further need for tapping after 1 month in patients with a resulting normal radiographic result or less than 500 mL of residual fluid remaining.

**TABLE 40.2-3.** Videothoroscopic Talc Pleurodesis for Malignant Pleural Mesothelioma

Effusion control via palliative surgery is occasionally attempted after lesser procedures (including sclerotherapy) have failed because of the inability of the lung to expand. Generally, the procedure of choice for such palliation is a pleurectomy with or without decortication of the underlying lung. The use of EPP for palliative intent is only rarely described in the literature and because of its morbidity and mortality some surgeons state that EPP should never be used for palliative purposes.<sup>1</sup>

#### Pleurectomy

**MORBIDITY AND MORTALITY.** When performed routinely pleurectomy for mesothelioma can be associated with few major complications ([Fig. 40.2-1](#)). In the series that specify postoperative morbidity, the most common complication was prolonged air leak (i.e., greater than 7 days), occurring in 10% of the patients. On average the chest tubes can be removed in approximately 5.5 days with greater than 50% of the patients having the chest tube removed within 4 days. Pneumonia and respiratory insufficiency may occur and are usually related to the burden of disease and preoperative functional status. Empyema is a rare occurrence (2%) and is managed by prolonged chest tube drainage and antibiotics. Hemorrhage requiring reexploration is rare (i.e., less than 1%).

**FIGURE 40.2-1.** Pleurectomy for diffuse pleural mesothelioma. Preoperative tomograms demonstrate thickened pleura and fluid. The operative photograph and specimen are depicted.

Earlier studies in patients requiring pleurectomy (but not having mesothelioma) had an inhospital or operative mortality of 10% to 18% in the 1960s.<sup>126,127</sup> The modern-day mortality from pleurectomy has decreased and is generally considered to be 1.5% to 2.0%, with death either from respiratory insufficiency or hemorrhage. Most recently, total pleurectomy in 50 patients performed for mesothelioma had a 30-day mortality of 2%.<sup>6</sup> In a series of 39 pleurectomies, the hospital mortality was

**SHORT- AND LONG-TERM RESULTS** Pleurectomy and decortication are effective in controlling malignant pleural effusion. Law et al. report effusion control in 88% of patients having decortication for mesothelioma.<sup>129</sup> In 63 patients having partial decortication and pleurectomy Ruffie et al.<sup>119</sup> reported 86% control of effusion, and Brancatisano et al. reported a 98% control of effusion after pleurectomy in 50 cases of pleural mesothelioma.<sup>130</sup>

Many of the published series using pleurectomy for palliative management have added therapies postoperatively in an uncontrolled, institution-related fashion ( [Table 40.2-4](#)). The majority have no sampling of the mediastinal nodes, little less a mediastinal dissection. Nevertheless, the overall median survival for patients having pleurectomy alone is approximately 13 months. The patients who receive pleurectomy and decortication alone usually have early effusive disease with minimal bulk tumor. If these patients have epithelial mesothelioma and are not found to have nodal involvement, survival rates can be significantly longer than that quoted previously.

### Radical Curative Surgery: Extrapleural Pneumonectomy

**INDICATIONS.** Radical EPP classically has been described for pure epithelial tumor, stage I that is technically resectable and encapsulated by the parietal pleura ([Fig. 40.2-2](#)). Due to sampling error it is impossible to clarify with 100% certainty whether the tumor is a pure epithelial type or mixed tumor based on the preoperative or intraoperative biopsy.

**FIGURE 40.2-2.** Left-sided diffuse mesothelioma. Two computed tomographic cuts show chest wall, fissure involvement, and aortic arch abutment. The surgical photograph demonstrates the skeletonized aorta, partial pericardiectomy, and partial diaphragmatic removal via a counterincision. The surgical specimen is demonstrated in the lower right.

The centers that are able to attract large numbers of mesothelioma patients due to ongoing prospective trials may be relaxing the so-called classic indications based on stage, age, and histology. Surgeons at these institutions are chiefly concerned with the patients' functional ability to tolerate the operation, and the ability to accomplish maximal tumor debulking. If, indeed, higher stage patients can undergo the operation with risks equal to pleurectomy and decortication, enthusiasm for its general incorporation in more aggressive adjunctive trials would be justified.

There are few patients who actually qualify for exploration outside the research setting. In Butchart's review, 29 of 46 or 63% of patients were eligible for EPP.<sup>95</sup> The only other series that reveals this percentage is DaValle's in which 33 of 56 patients over a 27-year period had EPP (59%).<sup>136</sup> Sugarbaker reported 50% of the patients seen at his institution are not eligible for EPP and adjuvant therapy. Unfortunately, these series really do not define why one patient may have a pleurectomy while another would have EPP, and it is obvious, however, that some institutions have simply never adopted the operation as feasible for treatment of the disease.

Probably the most enlightening study on eligibility was the Lung Cancer Study Group malignant mesothelioma pilot study from 1985 through 1988.<sup>135</sup> To be eligible for entry into the study the patient was required to have disease limited to the hemithorax by roentgenographic evaluation, a residual FEV<sub>1</sub> after resection of at least 1 L/second, and no significant cardiovascular illness, clearly more lenient criteria than those that limited eligibility due to age, histologic type, or presumed stage. Even with these relaxed criteria only 20 of the 83 evaluated patients were resected with an EPP. The reasons that EPP could not be performed were chiefly extent of disease not allowing complete gross resection (54%), inadequate respiratory reserve (33%), stage IV disease (11%), and concurrent medical illness (10%) ([Table 40.2-5](#)).

\*Multimodality series performed over 14 years.  
NA, not applicable.

**TABLE 40.2-5.** Extrapleural Pneumonectomy: Results

**COMPLICATIONS.** Due to its magnitude, EPP has significantly greater morbidity than pleurectomy. The major complication rate ranges from 20% to 40%, and arrhythmia requiring medical management is the most common complication. In the most recent report of Sugarbaker et al., major morbidity occurred in 24% of the

patients having EPP and minor morbidity in 41%.<sup>93</sup> The rate for bronchopleural fistula is greater with right-sided EPPs with an overall fistula rate of 3% to 20%. The bronchopleural fistula can be handled for the most part with open thoracostomy drainage with or without muscle flap interposition.

**MORTALITY.** The mortality following EPP was unacceptably high in the 1970s, with 31% reported by Butchart et al.<sup>95</sup> Since then, however, there has been a steady decline in the operative mortality for the operation to consistent rates less than 10% in series of 20 or more patients. Mortality occurs chiefly in older patients from respiratory failure, myocardial infarction, or pulmonary embolus. Rusch and Venkatraman<sup>91</sup> reported a perioperative mortality of 6% (3 of 50) after EPP and Sugarbaker et al. reported a perioperative mortality of 3.8% from myocardial infarction and presumed pulmonary emboli.<sup>93</sup>

### Recurrence after Extrapleural Pneumonectomy

Rusch et al.<sup>135</sup> described sites of recurrence after EPP to be distant areas compared with biopsy only or pleurectomy and decortication, and the local control was superior to that of the other modalities. Pass et al. also found a higher proportion of first sites of local recurrence seen in the pleurectomy population compared with the patients having EPP.<sup>128</sup> In the series of patients reported by Sugarbaker et al., Baldini et al. have reported that the sites of first recurrence were local in 35% of patients, abdominal in 26%, the contralateral thorax in 17%, and other distant sites in 8%.<sup>140</sup>

**survival.** Long-term survival rates after EPP remain disappointing, with the median survivals ranging from 9.3 to 17.0 months for the majority series. Rusch and Venkatraman reported a median survival of 10 months in their series of 50 EPP,<sup>91</sup> and the median survival of malignant pleural mesothelioma patients having EPP (all histologies) in the National Cancer Institute series is 9.4 months. The majority of patients were pathologic stage II or III in these two series. Most recently, Sugarbaker et al.<sup>93</sup> reported a 17-month median survival in a series heavily weighted with stage I, epithelial patients (52 of 183), using a multimodality approach (see [Combined Modality Approaches](#), later in this chapter) whose 2- and 5-year survivals were 68% and 46%. In the series by Rusch and Venkatraman, the 2- and 5-year survivals of stage I patients (16 of 131) were 65% and 30%, respectively.

### RADIATION THERAPY

The efficacy of irradiation, like that of other treatment modalities, remains uncertain in the definitive treatment of patients with pleural mesothelioma. While there are no prospective randomized clinical trials that define a role for radiation therapy, several studies suggest benefit. However, the variable clinical course of the disease and the frequent use of radiation in conjunction with either surgery or chemotherapy make assessment of its contribution to an overall treatment program difficult. One report suggests prolonged patient survival among patients with malignant pleural mesothelioma receiving combined modality treatment versus supportive care alone or single modality therapy.<sup>141</sup>

Mesothelioma cell lines seem to be more sensitive to radiation (as assessed by the surviving fraction after 2 Gy) than non-small cell lung cancer cell lines, but less sensitive than small cell lung cancer cells.<sup>142</sup> The results of a more recent study suggest that mesothelioma cell lines from different patients exhibit remarkable differences in radiosensitivity.<sup>143</sup> The use of radiation for mesothelioma, however, differs considerably from its use in lung cancer because of the extensive pleural involvement seen in mesothelioma. If radiation is to be used for definitive treatment of malignant mesothelioma, treatment of the entire ipsilateral pleura is indicated. This target volume is extremely difficult to radiate to tumoricidal doses without exposing patients to a risk of normal tissue injury to adjacent lung, heart, spinal cord, and liver.<sup>144</sup>

Most reports from the literature document occasional regressions of gross disease with modest doses of radiation, but do not indicate that survival is significantly altered by irradiation compared with supportive care ([Table 40.2-6](#)). Between 1971 and 1980, 116 patients with good performance status and without evidence of extrathoracic disease were evaluated at the Brompton and Royal Marsden Hospitals in London.<sup>129,146</sup> Fifty-two patients underwent active treatment, whereas the other 64 received supportive care. No difference in survival was seen between the two groups at 2 (33%) and 4 years (0% to 11%). Active treatment consisted of nonradical parietal pleurectomy and decortication of the lung in 28 patients, radiation therapy in 12 patients (following surgery in 8), and chemotherapy in the remaining 12 patients (8 of whom also underwent operation). Radiation therapy consisted of 50 to 55 Gy using rotating arc fields designed to treat the pleura and spare underlying lung. One patient showed a dramatic response to radiotherapy, with resolution of effusion, pain, and dyspnea. She was doing well 4 years after completion of treatment. Two other patients experienced sustained regression of recurrent pleural effusions after radiation therapy. Thus, although the treatment volume and adjuvant normal tissue limit radiation dose, radiation therapy to bulky tumors occasionally produces significant regression and palliation.

Institution	No. of Patients	Dose (Gy)	Outcome
University of Iowa <sup>145</sup>	5	30-55	Symptomatic improvement

**TABLE 40.2-6.** Radiation Series

Because of the variable course of the disease, different radiation treatment techniques used (anteroposterior and posteroanterior, rotational arc, combined photon electron), and normal tissue constraints on radiation dose, the relationship between treatment response and radiation dose is not well established. The series from the Joint Center for Radiation Therapy in Boston included 29 treatment courses for palliation between 1968 and 1980.<sup>110</sup> Relief of dyspnea, pain, and other symptoms was seen in four of six patients treated with doses of greater than or equal to 40 Gy, whereas only 1 of 23 treatment courses at lower doses of radiation achieved palliation of symptoms. Doses of 15 to 20 Gy (the normal tissue tolerance dose of whole lung irradiation) did not control disease in patients with diffuse involvement of the visceral pleura with 1- to 2-mm nodules.

A series from the Peter MacCallum Cancer Institute in Australia described good palliation in 17 of 26 (65%) evaluable palliative radiation courses.<sup>152</sup> Short-course treatment for palliation with 20 Gy in five fractions appeared to give similar results with more protracted courses (30 to 40 Gy in 10 to 15 fractions). Fifteen patients were given high-dose radiotherapy with radical intent. Twelve completed treatment to 50 Gy. The median survival of the 12 patients completing treatment was 17 months, with an estimated 2-year survival of 17%.<sup>152</sup> A more recent study from the Peter MacCallum Cancer Institute on 111 patients showed that 60% of the patients obtained successful palliation, with a median survival of 5 months. No dose-response curve for palliation could be identified.

In a series from Thomas Jefferson Medical School in Philadelphia, two of nine patients had local control at 20 and 40 months after 60 Gy to the entire ipsilateral pleura, mediastinum, and involved areas of lung.<sup>148</sup> Radiation was delivered in three courses of 20 Gy over a total of 10 weeks by a split-course technique.

While the volume of disease can influence radiotherapeutic outcome in many other tumors, its effect on the radiation response of pleural mesothelioma is not well characterized. The combination of radiation therapy with debulking surgery can be rationalized if only microscopic disease on the majority of the pleural surfaces remains after surgery. Radiation is more effective at a given dose level when treating microscopic compared with gross disease. Higher doses of boost irradiation with either a shrinking-field technique or brachytherapy can be used on sites of residual gross disease. Such a strategy likely maximizes local control while minimizing the normal tissue complications from irradiation.

Radiation therapy can be used to prevent seeding of biopsy tracts and surgical wounds. In a series from Marseilles, France, radiation treatment of 21 Gy in three fractions prevented wound seeding after thoracoscopy or thoracotomy in 24 patients.<sup>153</sup> Before initiation of an adjuvant irradiation policy in this setting, wound seeding occurred in 17 of 33 (61%) patients. None of the patients who developed growth of nodules in an incision site responded to subsequent irradiation.

When considering the use of radical radiation therapy in this disease, the potential complications of high-dose irradiation to a large volume should also be weighed in the treatment decision. The frequency, type, and severity of radiation complications depends on volume, dose, fractionation, technique, and normal tissue in the field, as well as type and timing of any other treatment, such as chemotherapy. Remarkably, some earlier series reported no acute or chronic complications from the use of radiotherapy alone.<sup>110,147</sup> This may have been the result of limited volume treatment or short survival. One series noted few complications with radiotherapy when 50 to 55 Gy were delivered with an off-axis rotational technique. Among 12 patients, complications included nausea and malaise in six, transient radiation hepatitis in one, and mild esophagitis in another.<sup>129,146</sup> No case of radiation pneumonitis was noted. However, in cases in which no attempt has been made to shield lung or when the organ tolerance of other tissues such as the liver has been exceeded, significant complications have been seen. Ball and Cruickshank reported a case of fatal radiation hepatitis in a patient treated for a right pleural mesothelioma and one case of radiation myelitis (after 40 Gy) in their series of 12 patients treated with radical irradiation.<sup>152</sup> Maasilta et al. reported deterioration in lung function after high-dose irradiation (55 to 71 Gy) given with chemotherapy.<sup>154,155</sup> Indeed, forced vital capacity and diffusing capacity showed a significant decline at 1.5 to 2.0 months following radiotherapy and continued to decline over the year following the end of radiation. By radiologic assessment, treatment essentially obliterated lung function on the affected side. Of note, hypoxemia and pathologic and physiologic shunting increased in two of six patients monitored. Hence, lung function should be evaluated to assess potential tolerance before undertaking hemithorax irradiation. Liver position and volume should be determined, and adequate hepatic shielding should be used. Maasilta and Hallman et al. have reported the association of bronchoalveolar lavage plasmin and surfactant in mesothelioma patients with radiation pulmonary injury.<sup>155,156</sup>

The use of radioactive colloids such as <sup>198</sup>Au or chromic phosphate-<sup>32</sup>P instilled into the pleural space has also been studied. Pleural effusions have been reported to disappear for up to 3.5 years.<sup>157</sup> The exact response rate and duration to this approach is not known. In a series from Hahnemann Medical College, all six patients were alive at 12 months or longer after instillation of isotopes.<sup>158</sup> The extent of other treatment and exact length of survival, however, was not reported. Because of the physical characteristics of these isotopes, their effect on gross disease is limited. <sup>32</sup>P is a pure beta (electron) emitter with maximum tissue penetration of 8 mm, and the bulk of energy deposited in the first 2 mm. <sup>198</sup>Au emits 90% of its energy as beta particles (electrons) with an energy of 0.96 MeV. These have tissue penetration of less than 5 mm, although the emitted photons have energies of 0.412 to 1.099 MeV and would penetrate several centimeters. An equally important limitation on the use of radiocolloids is the problem of obtaining optimal distribution of isotope throughout the pleural space. Gordon and colleagues reported an attempt at radioisotope instillation in three patients, but fluoroscopy or gamma camera measurements indicated that the distribution was suboptimal.<sup>110</sup> Hence, both agents may have a limited role in patients with low-volume disease or in conjunction with surgery in patients with an adequate pleural distribution. The distribution of a radiotracer or contrast material should be tested before a therapeutic administration of these agents is considered.

### Radiation Therapy Techniques

Different radiotherapy techniques have been used to irradiate the pleura to high doses. Because of the extensive pleural involvement, the target volume is large and includes the pleural surface, diaphragm, and mediastinum. Attempts at radical radiation should be limited to those patients with disease confined to one hemithorax. Field borders must extend above the first rib superiorly, below the diaphragmatic reflection of the pleura inferiorly, which is usually at about the lower border of the twelfth thoracic vertebra, laterally to clear the bony rib cage, and include the full width of the mediastinum. The field size can be increased to include masses extending into the chest wall or diaphragm, or to include the whole heart when the pericardium is involved. The identification of sites of residual gross disease with surgical clips at thoracotomy greatly facilitates radiation planning by allowing accurate, well-defined high-dose boost volumes and lessens the likelihood of normal tissue injury. CT scanning can also help delineate sites of gross disease, but may miss invasion of tumor into the mediastinum or through the diaphragm, as well as areas of miliary seeding of the pleura.<sup>96,159</sup> MRI has been reported to delineate mediastinal invasion by mesothelioma<sup>160</sup> and may have a role in radiologic assessment and treatment planning.

Radical irradiation commonly delivers 40 to 55 Gy to the entire pleural surface (with the exception of the reflections extending into the fissures in the lung) and the mediastinum. Other structures, such as the heart, are included as clinically indicated. This has been followed by boosts to focal areas of gross disease through reduced portals to doses of 55 to 71 Gy. While some have chosen to irradiate the entire hemithorax with opposed anterior and posterior photon fields to doses of 40 to 50 Gy without lung shielding followed by a cone-down to smaller fields,<sup>144,152</sup> such techniques are associated with irreversible pulmonary injury.<sup>144</sup> Hence, techniques have been developed to spare the lung. One involves the use of an off-axis beam rotational technique to irradiate the pleural space to high dose while shielding underlying lung.<sup>129,146</sup> Several others involve matching photon and electron beams.<sup>148,161</sup> These involve the use of large, opposed anterior and posterior external-beam portals with central lung blocking. The pleural areas underneath the blocks are treated with electron beams of appropriate energy (generally 10 to 15 MeV). CT scans are used to define the thickness of the chest wall, delineate patient contour, and plan treatment. Tissue compensators may improve dose distribution. None of these techniques are ideal. Even careful photon and electron techniques deliver substantial doses to the lung because of the penetrating ability of the electron beams in the lung and contribution from side-scattered electrons set in motion during photon irradiation.<sup>161</sup>

Advances in sophisticated conformal radiotherapy may improve the available dose distribution.<sup>162</sup> A single report using fast neutrons describes a complete regression of bulk disease without evidence of recurrence 78 months after treatment.<sup>163</sup> However, a portion of the disease was treated with cobalt 60 irradiation with similar response. Because of the poor depth dose characteristics of the available neutron beams, only thin patients could be treated with a pure neutron technique. However, these or other particles may have a role in selected patients in delivering boost treatment to sites of gross disease. Other particles, such as protons, may have a role in selected patients in delivering boost treatment to sites of gross disease.

Intensity modulated radiation therapy techniques permit higher doses of radiation to be delivered to target tissue while limiting radiation dose to the lung and other normal tissues (Fig. 40.2-3).

**FIGURE 40.2-3.** Coronal (top), sagittal (middle), and axial (bottom) views of an intensity-modulated radiation therapy treatment plan for a patient with malignant pleural mesothelioma. In this patient the target tissue surrounds the lung. In this plan the target tissue receives 54 Gy while limiting the dose to the majority of the lung to less than 20 Gy. The spinal cord, heart, and contralateral lung also receive acceptable low doses of radiation. (Courtesy of the Department of Radiation Oncology, Columbia University, New York.)

When conventional fractions of 1.8 to 2.0 Gy are given daily five times per week, reasonable treatment precautions would limit the spinal cord dose to 40 Gy, the esophagus to 45 to 50 Gy, the whole lung to 20 Gy, a functional portion of the liver to 30 Gy, and 50% of the heart to 40 Gy. Radiation tolerances may be lowered when radiation is given in conjunction with chemotherapy, especially doxorubicin, despite temporal separation of the two modalities by weeks or even months.

## CHEMOTHERAPY

### Single-Agent Studies

Before the wide availability of CT scans, most mesotheliomas were not strictly measurable. Measurable masses on chest radiography were frequently obscured by effusions that are totally unreliable in determining response to therapy. Response rates to standard agents remain difficult to define. Relatively small positive studies are reported promptly, whereas larger series with lower response rates may never be published. Nevertheless, data from single-agent studies are shown in [Table](#)

40.2-7. Response rates are included in the table when the number of evaluable patients exceeds ten.

Agent	No. Evaluable	No. Responding	Response Rate	Reference
<b>Single-Agent Chemotherapy</b>

TABLE 40.2-7. Single-Agent Response Rates in Malignant Mesothelioma from Series with More Than Five Patients

Doxorubicin appears to have some activity against mesothelioma although response rates vary considerably. Methotrexate with rescue, 5-azacitidine, and 5-fluorouracil may also have single-agent activity. Neither cisplatin nor paclitaxel as single agents appear to be significantly active.

### Intrapleural Cytokine Therapy

Interferon-g has had intriguing results by the intrapleural route as documented by Boutin et al.<sup>230</sup> Interferon was administered at a dose of 40 million U twice a week for 8 weeks intrapleurally via a catheter or an implantable port for 89 patients over 46 months. Thoracoscopic or surgical biopsy was performed if CT scan 2 weeks after the end of treatment demonstrated a reduction in tumor size. Eight histologically confirmed complete responses and nine partial responses with at least a 50% reduction in tumor size were obtained. The overall response rate was 20%. The response rate for patients with stage I disease was 45%, with the main side effects being hyperthermia, liver toxicity, neutropenia, and catheter-related infection.

IL-2-based regimens have also been exploited in mesothelioma. The largest experience to date with *intrapleural* IL-2-based therapy has been reported by Astoul et al.<sup>233</sup> Of 22 patients with mesothelioma (19 epithelial, 2 mixed, 1 sarcomatous) treated with intrapleural IL-2 (21 × 10<sup>6</sup> IU/m<sup>2</sup>/day for 5 days) 11 responded partially and 1 completely. The median survival was 18 months. The 24- and 36-month survival rates for responders were 58% and 41%, respectively.<sup>233</sup>

### Combination Chemotherapy

Response rates for combination regimens range from 0% to 48% (Table 40.2-8). The highest response rate reported is for cisplatin and gemcitabine (48% in 21 patients). Nine of ten responders and three of nine with stable disease has symptomatic improvement, and three responders had improved vital capacity on functional testing.<sup>234</sup>

TABLE 40.2-8. Reported Combinations in Series with More Than 15 Patients

### Randomized Trials in Mesothelioma

Doxorubicin and cyclophosphamide with or without dacarbazine yielded response rates of 7% in both arms of a large randomized trial that accrued advanced patients concurrently with a second study for stage I and II mesothelioma.<sup>235</sup> Thus, the response rates may be artificially low in this study because better prognosis patients were treated on a competing study.

The Cancer and Leukemia Group B randomized 79 patients with measurable mesothelioma to cisplatin and doxorubicin versus cisplatin and mitomycin C. The objective response rates in patients with measurable disease (24%) were similar but time to treatment failure (4.8 vs. 3.6 months) and survival (8.8 vs. 7.7 months) were slightly longer for the doxorubicin and cisplatin combination compared with mitomycin and cisplatin.<sup>236</sup>

### Intrapleural Chemotherapy

Based on the activity of intraperitoneal cisplatin (see [Intraperitoneal Chemotherapy](#), below), the Lung Cancer Study Group completed a trial of 47 patients treated with intrapleural cisplatin and cytarabine. Of the 37 patients evaluated, 49% had at least 75% decrease in the size of their effusion.<sup>135</sup>

Pharmacokinetic data in 12 patients treated with intrapleural cisplatin and mitomycin showed three- to fivefold higher pleural to plasma levels of both drugs.<sup>237</sup> In an Italian pharmacokinetic study of four patients treated with 90 mg/m<sup>2</sup> intrapleurally compared with seven patients treated with the same dose intravenously, the mean area under the concentration versus time curve was 50 times greater than that detected in plasma. Intrapleural cisplatin resulted in significantly lower plasma mean area under the concentration versus time curve and prolonged plasma levels of filterable platinum compared with intravenous administration.<sup>238</sup>

The use of an implantable port facilitates repetitive intrapleural administration and probably decreases the risk of infection.<sup>239</sup>

## MULTIMODALITY TREATMENT

### COMBINED RADIOTHERAPY AND CHEMOTHERAPY

Theoretically, cisplatin or doxorubicin could be used as a radiosensitizer and may be more effective than radiotherapy or chemotherapy alone. A small group of South African patients treated with doxorubicin and radiation of 10 Gy every 6 weeks for four courses survived a median of 23 months.<sup>269</sup> Paclitaxel has been described as a radiation sensitizer.<sup>270</sup> A phase I report from the National Cancer Institute combining a 120-hour (5-day) continuous infusion of paclitaxel every 3 weeks during thoracic radiation therapy (57.6 to 63.0 Gy) has been shown to be safe in 27 patients with malignant pleural mesothelioma.<sup>271</sup> Many patients achieved local control; however, only four patients were alive with a median follow-up of 15 months. One of these patients is without evidence of disease at 14 months.

A nonrandomized phase II study from University Hospital in Lund, Sweden, compared the effect of hemithorax radiation (40 Gy) alone or combined with doxorubicin and cyclophosphamide in 47 patients with biopsy only.<sup>272</sup> No significant difference was detected between the two groups of patients with regard to tumor response, survival, or palliation of tumor-related pain.

## **SURGERY WITH POSTOPERATIVE ADJUVANT THERAPY**

The majority of patients with mesothelioma, independent of staging, cannot be rendered free of disease with surgical therapy alone. In a Memorial Sloan-Kettering Cancer Center report of 41 patients who underwent parietal pleurectomy between 1976 and 1982, disease at the completion of surgery remained on the diaphragm (49%), visceral pleura (51%), mediastinum (49%), chest wall (27%), and lung (5%).<sup>273</sup> Seventy-eight percent had residual gross disease after surgery. Radical pleuropneumectomy can remove more disease in selected patients, but many still have residual microscopic or gross tumor after even the most aggressive surgical resection.

Alberts et al.,<sup>269</sup> in a series of 26 selected patients (10% of a total of 262 patients), reported an 11-month median survival after maximal pleural cytoreduction, 4500 cGy postoperative radiation therapy, and doxorubicin, cyclophosphamide, and procarbazine. The results, however, may reflect a generally poor risk group as the duration of symptoms was usually less than 6 months.

A nonrandomized prospective study from Helsinki University Central Hospital<sup>274</sup> reported on 100 patients treated between 1977 and 1989 with debulking surgery, chemotherapy, and hemithorax irradiation. The median survival time was increased from 8 to 12 months for those patients who completed one of five protocols. The first protocol (1977 to 1981, 16 patients) was 20-Gy hemithorax irradiation in ten fractions over 2 weeks and a variable number of courses of cyclophosphamide, vincristine, doxorubicin, and dacarbazine. The second study (1982 to 1984, 26 patients) was a split-course radiation therapy program consisting of 55 Gy in 25 fractions over 7 weeks with a midway 2-week rest. Major tumor areas were boosted with 15 Gy in six fractions. Chemotherapy was as described for the first protocol. The third protocol (1985 to 1986, 15 patients) was hemithorax irradiation using a hyperfractionation schedule to 70 Gy (1.25 Gy twice daily) over 7 weeks with a 10-day rest halfway through. Radiation was preceded by single-agent chemotherapy with mitoxantrone for a maximum of six cycles. The fourth protocol (1986 to 1988, 24 patients) included 35-Gy hyperfractionated into 28 fractions over 3 weeks and hypofractionation of 36 Gy into nine fractions every other day over 3 weeks. This schedule was preceded with 4-epirubicin for a maximum of six cycles. The fifth and final protocol (1988 to 1989, 19 patients) included hemithorax irradiation using 38.5 Gy in 11 fractions over 15 days. A maximum of six cycles of etoposide preceded the radiation therapy. None of the protocols prevented progression of local disease or spread of tumor outside the hemithorax. Significant lung injury (radiation pneumonitis and fibrosis) occurred in regimens 2, 3, 4, and 5.

### ***Pleurectomy, Intraoperative Brachytherapy, and Postoperative Radiation***

Memorial Sloan-Kettering Cancer Center has been the leading proponent of this technique, which includes as complete a parietal pleurectomy as possible to remove the bulk of the tumor followed by permanent (<sup>125</sup>I) or temporary (<sup>192</sup>Ir) implantation to deliver 3000 rads in 3 days to a 1-cm distance from the implant plane.<sup>273</sup> Radioactive <sup>32</sup>P is selectively instilled intrapleurally 5 to 7 days after thoracotomy, followed by external-beam radiation therapy commencing 4 to 6 weeks postoperatively using electrons and photons to deliver 4500 rads in 4.5 weeks. They report minimum morbidity in the 41 patients discussed, and the median survival was 21 months at the time of their report. The majority of patients had recurrences at distant sites (54%) with or without local recurrence. Unfortunately, there has been little follow-up information with regard to the ongoing status of these patients, as the median follow-up in 40% of the patients was 12 months or less at the time of the first report in 1984.

## **PLEURECTOMY, INTRAPLEURAL CHEMOTHERAPY, WITH OR WITHOUT POSTOPERATIVE CHEMOTHERAPY**

Few studies of combining debulking surgery with intracavitary treatment of pleural mesothelioma have appeared since the first reports of intrapleural chemotherapy alone for malignant mesothelioma. In a report describing intrapleural chemotherapy without surgery for malignant pleural mesothelioma in 1987, 21 patients received 20 to 30 mg of doxorubicin weekly for 4 weeks and then monthly.<sup>275</sup> The average survival was 21 months, but the indications for the therapy and the monitoring of responses and recurrence data were difficult to extract from the report. Kirmani et al.<sup>276</sup> treated 17 patients with intrapleural cisplatin (90 to 100 mg/m<sup>2</sup>) weekly for 3 weeks followed by a 3-week rest. Only 2 of 12 evaluable patients with pleural mesothelioma responded, with a median survival of 4 months. The 2 responders survived 9 months.

Rusch et al.<sup>277</sup> combined the elements of intrapleural chemotherapy with cisplatin and cytarabine after surgical debulking followed by systemic chemotherapy in ten patients. One patient died postoperatively, but the chemotherapy complications were reversible, making such an approach feasible. They followed this regimen with an even more aggressive regimen of pleurectomy, immediate intracavitary cisplatin and mitomycin C, followed by two cycles of cisplatin and mitomycin C systemically.<sup>278</sup> Toxicity was acceptable. The overall survival rate of the 27 patients was 68% at 1 year and 44% at 2 years, with a median survival of 17 months. Recurrences, however, were chiefly locoregional.

A similar regimen combining cisplatin and mitomycin C has been attempted at the Cleveland Clinic Foundation of 14 patients.<sup>279</sup> The projected 18-month survival was 31%, yet patients' tolerance permitted delivery of only 50% of the chemotherapy treatments adjuvantly.

In an Italian study, pleurectomy and diaphragmatic or pericardial resection was combined with intrapleural cisplatin and cytarabine for 4 hours immediately after pleurectomy and systemic epirubicin and mitomycin C. The median time to disease progression was 7.4 months, and median survival was 11.5 months in 20 patients.<sup>280</sup>

Pleurectomy with intrapleural chemotherapy with or without radiation therapy remains an intriguing strategy, but its efficacy is not established. Further investigation should include standard debulking with definition of the extent of residual disease, a tolerable but effective intrapleural regimen, and compulsive follow-up to document recurrence patterns.

## **EXTRAPLEURAL PNEUMONECTOMY, INTRAVENOUS CHEMOTHERAPY, AND POSTOPERATIVE RADIOTHERAPY**

An ongoing interest in a multimodal approach to malignant mesothelioma was developed at the Dana Farber Cancer Institute beginning in 1980.<sup>111</sup> The program has evolved with regard to the chemotherapy, and presently consists of EPP, followed by two cycles of paclitaxel and carboplatin. Concurrent radiation to a dose of 40.5 Gy is given with weekly paclitaxel. Over a 19-year period, 183 patients were treated, with a perioperative mortality of 3.8%. The median survival in this group of patients is approximately 17 months, which is a significant improvement over other trials. Favorable subgroups include those with no mediastinal nodal involvement and epithelial histology.<sup>93,281</sup>

A series of 93 patients from Hamburg who chose either multimodal treatment or best supportive care has also shown some prolongation of life expectancy with multimodal treatment.<sup>282</sup> The treated patients, however, were younger, had a better performance status at presentation, and had no medical contraindications to surgery. Surgery consisted of pleurectomy decortication or EPP followed by systemic chemotherapy with doxorubicin, cyclophosphamide, and vindesine. Patients in remission at the end of the chemotherapy (16 of the 57 accrued) received 45 to 60 Gy of radiation therapy to the hemithorax. Median survival was 13 months compared with 7 months for those receiving best supportive care.

## **NOVEL MULTIMODAL APPROACHES**

### ***Intrapleural Photodynamic Therapy***

Photodynamic therapy (PDT) involves the light-activated sensitization of malignant cells.<sup>283</sup> Photofrin II, the sensitizer, is retained by malignant tissue *in vivo* in comparison with normal tissue. The sensitizer is activated by 630-nm light and then interacts with molecular oxygen to produce an excited reactive oxygen species. Singlet oxygen forms the basis of PDT cytotoxicity. The potential for minimal normal tissue toxicity due to the selective retention of the sensitizer within tumors has prompted an interest in studying PDT for the treatment of a variety of tumors including skin, bladder, lung, head and neck, brain, and esophagus. From July 1993 to June 1996, 63 patients at the National Cancer Institute, National Institutes of Health, with localized malignant pleural mesothelioma were randomized to surgery, with or without intraoperative PDT. All patients received postoperative immunotherapy with cisplatin, tamoxifen, and interferon. Median survival (14.4 vs. 14.1

months), median progression-free time (8.5 vs. 7.7 months), and sites of first recurrence were similar. Thus, aggressive multimodal therapy incorporating PDT can be delivered for patients with higher stage malignant pleural mesothelioma, but first-generation PDT does not prolong survival or increase local control for malignant pleural mesothelioma.

### **Pleural Perfusion**

There has been a resurgence of interest in the delivery of intrapleural cytotoxic chemotherapy at the time of operation for pleural mesothelioma. Using hyperthermic pleural space perfusion, Ratto et al. delivered cisplatin to the pleural space after pleurectomy or EPP in 10 patients.<sup>284</sup> This study has recorded the pharmacokinetics, but has no data as of yet on survival or recurrences.

### **Gene Therapy**

A tumor cell infected with an adenovirus construct TK gene (AdHSVtk) containing the herpes simplex thymidine kinase (TK) gene can be killed with ganciclovir. The goals of phase I trial at the University of Pennsylvania were to assess the safety, toxicity, and maximally tolerated dose of intrapleural AdHSVtk, to examine patient inflammatory response to the viral vector, and to evaluate the efficiency of intratumoral gene transfer. Twenty-one previously untreated patients were enrolled in this viral titer dose-escalation study. A replication-incompetent recombinant adenoviral vector containing the HSVtk gene under control of the Rous sarcoma virus promoter-enhancer was introduced into the pleural cavity of patients with malignant mesothelioma followed by 2 weeks of systemic therapy with 5 mg/kg twice a day of ganciclovir. The initial 15 patients underwent thoracoscopic pleural biopsy before and 3 days after vector delivery. The last six patients underwent only the postvector instillation biopsy. Dose-limiting toxicity was not reached. Side effects were minimal and included fever, anemia, transient liver enzyme elevations, and bullous skin eruptions, as well as a temporary systemic inflammatory response in those receiving the highest dose. Strong intrapleural and intratumoral immune responses were generated. Using RNA polymerase chain reaction, *in situ* hybridization, immunohistochemistry, and immunoblotting, HSVtk gene transfer was documented in 11 of 20 evaluable patients in a dose-related fashion.<sup>285,286</sup>

A similar approach is under investigation by the group at Louisiana State University.<sup>287,288</sup> In *in vitro* mixing experiments, gene-modified tumor ovarian tumor cells killed both mouse and human mesothelioma cells in a dose-dependent manner. Use of the ovarian HSVtk ovarian cells also prolonged survival of mice with mesothelioma in a dose-dependent fashion. These data have served as the basis for an ongoing phase I clinical gene therapy trial to determine the maximal tolerated dose of an HSVtk-transduced ovarian cancer cells infused into the pleural cavities of mesothelioma patients followed by systemic administration of ganciclovir.

## **MALIGNANT PERITONEAL MESOTHELIOMA**

### **PRESENTATION**

Patients usually present with symptoms and signs of advanced disease including pain, ascites, weight loss, or an abdominal mass.<sup>289,290</sup> and <sup>291</sup> A cake of tumor in the omentum may be palpable as an epigastric mass. No satisfactory staging system has been proposed for peritoneal mesotheliomas, which are usually confined to the abdomen at diagnosis. Chest radiography reveals pleural plaques in approximately 50% of patients with peritoneal primaries, compared with 20% in patients with pleural mesothelioma, reflecting the higher level of asbestos exposure in patients with peritoneal disease. Classic findings on CT scan include mesenteric thickening, peritoneal studding, hemorrhage within the tumor mass, and ascites; however, patients may have advanced disease with relatively normal CTs.<sup>292,293</sup> MRI offers the possibility of improved resolution. Given the low incidence of bone, brain, or liver metastasis at presentation, extensive evaluation for metastatic disease is inappropriate in the absence of laboratory abnormalities. Adrenal, intrapulmonary, or bony metastasis should raise the possibility of an alternative diagnosis.

Peritoneal fluid from malignant ascites may be a watery transudate or a viscous fluid rich in mucopolysaccharides. No diagnostic significance has been attached to the character of the fluid, although a viscous ascites (with high fluid hyaluronidase levels) may suggest the diagnosis. Massive ascites may result in confusion of mesothelioma with severe cirrhosis. Cytology establishes the diagnosis in only 5% to 10% of cases.<sup>291</sup> Ultimately, definitive diagnosis requires adequate tissue sampling, preferably from peritoneoscopy or an open directed biopsy. A generous biopsy specimen is required to perform immunohistochemical stains, as well as electron microscopy. Open biopsy also permits inspection of the abdominal cavity for extent of disease with particular attention to the bowel and ovaries to distinguish mesothelioma from other more common causes of peritoneal carcinomatosis. Peritoneal mesotheliomas can be confused with adenocarcinomas arising from any abdominal organ, but the pattern of spread and tendency to accumulate in the pelvis readily leads to confusion with adenocarcinoma of the ovary or carcinoma arising from Müllerian duct remnants in the peritoneum.

The tumor generally remains confined to the abdomen until late in the course and even then is more likely to spread to one or both pleural cavities than to disseminate hematogenously. Thrombocytosis is common and associated with high levels of IL-6 and a poor prognosis. Other common clotting abnormalities include phlebitis, emboli, hemolytic anemia, and disseminated intravascular coagulation. Most patients die without metastases or involvement of the chest.<sup>291</sup> Esophageal achalasia, secondary amyloidosis, and dermatomyositis have been reported.<sup>294,295</sup> and <sup>296</sup> The median survival of untreated patients in most series is short, 4 to 12 months.<sup>114,289,290,297</sup>

### **WELL-DIFFERENTIATED PAPILLARY MESOTHELIOMA OR CYSTIC MESOTHELIOMAS OF THE PERITONEUM**

Rare, well-differentiated papillary variants and a syndrome of recurrent peritoneal mesothelial cysts have both been found predominantly in younger women associated with a prolonged survival despite bulky disease.<sup>298</sup> Rarely, the disease progresses over time to a typical malignant mesothelioma.<sup>299</sup> Approximately 130 cases of multiloculated peritoneal inclusion cysts (also called *benign cystic peritoneal mesotheliomas*) have been described, mainly in the pathologic and surgical literature.<sup>300</sup> Some authors have advocated classifying this lesion as reactive proliferation rather than as malignant.<sup>301</sup> The radiologic differential diagnosis has been reviewed.<sup>300</sup>

Frequently associated with prior surgery, endometriosis, or pelvic inflammatory disease,<sup>301</sup> they occur predominantly in women,<sup>302</sup> but can occur in men.<sup>300,303</sup>

Treatment should be provided for palliation of symptoms or for clearly documented progression.<sup>299,304</sup> Despite initial surgical resection, approximately one-half recur locally. Neither lesion size nor proliferation correlates with outcome.<sup>301</sup> Tamoxifen resulted in a prolonged response in a 19-year-old woman.<sup>305</sup> Permanent transvaginal catheter drainage in a patient with recurrent cysts resulted in infection and obliteration of the cyst.<sup>306</sup> The potassium titanil phosphate laser has also been used in treatment of benign multicystic peritoneal mesothelioma.<sup>307</sup>

### **THERAPY**

#### **Surgery**

Surgical and autopsy series have shown that peritoneal mesothelioma involves all peritoneal surfaces, often with masses of 5 cm or more. Sites of local invasion included the liver, abdominal wall, diaphragm, retroperitoneum, gastrointestinal tract, and bladder. Seeding of laparotomy scars and biopsy tracts has also been observed. The tumor is most often confined to the peritoneal cavity at the time of initial diagnosis and remains there for much or all of the subsequent clinical course.<sup>114</sup> Hence, effective local therapy may have a substantial effect on the survival of patients with this disease. Complete surgical resection is rarely, if ever, feasible, and has not been shown to afford survival benefit in the absence of additional therapy. Nevertheless, surgical intervention can provide palliation for small bowel obstruction and relief of massive ascites by peritoneovenous shunting or paracentesis via Tenckhoff's catheter.<sup>308</sup>

#### **Radiation**

Despite its use in the few reported survivors in this disease, the role of radiation therapy remains unclear. Megavoltage external radiotherapy can deliver a homogeneous dose to the entire abdominal cavity and its contents, although critical organ tolerance limits dose in several areas. Several techniques have been described and used predominantly for the therapy of ovarian carcinoma.<sup>309</sup> The first report was the *moving strip* technique,<sup>310</sup> which was necessary because of limited field size and dose rate with cobalt 60 units but that was shown to have a higher morbidity than the *open field* techniques.<sup>310</sup> The technique reported from the Joint Center for Radiation Therapy uses open fields with a 67% transmission block to attenuate the dose given to the abdomen superior to the L-5 to S-1 interspace.<sup>311</sup> The

superior border of the field is placed above the maximum excursion of the diaphragm by 1 to 2 cm as observed by fluoroscopy. The inferior border is placed at the ischial tuberosities. Laterally, the field extends 1 to 2 cm beyond the peritoneal fat stripe. Daily fractions of 1.2 Gy in the upper abdomen and 1.8 Gy in the pelvis are given five times weekly to opposed anterior and posterior fields, with both fields treated daily. Doses are prescribed to midplane on the central axis. Total doses of 30 Gy in the upper abdomen and 45 Gy in the pelvis are given in 5 weeks. Full-thickness kidney blocks are added to both anterior and posterior fields at 18 Gy. When intraperitoneal chemotherapy is used, the transmission block is omitted and a uniform daily dose of 1.2 Gy is given to a total dose of 30 Gy. Blocks are also placed over a portion of the heart and the inferior pelvis lateral to the abdominal cavity to protect the femoral heads and soft tissue. Treatment breaks are given when the total leukocyte count drops to 1500 to 2000/ $\mu$ L or the platelet count drops below 75 to 100,000/ $\mu$ L.

Intraperitoneal instillation of radioactive colloidal gold ( $^{198}\text{Au}$ ) was first reported to improve the symptoms of peritoneal mesothelioma in 1955.<sup>312</sup> Nine other patients treated by the administration of colloidal  $^{198}\text{Au}$  have been reported.<sup>183</sup> Two of nine were free of disease for 3.5 and 5.0 years, respectively. Four other patients were reported to have clinical improvement of symptoms. The concentration of radiocolloid is generally greatest in the pelvis and lateral gutters, but adhesions from prior surgery and tumor can cause adherence of loops of bowel that may result in inhomogeneous spread of the radiocolloid.<sup>182,313</sup> Neither  $^{198}\text{Au}$  nor  $^{32}\text{P}$  give substantial dose to tumor cells within gross tumor masses. The estimated dose from 20 mCi of  $^{32}\text{P}$  is 180 Gy at 0.04 mm, but only 43 Gy at 1 mm and 17 Gy at 2 mm.<sup>314</sup> The distribution of a radiotracer or contrast material should be tested before the therapeutic administration of these agents. The major complication associated with intraperitoneal instillation of radiocolloids is small bowel obstruction, which occurs in 2% to 10% of patients.<sup>315,316</sup> When external-beam irradiation is also given to the pelvis, as many as 33% of patients may develop bowel complications.<sup>311,317</sup>

### **Intraperitoneal Chemotherapy**

Because the results of intravenous chemotherapy in patients with malignant mesothelioma have been disappointing, and given the tendency of the disease to remain confined to the peritoneum, interest has focused on the use of intraperitoneal chemotherapy. The primary theoretical obstacle to this form of treatment is the shallow depth of drug penetration into tumor nodules. Advantages include greatly enhanced drug concentrations in the peritoneal cavity and decreased systemic toxicity. In addition, substantial intravenous drug concentrations are obtained from peritoneal absorption of some drugs such as cisplatin. Thus, the combination of free surface diffusion and intracapillary drug flow may be potentially more efficacious than intravenous treatment alone.

Intraperitoneal cisplatin and intravenous thiosulfate protection have resulted in a 59% complete response rate. However, many patients in this study have relapsed quickly after treatment, implying incomplete eradication of tumor using cisplatin alone.<sup>318</sup> Mitomycin C, doxorubicin, and epidoxorubicin have also been used intraperitoneally.<sup>290,319,320</sup>

Intraperitoneal cisplatin in 19 patients (with mitomycin in as well in 18) resulted in 2 (10%) disease free more than 5 years from therapy.<sup>321</sup> Cisplatin and etoposide resulted in one complete response in five patients with measurable disease.<sup>322</sup>

Of four patients receiving cisplatin-based intraperitoneal therapy in a Dutch study, two responded, one completely. At 2 years he developed intestinal obstruction. Laparotomy revealed only adhesions.<sup>323</sup> A case report noted continuing complete response at 53 months in a patient treated with intraperitoneal cisplatin and cytarabine.<sup>324</sup>

### **Combined Modality Approaches**

Because surgery or radiotherapy alone has resulted in only a few anecdotal long-term mesothelioma survivors, intensive combined modality approaches are being studied at several institutions. One of four patients treated at Seattle with surgery, radiotherapy, and chemotherapy had no tumor by follow-up CT scan at the time of publication.<sup>325</sup>

In a retrospective review of 15 women with peritoneal mesothelioma, clinical features included abdominal or pelvic masses in 93%, abdominal distention in 73%, ascites in 60%, abdominal pain in 40%, thrombocytosis in 27%, thromboembolic manifestations in 20%, and elevated CA-125 in four of four. The response rate to first-line chemotherapy regimens was 30% overall, but 67% to paclitaxel and cisplatin. The median survival of all patients was 12 months. The median survival was longer for patients who underwent cytoreductive surgery versus biopsy only (14 vs. 6 months,  $P = .24$ ), and chemotherapy versus none (29 vs. 1 month,  $P = .03$ ).<sup>326</sup>

In three sequential studies by Antman and colleagues of patients with peritoneal mesothelioma treated with surgery, radiotherapy, and chemotherapy, one of three patients treated in the first trial with surgery, whole abdominal radiotherapy, and cyclophosphamide, doxorubicin, and dacarbazine remains alive more than 15 years from diagnosis.<sup>290</sup> Of seven patients treated on a second phase I trial between 1982 and 1985 with debulking of all lesions greater than 1 cm, and intraperitoneal doxorubicin (20 to 50 mg) alternating every 2 weeks with intraperitoneal cisplatin (20 to 100 mg/ $\text{m}^2$ ) for a total of 8 to 12 treatments. At the time of second laparotomy for removal of the access device, all six patients had at least an objective 50% decrease in the size of the tumor. Chemotherapy was followed by whole abdominal irradiation in four patients. (One patient refused and a second had had prior irradiation for Hodgkin's disease.) Four of the six patients (including three of the four who received irradiation) remain disease free more than 14 years after diagnosis.<sup>290,297</sup> One patient requires chronic intravenous hyperalimentation due to malabsorption; the remaining three patients have normal performance status. In the third (phase II) trial begun in 1986,<sup>297</sup> 20 patients have completed debulking, intraperitoneal doxorubicin, and cisplatin and radiation as above. The median survival for the entire treated group is 16.4 months. Thus, intensive multimodality therapy produces a high response rate and may ultimately prolong survival for this otherwise rapidly fatal disease.

Of 18 patients with primary peritoneal mesothelioma who underwent tumor debulking followed by a 90-minute continuous hyperthermic peritoneal perfusion with cisplatin as part of three consecutive phase I trials conducted at the National Cancer Institute, 13 had associated ascites. One patient had a symptomatic, multiply recurrent, benign, cystic peritoneal mesothelioma. Three patients who had a recurrence after a progression-free interval of more than 6 months after continuous hyperthermic peritoneal perfusion underwent reoperation. Two patients had superficial wound infections, and one patient each had atrial fibrillation, pancreatitis, fascial dehiscence, ileus, line sepsis, and *Clostridium difficile* colitis, but no toxic deaths occurred. Renal toxicity occurred at cisplatin doses above the recommended phase II dose. Nine of ten patients had resolution of their ascites postoperatively. Three patients with recurrent ascites at 10, 22, and 27 months after initial treatment had resolution of their ascites with ongoing responses at 4, 6, and 24 months after the second perfusion. The median progression-free survival is 26 months, and the overall 2-year survival is 80%.<sup>327</sup>

## **MALIGNANT MESOTHELIOMA OF THE TUNICA VAGINALIS TESTIS**

Approximately 75 cases have been reported in the literature,<sup>328</sup> most often in patients between ages 55 and 75 years, although approximately 10% of the patients were younger than 25 years and occasional children are affected.<sup>329</sup>

Asbestos exposure was documented in approximately one-half of the more recently reported cases.<sup>330</sup>

Patients generally present with a hydrocele or *hernia*. An accurate preoperative diagnosis was reported in only two cases.<sup>331</sup> Diffuse peritoneal or abdominal lymph node involvement may be present at the time of diagnosis.

Mesotheliomas arising in the tunica vaginalis testes appear to have a more indolent disease course.<sup>330,332</sup> The overall recurrence rate (local and disseminated) was 52%, and 38% died of disease progression.<sup>328</sup> Local recurrence occurred in 36% of patients who underwent local resection of the hydrocele wall, 10% after scrotal orchiectomy, and 12% after inguinal orchiectomy.<sup>328</sup> More than 60% of recurrences developed within the first 2 years of the follow-up. The median survival of the patients was 23 months, but was 14 months after recurrence.

In some cases of disseminated mesothelioma, adjuvant chemotherapy or radiotherapy was given. Survival correlated significantly with younger patient's age ( $P = .01$ ), and with localized as opposed to disseminated disease ( $P = .05$ ) in univariate analysis. A multivariate Cox regression model of prognostic parameters concerning survival did not yield statistically significant results.<sup>328</sup>

## **MALIGNANT MESOTHELIOMA OF THE PERICARDIUM**

There are approximately just over 100 cases reported in the literature in adults<sup>333</sup> and children.<sup>334</sup> Asbestos exposure has not been documented in most reported cases. Patients generally present with a pericardial effusion,<sup>333,334</sup> congestive heart failure,<sup>335</sup> an anterior mediastinal mass,<sup>336</sup> or tamponade.<sup>337</sup> Diffuse pericardial involvement is found at surgery. The diagnosis is often unsuspected before surgery or autopsy.

## BENIGN MESOTHELIOMA

Benign tumors involving mesothelium arise with some frequency in the pleura and peritoneum, the tunica vaginalis testis,<sup>338</sup> the atrioventricular node of the heart,<sup>339</sup> and rarely in the mediastinum,<sup>340</sup> liver,<sup>341</sup> and adrenal.<sup>342</sup> Those of peritoneum, including tunica vaginalis testis and adrenal, are mesothelial derived, but the others are of disputed histogenesis (atrioventricular node) or appear to arise from submesothelial mesenchymal cells that do not exhibit mesothelial differentiation.

## BENIGN FIBROUS TUMORS OF THE PLEURA

Benign fibrous tumors of the pleura are approximately one-third as common as diffuse malignant mesotheliomas<sup>343</sup> and are most common from age 40 to 70 years. Because they appear to arise from subsurface fibrous tissue, rather than from the mesothelial lining, they have also been called submesothelial fibromas, localized fibrous mesothelioma, or solitary fibrous tumor of the pleura.<sup>343,344</sup> and<sup>345</sup> Few patients have been exposed to asbestos, approximating the incidence of exposure in the general population. CT scan and MRI are useful but nonspecific. The differential diagnosis between benign and malignant lesions is based on histologic study.<sup>346</sup> Lesions have ranged in size from 1 to 36 cm. Associated effusions can be serosanguineous. Hypertrophic pulmonary osteoarthropathy has occurred in approximately one-third of patients, particularly associated with lesions more than 10 cm in size. Hypoglycemia has also been associated with large lesions, associated in some cases with tumor production of insulin-like growth factor.<sup>347,348</sup>

Mesotheliomas are often pedunculated and 80% arise from but usually do not invade the visceral pleura.<sup>120</sup> Thus, benign pleural mesotheliomas usually have a sharp separation between tumor and compressed lung, and resection can be performed without pulmonary resection. Others may require a limited chest wall resection. While generally cured if completely resected, recurrences have occurred after several decades<sup>349</sup> and 12% of patients eventually die of extensive local tumor.<sup>343</sup> Localized *malignant* fibrous tumors of the pleura have also been described. Of 82 malignant localized tumors, 45% were cured by simple excision.<sup>120</sup> If the nature of the lesion is ambiguous, involvement of the pleura on random biopsy would establish a diagnosis of diffuse (i.e., malignant) disease.

## BENIGN FIBROUS MESOTHELIOMAS OF THE GENITAL TRACTS

Called *benign mesotheliomas* in the past, these neoplasms are probably more accurately designated *adenomatoid tumors*.<sup>350,351</sup> They generally arise in the scrotum and epididymis. Similar tumors histologically also are occasionally described in women. Talc granulomas have been described in proximity to the tumor in one case.<sup>352</sup>

## BENIGN MESOTHELIOMA OF THE CARDIAC ATRIOVENTRICULAR NODE

The histologic origin of benign mesotheliomas of the atrioventricular node is disputed.<sup>353</sup> Patients with benign mesotheliomas of the atrioventricular node have ranged in age from newborn<sup>354</sup> to elderly, and present most frequently with heart block.<sup>355</sup> The diagnosis is often made at autopsy,<sup>356</sup> although clinical excision has been reported.<sup>357</sup> Sudden death has sometimes occurred despite the implantation of a pacemaker.

#### INTRODUCTION

In skin cancer, the interaction between genes and the environment figures prominently. At the molecular level, skin tumors appear to result from a succession of genetic alterations; many of these changes are caused by carcinogens, such as sunlight. At the cellular level, one of the mutant genes, *p53*, causes a deficiency in the programmed cell death of damaged keratinocytes. Without such apoptosis, large numbers of precancerous cells accumulate in the sun-exposed skin of normal individuals. A second gene, *PTCH*, affects skin development and is mutated in basal cell carcinomas (BCC). Various aspects of these advances have been reviewed.<sup>1,2,3,4</sup> and <sup>5</sup>

#### SKIN CARCINOGENS

Nonmelanoma skin cancer is associated with exposure to chimney soot in chimney sweeps, burn scars, arsenic ingestion, and exposure to sunlight.<sup>6</sup> Sunlight is the principal skin carcinogen in humans and the human carcinogen whose mechanism is clearest. Basal and squamous cell carcinomas are most frequent at low latitudes, in outdoor workers, on exposed regions of the body, and in light-skinned individuals with blonde or red hair who have a tendency to burn rather than tan.<sup>7</sup> Many BCCs that occur on body sites not chronically exposed to sunlight, such as the trunk and legs, seem related to intermittent sun exposure.<sup>8</sup> In experimental animals, the most effective wavelengths are the ultraviolet B (UVB) region of the solar spectrum; the UVA used in tanning parlors can cause skin tumors as well.<sup>5</sup> UVB's effectiveness is due to its ability to partially penetrate the ozone layer and stratum corneum and then be absorbed by DNA.<sup>9</sup> Nonmelanoma skin cancers exceed the incidence of all other cancers combined in the southern United States, Hawaii, and Australia.<sup>10,11</sup>

The first molecular step in sunlight-induced carcinogenesis is the induction of DNA photoproducts by UVB photons. The most frequent photoproducts involve adjacent pyrimidines.<sup>1</sup> UV photons tend to be absorbed at the 5-6 double bond of pyrimidines, allowing the bond to open. The result is either the cyclobutane dimer or a pyrimidine-pyrimidone (6-4) photoproduct (Fig. 41.1-1).<sup>2</sup> Both lead to abnormal DNA structures. When DNA is copied during subsequent DNA replication, the DNA polymerase often incorrectly inserts an adenine opposite a damaged cytosine. At the next round of replication, the adenine correctly codes for thymine opposite. After UV, these C→T mutations occur only where a cytosine lies next to a thymine or another cytosine, reflecting the specificity of the sites at which UV photoproducts occur. If two adjacent cytosines mutate, the result is CC→TT. These distinctive patterns of mutation are pathognomonic for UV radiation.<sup>12</sup>

FIGURE 41.1-1. Ultraviolet light photoproducts. TT cyclobutane pyrimidine dimer (left) and TC pyrimidine-pyrimidone (6-4) photoproduct (right).

Mutations are prevented by DNA repair systems that excise UV photoproducts from DNA.<sup>13,14</sup> A transcription-coupled repair system rapidly removes lesions from the transcribed strand of active genes, whereas a slower global excision system removes lesions from inactive genes and from the nontranscribed strand of active ones. Individuals with xeroderma pigmentosum group A (XPA) are defective in both pathways, resulting in acute sun sensitivity and a 2000-fold elevated incidence of skin cancer.<sup>15</sup> The XPC subtype is defective in only the global system, yet has similar clinical features. Cockayne's syndrome is defective in only the transcription-coupled pathway and, though sun-sensitive, does not have an increased skin cancer incidence. Most genes corresponding to the XP and Cockayne's syndrome subtypes have been cloned, and their protein products successively recognize and excise not only UV photoproducts but other forms of DNA damage as well.

#### GENETIC EVENTS

##### PTCH

Two genes normally prevent cancers but are inactivated in skin tumors. *PTCH*, a component of a cellular signaling pathway, is mutated in perhaps 90% of BCCs. *p53*, which encodes a regulator of the cell cycle and cell death, is mutated in half of BCCs and more than 90% of squamous cell carcinomas (SCC).

*PTCH* was discovered as the gene mutated in nevoid basal cell carcinoma syndrome, an autosomal dominant disorder characterized by multiple BCCs, jaw cysts, and pits of the palms and soles. It is a human homologue of the *Drosophila* gene *patched*.<sup>16,17</sup> Most sporadic BCCs have inactivating *PTCH* mutations,<sup>18</sup> and almost all tumors without *PTCH* mutations have activating mutations in its partner, *smoothed*.<sup>19</sup>

*Patched* is important in establishing anterior-posterior relationships of the segments of developing *Drosophila* embryos. It encodes a large transmembrane protein that, in a complex with *smoothed*, another transmembrane molecule, is believed to serve as the receptor for the secreted molecule hedgehog.<sup>20</sup> In hedgehog's absence, *smoothed* and *patched* form an inactive complex. On hedgehog binding, *smoothed* is released from inhibitory effects of *patched* and transduces a signal (Fig. 41.1-2). Mutations that inactivate *patched* switch on the hedgehog pathway without hedgehog.<sup>18</sup> *Smoothed* functions as an oncogene when switched on in mouse skin, and some BCCs result from activating mutations of *smoothed* instead of inactivating mutations of *patched*.<sup>19</sup> *GLI1*, a downstream transcription factor in the hedgehog pathway, is an oncogene in brain tumors, and its overexpression causes epidermal proliferation in frogs.<sup>21</sup> Activating *GLI* turns on transcription of *WNT*, which is known to act as an oncogene in mammary tumors in mice, as well as members of the tumor growth factor- $\beta$  family. The latter genes have complex roles in regulating differentiation and cell growth.

**FIGURE 41.1-2.** Interactions among patched (PTCH), smoothed (SMO), and hedgehog (HH) proteins. Patched represses transcription of hedgehog target genes by inactivating smoothed. Hedgehog binds to patched, thereby activating smoothed and causing increased transcription of GLI, itself a transcription factor, and its downstream targets, such as WNT and transforming growth factor- $\beta$  (TGF- $\beta$ ). In the absence of patched, smoothed may be constitutively activated, resulting in the overexpression of these genes.

Mutating the hedgehog pathway is an early step in tumor development because minute BCCs are as likely as large tumors to have patched mutations, and all histologic subtypes have a high frequency of loss of patched. A congenital lesion that can progress to BCC, the sebaceous nevus, has allelic loss in the *PTCH* region in 40% of cases.<sup>22</sup> No tumors have loss on other chromosomes without involvement of the *PTCH* locus,<sup>23</sup> so *PTCH* appears to function as a “gatekeeper gene” in basal cell carcinogenesis. Inactivating this function seems to be necessary before clonal expansion and accumulation of other genetic hits can lead to BCC formation.<sup>24</sup>

Nearly all hereditary BCCs have allelic loss as their second, somatic hit. This allelic loss is usually related to sunlight, since nevoid BCC syndrome tumors are most frequent on sun-exposed skin and are rare in African Americans.<sup>25</sup> However, UVB causes this type of gross rearrangement of genetic material only rarely, so other wavelengths, such as UVA, may be important. Sporadic BCCs from XP group A patients contain *PTCH* mutations that are UVB-like, with CC@TT mutations predominating.<sup>26</sup> However, in typical patients, approximately one-third of BCCs have mutations that are clearly not UVB-induced.<sup>18</sup> These may reflect factors such as UVA, oxidative damage, or arsenicals. Sunscreens may need to block both UVB and UVA to be completely protective against BCC.

### p53

The distinctive mutations caused by UVB radiation identify a tumor suppressor gene critical for both BCC and SCC: *p53*. More than 90% of SCC of the skin in U.S. patients contain mutations in *p53*.<sup>4,27</sup> These are predominantly C@T and CC@TT base substitutions at sites of adjacent pyrimidines, directly implicating cytosine-containing cyclobutane dimers or (6-4) photoproducts and sunlight UVB as the mutagen. Each *p53* mutation changes the amino acid, indicating that the mutation was selected for and contributed to tumor development, rather than being solely an indicator of sun exposure. *p53* is a transcription factor that turns on or off the expression of other genes involved in the cell cycle, programmed cell death, and DNA repair.<sup>28,29</sup> Most mutations inactivate *p53*'s transcriptional activator function. The gene is mutated in approximately one-half of all human cancers and is considered a tumor suppressor gene because these mutations inactivate the gene's ability to suppress growth of tumor cells in culture.<sup>30</sup>

BCCs, though usually diploid and nonmetastasizing, also contain UV-induced *p53* mutations.<sup>4</sup> Approximately one-third of BCCs occur on body sites that are relatively sun-shielded; *p53* mutations from these tumors resemble those seen with UVA, ionizing radiation, or oxidative damage, rather than UVB.<sup>31</sup> UVB-induced *p53* mutations are frequent in skin cancers from XP patients, with CC@TT mutations being prominent, and in carcinoma *in situ*.<sup>32,33</sup> and <sup>34</sup> Aggressive tumors from patients with exposure to both sun and tobacco or agricultural chemicals contain multiple unrelated *p53* mutations, as if multiple tumors arising in an abnormal field had merged.<sup>35</sup> In Taiwanese arsenic-induced BCC and SCC, *p53* mutations are not UV-like.<sup>36</sup> Non-UV *p53* mutations are common in keloids, results of dysregulated wound healing.<sup>37</sup>

The *p53* mutations in skin cancers tend to cluster at nine mutation hot spots.<sup>38</sup> DNA photoproducts are not particularly frequent at these sites,<sup>38</sup> but excision of UV photoproducts is slower than at surrounding nucleotides.<sup>39</sup> Excision repair of UV photoproducts is reduced in T lymphocytes from patients with BCC or a family history of skin cancer.<sup>40</sup>

Sunlight mutates *p53* quite early. UVB-induced mutations are found in actinic keratoses, which occasionally progress to SCC; each lesion has a different *p53* mutation.<sup>41,42</sup> Strikingly, some 60,000 tiny clones of *p53*-mutant cells are found in sun-exposed skin from normal individuals ( Fig. 41.1-3).<sup>43,44</sup> Thus, precancerous cells are not only made early in life but begin to proliferate early. The molecular evidence supports migration studies indicating that sunlight exposure critical for skin cancer occurs before age 15 to 20.<sup>45,46</sup>

**FIGURE 41.1-3.** p53-mutant clone in whole-mount preparations of human epidermis. Sun-exposed skin from normal individuals contains 60,000 such clones. (From ref. 43, with permission.)

## CELLULAR EVENTS

The contribution of a *p53* mutation to tumorigenesis is partially understood. The p53 protein is not required for normal development but is elevated in cells treated with DNA-damaging agents and in cells with cell-cycle abnormalities.<sup>28,29</sup> The signal for UV induction of p53 originates from active genes whose transcription has been blocked.<sup>47</sup> Elevated p53 protein has two effects on cells. In the “guardian of the genome” pathway, DNA damage induces the p53 protein. p53 then leads to cell-cycle arrest at a G<sub>1</sub>-phase checkpoint by inducing p21, an inhibitor of cell-cycle-dependent protein kinases. In keratinocytes, however, UV induces p21 without p53.<sup>48</sup> p53 facilitates DNA repair by transcriptionally activating the p48 protein, which is required for global excision repair and is defective in XPE.<sup>49</sup> In the “cellular proofreading” pathway,<sup>4</sup> inducing p53 in an aberrant cell leads to apoptosis, a form of programmed cell death.<sup>41,50,51</sup>

In the epidermis, cellular proofreading is operative after DNA damage. UVB and UVA induce p53 by reducing its degradation rate.<sup>52,53</sup> and <sup>54</sup> p53 then causes irradiated keratinocytes to become the apoptotic “sunburn cells” familiar to dermatologists.<sup>55</sup> Inactivating the *p53* gene prevents sunburn cell formation.<sup>41</sup> Some point mutations in *p53* do not block apoptosis,<sup>56</sup> so different *p53* mutations may have different effects on tumor development. Mice inactivated for the *p53* gene develop more and earlier skin cancers after UV.<sup>57,58</sup> Cells defective in *p53*, or mice defective in UV-induced apoptosis due to a defect in the fas ligand, accumulate mutations at a rapid

rate.<sup>59,60</sup> Skin evidently uses the strategy that killing a damaged cell prevents it from becoming cancerous. Thus, if the *p53* gene itself is mutated by a previous sunlight exposure, the cell will be apoptosis-resistant. This cancer-prone cell will survive even if badly UV-damaged.

The situation can grow worse, due to a second consequence of death-resistance. Because the cancer-prone cell's normal neighbors undergo apoptosis when damaged, their death provides an opportunity for the *p53*-mutated cell to clonally expand. Sunlight exposure can thus act as a selection pressure favoring the clonal expansion of *p53*-mutated cells (Fig. 41.1-4). Indeed, transgenic mice carrying a *p53* point mutation that does not affect apoptosis have more tumors after UVB but no shortening of tumor latency.<sup>61</sup> Sunlight can thus act several times in skin carcinogenesis: first to mutate the *p53* or *PTCH* gene and then afterward to select for clonal expansion of a *p53*-mutated cell. These two actions correspond to tumor initiation and tumor promotion. UVB is known to have tumor-promoting activity in mouse skin.<sup>62,63</sup>

**FIGURE 41.1-4.** A model for genetic and cellular events in the onset of human skin cancer. Mutation of the *p53* tumor suppressor gene and selection for apoptosis-resistant *p53*-mutant cells by repeated sunlight exposure are described in the text. SBC, sunburn cells; UV, ultraviolet; UVB, ultraviolet B. (From ref. 41, with permission.)

Progression of a single mutant cell to a clone of precancerous or cancerous cells can be traced long after the fact. Taking advantage of *p53* mutations as lineage markers, it has been found that when an SCC is adjacent to carcinoma *in situ*, the two lesions carry the identical mutation.<sup>44</sup> Similarly, microdissecting BCCs into regions of 50 to 100 cells reveals that a BCC contains a dominant cell clone accompanied by subclones containing a second or even a third mutation.<sup>64</sup>

## THERAPEUTICS

The foregoing molecular findings are beginning to impact the clinic, first in the realm of diagnostics. Sunscreens of SPF 15 reduce cyclobutane dimers, p53 protein induction, sunburn cells, and *p53* gene mutations nearly tenfold.<sup>65,66,67,68</sup> and <sup>69</sup> Tumors in mice are reduced up to 50-fold,<sup>70,71</sup> consistent with simultaneous protection of several genes. This is reassuring, since some common sunscreen ingredients are mutagenic,<sup>72</sup> and protection against actinic keratoses in humans is only twofold.<sup>73,74</sup>

Molecular therapeutics is in its infancy. A gene therapy strategy is to restore p53 to render cells more sensitive to radiotherapy- or chemotherapy-induced apoptosis.<sup>75</sup> Obtaining a useful therapeutic index depends on apoptosis being greater in the tumor cells than in normal tissue. In fact, many treatments leading to apoptosis in transformed fibroblasts only growth-arrest their untransformed counterparts.<sup>76,77</sup> Since p53 is also sensitive to cell-cycle aberrations or other aberrations of tumor cells,<sup>26,29</sup> an alternative therapeutic strategy introduces p53 without adjunct treatment to induce apoptosis in transformed but not normal cells.<sup>78</sup> *In vivo* intraperitoneal delivery of a retroviral *p53* vector leads to a 75% reduction in peritoneal metastatic cells from murine pancreatic cancer.<sup>79</sup> Pharmacologic approaches include activation of latent normal p53 protein with small peptides<sup>80</sup> and destabilizing mutant p53 using modifiers of its interaction with heat-shock protein.<sup>81</sup> Several chemoprevention regimens increase apoptosis of premalignant cells, including dietary antioxidants<sup>77,82,83</sup> and caloric restriction.<sup>84,85</sup>

## INTRODUCTION

In 1999, approximately 1 million nonmelanoma skin cancers (NMSCs) were diagnosed in the United States.<sup>1,2</sup> One in five Americans will develop skin cancer during life, and more than 97% of these will be NMSCs.<sup>3</sup> Some studies suggest that development of NMSC, including basal cell (BCC) and squamous cell carcinoma (SCC), may indicate increased risk for internal malignancy.<sup>3</sup> However, the precise relationship between skin cancer and the risk of internal malignancy is not yet completely defined. The approach to diagnosis and management of common skin cancers, including BCC and SCC and other, less common tumors of follicular, neuroendocrine, and fibrohistiocytic origin, is discussed in this chapter.

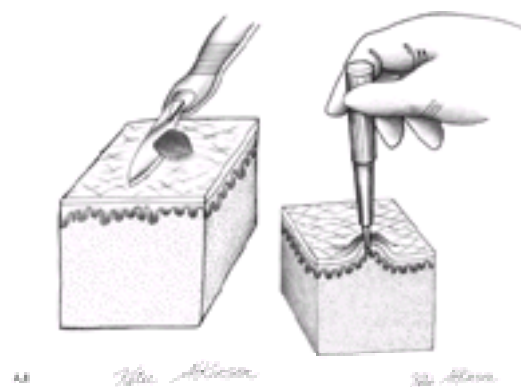

## DIAGNOSIS

Although many NMSCs present with classic clinical findings such as nodularity and erythema, definitive diagnosis can be made only by biopsy. Adequate tissue obtained in a nontraumatic fashion is critical to histopathologic diagnosis.

Skin biopsies may be performed by shave, punch, or fusiform excision. The type of biopsy performed should be based on the morphology of the primary lesion.<sup>4</sup> A shave biopsy usually is adequate for raised lesions such as nodular BCC, SCC, or tumors of follicular origin. Punch biopsy is effective for sampling flat, broad lesions for which shave or fusiform excision would be technically inappropriate. An excisional biopsy may be used to sample deep dermal and subcutaneous tissue. Excision is appropriate when it is necessary to distinguish between a benign lesion such as a dermatofibroma and a malignant tumor such as a dermatofibrosarcoma protuberans.

## SHAVE BIOPSY

The basic techniques involved in performing skin biopsies are demonstrated in [Figure 41.2-1](#). A shave biopsy is performed under clean conditions. Local anesthetic (lidocaine 1% with epinephrine 1:100,000, unless contraindicated) is injected with a 30-gauge needle. The use of a sterilized razor blade, which can be precisely manipulated by the operator to adjust the depth of the biopsy, often is superior to the use of a No. 15 scalpel. After the procedure, adequate hemostasis is achieved with topical application of aqueous aluminum chloride (20%) or electrocautery.

**FIGURE 41.2-1.** Biopsy techniques. **A:** Shave biopsy. A scalpel blade is precisely manipulated by the operator to adjust the depth of the biopsy, and hemostasis is achieved with topical application of aqueous aluminum chloride (20%), ferric chloride (25%), or electrocautery. **B:** Punch biopsy. The operator makes a circular incision to the level of the superficial fat using a rotating motion of the trephine. Traction applied perpendicularly to the relaxed skin tension lines minimizes redundancy at closure. Hemostasis is achieved by placement of sutures.

## PUNCH BIOPSY

A punch biopsy is performed under local anesthesia, using a trephine or biopsy punch. The operator makes a circular incision to the level of the superficial fat, using a rotating motion of the trephine. Traction applied perpendicularly to the relaxed skin tension lines minimizes redundancy at closure. Hemostasis is achieved by placement of simple, nonabsorbable sutures that can be removed in 7 to 14 days depending on anatomic site. If the punch biopsy is small and not in a cosmetically important area, the wound will likely heal very well by second intention.

## EXCISIONAL BIOPSY

After local anesthesia has been achieved under sterile conditions, a scalpel is used to incise a fusiform ellipse to the level of deep fat. Hemostasis is obtained with cautery as needed, and the wound is closed in a layered fashion using absorbable and nonabsorbable sutures. In most cases, postoperative care involves daily cleansing with mild soap and water followed by application of antibiotic ointment and a nonstick dressing. Though popular in the past, it is now known that hydrogen peroxide may not have a favorable effect on wound healing. The toxicity of hydrogen peroxide to keratinocytes has been well described,<sup>5,6</sup> and its use as an adjuvant to wound care is, in our opinion, contraindicated.

## GENERAL APPROACH TO MANAGEMENT OF SKIN CANCER

The management of skin cancer depends on the histologic nature of the tumor, the anatomic site, the underlying medical status of the patient, and whether the tumor is primary or recurrent. Because specific management varies with histologic diagnosis, an accurate interpretation of biopsy specimens is essential. Though the majority of BCCs and SCCs are straightforward, identification of the histologic subtypes is important because it can guide proper treatment. Depending on the aggressiveness of the tumor, cancers of the skin may be excised or, in some cases of superficial tumors or precancerous lesions, destroyed in a nonexcisional fashion. Electrodesiccation and curettage is the most common nonexcisional approach. If a cancer requires excision, the two options are conventional excisional surgery or extirpation by Mohs micrographic surgery (MMS).

### EXCISION

Excisional surgery involves removal of the cancer and a margin of clinically uninvolved tissue, followed by layered closure or second-intention healing, as indicated. Frozen or permanent sections interpreted by the pathologist determine adequacy of margins. Margins are assessed from representative sections of the specimen in "breadloaf" fashion, allowing for examination of approximately 3% of the excisional margin of the specimen. This degree of examination may occasionally result in a false-negative assessment of clear margins in cases of infiltrating or aggressive-growth cancers. Similar misdiagnosis may result when one relies on vertically cut frozen specimens for intraoperative margin control. Excision, especially that performed in a physician's office rather than a hospital operating room, is effective and cost-efficient when the cancer is small (<1 cm), nonrecurrent, or noninfiltrative.

### MOHS MICROGRAPHIC SURGERY

MMS facilitates optimal margin control and conservation of normal tissue in the management of NMSC.<sup>7,8 and 9</sup> Individuals specially trained in the technique perform MMS in an office setting under local anesthesia. Briefly, after gentle curettage, a tangential specimen of tumor with a minimal margin of clinically normal-appearing tissue is obtained, precisely mapped, and processed immediately by frozen section for microscopical examination (Fig. 41.2-2). Optimal margin control is obtained by examination of the entire perimeter of the specimen and contiguous deep margin. Meticulous mapping allows for directed extirpation of any remaining tumor. A key defining feature of MMS is that the surgeon excises, maps, and reviews the specimen personally, minimizing the chance of error in tissue interpretation and orientation. MMS has gained acceptance as the treatment of choice for recurrent skin cancers as well as for primary skin cancers located on anatomic sites that require maximal tissue conservation for preservation of function and cosmesis.<sup>10,11,12 and 13</sup>

**FIGURE 41.2-2.** Mohs micrographic surgery. **A–D:** After gentle curettage, a tangential specimen of tumor with a minimal margin of clinically normal-appearing tissue is obtained, precisely mapped, and processed immediately by frozen section for microscopical examination. Superior margin control is obtained through examination of the entire perimeter of the specimen. Precise mapping allows for directed extirpation of any remaining tumor. (Courtesy of Neil A. Swanson, M.D.) **E–G:** Conservation of cartilage allowed for retention of normal contour after healing in this case of basal cell carcinoma involving the ear, which was treated by Mohs micrographic surgery. **H–J:** In tumors involving the eyelid, conservation of normal tissue and superior margin control are essential. Note second intention healing.

### CURETTAGE AND ELECTRODESSICATION

Common methods of skin cancer destruction include curettage and electrodesiccation (C&D) and cryotherapy using liquid nitrogen.<sup>14,15,16,17,18 and 19</sup> C&D is performed under clean conditions with local anesthesia. Visible tumor is first removed by curettage. Curettage is extended for a margin of 2 to 4 mm beyond the clinical borders of the cancer. Electrodesiccation then is performed to destroy another 1 mm of tissue at the lateral and deep margins. Salasche<sup>20</sup> recommended that C&D be performed for three cycles. Others report satisfactory results after a single cycle of C&D for tumors smaller than 1 cm. Although this leads to decreased scarring, it may lead to higher rates of recurrence, as suggested by Robins and Albom,<sup>21</sup> who attributed to insufficiently aggressive treatment the higher rates of recurrence observed in young women with BCC. Tangential shave excision followed by gentle curettage and cauterization is an effective treatment approach for destruction of superficial BCCs.

### CRYOSURGERY

Cryosurgery exposes skin cancers to subzero temperatures, which causes tissue destruction (Fig. 41.2-3). Heat transfer occurs from the skin, which acts as a heat sink. Tissue damage is caused by direct effects initially and, subsequently, by vascular stasis, ice crystal formation, cell membrane disruption, pH changes, and thermal shock. Successful cryosurgery requires that temperatures reach  $-50^{\circ}$  to  $-60^{\circ}\text{C}$ , including deep and lateral margins. The subsequent thaw leads to vascular stasis and failure of local microcirculation. The open-spray technique is used most often and requires liquid nitrogen spray delivery from a distance of 1 to 3 cm. With the confined-spray technique, liquid nitrogen is delivered through a cone that is open at both ends. With the closed-cone technique, one end of the cone is closed and a shorter delivery time is required. With the cryoprobe technique, a prechilled metal probe is applied to the tumor. Delivery time is determined via a depth-dose estimation, which takes into account freeze time, lateral spread, and halo thaw time. Immediately after cryosurgery, local erythema and edema are apparent. An exudative phase ensues in 24 to 72 hours, which is followed by sloughing at approximately day 7. Complete healing usually is seen with facial lesions at 4 to 6 weeks and in nearly 12 to 14 weeks in lesions on the trunk and extremities.

**FIGURE 41.2-3.** Cryosurgery involves direct exposure of skin cancers to subzero temperatures to cause destruction.

Temporary complications may include extensive drainage, edema, bulla formation, and hypertrophic scarring. Rarely, delayed hemorrhage can occur suddenly approximately 2 weeks after the procedure, most commonly after treatment on the nose, temple, and forehead. Paresthesia may occur if superficial nerves are frozen. Other less common side effects may include headache, syncope, febrile reaction, cold urticaria, pyogenic granuloma, milia formation, or hyperpigmentation. Permanent complications may include tissue contraction, hypopigmentation, and scarring. Other less frequently reported complications are neuropathy, ulceration, tendon rupture, alopecia, and ectropion. Cryosurgery is not considered the standard of care for recurrent NMSC or any tumor other than very small, superficial BCC or SCC.

Cryosurgery and C&D both are limited by the inability to evaluate thoroughness of tumor eradication. The absence of margin control and the development of dense scar, which might obscure recurrence, make these methods valuable primarily in the care of histologically superficial NMSC. Close follow-up of the patient is necessary.

### **RADIATION THERAPY**

Radiation therapy (RT) is a treatment option for NMSC but is also limited by the inability to confirm the tumor margins definitively. In addition, treatment of an excessively large area around the tumor carries risk. RT, in properly fractionated doses, generally is indicated when the patient's health or size or extent of the tumor precludes surgical extirpation. Consideration of the permanent tissue effects of RT must include anticipation and management of recurrence.

After treatment for BCC or SCC, patients should be evaluated on an annual basis for the presence of skin cancers. In the case of a more aggressive tumor, evaluation should be more frequent and, in the case of squamous cell cancer, should include examination of draining lymph nodes. Laboratory evaluation, generally not indicated in uncomplicated cases of BCC and SCC, may be necessary for other types of particularly aggressive tumors. Imaging studies may be necessary in the case of aggressive tumors or in cases of long-neglected tumors impinging on vital structures. Magnetic resonance imaging allows visualization of the soft tissues, while computed tomography (CT) scan may be used to evaluate involvement of bone. In general, imaging studies have not proven helpful in definitively evaluating the presence of perineural invasion by NMSC.

## **NONMELANOMA SKIN CANCER AND PRECANCEROUS LESIONS**

### **ACTINIC KERATOSIS**

Actinic keratoses (AKs) are very common lesions that tend to occur on sun-exposed areas in blond or red-haired, fair-skinned, individuals with green or blue eyes.<sup>22</sup> Although not invasive, AKs are considered by some dermatopathologists to be SCC *in situ*.

AKs are caused by exposure to ultraviolet B light (UVB), and the possibility for progression to invasive SCC exists.<sup>22</sup> The risk for transformation of a single AK has been estimated to be as low as 1 per 1000 per year.<sup>23</sup> However, the long-term risk of the development of invasive SCC in patients with multiple AKs has been estimated to be as high as 10%. In one study, AK was histologically present or adjacent to invasive SCC in 82% of cases.<sup>24</sup> Molecular characterization of the role of the p53 tumor suppressor gene in AK, and its similar finding in SCC and BCC, suggests that the AKs represent an early stage in the molecular carcinogenesis of NMSC.<sup>25,26</sup> It has recently been suggested that the term *actinic keratosis* be replaced by another term, such as *solar keratotic intraepidermal SCC*.<sup>26</sup>

#### **Clinical Features**

AKs are red, pink, or brown papules with a scaly to hyperkeratotic surface ( Fig. 41.2-4). They occur on sun-exposed areas and are especially common on the balding scalp, forehead, face, and dorsal hands. A hypertrophic, indurated variant [hyperplastic AK (HAK)] exists and may be difficult to distinguish from SCC.

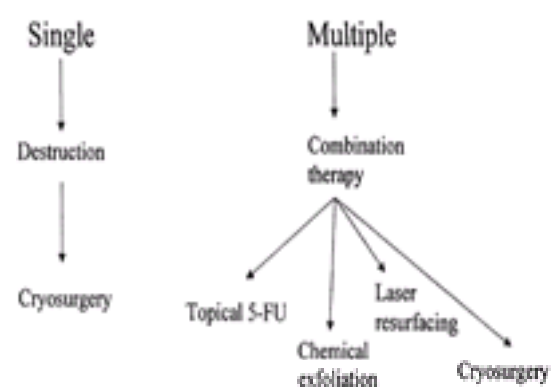

**FIGURE 41.2-4.** Actinic keratoses are characterized by erythema and rough surface.

The microscopical spectrum of AK includes hyperplastic, atrophic, bowenoid, acantholytic, and pigmented subtypes.<sup>27</sup> In each subtype, disordered, atypical keratinocytes with nuclear atypia are seen. In the hyperplastic variant, pronounced hyperkeratosis is intermingled with parakeratosis. Epidermal hyperplasia and downward displacement without dermal invasion are present. A thin epidermis devoid of rete ridges characterizes the atrophic variant. Atypical cells predominate in the basal layer. The bowenoid AK is indistinguishable from Bowen's disease, also known as SCC *in situ*. In this variant, considerable epidermal cell disorder and clumping of nuclei exist, giving a windblown appearance. The presence of suprabasal lacunae is characteristic of acantholytic AK. The acantholysis occurs secondarily to cellular changes. Excessive melanin is present within the basal layer in the pigmented variant of AK.

#### **Treatment**

Due to their potential to develop into invasive SCC, AKs usually should be treated. Numerous destructive options are available for the treatment of AKs, including cryosurgery, C&D, topical 5-fluorouracil (5-FU), chemical cauterization using trichloroacetic acid, or excision ( Fig. 41.2-5). Treatment of solitary lesions is straightforward. However, management of patients with hundreds of lesions can become complicated. In this situation, we initially treat the largest lesions by tangential excision followed by C&D. Raised lesions of smaller size are treated by destructive methods, especially the open-spray cryosurgery technique. When flat lesions are extensive, topical application of 5-FU with or without topical retinoids can be effective. The clinical effects of erythema, crusting, or discomfort associated with 5-FU therapy may limit compliance with its use ( Fig. 41.2-6). Alternative specialized deepithelializing techniques, such as laser and chemical exfoliation, may be helpful in the patient with severe solar damage and extensive AKs. Regardless of the treatment used, because AK is a clonal disease that results from exposure to UVB, the chance for developing new lesions over time is clinically significant.

**FIGURE 41.2-5.** Management of a solitary actinic keratosis does not present a therapeutic challenge, whereas management of multiple actinic keratoses is likely to require combination therapy. 5-FU, 5-fluorouracil.

**FIGURE 41.2-6.** Erythema, crusting, and discomfort secondary to the use of topical 5-fluorouracil limit compliance with its use.

## BASAL CELL CARCINOMA

BCC is a neoplasm of nonkeratinizing cells originating in the basal cell layer of the epidermis.<sup>28</sup> BCC is the most common human cancer, accounting for approximately 75% of all NMSCs and almost one-fourth of all cancers diagnosed in the United States.<sup>29,30</sup> Characteristically, BCC develops on sun-exposed areas of lighter-skinned individuals, with 30% of lesions occurring on the nose. Men are affected only slightly more often than are women and, although once rare before the age of 50, BCCs are becoming more common in younger individuals.<sup>1,31</sup>

The pathogenesis of BCC most commonly involves exposure to ultraviolet light (UVL),<sup>32</sup> particularly rays in the UVB spectrum (290 to 320 nm), which triggers mutations in tumor suppressor genes.<sup>25,32,33,34,35,36,37,38,39</sup> and <sup>40</sup> Other factors that appear to be involved in the pathogenesis include mutations in regulatory genes, exposure to ionizing radiation, and alterations in immune surveillance.<sup>41,42,43,44,45,46,47,48,49</sup> and <sup>50</sup>

BCC is a feature of inherited conditions. Included among these are the nevoid basal cell carcinoma syndrome (NBCCS), Bazex syndrome, Rombo syndrome, and unilateral basal cell nevus syndrome.<sup>42,47,51</sup> Patients with NBCCS may exhibit a broad nasal root, borderline intelligence, jaw cysts, palmar pits, and multiple skeletal abnormalities in addition to hundreds of BCCs (Fig. 41.2-7).<sup>52</sup> In one case, bilateral cystic adrenal lymphangiomas have been reported in association with NBCCS.<sup>53</sup> Recently, studies have indicated an association with mutations in the PTCH regulatory gene.<sup>42,54,55</sup> and <sup>56</sup> In addition, mutations in the PTCH gene have been identified in sporadic nonfamilial BCC.<sup>55</sup>

**FIGURE 41.2-7.** Nevoid basal cell carcinoma syndrome. Patients with this syndrome can present with hundreds of superficial basal cell carcinomas.

Bazex syndrome is transmitted in an X-linked dominant fashion. Patients present with multiple BCCs, follicular atrophoderma, dilated follicular ostia with ice-pick scars, hypotrichosis, and hypohidrosis.

In contrast, Rombo syndrome is transmitted in an autosomal dominant fashion. Patients present with vermiculate atrophoderma, milia, hypertrichosis, trichoepitheliomas, BCCs, and peripheral vasodilation. Hypohidrosis is not a feature of Rombo syndrome. Patients with unilateral basal cell nevus syndrome present with a congenital, unilateral lesion of comedones and epidermoid cysts, with basal cell proliferations that are thought to be basaloid follicular hamartomas.

The role of the immune system in the pathogenesis of skin cancer that is not completely understood.<sup>46,57</sup> Immunosuppressed patients with lymphoma or leukemia<sup>58,59</sup> and patients who have undergone transplants<sup>60,61,62,63</sup> and <sup>64</sup> experience a marked increase in the incidence of SCC but only a slight increase in BCC development. A potential link between UVL and immune surveillance has been suggested by Gutierrez-Steil et al., who demonstrated that UVL-induced BCC tumor cells express Fas ligand (CD95L) and further showed that these cells were associated with CD95-bearing T cells undergoing apoptosis.<sup>63</sup> This represents a potential mechanism by which UVL might mediate the tumor cells' avoidance of cytotoxic T lymphocytes. Patients with depressed cellular immunity secondary to human immunodeficiency virus (HIV) infection show a higher frequency of infiltrative BCC.<sup>64,65</sup>

### Clinical Behavior of Basal Cell Cancer

BCC is associated with extremely low metastatic potential, but it does invade locally. This biologic behavior depends upon angiogenic factors, stromal conditions, and the propensity for the cancer to follow anatomic paths of least resistance.<sup>66</sup> BCCs can elicit angiogenic factors that account for the telangiectatic vessels characteristically seen on the tumor's surface.<sup>68</sup> Necrosis occurs in tumors that have outgrown their blood supply. Recently, tumor microcirculation was examined *in vivo* in 12 BCCs from the head and neck by Bedlow et al.<sup>67</sup> Mean blood vessel size, density, and length per unit area were increased in BCC in comparison to normal tissue. An earlier study showed that mean vessel counts were increased in SCCs versus BCCs,<sup>68</sup> suggesting that angiogenesis may be linked to biologic

aggressiveness and that antiangiogenic factors may play a potential therapeutic role in the treatment of aggressive BCCs.

Tumor stroma is critical for both initiating and maintaining the development of BCC. <sup>66</sup> Transplants of neoplasms devoid of stroma usually are unsuccessful. In one study, Hernandez et al. <sup>69</sup> demonstrated that cultured BCC tumor cells stimulated collagenase production by fibroblasts. The concept of stromal dependence is supported by the low incidence of metastatic BCC.

BCC has a tendency to grow along the path of least resistance. Invasive BCC can migrate along the perichondrium, periosteum, fascia, or tarsal plate. <sup>66</sup> This type of spread accounts for higher recurrence rates noted in tumors involving the eyelid, nose, and scalp not treated by MMS. Embryonic fusion planes offer little resistance and can lead to deep invasion and tumor spread, with very high rates of recurrence, if complete tumor extirpation is not achieved ( Fig. 41.2-8). The most susceptible areas include the inner canthus, philtrum, middle to lower chin, nasolabial groove, preauricular area, and the retroauricular sulcus. <sup>66</sup>

**FIGURE 41.2-8.** Recurrent nodular basal cell carcinoma. Embryonic fusion planes offer little resistance to tumor spread.

Perineural spread is uncommon and occurs most often in recurrent, aggressive lesions. <sup>70,71,72,73</sup> and <sup>74</sup> In one series, Niazi and Lamberty <sup>74</sup> noted perineural invasion in 0.178% of BCC. In all cases, perineural extension was associated with recurrent tumors that were most often located in the periauricular and malar areas. Perineural invasion may present with paresthesia, pain, and weakness or, in some cases, paralysis. <sup>74,76,77</sup> Involvement of the cranial nerves and, in one case, thoracic spine has been reported. <sup>71,75,76</sup> and <sup>77</sup> Metastatic BCC is rare, with incidence rates varying from 0.0028% to 0.1%. <sup>78,79</sup> and <sup>80</sup> Metastases, when reported, have involved lung, lymph nodes, esophagus, oral cavity, and skin. <sup>80,81,82,83,84,85</sup> and <sup>86</sup> Although long-term survival has been reported, the prognosis for metastatic BCC is generally poor, survival of 8 to 10 months after diagnosis being the norm. <sup>86</sup> Platinum-based chemotherapy appears to have some effect in the treatment of metastatic BCC. <sup>87,88</sup>

### Basal Cell Carcinoma Subtypes

Clinical variants of BCC include nodular, superficial, morpheaform (also termed *aggressive-growth BCC* or *infiltrative BCC*), pigmented, and cystic BCC, and fibroepithelioma of Pinkus (FEP) ( Fig. 41.2-9, Fig. 41.2-10, Fig. 41.2-11, Fig. 41.2-12, Fig. 41.2-13, Fig. 41.2-14 and 41.2-15). <sup>28,29</sup> and <sup>30,89,90</sup> Nodular BCC presents as a raised, translucent papule or nodule, with telangiectasia, and has a propensity for involving sun-exposed areas of the face. Superficial BCC commonly presents as an erythematous scaly or eroded macule on the trunk and may be difficult to differentiate clinically from AK, SCC *in situ*, or a benign inflammatory lesion. Not uncommonly, superficial BCC may be mistakenly treated without response as eczema or even psoriasis. Biopsy in such cases is definitive. Morpheaform BCC presents as a flat, slightly firm lesion, without well-demarcated borders, and may be difficult to differentiate from a scar. The aggressive growth pattern of this subtype is highlighted by the fact that the actual size of the cancer is usually much greater than the clinical extent of the tumor. Pigmented BCC is a variant of nodular BCC and may be difficult to differentiate from nodular melanoma. The presence of pigment may be of value in determining adequate margins for excision. FEP usually presents as a pink papule on the lower back. <sup>91</sup> It may be difficult to distinguish clinically from amelanotic melanoma.

**FIGURE 41.2-9.** Superficial basal cell carcinoma presents as an erythematous patch and may be difficult to distinguish from dermatitis.

**FIGURE 41.2-10.** Nodular basal cell carcinoma. **A:** A red, translucent nodule with rolled border, as seen here, is a classic presentation of nodular basal cell carcinoma. **B:** Nodular basal cell carcinoma demonstrating ulceration.

**FIGURE 41.2-11.** Morpheaform or aggressive-growth basal cell carcinoma (BCC). **A:** Morpheaform BCC may be difficult to differentiate from scar. **B:** Microscopical examination reveals strands of basaloid cells aggressively infiltrating dense collagen. **C:** BCC may recur without an obvious clinical lesion. **D:** Recurrent BCC after extirpation by Mohs micrographic surgery in the patient depicted in **C**.

**FIGURE 41.2-12.** If neglected, basal cell carcinoma invades locally with devastating results. (Courtesy Neil A. Swanson, M.D.)

**FIGURE 41.2-13.** Pigmented basal cell carcinoma may be difficult to differentiate clinically from melanoma.

**FIGURE 41.2-14.** Nodular basal cell carcinoma (BCC). Microscopical examination of nodular BCC reveals islands of basophilic cells exhibiting typical BCC morphology.

**FIGURE 41.2-15.** Cystic basal cell carcinoma. This variant may resemble an epidermal inclusion cyst.

Histologic subtypes of BCC include superficial, nodular, and infiltrative BCC. <sup>89,92</sup> All BCC subtypes tend to share certain histologic characteristics. These include peripheral palisading of large, basophilic cells, nuclear atypia, and retraction from surrounding stroma. Nodular BCC accounts for approximately 50% of BCCs and is characterized by the presence of tumor cells in rounded masses within the dermis (see [Fig. 41.2-14](#)). Peripheral palisading of nuclei is prominent, and surrounding retraction artifact may be present. Groups of cells may be solid, or there may be dermal necrosis or degradation, with formation of cysts or microcysts. The stroma is characteristically coarse and myxoid. If nodules measure less than 15  $\mu\text{m}$ , the tumor may be called *micronodular*. Infiltrative histology is seen in 15% to 20% of BCCs and represents that subclass of BCCs referred to as *aggressive-growth* tumors. Tumor cells manifest irregular outlines with a spiky appearance. Palisading is characteristically absent. The stroma is less myxoid than in the nodular form. In the morpheaform variant, which accounts for approximately 5% of BCCs, small groups or cords of tumor cells infiltrate a dense, collagenous stroma parallel to the skin surface (see [Fig. 41.2-11B](#)). Superficial multifocal BCC accounts for approximately

15% of BCCs and is characterized by basophilic buds extending from the epidermis. Retraction artifact is present, as is peripheral palisading within the buds. FEP, which accounts for 1% of BCCs, is characterized by a polypoid lesion in which basaloid cells grow downward from the surface in a network of anastomoses of cords of cells in loose connective tissue. Mixed histology is apparent in approximately 15% of BCCs.

The significance of histologic subtype lies in the correlation with biologic aggressiveness. The infiltrative and micronodular types are the most likely to be incompletely removed by conventional excision. Rates of incomplete excision vary from 5% to 17%. Incompletely excised infiltrative and micronodular BCCs may recur at rates of 33% to 39%. Recurrences after RT show a tendency toward infiltrative histology and evidence of squamous transformation, and even recurrent BCC after excision or C&D may become metatypical. In general, recurrences are more frequent in BCCs with infiltrative and micronodular histology, when clear margins are less than 0.38 mm, and in the presence of squamous differentiation. Although historical reports in the literature<sup>66</sup> suggested that 60% of incompletely excised BCCs will not recur, none of these studies provided an appraisal of recurrence rates as a function of histologic subtype. In general, incompletely excised BCCs should be removed completely, preferably by MMS, especially if they occur in anatomically critical areas such as the central zone of the face, retroauricular sulcus, or periocular area.

Adequate treatment of BCC requires appreciation of the histopathologic pattern of the neoplasm. Though some BCCs are small and superficial and behave in essentially a “biologically benign” manner as long as they are conservatively removed, others behave more aggressively and thus require more aggressive treatment. Examples of the latter include clinical BCCs that ulcerate and those located in the central face or on the ear. Furthermore, BCCs that show an aggressive growth pattern histologically require definitive treatment with confirmation of histologically negative margins.

Occasionally, it may appear that a BCC has been adequately removed by biopsy alone, leading to the question of whether to render further treatment. In one study, 41 consecutive patients with 42 BCCs apparently removed by biopsy were treated by MMS, and blocks of tissue, sectioned consecutively until exhausted, were examined for the presence of residual tumor.<sup>93</sup> In 28 of 42 cases (66%), residual cancer was identified. The presence of residual cancer was not related to age, site, histologic subtype, or extent of surrounding inflammation. The results indicate that patients with small BCCs that appear to be completely removed by initial biopsy may be at risk for recurrence if not treated further.

### Characteristics Related to Anatomic Site

BCCs may demonstrate unique characteristics based on anatomic site. The nose is the most common site for cutaneous malignancies (30%), and BCCs involving the nose may be aggressive. A study of 193 cases of infiltrative BCC involving the nose confirmed that the majority of infiltrating and recurrent BCCs affect the ala.<sup>94</sup> Analysis of the recurrences' aggressive local behavior indicated that recurrent lesions were subjected to inadequate therapy initially. In one study, 26 recurrences were identified in 71 nasal skin cancers at an average of 36 months after non-MMS excision.<sup>95</sup> This suggests that MMS may be the treatment of choice for all BCCs involving the nose, especially those exhibiting aggressive growth characteristics.

Periocular BCC represents a significant therapeutic challenge. In one study, periocular BCC accounted for 7.3% of 3192 BCCs treated over a 10-year period.<sup>10</sup> Of these, 48.5% involved the medial canthus, 22.35% involved the lower eyelid, 10.7% involved the upper eyelid, and 5.6% involved the lateral canthus. BCC is the most common tumor affecting the eyelid. In a series of 97 cases of BCC involving the eyelid, 69% were nodular, 13% were infiltrative, 1% were ulcerated, and 12% were mixed (defined as having a significant nodular or ulcerative component in addition to an infiltrative component). Follow-up of 8 of 12 patients with mixed tumors revealed three recurrences. In one patient, orbital exenteration was required. This suggests that mixed tumors of the eyelid with aggressive growth histology warrant thorough treatment with complete margin control.

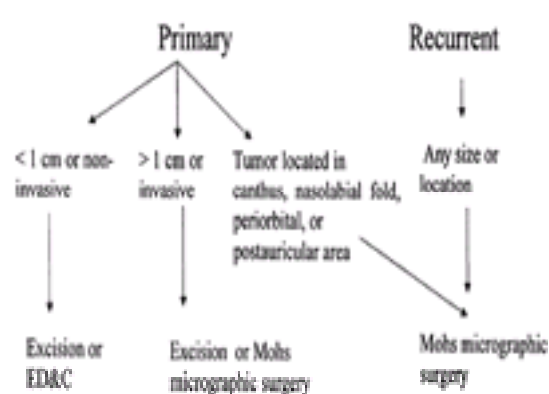

In a review of 24 eyelid tumors treated by MMS, high clearance rates were shown (100%), although follow-up was short (14.6 months).<sup>11</sup> In addition, 50% of patients were left with intact posterior lamellae, highlighting conservation of normal tissue. The results suggest that MMS followed by oculoplastic reconstruction, if necessary, is the preferred strategy in the management of periocular BCC.

Approximately 6% of BCCs involve the ear, a site notable for high rates of recurrence. In a recent study, nine patients with BCC involving the conchal bowl were treated by an interdisciplinary approach.<sup>96</sup> In each case, tumor extirpation was accomplished by MMS, and an otolaryngologist was available in the event of temporal bone involvement. There were no cases of recurrence at mean follow-up of 1 year.

It must be stressed that BCC can occur anywhere, even in non-sun-exposed areas, and has been reported to occur on the vulva, penis, scrotum, and perianal area.<sup>97,98,99,100</sup> and <sup>101</sup> In one series of vulvar BCC, mean age at presentation was 74 years. Patients have been seen with a history of local irritation that had been present for a few months to several years.

### Treatment

Excisional surgery, C&D, and cryosurgery have been used to treat circumscribed, noninfiltrating BCCs ( Fig. 41.2-16).<sup>102</sup> MMS is the treatment method of choice for all recurrent and infiltrative BCCs, particularly if a tumor is located on the face.<sup>103</sup> RT is best suited for older patients, particularly those with extensive lesions on the ear, lower limbs, or eyelids.<sup>104</sup> RT is not indicated for recurrent or morpheiform lesions.

**FIGURE 41.2-16.** Primary basal cell carcinomas may be managed by electrodesiccation curettage (ED&C), excision or Mohs micrographic surgery, depending on histology, size, and anatomic location. Recurrent basal cell carcinomas should be treated by Mohs micrographic surgery.

Surgical excision offers the advantage of histologic evaluation of the excised specimen. Although appropriate for management of most BCCs, cure rates for traditional excisional surgery are inferior to those for tumors treated by MMS in cases of recurrent BCC, infiltrative BCC, and BCC in high-risk anatomic sites.<sup>16</sup> It has been demonstrated that 4-mm margins are adequate for removal of BCC in 98% of cases of nonmorpheiform BCC of less than 2 cm in diameter.<sup>105</sup> Extending the excision into fat generally is adequate for a small primary BCC. It should be noted that the majority of BCCs are well treated with conventional excision or C&D. However, in the circumstances just outlined, MMS is especially helpful.

MMS permits superior histologic verification of complete removal, allows maximum conservation of tissue, and remains cost-effective as compared to traditional excisional surgery for NMSCs.<sup>7,12,102,106</sup> In a large study of treatment of primary BCC by Rowe et al.,<sup>107</sup> MMS demonstrated a recurrence rate of 1% over 5 years. This was superior to all other modalities including excision (10%), C&D (7.7%), RT (8.7%), and cryotherapy (7.5%). In a similar study of treatment of recurrent BCC, treatment with MMS demonstrated a long-term recurrence rate of 5.6%.<sup>108</sup> Once again, this was superior to all other modalities including excision (17.4%), RT (9.8%), and C&D (40%). MMS is the preferred treatment for morpheiform, recurrent, poorly delineated, high-risk, and incompletely removed BCC, and for those sites in which tissue conservation is imperative.<sup>7,8,31,109,110</sup>

C&D is the method most frequently used by dermatologists in the treatment of BCC. Knox et al.<sup>111</sup> noted cure rates as high as 98.3%, whereas Kopf et al.,<sup>112</sup> in an earlier study, cited a significant difference in the cure rates obtained between patients treated by private practitioners (94.3%) and those treated by trainees in the

New York University Skin and Cancer Unit (81.2%). This supports the premise that though C&D is simple and cost-effective, it is dependent on operator skill. In a series of 233 patients treated by Spiller et al.,<sup>113</sup> an overall cure rate of 97% was reported. The highest cure rate was obtained in lesions that measured less than 1 cm (98.8%), with recurrences observed in 2 of 165 patients treated. Recurrences were noted in 2 of 45 patients with lesions that measured between 1 and 2 cm, for an overall cure rate of 95.5%. Recurrences were significantly higher in patients with lesions larger than 2 cm, for whom the overall cure rate was 84%. In this series, as in others, recurrences were most commonly noted on the forehead, temple, ears, nose, and shoulders. Some practitioners advocate that the procedure be repeated for three cycles,<sup>16,19,114</sup> but we believe that the histology, location, and behavior of the tumor should dictate the number of cycles.

When surgery is contraindicated, RT is an option for treating primary BCC.<sup>104</sup> RT may be indicated postoperatively if margins are ambiguous. Advantages of RT include minimal to no discomfort for the patient and avoidance of an invasive procedure in a patient who may not be able to tolerate or is unwilling to undergo surgery. Disadvantages include lack of margin control, poor cosmesis over time, a drawn-out course of therapy, and possible increased risk of future skin cancers. In one series, control rates of 95% were achieved in BCC involving the eyelid treated with RT. The recurrence rate for primary BCC treated by RT approaches 5% to 10% over 5 years. In one study by Wilder et al.<sup>115</sup> local control rates among 85 patients with 115 biopsy-proven BCCs were compared. The local control rates varied significantly, a 95% control rate being achieved in primary BCC and a 56% control rate in recurrent BCC at 5 years. From the standpoint of cosmesis, scars from RT tend to worsen over time (Fig. 41.2-17), as contrasted to surgical scars, which improve over time.

**FIGURE 41.2-17.** After radiation therapy, scar and hypopigmentation can result.

Cryosurgery has been used to treat BCC.<sup>14,16,17,114,116,117</sup> Two freeze-thaw cycles with a tissue temperature of  $-50^{\circ}\text{C}$  are required to destroy the tumor sufficiently. A margin of normal skin also should be frozen to ensure eradication of subclinical disease. Complications include hypertrophic scarring and postinflammatory pigmentary changes. Fractional cryotherapy has been used with success in treating eyelid lesions.<sup>116,118</sup> The method has been described as quick and cost-effective. A serious potential adverse outcome is recurrent BCC that can become extensive because of concealment by the fibrous scar created when aggressive cryosurgery is used.

Ablation by the  $\text{CO}_2$  laser has been used in the treatment of BCC. In a recent study, Humphreys et al.<sup>119</sup> reported ablation of primary superficial BCC with the high-energy, pulsed  $\text{CO}_2$  laser. Because of the absence of margin control and lack of large series studies, physicians familiar with laser and tumor biology should use this method only in unique circumstances.

Management of BCC must be directed by the histologic nature of the tumor and the clinical context in which it presents. We recommend MMS for BCCs showing aggressive growth patterns and for BCCs occurring in high-risk anatomic sites or sites that require maximum conservation of normal tissue. For non-aggressive-growth BCCs on the trunk and extremities, fusiform excision with margins of 4 mm or C&D are appropriate. For patients with numerous BCCs, including patients with NBCCS, tangential excision followed by gentle curettage and cauterization for smaller, superficial lesions is effective. Cryosurgery can be helpful in the management of multiple, small BCCs of NBCCS.

It is imperative that patients with a history of BCC receive annual full-body skin examinations. Although most recurrences appear within 1 to 5 years, they can develop later.<sup>30</sup> Rowe et al.<sup>106</sup> found that 30% of recurrences developed within the first year after therapy, 50% within 2 years, and 66% within 3 years. Subsequent new primary BCC can present at rates of approximately 40%, with 20% to 30% of these developing within 1 year of treatment of the original lesion.<sup>30</sup>

## SQUAMOUS CELL CARCINOMA

SCC is a neoplasm of keratinizing cells that shows malignant characteristics, including anaplasia, rapid growth, local invasion, and metastatic potential.<sup>16,120</sup> Approximately 100,000 cases of SCC are diagnosed in the United States each year, making it the second most common human cancer after BCC. As with BCC, affected men tend to outnumber affected women.<sup>121,122</sup> People of Celtic descent, individuals with fair complexions, and those with poor tanning ability and a predisposition to sunburn are at increased risk for developing SCC (Fig. 41.2-18).<sup>123</sup> Patients taking immunosuppressive medications after organ transplantation are also at increased risk.<sup>48,124</sup> Another high-risk group includes patients treated with psoralens and ultraviolet A light (PUVA) for psoriasis.<sup>125,126,127,128</sup> and <sup>129</sup> Patients exposed to arsenic are at increased risk for SCC, particularly Bowen's disease.<sup>130,131,132</sup> and <sup>133</sup>

**FIGURE 41.2-18.** Extensive solar damage. Patients with this degree of solar damage are at increased risk for squamous cell carcinoma.

### Pathogenesis

Factors involved in the pathogenesis of SCC are similar to those for BCC and include exposure to UVL, genetic mutations, immunosuppression, and viral infection. The evidence for an association with UVL is even stronger for SCC than for BCC.<sup>25,33,134</sup> UVL may mediate development of SCC through several mechanisms.<sup>25,36</sup> Exposure to UVB appears to interfere with the density and antigen-processing capability of Langerhans' cells and may suppress production of the T helper 1 (Th1) cytokines interleukin-2 and interferon- $\gamma$ .<sup>135,136,137</sup> and <sup>138</sup> Recent studies have demonstrated that UVL may introduce mutations into the tumor suppressor gene p53.<sup>25,36,39,139,140</sup> This allows UVL to act as both tumor initiator and promoter. Development of SCC has been associated with radiation exposure, burn scars, chronic inflammatory dermatoses, ulcers, osteomyelitis, and arsenic ingestion.<sup>48,50,141,142,143,144</sup> and <sup>145</sup> Heritable conditions associated with SCC include xeroderma pigmentosum and oculocutaneous albinism. Immunosuppression also may play a role in pathogenesis. Skin cancers in immunosuppressed patients appear primarily on sun-exposed sites.<sup>60,62</sup> This correlation suggests that immunosuppression and UVL act as cofactors in the development of SCC. HIV patients tend to have a higher incidence of SCC than the general population.<sup>66,67</sup> However, the exact nature of the relationship between HIV and SCC has not yet been determined. The role of

human papillomavirus (HPV) in the development of SCC has been studied. Eliezri et al. <sup>146</sup> found a direct correlation between the venereal spread of HPV-16 and the initiation of SCC, and others have demonstrated an association of HPV-16 with periungual SCC. <sup>147</sup>

### Biologic Behavior

The biologic behavior of SCC is determined by a number of variables. <sup>148,149</sup> and <sup>150</sup> The overall invasiveness and depth of the neoplasm is significant when determining the risk of recurrence. SCCs that invade the reticular dermis and subcutis tend to recur if not properly treated. Immerman et al. <sup>151</sup> observed a 20% incidence of recurrence in 86 patients with invasive SCC. Degree of cellular differentiation is an important factor in recurrence also, with poorly differentiated neoplasms showing increased rates of recurrence.

SCC *in situ* tends to arise in association with preexisting AK. Arsenical keratoses are rarely seen nowadays but are associated with SCC. These lesions are considered to be at low risk for metastasis. While SCC *in situ* carries no risk of metastasis, invasive SCC can metastasize <sup>148,149</sup> and <sup>150</sup> and can originate in neglected SCC *in situ* (Fig. 41.2-19). The most common type arises on sun-damaged skin. The incidence of metastasis of such lesions is 3% to 5%. A higher incidence (10% to 30%) is associated with SCC arising on a mucosal surfaces (lip, genitalia) and in sites of prior injury (scars, chronic ulcers).

**FIGURE 41.2-19.** Metastatic squamous cell carcinoma (SCC). **A:** In this patient, primary cutaneous SCC metastasized to the parotid gland and draining lymph nodes. **B:** Metastatic SCC after multiple excisions.

The tendency for regional lymph node metastasis is variable. Tumors arising in areas of chronic inflammation have a 10% to 30% rate of metastasis, whereas the incidence of metastasis from SCC that is not due to preexisting inflammatory or degenerative conditions varies from 0.05% to 16%. <sup>148,149</sup> and <sup>150</sup> Although tumors that arise on sun-damaged skin may behave less aggressively than *de novo* SCC, all lesions have the potential to become invasive locally and to metastasize to draining lymph nodes. The large number of sun-mediated SCCs makes this clinical potential a concern. Friedman et al. <sup>152</sup> demonstrated that all trunk and extremity primary SCCs that later developed local or nodal recurrence were at least 4 mm deep and penetrated into the reticular dermis or subcutis. The extent of cellular differentiation also influences the metastatic potential in that tumors that invade regional lymph nodes tend to be more anaplastic than those that have not metastasized. Tumors are more likely to disseminate to regional lymph nodes than to distant sites, although intravascular metastases to viscera have appeared in as many as 5% to 10% of SCCs metastatic from skin.

Invasive SCC has the potential to involve nerves. <sup>72,148</sup> Regional lymph node and distant metastases may increase with perineural involvement. SCCs on the skin of the head and neck may metastasize to cervical lymph nodes and distantly to the central nervous system, the latter either hematogenously or via the perineural space, which directly connects to the subarachnoid space. SCCs on the midface and lip are prone to neural involvement. These patients show a lower 10-year survival (23% vs. 88%) and a higher local recurrence rate (47% vs 7.3%) than do those without neural involvement.

### Clinical Features

On the skin, SCC appears as a slightly raised, red, hyperkeratotic macule or papule on sun-exposed sites but may occur anywhere ( Fig. 41.2-20, Fig. 41.2-21, Fig. 41.2-22, Fig. 41.2-23, Fig. 41.2-24). It can be difficult to clinically distinguish an invasive SCC from a HAK, a benign seborrheic keratosis, or a benign inflammatory lesion. Appropriate biopsy should be performed on any lesion suspicious for SCC, considering the potential for invasive disease. Shave biopsy is sufficient and will not lead to spread of the cancer. Verrucous carcinoma, a variant of SCC, includes oral florid papillomatosis, giant condyloma of Buschke-Löwenstein, and epithelioma cuniculatum. <sup>153,154</sup> and <sup>155</sup> A biopsy should be performed on an atypical wart or one that is unresponsive to therapy to rule out the presence of verrucous carcinoma.

**FIGURE 41.2-20.** Recurrent squamous cell carcinoma, keratoacanthoma type, successfully treated by Mohs micrographic surgery.

**FIGURE 41.2-21.** Squamous cell carcinoma can arise within a cutaneous horn.

**FIGURE 41.2-22.** Periungual squamous cell carcinoma treated by Mohs micrographic surgery can result in sparing of a digit that otherwise may have been amputated.

**FIGURE 41.2-23.** Squamous cell carcinoma, keratoacanthoma type. This variant of squamous cell carcinoma presents as a rapidly growing nodule.

**FIGURE 41.2-24. A:** Bowen's disease presents as an erythematous macule or patch and can be difficult to differentiate from a benign inflammatory process. **B:** Bowen's disease is characterized by proliferation of atypical cells arranged in such a way as to suggest a windblown appearance.

Bowen's disease represents SCC *in situ* with a distinctive microscopical appearance (see [Fig. 41.2-24](#)).<sup>156</sup> Erythroplasia of Queyrat is simply Bowen's disease occurring on the penis.<sup>157</sup> Bowenoid papulosis classically presents as a reddish brown verrucous papule and is associated with HPV-16.<sup>158</sup> Bowenoid papulosis usually involves the genitals but may present elsewhere.<sup>159</sup>

SCC is characterized histologically by relatively large cellular size, lack of maturation, nuclear atypia, and the presence of mitotic figures (see [Fig. 41.2-24](#); [Fig. 41.2-25](#)).<sup>148</sup> Lack of dermal invasion separates SCC *in situ* from histologically invasive SCC. Verrucous carcinoma is characterized microscopically by an endophytic epidermal proliferation with atypia sufficient to distinguish it from verruca vulgaris, or common wart.<sup>160</sup> Variants of Bowen's disease are characterized by proliferation of atypical cells arranged in such a way as to suggest a windblown appearance.<sup>157</sup> A grading system was devised to classify SCC with respect to percentage of differentiated cells. Grade 1 tumors are described as having more than 75% well-differentiated cells, whereas in grade 2 SCC, 50% to 75% of cells are described as well-differentiated and, in grade 3 SCC, 25% to 50% of cells are described this way. Primary cutaneous SCC with fewer than 25% well-differentiated cells is termed *grade 4 SCC*. Prognosis worsens with decreased degree of differentiation.<sup>148,161</sup>

**FIGURE 41.2-25.** Squamous cell carcinoma (SCC), microscopical view. **A:** Infiltrative SCC. Note large cellular size and nuclear atypia. **B:** SCC demonstrating perineural invasion on microscopical examination.

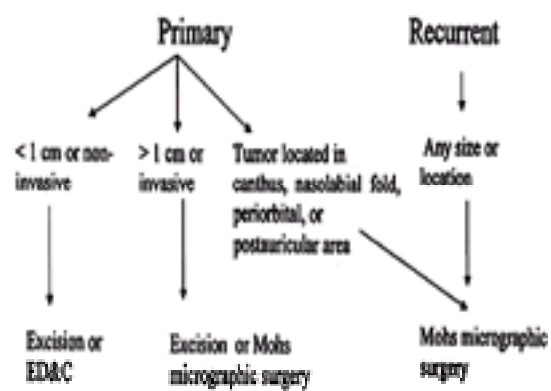

### Recurrence and Metastatic Risk

In a review of studies of SCCs from 1940 to 1992, Rowe et al.<sup>148</sup> correlated risk for local recurrence and metastasis with treatment modality, prior treatment, location, size, depth, histologic differentiation, evidence of perineural involvement, precipitating factors other than UVL, and immunosuppression. They found that with tumors greater than 2 cm in diameter, recurrence rates double from 7.4% to 15.2%. In addition, they demonstrated that tumors less than 4 mm deep were at low risk for metastasis (6.7%) as compared with tumors deeper than 4 mm (45.7%). Locally recurrent SCCs showed an overall metastatic rate of 30%, with high rates of metastasis in the context of local recurrence in skin (25%), lip (31.5%), and ear (45%). Immunosuppressed patients showed a 5- to 20-fold increase in the incidence of SCCs, with a reversal of the SCC/BCC ratio from 0.25:1 to 3:1. The number of SCCs per patient was increased, and the age at initial presentation was decreased. In immunosuppressed patients, SCCs metastasized at a rate of 12.9%. Poorly differentiated SCC metastasized more frequently (32.9%) than did well-differentiated SCC (9.2%). SCC arising on sun-exposed skin recurred at a rate of 7.9% and metastasized at a rate of 5.2%. Recurrence rates were increased in SCC on the lip (10.5%) and ear (18.7%), as were metastatic rates from the lip (13.7%) and ear (11%). SCCs with perineural invasion recurred in almost one-half of cases (47.2%) and

showed a similar rate of metastasis (47.3%).

### Treatment

Many of the treatments for BCC are appropriate for SCC (Fig. 41.2-26). The type of therapy should be selected on the basis of size of the lesion, anatomic location, depth of invasion, degree of cellular differentiation, and history of previous treatment.<sup>162</sup> There are three general approaches to treatment of SCC: (1) destruction by C&D or cryosurgery, (2) removal by traditional excisional surgery or MMS, and (3) RT.

**FIGURE 41.2-26.** Primary squamous cell carcinoma may be managed by electrodesiccation and curettage (ED&C), excision, or Mohs micrographic surgery, depending on histology, tumor size, and anatomic location. Recurrent squamous cell carcinomas should be treated by Mohs micrographic surgery.

C&D can be used for small lesions arising on sun-damaged skin. Well-differentiated, primary SCCs measuring less than 1 cm in diameter are amenable to this form of therapy. Honeycutt and Jansen<sup>163</sup> reported a 99% cure rate for 281 SCCs after a 4-year follow-up. In this study, two recurrences were noted in lesions less than 2 cm in diameter.

SCC *in situ* may be treated by cryotherapy. As with BCC, two freeze-thaw cycles with a tissue temperature of  $-50^{\circ}\text{C}$  are required to destroy the tumor sufficiently. A margin of normal skin also should be frozen to ensure eradication of subclinical disease. Complications include hypertrophic scarring and postinflammatory pigmentary changes. Concealment of recurrence within dense scar tissue presents a danger.

Surgical excision is another well-accepted treatment modality for SCC. Brodland et al.<sup>164</sup> demonstrated that lesions of less than 2 cm in diameter are best treated by excision, with margins of 4 mm, whereas high-risk SCC requires 6-mm margins. These investigators found that certain characteristics were associated with a greater risk of subclinical tumor extension, thus qualifying such tumors as high-risk. These included size of 2 cm or larger, histologic grade higher than 2, invasion of the subcutaneous tissue, and location in high-risk areas. Carcinomas of the penis, vulva, and anus usually are treated by excision because of the poor tolerance of these areas to irradiation.<sup>100,165,166</sup> Surgical excision is the treatment of choice for verrucous carcinoma.<sup>153</sup>

MMS is indicated in cases of large primary or recurrent SCC, as this modality allows conservation of normal tissue with preservation of function and enhanced cosmesis. MMS is also superior to other forms of treatment with regard to local recurrence.<sup>103,162</sup> Recurrence rates with Mohs surgery are superior to those obtained with traditional excisional surgery in primary SCC of the ear (3.1% vs. 10.9%), primary SCC of the lip (5.8% vs. 18.7%), recurrent SCC (10% vs. 23.3%), SCC with perineural invasion (0% vs. 47%), SCC larger than 2 cm (25.2% vs. 41.7%), and poorly differentiated SCC (32.6% vs. 53.6%).<sup>148</sup> MMS has proven useful in SCC involving the nail unit<sup>110</sup> and has been used as a limb-sparing procedure in cases of SCC arising in osteomyelitis.<sup>144</sup>

RT may be used for head and neck cutaneous SCC in which there is no spread to bone or cartilage and there is no evidence of metastasis.<sup>167</sup> As with BCC, RT may be indicated for elderly patients with SCC who are unwilling or unable to undergo surgery.<sup>104</sup> In one series, 108 patients with SCC of the lower vermilion lip were stratified into stage T1 (82.4%), T2 (15.7%), or T3 (1.9%) disease and were treated with RT. Recurrences occurred in 12.4% of patients with T1 disease and 6.7% of patients with T2 disease.<sup>168</sup> Radiation therapy often is used as an adjuvant modality after treatment of SCC in which perineural involvement is identified, although no controlled studies have proven its usefulness.

MMS is indicated for invasive lesions, poorly differentiated lesions, and lesions occurring in high-risk anatomic sites or sites in which conservation of normal tissue is essential for preservation of function or cosmesis.

Invasive SCC can be a potentially lethal neoplasm and warrants close follow-up. In one study, approximately 30% of patients with SCC developed a subsequent SCC, with more than one-half of these occurring within the first year of follow-up.<sup>169</sup> In another study, the median time to recurrence was 15 months.<sup>142</sup> Thus, it is recommended that patients with SCC be examined every 3 months during the first year following treatment, every 6 months during the second year after treatment, and annually thereafter. Evaluation should include total body cutaneous examination and palpation of draining lymph nodes. Currently, roentgenography, magnetic resonance imaging, and CT play no role in the routine workup of uncomplicated cutaneous SCC.

### MERKEL CELL CARCINOMA

Merkel cell carcinoma (MCC) is a potentially aggressive tumor of neuroendocrine cell origin. Though it primarily affects the head and neck, other areas may be involved.<sup>170</sup> MCC affects more men than women and most often occurs between the seventh and ninth decades of life.<sup>171,172</sup>

The pathogenesis of MCC is incompletely characterized. UVL has been indirectly implicated in its development, as 36% of such cancers arise on the face.<sup>173</sup> More than 50% of tumors occur on the head and neck, while 35% develop on the extremities. Mixed MCC/SCC<sup>174</sup> and, recently, MCC/BCC<sup>175</sup> have been reported, thus supporting the role of UVL exposure as a risk factor. Immunosuppression may play a role in the development of MCC, as rapid progression has been reported in the setting of immunosuppressive therapy after organ transplantation.<sup>176,177</sup> An association with arsenic-induced Bowen's disease has been reported, implicating arsenic exposure as a risk factor for development of MCC.<sup>132</sup>

Lymph node metastases have been identified in up to 20% of cases of MCC at initial presentation. Approximately 50% of patients experience nodal disease at some point in the disease course. Distant metastases have been reported in up to 30% of patients at presentation. Metastases have been noted in skin, lymph nodes, lung, liver, brain, intestine, bladder, and abdominal wall.<sup>178,179,180,181,182 and 183</sup> Although MCC is a highly aggressive and potentially lethal cancer, spontaneous regression has been reported.<sup>184</sup> The significance of this phenomenon is unknown.

MCC usually appears as a red, violaceous, dome-shaped papule or plaque on sun-exposed skin (Fig. 41.2-27).<sup>170</sup> It may develop on the extremities and can involve the trunk. Clinical differential diagnosis includes leukemia cutis, amelanotic melanoma, metastatic carcinoma, pyogenic granuloma, and SCC.

**FIGURE 41.2-27.** Merkel cell carcinoma presenting as a red to violaceous, dome-shaped papule or plaque on the sun-exposed skin of an elderly person.

Microscopical examination reveals sheets and cords of atypical cells in the dermis, extending to the subcutaneous layer, that sometimes form an interlacing trabecular or pseudoglandular pattern.<sup>170,185</sup> A grenz zone often is present, separating tumor from epidermis. Cell membranes often are indistinct, giving a syncytial appearance. Cells are round to oval and generally noncohesive. Cytoplasm tends to be scant, with round to oval nuclei containing two to three nucleoli. Foci of squamous differentiation resembling SCC have occasionally been noted. Special stains may prove useful in the histologic diagnosis of MCC. Cytokeratin-20 (CK-20) staining gives a characteristic paranuclear dot pattern.<sup>185</sup> Histologic differential diagnosis includes lymphoma, BCC, metastatic oat cell carcinoma, or noncutaneous neuroendocrine tumors. Lymphoma cells are differentiated in that they are CD45-positive and CK-20-negative. Melanoma can be differentiated in that melanocytes are strongly S-100-positive. In addition to CK-20, MCC stains positively for chromogranin neuron-specific enolase and may be weakly positive for S-100 protein.

MCC warrants aggressive therapy (Fig. 41.2-28). Evaluation of a patient with histologically confirmed MCC must include full-body skin examination and lymph node evaluation. A complete blood cell count and liver function tests should be performed as well. CT scanning of the chest, pelvis, and abdomen may be indicated to rule out the presence of small cell carcinoma of the lung. CT scanning of the head and neck may prove valuable in detection of nodal disease. MCC tends to spread in a cascade pattern, first affecting local, then regional lymph nodes and finally progressing to fatal distant metastatic disease.<sup>186</sup>

**FIGURE 41.2-28.** Merkel cell carcinoma should be treated by wide local excision followed by sentinel or complete lymph node dissection (SLND, CLND), radiation therapy (XRT), or chemotherapy, depending on stage.

Management of MCC follows staging of patients according to local, regional, or metastatic disease. Current recommendations support wide local excision (WLE) with lymph node dissection and adjuvant RT, if indicated.<sup>187</sup> In cases of local disease, sentinel lymph node dissection may be advisable, if available. In a recent study, 18 patients with stage I MCC underwent sentinel lymph node dissection. In two patients, involvement of the sentinel node was identified, resulting in complete lymph node dissection. Sentinel node–negative patients received no therapy other than wide and deep excision.<sup>188</sup> All patients remained free of recurrence at 7 months. Patients with negative sentinel nodes may be treated by WLE with margins of up to 3 cm and, possibly, adjunctive RT. Patients with positive sentinel nodes should be treated as patients with regional disease. The combination of WLE, therapeutic lymph node dissection, and RT has been suggested for treatment of regional disease.<sup>189,190</sup> Metastatic disease is treated with chemotherapy. The most common regimens used in the treatment of metastatic MCC include cytoxan, doxorubicin, and vincristine, and cisplatin and etoposide. However, brief responses were reported recently in a small series of patients treated with carboplatin and etoposide.<sup>191</sup> In a review by Voog et al.,<sup>192</sup> overall response to first-line chemotherapy for MCC was 61%, with a 57% response in metastatic disease and a 69% response in locally advanced disease. The 3-year survival rate was 17% in metastatic disease and 35% in locally advanced disease. In a recent series of nine patients with neuroendocrine tumors, complete response in a patient with inoperable MCC was reported using 5-FU, dacarbazine, and epirubicin. Patients with MCC must be followed up aggressively for potential local recurrence and development of metastatic disease.

### MICROCYSTIC ADNEXAL CARCINOMA

Microcystic adnexal carcinoma (MAC) was first described as a distinct entity in 1982 by Goldstein et al.<sup>193</sup> In this study, six cases of MAC were described. In each case, the tumor was originally misdiagnosed on initial biopsy as benign. MAC originates from pluripotent adnexal cells capable of eccrine and follicular differentiation. Synonyms for MAC include *sclerosing sweat duct carcinoma*, *sweat duct carcinoma with syringomatous features*, and *combined adnexal tumor of the skin*.

MAC is a tumor that primarily affects middle-aged individuals,<sup>194</sup> though it has been reported in an 11-year-old boy.<sup>195</sup> Unlike the other primary cutaneous malignancies considered thus far, affected women outnumber affected men.<sup>194</sup> The pathogenesis of MAC is not completely understood but may involve exposure to ionizing radiation. In many cases, patients with MAC have received RT. In general, these patients were treated with RT for conditions ranging from tinea capitis to thyroid carcinoma.<sup>196,197</sup> Treatment may precede development of MAC by as long as 40 years.

MAC is a locally aggressive tumor with low metastatic potential. It has been demonstrated that the increased stromal collagen observed in MAC is not due to soluble factors excreted by MAC cells.<sup>198</sup> Perineural invasion is common with MAC, as are involvement of muscle, perichondrium, and vascular adventitia.<sup>199,200</sup> Birkby et al.<sup>200a</sup> reported MAC on the face of a 51-year-old man that invaded the bone marrow of the mandible and spread along the inferior alveolar and mental nerves. Recently, the first case of MAC metastatic to lymph node was reported.<sup>201</sup>

MAC classically presents as a sclerotic or indurated plaque with intact epidermis and yellow hue ( Fig. 41.2-29A).<sup>193</sup> The tumor usually involves the central face and lip but is not limited to those anatomic sites.<sup>193,202,203</sup> MAC involvement of the eyelid,<sup>204</sup> scalp,<sup>205</sup> tongue,<sup>206</sup> and eyebrow<sup>207</sup> have been reported.

**FIGURE 41.2-29.** Microcystic adnexal carcinoma. **A:** Classic presentation is as an indurated plaque with intact epidermis and yellow hue. **B:** On microscopical examination, the dermis shows numerous basaloid cells forming cords, nests, small ducts, and horn microcysts.

On microscopical examination, MAC may be misdiagnosed as a benign adnexal process.<sup>208</sup> The epidermis is normal, although mild hyperkeratosis may be present. The dermis contains numerous basaloid cells forming cords, nests, small ducts, and horn microcysts (see Fig. 41.2-29B). Horn microcysts usually are present superficially, containing laminated keratin and, occasionally, small vellus hairs. Cysts may be calcified. Small ducts, either empty or filled with eosinophilic material composed of sialomucin, commonly are present. Ducts may be well-differentiated, with two rows of cuboidal cells, or less differentiated, with single strands without lumina. A dense sclerotic stroma is present. Immunohistochemical analysis may be useful in differentiating MAC from desmoplastic trichoepithelioma (DTE). Wick et al. reported that MACs were reactive to hard keratin subclasses AE13 and AE14, epithelial membrane antigen, carcinoembryonic antigen, and LeuM1.<sup>209</sup> DTEs were positive for AE14, epithelial membrane antigen, and LeuM1 only focally and were, in contrast, negative for carcinoembryonic antigen. Correct diagnosis of MAC is imperative, as the tumor can be highly invasive and may involve adipose, muscle, perichondrium, or bone.

MAC has been treated by WLE as well as MMS.<sup>194</sup> In a recent series, 11 cases of MAC treated by MMS remained free of tumor for a median of 5 years.<sup>210</sup> This suggests that extirpation by Mohs technique may prove beneficial in the management of MAC. However, these findings must be interpreted cautiously, as recurrences have been reported up to 30 years after surgical excision.<sup>208</sup> Non-Mohs surgical excision is associated with recurrence rates of 47% to 59%.<sup>201</sup> It appears that the tumor is resistant to RT, thus presenting difficulties in the management of MAC with perineural invasion.

After surgery for MAC, patients must be evaluated regularly for recurrence and for development of other skin cancers. Evaluation should include examination of skin and lymph nodes and, due to the potential for recurrence long after treatment, continue indefinitely.

## SEBACEOUS CARCINOMA

Sebaceous carcinoma (SC) is a malignant adnexal tumor with variable sites of origin, histologic growth patterns, and clinical presentations.<sup>211,212</sup> Ocular SC is more common and may arise from meibomian glands and, less frequently, from the glands of Zeis. The upper eyelids are most frequently involved. Approximately 50% of SCs are initially incorrectly diagnosed histologically and, in some series, all have been initially misdiagnosed clinically.<sup>211,212</sup> SC is the second most common eyelid malignancy after BCC<sup>213</sup> and is the second most lethal after melanoma.<sup>214</sup>

In SC, women are affected more commonly than men, at a ratio of approximately 2:1.<sup>211,212</sup> and <sup>213,215</sup> SC classically presents in the seventh to ninth decade.<sup>211,212</sup> SC is associated with sebaceous adenomas, radiation exposure, Bowen's disease, and Muir-Torre syndrome. In Muir-Torre syndrome, an autosomal dominant heritable condition, SC and (more commonly) sebaceous adenoma (or sebaceous epithelioma) are associated with a second internal malignancy, usually a carcinoma of the colon or urogenital tract. SC may be associated with a history of RT. SC has been reported after RT for retinoblastoma,<sup>216</sup> eczema,<sup>217</sup> and cosmetic epilation.<sup>218</sup> In one study, SC was associated with thiazide diuretic use.<sup>213</sup> In addition, recent studies have identified HPV DNA<sup>219</sup> and overexpression of p53 protein in some SCs.<sup>220</sup>

Commonly, SC presents as a slowly growing, deeply seated nodule of the eyelid and may present as chronic diffuse blepharoconjunctivitis or keratoconjunctivitis.<sup>211,212,213</sup> and <sup>214</sup> Upper eyelid involvement is more common. Approximately 25% of cases of SC involve extraocular sites, which may include head and neck, trunk,<sup>221,222</sup> and <sup>223</sup> and external genitalia.<sup>219</sup> A case of SC has occurred within a benign dermoid cyst of the ovary.<sup>224</sup>

SC can spread by lymphatic or hematogenous routes or by direct extension.<sup>211,212</sup> Distant metastases are reported in up to 20% of cases and may involve the lungs, liver, brain, bones, and lymph nodes.<sup>211,212</sup> The parotid gland may be involved secondarily.<sup>225</sup> Ocular SC may spread via the lacrimal secretory and excretory systems.<sup>213</sup>

On microscopical examination, SC shows nonencapsulated tumors within the dermis.<sup>211</sup> Sebaceous cells exhibiting varying degrees of differentiation, nuclear pleomorphism, hyperchromatism, and locally infiltrating surrounding tissues and neurovascular spaces are observed. Poor prognostic indicators in SC have been reviewed.<sup>226</sup> These include multicentric origin, poor differentiation, infiltrative pattern, pagetoid changes, vascular invasion, lymphatic channel involvement, and orbital spread.

Treatment options for SC include traditional excisional surgery and extirpation by MMS. In one study of 14 cases of SC excised with frozen-section margin control, 5 recurrences were observed in cases with surgical margins of 1 to 3 mm, whereas no recurrences were seen with margins of 5 mm.<sup>227</sup> Potential difficulties arise because tumors are often multicentric, and pagetoid spread is difficult to determine even on high-quality, paraffin-embedded sections. Extirpation of SC by Mohs has thus far yielded varying results. Folberg et al.<sup>228</sup> reported recurrences in two of three patients treated by the Mohs technique, with tumor noted at reconstruction in one of the three patients. Dzubow<sup>229</sup> reported two patients with recurrent SC who underwent MMS. One patient who underwent MMS followed by oculoplastic repair was tumor-free at 6 months. In the other patient, tumor distal to the Mohs defect was noted at reconstruction. A case of poorly differentiated SC successfully treated with RT has been reported.<sup>230</sup>

Patients with SC should be evaluated by an internist, and routine screening for internal malignancy (stool for occult blood, analysis of urine, colonoscopy) should be current. A family history for internal malignancy should be sought and family members screened, if indicated, to rule out Muir-Torre syndrome.<sup>231</sup> After treatment for SC, patients should be followed up for recurrence or progression through regular examination of skin and lymph nodes.

## ATYPICAL FIBROXANTHOMA

Atypical fibroxanthoma (AFX) is a spindle cell tumor that occurs on the head and neck of sun-exposed individuals and on the trunk and extremities of younger patients.<sup>232,233</sup> and <sup>234</sup> Tumors of the head and neck characteristically present during the eighth decade, whereas tumors involving the extremities often present during the fourth decade.<sup>231</sup> The ratio of affected men to affected women appears to be equal.<sup>232</sup>

The pathogenesis of AFX may involve exposure to UVL, ionizing radiation, or aberrant host response. In one study of ten cases of AFX, seven cases showed mutation in p53. Of the seven, all showed abnormal single-strand conformation polymorphism, with four of those showing C@T mutations characteristically induced by UVL.<sup>235</sup> Exposure to ionizing radiation may play a role in the development of the tumor, as AFX after RT has been demonstrated.<sup>236</sup> An increased incidence of AFX was shown in a study of 642 renal transplant patients,<sup>237</sup> and invasive AFX has been reported in a heart transplant patient.<sup>238</sup> Finally, metastatic AFX has been reported in a patient with null cell variant chronic lymphocytic leukemia.<sup>239</sup>

AFX usually presents as an asymptomatic papule or nodule. There may be hyperpigmentation or ulceration.<sup>240</sup> The clinical appearance is not distinctive, and the lesion may be confused with pyogenic granuloma, SCC, or BCC.<sup>241,242</sup> The tumor characteristically presents on the head and neck of the elderly or the trunk or extremities of younger individuals but is not limited to these sites. Occurrences on the eyelid<sup>243</sup> and within the ethmoid sinus<sup>244</sup> and oral cavity<sup>236</sup> have been reported.

Although AFX rarely metastasizes, it is a locally aggressive tumor with metastatic potential.<sup>245</sup> Metastases to parotid gland,<sup>246</sup> lymph nodes,<sup>247</sup> and lung<sup>248</sup> have been reported. In a series of eight cases of metastatic AFX, poor prognostic indicators included vascular invasion, recurrence, deep tissue penetration, necrosis, and impaired host resistance.<sup>246</sup>

On microscopical examination, there is a dermal nodule with a dense infiltrate of bizarre spindle cells arranged in haphazard fashion ( Fig. 41.2-30).<sup>240</sup> Often, bizarre giant cells are present, and there is no connection to the epidermis.<sup>240</sup> Special stains for vimentin are positive and for CD68 are weakly positive, while stains for HMB-45 and S-100 are negative, distinguishing this lesion from spindle cell melanoma.<sup>249,250</sup> Differentiation from malignant fibrous histiocytoma (MFH) may be aided by special stains, as AFX stains negatively for LN-2, a marker present on B cells, Reed-Sternberg cells, and macrophages, and MFH cells are positive for LN-2 in

90% of cases.<sup>251</sup>

**FIGURE 41.2-30.** Atypical fibroxanthoma. On microscopic examination, there is a dermal nodule with a dense infiltrate of atypical spindle cells arranged in haphazard fashion and associated with bizarre giant cells.

Treatment options for AFX include WLE and MMS. In one large series comparing WLE with MMS,<sup>232</sup> recurrences were observed during a mean follow-up period of 73.6 months in 12% of 25 cases treated by WLE. Metastatic involvement of the parotid gland occurred in one of these patients, for an overall regional metastatic rate of 4%. In contrast, no recurrences or metastases were observed over a mean follow-up period of 29.6 months in any patient treated by MMS. Others have reported similarly favorable outcomes after treatment of AFX by MMS, albeit with smaller numbers of cases.<sup>252,253</sup> The authors favor the use of MMS for AFX because of the superior margin control and conservation of normal tissue.

### MALIGNANT FIBROUS HISTIOCYTOMA

MFH is an aggressive spindle cell cancer and is the most common soft tissue tumor in the elderly, primarily affecting the extremities.<sup>254,255</sup> Peak incidence is during the seventh decade.<sup>253</sup>

Though the pathogenesis of MFH is incompletely understood, there appears to be a predilection for development in scar tissue. Inoshita et al.<sup>256</sup> report development of MFH in an amputation site in one patient and in a hernioplasty scar in another. In both patients, the initial clinical diagnosis was subcutaneous abscess. MFH in a burn scar has also been reported.<sup>257</sup> A case of MFH associated with discoid lupus erythematosus has also been described.<sup>258</sup> Decreased immune surveillance may play a role in the development of MFH. A significant increase in the incidence of MFH (158 per 100,000) has been reported in a large series of renal transplant patients.<sup>237</sup>

MFH is aggressive, with high metastatic potential. In one series, a higher percentage of histologically infiltrative tumors (83% vs. 24%) were observed in subcutaneous MFH as opposed to intramuscular MFH.<sup>259</sup> An increased percentage of local recurrences (17% vs. 0%) were observed in the subcutaneous variant. However, infiltrative growth pattern was not predictive of metastatic potential. In one large series, the local recurrence rate was 44%, and the rate of metastasis was 42%.<sup>254</sup> Metastasis, in this series, occurred most commonly in lung (82%) and lymph nodes (32%). Factors that appeared to influence metastasis included depth and size of tumor and inflammatory response. Small, superficially located tumors and tumors with a prominent inflammatory component metastasized less frequently.

Clinically, MFH may present as a subcutaneous mass<sup>256</sup> or ulcerative nodule.<sup>255</sup> In one large series, MFH occurred principally as a mass on an extremity (lower extremity, 49%; upper extremity, 19%) or in the abdominal cavity or retroperitoneum (16%) of adults.<sup>254</sup> Deep fascial involvement was typical (19%), as was involvement of skeletal muscle (59%). Fascial involvement was absent in only a small percentage of cases (7%).

On microscopic examination, morphologic features vary, and MFH may show transitions from areas with a highly ordered, storiform pattern to less differentiated areas with a pleomorphic appearance. Differentiation from AFX may be aided by staining with LN-2, a marker present in 90% of MFHs in one series but absent or only weakly present in AFX.<sup>251</sup>

Treatment options for MFH include WLE, although recurrence rates of up to 40% have been reported with this approach.<sup>254</sup> Some authors have reported successful treatment of subcutaneous MFH with MMS.<sup>251,259</sup> Brown and Swanson<sup>260,261</sup> reported no recurrences over a 3-year follow-up period among 17 patients with 20 tumors treated by MMS. Hafner et al.<sup>252</sup> reported successful treatment of MFH by MMS with margin control achieved using paraffin-embedded tissue sections. After treatment for MFH, patients should be followed up aggressively for development of recurrent and metastatic disease.

### DERMATOFIBROSARCOMA PROTUBERANS

Dermatofibrosarcoma protuberans (DFSP) is a low-grade cutaneous sarcoma with well-characterized clinical and histopathologic features. The lesion frequently appears as a plaque on the trunk and, less commonly, on the extremities of middle-aged adults.<sup>262,263</sup> Gender distribution of DFSP tends to vary in published series.<sup>262</sup>

The pathogenesis of DFSP is incompletely understood but may involve factors as diverse as aberrant tumor suppressor genes or history of local trauma. In one study, increased p53 protein immunoreactivity was found in DFSP but not in dermatofibrosarcoma, suggesting that expression of the protein may be important in the pathogenesis of DFSP.<sup>264</sup> In addition, DFSP has been reported to occur at previously traumatized sites.<sup>265</sup>

DFSP has a tendency to recur locally, with an overall rate of 50%. However, metastases are rare. In one series of 19 cases of DFSP, there were 20 local recurrences in 8 patients.<sup>266</sup> Recurrences in this series followed narrow excision. No recurrences were noted during a mean follow-up period of 13.2 years after WLE with margins greater than 2 cm. Lymph node metastases occur in approximately 1% of cases and distant metastases, principally to lung, occur in approximately 4% of DFSP cases.<sup>266</sup> A fibrosarcomatous variant, FS-DFSP, represents an uncommon form of DFSP.<sup>267</sup> In a series of 41 patients with FS-DFSP, follow-up in 34 patients for a mean period of 90 months revealed a local recurrence rate of 58%. Metastases were observed at a rate of 14.7%. Thus, fibrosarcomatous change in DFSP is indicative of a more aggressive clinical course.<sup>267</sup> A case of acral DFSP with fibrosarcomatous change and pulmonary parenchymal metastases was reported recently.<sup>268</sup>

DFSP classically presents as a plaque on the trunk and, less frequently, on the extremities but may occur anywhere.<sup>262</sup> The tumor may be difficult to differentiate clinically from a dermatofibroma or a keloid.<sup>270</sup> The tumor most commonly presents during early or middle adulthood, though it can occur during childhood.<sup>271,272</sup> The Bednar tumor is a rare pigmented variant of DFSP.<sup>273</sup>

Microscopically, the tumor is composed of monomorphous spindle cells arranged in a storiform pattern and embedded in a sparse to moderately dense fibrous stroma.<sup>262</sup> The distinction between deep penetrating dermatofibroma (DPDF), which involves the subcutis, and DFSP may be challenging. In most instances, attention to the cytologic constituency of the lesions and the overall architecture is sufficient for differentiation. DPDF is typified by cellular heterogeneity. DPDF includes giant cells and lipidized histiocytes and extends deeply, using the interlobular subcuticular fibrous septa as scaffolds, or in the form of broad fronts. In contrast, DFSP tends to be monomorphous, surrounding adipocytes diffusely or extending in stratified horizontal plates. Immunostaining for factor XIIIa and CD34 may be helpful in distinguishing DPDF from DFSP. Characteristically, DPDF is diffusely factor XIIIa-positive and CD34-negative, whereas DFSP is factor XIIIa-negative and CD34-positive.<sup>274,275</sup>

Treatment options for DFSP include WLE and MMS. Some authors advocate surgical excision with a minimal margin of 2 to 3 cm of surrounding skin, including the underlying fascia, without elective lymph node dissection.<sup>266</sup> Although WLE has been the standard treatment of DFSP, recurrence rates approach 50%. In one series, 58 patients with DFSP treated by MMS at three institutions showed a local recurrence rate of 2%.<sup>277</sup> There were no cases of regional or distant metastases. Other

studies support MMS as the treatment of choice for DFSP, based on low recurrence rate and maximal conservation of normal tissue.<sup>269,276,277</sup> Caution is advised in attempting to interpret immunostains on frozen sections of DFSP since, in one study, microscopical examination of paraffin-embedded sections showed CD34-negative DFSP tumor cells with positive staining of endothelial cells.<sup>278</sup> The authors favor extirpation of tumor by MMS, using frozen sections with confirmation by examination of paraffin-embedded sections. Patients with DFSP should be followed up closely for evidence of local or regional recurrence or metastatic disease.

## ANGIOSARCOMA

Angiosarcoma (AS) is an aggressive, usually fatal neoplasm of vascular cells.<sup>279</sup> Four variants of cutaneous AS currently are recognized, including AS of the scalp and face, AS in the context of lymphedema (Stewart-Treves syndrome), radiation-induced AS, and epithelioid AS. Although these variants differ in presentation, they share key features, including clinical appearance of primary lesions, a biologically aggressive nature and, ultimately, poor outcome.

Cutaneous AS of the head and scalp usually affects the elderly, with men being affected more often than women.<sup>280</sup> Although no predisposing factors have been identified, exposure to UVL has been suggested as a risk factor due to the propensity for the tumor to affect sun-exposed sites of the scalp and face. Other researchers have questioned this connection because, in several series, AS has presented on scalps protected by hair as frequently as on bald scalps. Others have demonstrated that patients with AS show no significant increase in numbers of BCCs and SCCs, thus arguing against increased UVL exposure.

AS presents as a violaceous to red ill-defined plaque, often initially resembling a bruise ( Fig. 41.2-31). The differential diagnosis may include benign vascular tumors, hematoma secondary to trauma, or an inflammatory dermatosis. Unexplained facial edema may be a presenting sign as well. As AS progresses, lesions increase in size, become indurated, and may eventually ulcerate. Satellite lesions are common.

**FIGURE 41.2-31.** Angiosarcoma may present as a violaceous, ill-defined plaque on the scalp.

On microscopical examination, it becomes evident that AS extends far beyond clinical margins. In well-differentiated lesions, histology shows irregularly dilated vascular channels lined by flattened endothelial cells.<sup>278</sup> Less differentiated tumors show proliferation of polygonal or spindle-shaped, pleomorphic endothelial cells and anastomosing vascular channels. The state of cellular differentiation has not been shown to correlate with prognosis. Special stains may be of value in histologic diagnosis of AS, as cells stain positively for *Ulex europaeus* I lectin and factor VIII-related antigen. *Ulex* I is considered to be more sensitive for AS. In addition, AS cells express stem cell antigen CD34 and endothelial cell surface antigen CD31.

AS is a biologically aggressive tumor with high metastatic potential. Metastases to lymph nodes, lung, and brain are common. Prognosis for metastatic disease is poor. Although prognosis does not correlate with degree of cellular differentiation, there appears to be a correlation with lesion size at presentation: Increased survival has been demonstrated in lesions smaller than 5 cm at time of presentation.

Owing to the aggressiveness and poor prognosis of AS, treatment options are limited. Radical excision is currently the treatment of choice and may be difficult to accomplish in tumors involving the face. Amputation with shoulder disarticulation or hemipelvectomy are recommended for tumors involving the extremities. As stated, AS tends to extend far beyond clinically appreciated margins, thus complicating excision. Several cases of AS have been treated by MMS in an attempt to control margins; however, the difference between AS and normal vasculature may be difficult to interpret on frozen sections, even with the use of immunohistochemical stains. Prognosis of AS is poor, with a mortality rate of 50% at 15 months after diagnosis. The 5-year survival rate is approximately 12%.

Lymphedema-associated AS (LAS) was first reported by Stewart and Treves<sup>281,282 and 283</sup> in 6 patients with postmastectomy lymphedema. In each case, AS developed in the ipsilateral arm and occurred several years after mastectomy. Subsequently, LAS was reported after axillary node dissection for melanoma and in the context of congenital lymphedema, filarial lymphedema, and chronic idiopathic lymphedema. The risk for developing LAS 5 years after mastectomy is approximately 5%. The most common site is the medial aspect of the upper arm.

LAS presents as a violaceous plaque or nodule superimposed on brawny, nonpitting edema. Ulceration may develop rapidly. The pathogenesis of LAS is incompletely understood and may be related to imbalances in local immune regulation or angiogenesis, leading to proliferation of neoplastic cells. The prognosis is poor, and survival rates are comparable to AS involving the scalp and face. Long-term survival has been reported after amputation of the affected limb.

Radiation-induced AS has been reported to occur after RT for benign or malignant conditions.<sup>279,284,285 and 286</sup> AS may occur from 4 to 40 years after RT for benign conditions, including acne and eczema, or from 4 to 25 years after RT for malignancies. Lesions appear at sites treated with radiation and are clinically and histologically similar to AS involving the scalp and face. Prognosis is poor and comparable to that observed in other forms of AS.

Epithelioid AS (EAS) is a rare, recently described variant of AS. It tends to involve the lower extremities.<sup>278</sup> On microscopical examination, the tumor may mimic an epithelial neoplasm, with sheets of rounded, epithelioid cells intermingled with irregularly lined vascular channels. Epithelioid AS results in widespread metastases within 1 year of presentation. Prognosis, as in other forms of AS, is poor.

## KAPOSI'S SARCOMA

Kaposi's sarcoma (KS) is an indolent vascular tumor that has been subdivided into epidemiologic variants including classic KS, African endemic KS, iatrogenic KS, and epidemic, acquired immunodeficiency syndrome-associated (AIDS-associated) KS.<sup>62,279,287,288 and 289</sup> Classic KS affects elderly men, with increased incidence in Ashkenazi Jews and in persons of Mediterranean descent. Classic KS typically presents with violaceous macules on the lower extremities. Slow progression with coalescence to plaques is observed. Eventually, the disease enters a nodular phase and may ultimately progress to a hyperkeratotic or even ulcerative phase.

African endemic KS can be further subdivided into a generally benign nodular disease, predominantly affecting young adults, and a fulminant lymphadenopathic disease, predominantly affecting children.<sup>289</sup> Nodular African endemic KS also presents with violaceous macules that eventually progress to form plaques and nodules. Cutaneous and mucous membrane involvement are rare in lymphadenopathic endemic KS.

Iatrogenic KS occurs in the context of immunosuppressive drug therapy.<sup>62</sup> Iatrogenic KS is usually chronic but may be somewhat more aggressive than classic KS. Iatrogenic KS presents with lesions similar to those observed in classic KS. The lesions may regress on withdrawal of the immunosuppressive agent.

Epidemic KS appears in approximately 21% of homosexual men with AIDS.<sup>287</sup> It is considered to be a sexually transmitted disease, and the etiologic agent appears to be human herpesvirus-8 (HHV-8). Epidemic KS presents with violaceous macules involving the face, chest, and oral mucosa. The hard palate and ocular conjunctiva are frequently involved.

KS, for the most part, behaves in an indolent fashion, with some variance according to epidemiologic subtype. Patients with long-standing classic KS may show

visceral involvement, but this is usually asymptomatic. The adult variant of endemic KS tends to follow an indolent course as well. In contrast, lymphadenopathic endemic KS progresses to fulminant, fatal disease. Iatrogenic KS is somewhat more aggressive than classic KS; however, lesions usually regress on discontinuation of immunosuppressive therapy. In epidemic KS, extracutaneous involvement is commonly encountered in lymph nodes, gastrointestinal tract, and lungs. Disseminated disease accounts for death in 10% to 20% of patients with epidemic KS.

On microscopical examination, KS varies according to patch, plaque, and nodular subtypes. The histologic changes in early patch-stage KS are inconspicuous, leading to misdiagnosis of a benign inflammatory process. A superficial and deep perivascular infiltrate with increased numbers of jagged vascular spaces is observed in the dermis. The thin-walled vessels surround normal vessels and adnexal structures, resulting in the so-called promontory sign. Plasma cells may be seen surrounding the newly formed vessels. In plaque-stage KS, the entire dermis and superficial fat may be involved, with an increase in the number of spindle cells arranged in small fascicles between collagen bundles centered around proliferating vascular channels. The spindle cells outline irregular slit-like vascular spaces that contain erythrocytes. In nodular KS, the number of spindle cells increases. They are arranged in interwoven fascicles with erythrocytes scattered in the interstices. Although nuclear atypia, mitotic figures, and pleomorphism may be observed, these are not prominent. Cells that stain positively for factor VIII-related antigen and spindle cells that stain positively for *Ulex europaeus* I lectin line well-formed vessels within KS lesions.

Both local and systemic therapies have been used in the management of KS, depending on epidemiologic context, extent of disease, and concomitant disease.<sup>279,290,291,292,293</sup> and <sup>294</sup> KS has been treated successfully using cryosurgery, RT, laser ablation, and intralesional injection of cytotoxic agents. Local infiltration with vincristine has been particularly effective in the treatment of oral lesions in epidemic AIDS-associated KS. Other, more aggressive approaches have included systemic therapy with interferon or with single- or multiagent chemotherapy. Tur and Brenner<sup>293</sup> treated 11 classic KS patients with low-dose subcutaneous interferon- $\alpha$  for 6 months. Initial response, defined as reduction of lesion size and fading of color, was noted in 9 of the 11 patients after 3 to 13 weeks of treatment. Maximum response was noted in 4 to 6 months, with remission lasting from 4 to 72 months. Experimental therapies including antiangiogenesis agents TNP-470 and thalidomide, 9-*cis* retinoic acid, and human chorionic gonadotropin may prove useful in management of KS in the future.<sup>295</sup>

## CARCINOMA METASTATIC TO SKIN

The relative frequencies of cutaneous metastases are similar to those observed with primary cancers.<sup>296</sup> The most frequently observed cutaneous metastatic cancers are breast, colon, and melanoma in women and lung, colon, and melanoma in men. Cutaneous metastases may represent an opportunity to detect a potentially treatable cancer before other evidence of it is present, to modify therapy as appropriate to the tumor stage or, possibly, to use the cutaneous lesion as a source of easily accessible tumor cells for specific therapy. Cutaneous metastatic disease as the first sign of internal cancer is most commonly seen with cancer of the lung, kidney, and ovary. Cutaneous involvement is also seen in the leukemias, with a wide variation in morphology of lesions.<sup>296</sup> The scalp is a common site for cutaneous metastatic disease (Fig. 41.2-32). Perhaps the most widely known cutaneous manifestation of an internal carcinoma is the Sister Mary Joseph nodule.<sup>297</sup> Dr. William Mayo's surgical assistant, Sister Mary Joseph, noted the association of the presence of an indurated umbilical nodule in the setting of gastric cancer with poor prognosis. The discovery of cutaneous metastatic disease should result in prompt consultation with an oncologist for staging and management ( Fig. 41.2-33).

FIGURE 41.2-32. The scalp is a common site for cutaneous metastatic disease.

MAC	MMS
Sebaceous carcinoma	Excision or MMS
AFX	MMS
MFH	WLE or MMS
DFSP	MMS with permanent section confirmation
Angiosarcoma	WLE or MMS with permanent section confirmation
Kaposi's sarcoma	Cryosurgery, intralesional, or systemic chemotherapy

FIGURE 41.2-33. The appropriate management of less common skin cancers may include wide local excision (WLE), Mohs micrographic surgery (MMS), cryosurgery, or intralesional or systemic chemotherapy. AFX, atypical fibroxanthoma; DFSP, dermatofibrosarcoma protuberans; MAC, microcystic adnexal carcinoma; MFH, malignant fibrous histiocytoma.

## CONCLUSION

The discovery of an atypical skin lesion should result in consultation with a dermatologist for evaluation. It is necessary that skin biopsy specimens be sent to a dermatopathologist for interpretation to minimize misdiagnosis and delayed treatment of skin cancers. Management of skin cancer is based on histopathologic analysis of a given lesion; hence, accurate interpretation of skin biopsy specimens is essential. After treatment for skin cancer, patients should be followed up regularly, through full-body skin examinations performed by a dermatologist, for the development of recurrences as well as new primary skin cancers.

#### BASAL CELL CANCER

Basal cell cancer, the most common cancer among humans, can present with a variety of clinical lesions. Familiarity with the spectrum of basal cell cancer permits early diagnosis, when treatment is most easily accomplished.

FIGURE 41.3-1. Nodular basal cell carcinoma on nasal tip. Note pearly, translucent appearance with telangiectasias.

FIGURE 41.3-2. Nodular basal cell carcinoma on right cheek. Note confluence of multiple nodular lesions with telangiectasias.

FIGURE 41.3-3. Nodular basal cell carcinoma of the left glabella with central depression. Note classic rolled borders and pearly appearance. There is also a large violaceous nodule in the left medial canthus. This long-standing lesion is an eccrine acrospiroma.

FIGURE 41.3-4. Large nodular basal cell carcinoma of the forehead with classic rolled border.

**FIGURE 41.3-5.** **A:** Nodular basal cell carcinoma of the forehead at the site of a previous automobile injury. The patient states that she had multiple fragments of glass removed over a long period of time. Basal cell carcinoma and squamous cell carcinoma are known to develop at the site of chronic scar. **B:** Microscopical example of nodular basal cell carcinoma demonstrating peripheral palisading of basal cells, retraction of tumor masses from dermis, and hyperchromatic cells. **C:** Defect following Mohs micrographic excision, demonstrating extension of cancer to the periosteum. The patient subsequently underwent skin flap repair.

**FIGURE 41.3-6.** Superficial basal cell cancer on the left upper lip of a 27-year-old woman. The patient, an aspiring actress, did not want treatment with surgery or radiation therapy. A course of intralesional interferon was successful at eliminating the cancer. It should be noted that this approach should only be used in superficial, easy to monitor basal cell cancer and has a recurrence rate of 20%.

**FIGURE 41.3-7.** Superficial basal cell cancer on an extremity. This lesion had been treated for many years as eczema and psoriasis. Topical corticosteroids provided no benefit. Any persistent rash that does not respond to topical treatment or is not otherwise diagnosed should be promptly biopsied.

**FIGURE 41.3-8.** Superficial basal cell carcinoma on trunk.

**FIGURE 41.3-9.** Pigmented basal cell carcinoma with nodular morphology.

**FIGURE 41.3-10.** Large pigmented basal cell carcinoma. The differential diagnosis includes melanoma.

**FIGURE 41.3-11.** Ulcerating basal cell carcinoma of the angle of the jaw.

**FIGURE 41.3-12.** Extensive basal cell carcinoma of the medial eyebrow and nasal root. Proximity to the supraorbital nerve raises the possibility of perineural extension of cancer in this long-standing carcinoma.

**FIGURE 41.3-13. A:** Large nodular basal cell carcinoma in the medial canthus. Deep extension of the cancer in this area can involve the lacrimal duct. **B:** Defect following Mohs micrographic surgery indicates complete elimination of cancer. The lacrimal duct was not involved.

**FIGURE 41.3-14.** Extensive basal cell carcinoma of the right medial canthus, nasal sidewall, and distal nose. Basal cell cancer is typically a slow-growing tumor, but neglect can result in extensive destruction sometimes requiring removal of the orbital contents.

**FIGURE 41.3-15.** Cystic basal cell carcinoma of the glabella. This tumor was misdiagnosed as a cyst until a biopsy confirmed that it was a basal cell carcinoma, cystic type.

**FIGURE 41.3-16.** Morpheaform basal cell carcinoma of the left chin. Note light coloration and smooth texture. Although it appears to be well demarcated, the infiltrative histologic nature of this cancer can be expected to result in a larger defect upon complete extirpation.

**FIGURE 41.3-17.** Long-standing morpheaform basal cell carcinoma of the left cheek. Note smooth, white appearance, slightly elevated from the surrounding tissue. Crust in the center is an indication of tumor necrosis. Patients who have this type of cancer diagnosed histologically must be prepared for the large extent of the defect.

**FIGURE 41.3-18.** Morpheaform basal cell carcinoma, a form of aggressive growth basal cell cancer, is noted on the right cheek of a 30-year-old woman. It had been long-standing and was noted to grow very slowly. Especially in young patients, the true extent of the cancer must be discussed in advance and proper preparation must be made so that optimal reconstruction results in the best aesthetic outcome. This cancer, located in the embryonic fusion plain, must be removed with Mohs micrographic surgery to minimize the chance of recurrence. Recurrent basal cell cancer, especially in this region, is at high risk for extension deep in the facial planes.

**FIGURE 41.3-19.** Poorly defined morpheaform basal cell carcinoma of the right upper eyebrow in a 55-year-old woman. The patient had this lesion for some time before noting that it had changed. The extent of the cancer is larger than it appears clinically. It is best treated with the Mohs micrographic surgery method.

**FIGURE 41.3-20.** Morpheaform basal cell carcinoma of the right upper eyebrow. The patient believed that she had a scar at the site for many years but could not identify an episode of related trauma. This is the classic appearance of a morpheaform basal cell cancer, the true extent of which is significantly greater than appears clinically.

**FIGURE 41.3-21.** Large basal cell cancer of the left upper outer arm. The cancer had been present for approximately three years before the patient sought treatment.

**FIGURE 41.3-22.** Extensive basal cell carcinoma of the left face. Although this is an extreme example, it highlights the potentially aggressive nature of basal cell carcinoma. Despite the very low risk of metastasis, the cancer can be extremely locally destructive and, if present near vital organs, lethal.

**FIGURE 41.3-23.** Young patient with a nevus sebaceus on the left cheek. This is a benign tumor of sebaceous glands but is associated with basal cell carcinoma. Current recommendations are that a nevus sebaceus be removed in young adulthood to minimize the risk of basal cell cancer.

**FIGURE 41.3-24. A:** Multiple small papules in the periorbital region. Patients may present concerned that these represent cancer. In fact, they are syringomas, or benign tumors of the sweat glands. No treatment is necessary. **B:** This patient was referred because of concern that the red patch on the cheek, of long-standing duration, represented basal cell cancer. This is the classic appearance of rosacea, an adult form of acne. The condition responds promptly to topical therapy.

**FIGURE 41.3-25.** Severe solar damage of left face. This is the classic setting for the development of non-melanoma skin cancer. Note fair skin, mottled pigmentation, and telangiectasias.

**FIGURE 41.3-26.** Close-up of patient in [Fig. 41.3-25](#). This patient has skin type I. When exposed to ultraviolet radiation from the sun, he always burns and never tans. The absence of the tanning response probably increases the risk for epidermal mutations from solar radiation. Actinic keratoses, hypopigmentation from previous cryotherapy, and telangiectasias are noted.

**FIGURE 41.3-27.** This patient has had lifelong problems with basal cell carcinoma. Some patients who received radiation therapy for acne later developed multiple basal cell cancers. Despite multiple surgeries, topical chemotherapy, and cryotherapy, the patient continues to develop new basal cell carcinomas.

**FIGURE 41.3-28. A:** This patient worked for many years in his youth as a lifeguard. Evidence of basal cell cancer and solar damage, as well as scar related to previous surgery, are noted. **B:** The same patient 10 years later with progressive basal cell cancer and areas of scar associated with basal cell cancer recurrence. Although we refer to these lesions as recurrences, histologic evaluation of the patient's facial skin indicates widespread basaloid budding in the epidermis, consistent with a field defect.

**FIGURE 41.3-29.** Elderly patient with multiple basal cell cancers. This patient has a history of arsenic exposure, which is associated with the development of basal cell carcinomas.

**FIGURE 41.3-30.** Nodular basal cell carcinoma on the nasal sidewall of a 40-year-old woman. Although most likely to be basal cell carcinoma, all such lesions must be biopsied. Melanoma and other forms of non-melanoma skin cancer are in the differential diagnosis, although they are less likely.

**FIGURE 41.3-31.** Ulcerated nodular basal cell carcinoma of the nose.

**FIGURE 41.3-32.** Nodular basal cell carcinoma of the left upper lip and alar groove. Basal cell cancer is thought to double in size over approximately 1 year. The size of this lesion suggests it has been present for many years. It is at risk for deep infiltration into the nasolabial groove.

**FIGURE 41.3-33.** Basal cell carcinoma of the tip of the nose. Because of the ill-defined margins of this cancer and its technically challenging location, Mohs micrographic surgery is indicated.

**FIGURE 41.3-34.** Basal cell carcinoma of the right nose. Patients must be advised of the likely size of the cancer, which is often larger than appears clinically. The final wound and reconstruction may be unsettling to the patient if he or she has not been properly prepared.

**FIGURE 41.3-35.** Small basal cell carcinoma of the left upper lip.

**FIGURE 41.3-36.** Basal cell carcinoma of the nose. Note the extensive nodularity under the surface of the skin. This cancer is likely to be at least 50% larger than it appears on the surface.

**FIGURE 41.3-37.** Nodular basal cell carcinoma of the left ala. This lesion is easily treated by Mohs micrographic surgery. Because of its presence in the alar groove,

healing by second intention is often an acceptable alternative plastic reconstruction.

**FIGURE 41.3-38.** **A:** Recurrent basal cell carcinoma on the left nose of an individual who works outdoors. Although very little scar tissue is noted on clinical exam, the cancer proved to be approximately twice the clinical size because of the extension of cancer cells within and under scar tissue. **B:** The defect following Mohs micrographic surgery. **C:** Immediately after Mohs micrographic surgery, the defect was repaired in a linear fashion, which will result in a fine-line scar. Patients must be advised that the complete healing process takes approximately 12 months. Maturation and fading of the scar continues during this whole period.

**FIGURE 41.3-39.** Ulcerating nodular basal cell carcinoma of the left alar rim. Because of its proximity to the alar rim as well as to the embryonic fusion plain, Mohs micrographic excision is indicated. A shallow defect in this area can be allowed to heal by second intention with excellent results. Alternatively, plastic reconstruction may be required to preserve normal anatomic and functional relationships.

**FIGURE 41.3-40.** Linear erosions on the right alar rim of a patient with a history of squamous cell cancer of the cheek. The patient also has a history of prurigo. The area was biopsied and failed to reveal any cancer. The patient admits to scratching. If topical treatment with corticosteroids fails to resolve the problem, a deeper biopsy may be indicated.

**FIGURE 41.3-41.** Nodular basal cell carcinoma on the left ala, similar to [Fig. 41.3-39](#).

**FIGURE 41.3-42.** Extensive basal cell carcinoma of the left nose. Mohs micrographic treatment surgery is the treatment of choice. The reconstruction technique depends on the final defect.

**FIGURE 41.3-43.** Large eroding basal cell carcinoma of the nasal bridge. This patient, of northern European ancestry, had worked outdoors his whole life. Several other basal cell carcinomas are noted on the cheek and lip.

**FIGURE 41.3-44. A:** Large basal cell carcinoma of the left ala. Note elevation and retraction of the alar rim. This is an indication of extensive deep infiltration by basal cell carcinoma. **B:** Defect following Mohs micrographic surgery. The patient was referred for complex flap reconstruction.

**FIGURE 41.3-45. A:** Large nodular basal cell carcinoma of the left upper lip and left nostril. **B:** Defect following Mohs micrographic surgery. It is essential to minimize the recurrence of cancer in this location, as recurrent tumor is likely to invade deeply. The patient was referred for plastic reconstruction. Recurrence of cancer under complex flaps may be concealed, so careful examination including bimanual palpation of the region is necessary.

**FIGURE 41.3-46. A:** Extensive basal cell carcinoma of the left upper lip. Excision with conventional margins would not have adequately removed the cancer. Mohs micrographic surgery was performed. **B:** Following Mohs micrographic excision with preservation of the orbicularis oris. **C:** After reconstruction using an Abbe flap. (Fig. 41.3-46C courtesy of Dr. Stephan Ariyan.)

**FIGURE 41.3-47.** Nodular basal cell carcinoma of the right upper lip.

**FIGURE 41.3-48. A:** Morpheaform basal cell carcinoma of the left cheek with indistinct margins. Excision by the Mohs micrographic surgery technique resulted in a 5-cm defect. The wound was repaired under local anesthesia at the time of Mohs surgery. **B:** Three months following reconstruction with cheek advancement flap.

**FIGURE 41.3-49. A:** Long-standing basal cell carcinoma of the left cheek. Note areas of nodularity, hypopigmentation, and crusting resulting from bleeding from the surface of the cancer. **B:** Extensive defect following Mohs micrographic excision demonstrates histologic extent of cancer. Incomplete excision of cancer is an important cause of recurrence. Proper preparation of the patient for the extent of this defect was essential. Repair was performed without complication.

**FIGURE 41.3-50.** Ill-defined extensive basal cell carcinoma of the left temporal region.

**FIGURE 41.3-51. A:** Neglected basal cell carcinoma of the right temporal region and ear. Cancer in this area, especially when long-standing, has the potential for deep invasion. **B:** Defect following Mohs micrographic surgery reveals temporalis muscle. **C:** Despite the very high cure rates associated with Mohs micrographic surgery, risk of recurrence is proportional to the size of the cancer. Because of concern about concealing any recurrence, the wound was allowed to heal by second intention. The wound is pictured here at approximately 4 weeks status post excision. **D:** Completely healed wound at 3 months. The patient did not wish to have reconstructive surgery done on the helix of the ear.

**FIGURE 41.3-52.** Basal cell cancer within the triangular fossa of the ear. Basal cell cancer on the antihelix is not uncommon, and the recommended treatment is Mohs micrographic excision.

**FIGURE 41.3-53.** Ill-defined nodular basal cell carcinoma of the forehead.

**FIGURE 41.3-54.** Large basal cell carcinoma of the right lower eyelid. Retraction of surrounding tissue indicates deeply infiltrative nature of the cancer. The patient was treated with Mohs micrographic surgery and referred for reconstruction to minimize the risk of ectropion.

**FIGURE 41.3-55.** Very large ulcerated basal cell carcinoma of the glabella.

**FIGURE 41.3-56.** Basal cell carcinoma of right lower eyelid in an African American. Although basal cell carcinoma is most common in light-skinned people, it can occur in more darkly pigmented individuals.

**FIGURE 41.3-57.** Ulcerated basal cell carcinoma on the root of the nose. The majority of facial basal cell carcinomas occur on the nose.

**FIGURE 41.3-58.** Extensive basal cell carcinoma of the left nose extending into the medial canthus and along the lower eyelid. Treatment of this cancer requires an interdisciplinary approach. Following Mohs micrographic surgery, the patient was referred for plastic reconstruction. Because of the large size of the lesion, the patient must be monitored for recurrence.

**FIGURE 41.3-59. A:** Extensive basal cell carcinoma in a young man. The location in the medial canthus, the long-standing nature of the cancer, and its size create a

high risk that if the lesion recurs it will extend into the orbit. The patient was treated with Mohs micrographic surgery. **B:** Defect following Mohs micrographic surgery demonstrating the canthal ligament.

**FIGURE 41.3-60.** Basal cell cancer of the nasal root extending into the medial canthus.

**FIGURE 41.3-61.** Large nodular basal cell cancer of the lower eyelid. Mohs micrographic excision was performed followed by plastic reconstruction. Based on its size, this lesion had been present for many years.

**FIGURE 41.3-62.** Extensive basal cell carcinoma with retraction of the medial canthus. This clinical appearance suggests that the cancer likely extends deeply and may be at risk for involving the infraorbital nerve.

**FIGURE 41.3-63.** Recurrent nodular basal cell carcinoma of the post-auricular sulcus. Basal cell cancer in this region can extend widely along the cartilage and posterior scalp before it is diagnosed. Mohs micrographic excision is indicated.

**FIGURE 41.3-64.** Nodular basal cell carcinoma within an area of previous excision consistent with recurrent cancer.

**FIGURE 41.3-65.** Extensive basal cell carcinoma of the ear and temple. Because of the extensive nature of this cancer, radiation therapy was used with a good result. The therapeutic plan was to use Mohs micrographic surgery if the cancer recurred.

**FIGURE 41.3-66.** Multiple nodular and papular lesions on the scalp in an individual with severe solar damage. Although the clinical diagnosis of the large lesion on the right is basal cell cancer, the red nodular lesions are concerning and require biopsy as well to obtain a definitive diagnosis.

**FIGURE 41.3-67.** Large superficial basal cell carcinoma on the right breast. This was successfully treated with radiation therapy, although Mohs micrographic surgery and reconstruction would have been an equally acceptable alternative.

**FIGURE 41.3-68.** Large nodular basal cell carcinoma on the chest. The differential diagnosis includes squamous cell carcinoma.

**FIGURE 41.3-69.** Basal cell carcinoma on the shin of a 60-year-old woman. Basal cell carcinoma on the lower extremity is more common in women than in men. This highlights the likely association between solar exposure, secondary to clothing styles, and basal cell cancer.

**FIGURE 41.3-70.** Additional basal cell cancer on the lower extremity in the same patient as in [Fig. 41.3-69](#).

**FIGURE 41.3-71.** Multiple basal cell carcinomas of the lower extremity with evidence of venous stasis changes. Treatment of cancer in this area is extremely difficult because of the dependent location and the resultant slow healing in older patients. Treatment by Mohs micrographic excision with healing by second intention provides excellent results. While skin grafting creates secondary wounds in the patient that require additional healing, new biologic dressings and allograft permit excellent healing while minimizing limitations on activity.

**FIGURE 41.3-72.** Large nodular basal cell carcinoma on the upper extremity.

**FIGURE 41.3-73.** Nodular basal cell carcinoma on the upper extremity, side view, indicating the exophytic nature. The differential diagnosis includes squamous cell cancer and melanoma.

**FIGURE 41.3-74.** Superficial basal cell carcinoma on the shoulder of a 45-year-old male. This lesion can be treated easily with electrodesiccation and curettage.

**FIGURE 41.3-75.** Basal cell carcinoma on the instep of an elderly woman.

**FIGURE 41.3-76. A:** Basal cell carcinoma with ill-defined clinical margins on the nasal tip of a 50-year-old man. The lesion had been treated for several years as rosacea. Biopsy confirmed the presence of rosacea but also revealed a few foci of superficial basal cell carcinoma. **B:** Defect following Mohs micrographic surgery.

**FIGURE 41.3-77.** Basal cell carcinoma on the philtrum complicated by an outbreak of herpes labialis. Surgery was deferred until the lesion resolved. Prophylactic antiviral medication was used. This case highlights the occasional misdiagnosis of basal cell carcinoma for herpes labialis. The chronic, recurring nature of both, in certain circumstances, may be responsible for the confusion. Basal cell cancer is not associated with a prodrome.

**FIGURE 41.3-78. A:** Basal cell carcinoma of the right medial canthus. This red, scaling lesion had been treated for many years as a form of eczema. Biopsy was eventually performed when the patient was seen by his dermatologist, and it revealed basal cell cancer. **B:** Defect following Mohs micrographic surgery. **C:** Two weeks after placement of a full-thickness skin graft. **D:** After complete healing of skin graft. **E:** Recurrent basal cell carcinoma at upper edge of graft 10 years after original surgery.

**FIGURE 41.3-79.** Multiple basal cell carcinomas in a severely sun-damaged patient. Compare this clinical presentation with that in [Fig. 41.3-25](#), [Fig. 41.3-26](#), [Fig. 41.3-27](#), [Fig. 41.3-28](#), and [Fig. 41.3-29](#). Surgery and radiation therapy are generally the only treatments currently available. Photodynamic therapy, incorporating the use of topical aminolevulinic acid, which avoids systemic adverse effects, holds promise for treatment of large numbers of lesions. The long-term benefit of this approach remains to be determined.

**FIGURE 41.3-80.** Multiple basal cell carcinomas in a patient who received radiation therapy for acne 50 years earlier. Any new therapeutic modality that is practiced on the skin today may yield unanticipated complications decades later. In most cases, it is difficult to anticipate what those effects might be, and the need for effective current management typically outweighs unknown delayed risks.

## NEVOID BASAL CELL CARCINOMA SYNDROME

Nevoid basal cell carcinoma syndrome is relatively rare and accounts for less than 0.5% of basal cell cancer cases. It is extremely important, however, because patients with this condition represent a management challenge. It is also important because the basal cell cancer gene was first identified in this group of patients.

The PTC gene has since been shown to be mutated in sporadic cases of basal cell cancer as well.

**FIGURE 41.3-81.** Multiple 2- to 4-mm, slightly pigmented papules are noted on the cheek of this individual with nevoid basal cell carcinoma syndrome (Gorlin's syndrome). It is now known that this syndrome, associated with a range of developmental defects, is caused by mutations in the PTC gene. Management of these tumors is often a challenge. Because of the multiple lesions, patients become frustrated with ongoing surgery. A comprehensive approach using a combination of electrodesiccation and curettage, cryosurgery, Mohs surgery in critical locations, and, in the future, photodynamic therapy permits control of the lesions. Intralesional interferon was also used in this patient with some success but has not proven routinely successful. Suppression of new cancers may be achieved with oral isotretinoin or related compounds, but side effects limit its use, and the cancer incidence returns to pre-treatment levels when medication is discontinued.

**FIGURE 41.3-82.** This patient has nevoid basal cell carcinoma syndrome and presented with multiple extensive basal cell cancers of the scalp, face, and trunk. She received radiation therapy as a child for medulloblastoma, and this may have increased the incidence of basal cell cancers of the scalp. After a persistent effort at removing individual lesions, it was determined that the continued growth rate necessitated complete removal of the scalp tissue. Whole-scalp skin grafting was performed.

**FIGURE 41.3-83.** Multiple basal cell carcinomas of the trunk are noted in the patient depicted in [Fig. 41.3-82](#). These can be treated with electrodesiccation and curettage or with cryosurgery. Excision is sometimes needed. On the back, the risk of recurrence must be considered, because the thickness of the dermis invites deep penetration of recurrent basal cell cancer.

**FIGURE 41.3-84.** A small basal cell carcinoma of the tip of the nose in a 14-year-old boy with nevoid basal cell carcinoma syndrome. When these lesions are small, simple electrodesiccation and curettage or excision with Mohs micrographic surgery followed by second intention healing often provides excellent results. Nonetheless, the tendency in this syndrome is to develop numerous skin cancers that eventually can make surgery impractical. The search for nonsurgical treatment options continues.

**FIGURE 41.3-85.** Nevus sebaceus on the left cheek of a 14-year-old girl. This benign congenital lesion has a well-documented tendency to transform into basal cell cancer. It is currently recommended that the lesion be considered for excision at or around puberty.

**FIGURE 41.3-86.** Nevus sebaceous of the scalp demonstrating area of alopecia and tumor nodularity. Because the location of this lesion makes it difficult to monitor for the development of basal cell cancer, excision is indicated. The additional benefit is the elimination of the area of alopecia.

## SQUAMOUS CELL CARCINOMA

Squamous cell cancer of the skin is most commonly caused by ultraviolet radiation from the sun. Its clinical distribution is the same as that of basal cell cancer, but this cancer does have the potential for metastasis. Identification of precursor lesions, known as *actinic keratoses*, is important, as is close management of patients who are immunosuppressed. The incidence of squamous cell cancer in these patients is increased compared with the general population. Approximately 2000 people per year die from metastatic cutaneous squamous cell cancer.

**FIGURE 41.3-87.** Dorsal hand demonstrating moderate to severe solar damage. Irregular pigmentation, skin laxity due to solar elastosis, and actinic keratoses are hallmarks of excessive sun exposure. Studies of such sun-damaged skin have demonstrated ultraviolet radiation-induced mutations in the tumor suppressor gene, p53.

**FIGURE 41.3-88. A:** Squamous cell carcinoma in the popliteal fossa of a middle-aged woman with extensive solar damage of the lower extremity. This lesion must be distinguished from a hypertrophic actinic keratosis by biopsy, and excision is indicated if squamous cell carcinoma is identified. **B:** Infiltrative squamous cell carcinoma at the base of the fourth toe in the same patient. This lesion was causing severe pain. Excision by the Mohs micrographic technique is indicated to minimize damage to adjacent anatomic structures and optimize the cure rate.

**FIGURE 41.3-89.** Multiple actinic keratoses, hypertrophic actinic keratoses, and early squamous cell carcinoma on the lower extremity of a patient similar to the one depicted in [Fig. 41.3-88](#). Squamous cell carcinoma of the lower extremity in women is a major challenge because of the frequent extensive nature of the lesions. Photodynamic therapy is currently being explored as an option for treatment of widespread disease. Surgical excision remains the standard treatment, but management of precancerous lesions by cryosurgery and topical medications such as 5-fluorouracil and imiquimod (experimental) may minimize the number of lesions that evolve into squamous cell cancer.

**FIGURE 41.3-90. A:** Severe solar damage on the dorsal hand of a 70-year-old man. This individual had fair skin and a history of extensive sun exposure. The lesions

noted on the dorsal hand include hypertrophic actinic keratoses, squamous cell carcinoma, and actinic keratoses. Squamous cell carcinoma in this area, as in other skin sites such as the temple and lip, can metastasize. Aggressive management of these lesions with monthly visits may help minimize the development of infiltrative squamous cell cancer. **B:** Multiple actinic keratoses on the lower extremity of a 60-year-old woman. Close monitoring is necessary to treat any squamous cell carcinoma that develops. Because of healing problems related to the lower extremities, extensive excision is often problematic. The tissue-preserving benefits of Mohs micrographic surgery as well as conservative tangential excision with cautery of the wound base contribute to successful management of the cancers in these patients.

**FIGURE 41.3-91.** Hypertrophic actinic keratosis in the digital web space. This lesion may be treated by cryosurgery, excision, or electrodesiccation and curettage.

**FIGURE 41.3-92.** Squamous cell carcinoma. This 4-mm lesion appeared clinically similar to an actinic keratosis. Because it persisted, a shave biopsy was performed, which confirmed the presence of squamous cell carcinoma.

**FIGURE 41.3-93. A:** Cutaneous horn on the helix of the right ear. This horn consists of keratin produced by well-differentiated squamous cell carcinoma and is best treated by Mohs micrographic surgery. Note previous scar superior to the site where a skin cancer was previously treated. Proximity of the horn to scar raises the possibility that it is a recurrent lesion. **B:** Cutaneous horn of the left helix. Note extension of squamous cell carcinoma beyond the immediate area of the protruding horn. One treatment option for this lesion is Mohs micrographic surgery. In this situation, the tissue-sparing method will likely permit preservation of underlying cartilage and optimum healing.

**FIGURE 41.3-94.** Extensive actinic keratosis of the right infraorbital area. This lesion is marked by a broad plaque of erythema and hyperkeratosis. Biopsy of the most atypical area is indicated. It would not be surprising for the biopsy to reveal squamous cell carcinoma in association with hypertrophic actinic keratosis. Excision is indicated because of the proximity to the eye and the likelihood of progression to invasion. Recurrence can be minimized by Mohs micrographic surgery.

**FIGURE 41.3-95.** Concretion of keratin and debris on the scalp of an individual with skin type I (which always burns and never tans in response to exposure to sunlight). The lesion had been present for many years. Removal of the debris, which was accomplished by pre-moistening with water, revealed the underlying

squamous cell carcinoma.

**FIGURE 41.3-96.** Similar to the patient depicted in [Fig. 41.3-95](#), hyperkeratosis in multiple areas is associated with severe solar damage and squamous cell carcinoma. Neglected squamous cell carcinoma in the temple and scalp may metastasize.

**FIGURE 41.3-97. A:** Similar to the patient in [Fig. 41.3-94](#), this patient has multiple areas of actinic keratosis and possible squamous cell carcinoma. The area was previously treated by cryosurgery. Note hypopigmented atrophic scarring. Treatment by electrodesiccation and curettage was performed in this case. **B:** Hypertrophic actinic keratosis of the nose in a 50-year-old woman. This lesion requires biopsy to rule out squamous cell carcinoma.

**FIGURE 41.3-98. A:** Extensive squamous cell carcinoma *in situ* (Bowen's disease) of the neck and jaw area. This region was previously treated by topical 5-fluorouracil but recurred. Mohs micrographic excision is an option, but the surgical defect would be extensive. A trial of imiquimod, an immunomodulator shown to have some effect on superficial skin cancer, was attempted. Alternatively, treatment by ultrapulse carbon dioxide laser may be palliative. Extension of Bowen's disease down the hair follicles, which may not be destroyed by laser or topical treatments, raises the possibility of recurrence and even the development of invasive squamous cell carcinoma. **B:** Microscopical example of squamous cell carcinoma *in situ* (Bowen's disease). Note thickened epidermis and large atypical squamous epithelial cells with a wind-blown appearance.

**FIGURE 41.3-99.** Multiple actinic keratosis associated with areas of Bowen's disease. The spectrum of sun-induced atypical epithelial lesions extends from actinic keratosis to Bowen's disease to invasive squamous cell carcinoma.

**FIGURE 41.3-100.** Small eroded nodule on the anti-helix of an elderly man. The differential diagnosis includes chondrodermatitis nodularis helices, which is usually painful, and squamous cell cancer, which may bleed but is usually not tender.

**FIGURE 41.3-101.** Ulcerated painful lesion on right ear. Biopsy is necessary to rule out squamous cell carcinoma. If chondrodermatitis is suspected because of pain on pressure, a trial of intralesional corticosteroid is a reasonable first approach.

**FIGURE 41.3-102.** Bowen's disease of the lower extremity demonstrating that squamous cell carcinoma *in situ* can develop in individuals with a range of cutaneous pigmentation.

**FIGURE 41.3-103.** Hypertrophic Bowen's disease of the lower extremity. Note hyperkeratosis, erythematous background, and extensive size of lesion. Bowen's disease may rarely be associated with arsenic exposure, but the most common cause is solar radiation.

**FIGURE 41.3-104.** Same patient as depicted in [Fig. 41.3-103](#) after treatment with emollients to remove hyperkeratosis. This was done in preparation for surgery.

**FIGURE 41.3-105.** Mohs micrographic surgery. After the cancerous area was prepared with local anesthesia, it was scored in accordance with the Mohs micrographic technique in preparation for removal and mapping of all margins. Because of healing issues related to the lower extremity, the tissue preserving method of the Mohs technique is the treatment of choice for this large lesion.

**FIGURE 41.3-106.** Squamous cell carcinoma *in situ* of the left ear in an immunocompromised patient. During complete extirpation by Mohs surgery, invasive squamous cell carcinoma was detected and removed. This highlights the fact that invasive squamous cell cancer can develop in long-standing lesions of Bowen's disease.

**FIGURE 41.3-107.** Recurrence of squamous cell carcinoma *in situ* within a scar line of a previous Mohs micrographic surgery excision. The small area recurred approximately one year after the initial treatment.

**FIGURE 41.3-108.** A 1.3-cm hypertrophic nodule in the center forehead on a patient with skin type I. The differential diagnosis includes squamous cell carcinoma, hypertrophic actinic keratosis, and inflamed seborrheic keratosis. Biopsy is indicated.

**FIGURE 41.3-109.** Infiltrating squamous cell carcinoma of the right cheek. The location of this lesion over the infraorbital nerve is a special concern. Careful questioning regarding symptoms referable to the infraorbital nerve is important prior to treatment. Imaging studies have not proved especially helpful, but new magnetic resonance imaging methods may help determine whether perineural invasion is present.

**FIGURE 41.3-110.** Squamous cell carcinoma *in situ* of the upper eyelid in a 70-year-old woman. This lesion had been present for approximately 20 years. The patient's physician advised her that it was eczema and treated it with a variety of topical medications. Despite the persistence of the lesion, a biopsy was not done until the patient consulted a dermatologist. Removal of the eyelid and orbital contents was recommended. The patient was referred for Mohs surgery, and the squamous cell carcinoma was removed in its entirety, preserving the upper eyelid for reconstruction. Upon removal of the cancer, invasive squamous cell carcinoma and perineural invasion was noted. The use of adjuvant radiation therapy in the management of perineural involvement by squamous cell cancer should be considered if the draining lymph node group is known. Six months after removal of the cancer, the patient developed metastases to the parotid gland and neck nodes.

**FIGURE 41.3-111.** **A:** Hyperkeratotic lesion of the chest present for several years in an elderly woman. **B:** Hyperkeratotic debris was removed with a moist gauze revealing friable, nodular squamous cell carcinoma.

**FIGURE 41.3-112.** Squamous cell carcinoma on the lower extremity. This patient had received ultraviolet A therapy with psoralens [psoralen plus ultraviolet A (PUVA)] for treatment of psoriasis. Note the extensive freckling and solar damage. Development of multiple squamous cell carcinomas is a known complication of long-term PUVA therapy.

**FIGURE 41.3-113. A:** Deeply infiltrative squamous cell carcinoma of the left jaw. **B:** Defect following Mohs excision demonstrating depth of cancer and thus risk of injury to facial artery and marginal mandibular nerve. **C:** Repair of defect under local anesthesia at time of Mohs surgery. Minimal undermining is performed to prevent the risk of extension of cancer in tissue planes should it recur.

**FIGURE 41.3-114.** Extensive squamous cell carcinoma of the chin in a middle-aged woman. This lesion had been present for some time. It demonstrates multiple keratin cysts resulting from the atypical epithelial cells of the well-differentiated squamous cell carcinoma. Despite the well-differentiated nature of the cancer, it was deeply infiltrative and involved the underlying muscle. After excision by Mohs micrographic surgery, adjuvant radiation therapy was performed.

**FIGURE 41.3-115.** Large squamous cell carcinoma of left forehead present for approximately 1 year. The lesion was removed by Mohs micrographic surgery and revealed presence of basal cell carcinoma as well.

**FIGURE 41.3-116.** Large cutaneous horn of the right jaw. This squamous cell carcinoma developed in a patient who previously underwent orbital exenteration for multiply recurrent basal cell carcinoma of the forehead and eye region.

**FIGURE 41.3-117.** Squamous cell carcinoma of the dorsal nose in a 75-year-old woman. Note the nodularity of this lesion.

**FIGURE 41.3-118.** Squamous cell carcinoma, keratoacanthoma type, at the oral commissure of a 55-year-old woman. This small lesion may be excised with margins or removed using Mohs micrographic surgery technique. Although keratoacanthoma has been considered a relatively benign self-regressing lesion, on the central face it can behave aggressively. It must be treated as a squamous cell cancer.

**FIGURE 41.3-119. A:** Squamous cell carcinoma, keratoacanthoma type, of the left temple. This lesion developed rapidly over a short period, which is the classic history for a lesion of this sort. Excision by Mohs micrographic surgery, conventional excision, radiation therapy, and intralesional methotrexate are options. The preferred treatment in this location is excision by Mohs micrographic surgery followed by immediate reconstruction if indicated. **B:** Recurrent squamous cell carcinoma, keratoacanthoma type, of the right lateral canthus. Note scar from previous surgery and retraction of lower eyelid indicating depth of penetration of this lesion. Although keratoacanthoma has previously been considered to behave in a benign fashion, it is now recognized as a form of squamous cell cancer and must be managed accordingly. Recurrent behavior highlights the potentially aggressive nature of this cancer. Mohs micrographic surgery was indicated to ensure complete removal. No recurrence has developed.

**FIGURE 41.3-120. A:** Large squamous cell carcinoma, keratoacanthoma type, of the left upper lip. Squamous cell carcinoma of this size and in this region is at risk for metastasis. **B:** Microscopical example of keratoacanthoma revealing squamous cell carcinoma in an eruptive cup-like formation.

**FIGURE 41.3-121. A:** Hyperkeratotic lesion on the right nose consistent with keratoacanthoma. Note that this does not have the typical appearance of the lesions depicted in [Fig. 41.3-118](#), [Fig. 41.3-119](#), and [Fig. 41.3-120](#). This patient elected not to undergo treatment. **B:** Same patient after lesion regressed on its own. Observation is not recommended as keratoacanthoma is a squamous cell carcinoma. Certain forms of intralesional chemotherapy may be considered depending on the clinical circumstances.

**FIGURE 41.3-122.** Large squamous cell carcinoma on the upper extremity of a 76-year-old woman. Excision is indicated, although this cancer would also likely respond to radiation therapy.

**FIGURE 41.3-123. A:** Eroded lesion in the nasolabial fold of a 50-year-old woman. This lesion was previously diagnosed as keratoacanthoma and treated with a variety of topical medications and cryosurgery. It failed to respond to treatment. The patient declined surgery and elected radiation therapy instead. **B:** The final cosmetic result after a course of radiation therapy. No recurrence has been reported.

**FIGURE 41.3-124.** Large infiltrative squamous cell carcinoma of the forehead. This lesion is at risk for perineural extension to the supraorbital and supratrochlear nerves. Sensory changes in the forehead may be an indication of nerve involvement by the cancer.

**FIGURE 41.3-125.** Microscopical example of perineural invasion by squamous cell carcinoma. The skip-like nature of perineural invasion makes it difficult to be certain that negative margins indeed reflect complete eradication of the cancer. Many recommend adjuvant radiation therapy as an additional means of preventing recurrence and extension. Use of radiation therapy in these situations must be determined by the overall clinical circumstances.

**FIGURE 41.3-126.** Recurrent squamous cell carcinoma in a previous surgical scar. The rapidly recurrent nature of the squamous cell carcinoma in this case suggests an aggressive behavior. Mohs surgery is indicated. Follow-up radiation therapy may be indicated as well.

**FIGURE 41.3-127.** Subcutaneous nodule above right eyebrow contiguous with an old scar. The clinical presentation was that of an epidermoid cyst. Despite the mobile nature of the lesion, because of the patient's history of previous squamous cell carcinoma and immune suppression, the lesion was excised and proved to be a squamous cell carcinoma. A high index of suspicion is necessary in any patient who is immunocompromised, as this group of patients is at high risk for the development of nonmelanoma skin cancer.

**FIGURE 41.3-128.** Multiple scalp nodules consistent with internal malignancy metastatic to the scalp. Absence of histologic connection with the epidermis confirms noncutaneous origin of cancer. Lung, breast, and colon cancer are among the most common internal malignancies that metastasize to the skin.

**FIGURE 41.3-129. A:** Recurrent squamous cell carcinoma of the central upper lip and right oral commissure in a patient with a long history of squamous cell carcinoma. The upper lip had been previously treated with radiation therapy for squamous cell carcinoma. **B:** Defect following Mohs micrographic surgery. **C:** Immediate appearance after reconstruction under local anesthesia at time of Mohs surgery. **D:** Final cosmetic result. In the interim the patient underwent Mohs surgery for excision of squamous cell carcinoma of the nose.

**FIGURE 41.3-130. A:** Squamous cell carcinoma adjacent to left lower lip. This large lesion is at risk for metastasis. Treatment by Mohs micrographic surgery may be followed by radiation therapy if indicated. **B:** Microscopical example of squamous cell carcinoma. Note large eosinophilic epithelial cells with enlarged hyperchromatic nuclei.

**FIGURE 41.3-131.** Small hyperkeratotic lesion on sun-damaged lower lip. The biopsy revealed squamous cell carcinoma. The lesion had been present for some time, and its early stage was clinically consistent with actinic cheilitis. Actinic cheilitis is equivalent to the precancerous condition noted elsewhere on sun-damaged skin referred to as *actinic keratosis*. Treatment of actinic cheilitis depends on the severity of the lesion, whether it is symptomatic, and whether the patient is considered at special risk for developing squamous cell carcinoma.

**FIGURE 41.3-132.** Squamous cell carcinoma on the lower lip of a man in his 30s. This individual works in a marina and has extensive sun damage. In addition, severe actinic cheilitis is present on the lower lip, which is more exposed to solar radiation than is the upper lip. The squamous cell carcinoma was treated by Mohs

micrographic surgery and proved extensive.

**FIGURE 41.3-133.** **A:** Squamous cell carcinoma of the left lower lip in an elderly gentleman. **B:** Defect following Mohs surgery indicating true extent of cancer. Because the cancer was not especially deep, it was allowed to heal by second intention with an excellent result. In addition, absence of flap reconstruction permitted monitoring for evidence of recurrence.

**FIGURE 41.3-134.** Long-standing extensive squamous cell carcinoma on the lower lip of a 65-year-old woman. This lesion was treated by Mohs micrographic surgery on three occasions. Each time the lesion recurred the cancer appeared more poorly differentiated. Eventually the cancer metastasized to the jaw. This highlights the potentially aggressive nature of squamous cell carcinoma of the lip and its risk for metastasis.

**FIGURE 41.3-135.** Large squamous cell carcinoma of the lower lip. This large, aggressive lesion was treated by Mohs micrographic surgery. Following excision, radiation therapy to the surgical site and draining lymph nodes must be considered and pursued based on the clinical circumstances.

**FIGURE 41.3-136.** Periungual wart. Long-standing periungual wart may be associated with carcinogenic subtypes of human papilloma virus. Biopsy is indicated to rule out squamous cell carcinoma *in situ*.

**FIGURE 41.3-137.** Squamous cell carcinoma *in situ* of the thumb. Mohs micrographic surgery is indicated to preserve tissue and obtain the highest cure rate. Even with the Mohs technique, because of the viral origin of this cancer and the presence of carcinogenic virus in normal-appearing adjacent skin, there is a risk of recurrence.

**FIGURE 41.3-138.** Squamous cell carcinoma of the distal finger. The patient was advised to have an amputation but elected to undergo Mohs micrographic surgery instead. The defect was allowed to heal by second intention, and the distal phalanx was preserved.

**FIGURE 41.3-139. A:** Squamous cell carcinoma *in situ* of the glans penis, also referred to as *Erythroplasia of Queerat*. The patient did not want to undergo a recommended penectomy, so Mohs micrographic surgery was performed. **B:** Defect following Mohs micrographic surgery. This was allowed to heal by second intention without any compromise of function.

**FIGURE 41.3-140.** Erythema and scale of the glans penis consistent with ill-defined squamous cell carcinoma *in situ*.

**FIGURE 41.3-141. A:** Multiple scars of the left temple indicating previous surgery in an elderly Mediterranean man. Small nodules are noted as well, representing recurrent squamous cell carcinoma and metastatic *in transit* squamous cell carcinoma. **B:** Defect following Mohs micrographic surgery. Surgery in this region is at risk for injury to the temporal branch of the facial nerve, which can result in brow and eyelid ptosis. This patient developed metastases to regional lymph nodes and died from his skin cancer.

**FIGURE 41.3-142. A:** A preauricular nodule present for several years. Biopsy revealed squamous cell carcinoma, and the lesion was removed by Mohs micrographic surgery. The cancer was deep-seated but did not extend to the parotid gland. **B:** Large nodule of the preauricular region. Clinically this was consistent with a basal cell carcinoma or squamous cell carcinoma. Biopsy is indicated to confirm the precise nature of the cancer prior to treatment. Because of its location, extension of the cancer into the retroauricular sulcus and metastasis to the parotid gland is a distinct possibility.

**FIGURE 41.3-143. A:** A 70-year-old man with extensive squamous cell carcinoma of the forehead. Note hypopigmentation from previous treatments with cryosurgery. **B:** Defect in the same patient following Mohs micrographic surgery. At the time of Mohs micrographic surgery, squamous cell carcinoma was found in a perineural distribution and infiltrating muscle. The decision was made to discontinue surgery and consider radiation therapy. Because of his age and the likely slow progression of this disease, the patient elected not to pursue further therapy. Management of complicated skin cancer must be based on the clinical setting and knowledge of the biologic behavior of the cancer.

**FIGURE 41.3-144.** Erythema, hyperkeratosis, previous skin graft, and irregular pigmentation are all consistent with severe solar damage of the scalp in this 69-year-old man. He previously underwent excision of squamous cell carcinoma of the scalp with grafting but continued to develop new squamous cell cancers. In an attempt to minimize the development of the cancers, the patient underwent carbon dioxide laser resurfacing to destroy the abnormal clones of epidermal cells thought to give rise to the actinic keratoses that can evolve into squamous cell cancer. He did relatively well after treatment with a decreased number of new lesions. This approach must be considered only in special circumstances in which close follow-up is possible. There is a theoretical possibility that the laser-treated site may conceal the development of invasive squamous cell carcinoma beneath the surface of otherwise well-healed skin.

**FIGURE 41.3-145. A:** Metastatic squamous cell carcinoma on the scalp of a 90-year-old man. The patient underwent multiple excisions of squamous cell carcinoma of the scalp but continued to develop new lesions within several months following each excision. **B:** The patient was referred for Mohs micrographic surgery. The post-surgical defect demonstrates the depth of the cancer invasion. This treatment was unsuccessful, as the patient continued to develop new *in transit* metastases.

**FIGURE 41.3-146.** Extensive squamous cell carcinoma of the scalp of a kidney transplant patient. Squamous cell carcinoma in renal transplant patients is very common and can behave aggressively. Close monitoring of these patients is essential to diagnose and treat cutaneous cancers at the earliest possible stage.

**FIGURE 41.3-147.** Extensive squamous cell carcinoma of the scalp in an elderly man. This lesion started as a small tumor, similar to the lesion noted in [Fig. 41.3-98](#). Despite aggressive treatment by Mohs micrographic surgery and radiation, the lesion continued to recur. The patient died from extension of the cancer through the calvarium and into the dura.

**FIGURE 41.3-148.** Extensive squamous cell carcinoma of the forehead with associated satellite lesions representing *in transit* metastasis.

**FIGURE 41.3-149. A:** Recurrent squamous cell carcinoma of the nose following radiation therapy. When seen at the time of his initial consultation, the patient complained of severe chronic pain in the nose. No clearly defined lesion was noted on palpation, but the bridge of the nose was distinctly firm and tender throughout. **B:** Biopsy on the left lateral nose revealed highly infiltrative squamous cell carcinoma. **C:** Complete rhinectomy resulted from Mohs micrographic surgery. Although margins were negative, the infiltrative nature of this cancer represented a high risk of recurrence. Following healing by second intention the patient continued to complain of pain in the upper maxilla. **D:** In order to monitor for recurrence, reconstruction was not performed. Instead a prosthesis was developed with which the patient was satisfied. Identification of cancer within the maxilla explained his ongoing pain and was treated by maxillectomy.

**FIGURE 41.3-150.** Extensive squamous cell carcinoma *in situ* of the left parietal scalp and ear. Because of the extensive nature of this lesion and the patient's desire to avoid surgery, radiation therapy was performed in multiple fractionated doses. He obtained an excellent result.

## NONSURGICAL MANAGEMENT OF NONMELANOMA SKIN CANCER

There is a variety of nonsurgical treatments that can be used in the management of skin cancer. Most are beneficial in the control of premalignant lesions such as actinic keratoses. Side effects of these treatments must be understood because they can limit compliance with the treatment regimen. In addition to the therapeutic approaches demonstrated here, photodynamic therapy may become a more realistic treatment possibility for a range of cutaneous cancers. Recent refinement of target compounds and the potential for topical administration, which minimizes side effects, have renewed interest in photodynamic treatment of skin cancer and pre-skin cancers.

**FIGURE 41.3-151.** An actinic keratosis on the forehead consisting of erythema and scale. This lesion is at risk for development into squamous cell carcinoma. Although the precise rate of malignant transformation is difficult to calculate, the molecular hallmarks of malignancy, such as mutation in the p53 tumor suppressor gene, occur in actinic keratoses as well as squamous cell cancers. Treatment of actinic keratoses must be based on the clinical circumstances. Single lesions may be treated by cryosurgery. Multiple lesions require management by topical chemotherapy.

**FIGURE 41.3-152.** The most effective way of treating an isolated actinic keratosis is cryosurgery. Here, a cotton-tipped applicator soaked in liquid nitrogen is applied to the actinic keratosis. The frosting of the actinic keratosis is the clinical end point of treatment. Overtreatment can result in hypopigmentation and scarring. If the

lesion recurs multiple times, biopsy is needed to rule out squamous cell cancer.

**FIGURE 41.3-153.** Erythema, crusting, and swelling secondary to treatment with 5-fluorouracil. This therapy, which has been in use for at least 30 years, can cause significant side effects that may limit patient compliance. The proper treatment course requires application for 4 weeks, although dermatologists customize treatment to patient needs. Combination regimens that include topical tretinoin and other compounds have been shown to provide some additional benefit.

**FIGURE 41.3-154.** This patient self-treated with 5-fluorouracil and developed culture-proven impetigo. The 5-fluorouracil was discontinued and the infection resolved with antibiotic therapy. No scarring is noted. Rare cases of cribriform scarring have developed with the extensive use of 5-fluorouracil. Patients who are initiated on this therapy should be seen after the initiation of therapy to evaluate the progress and determine the extent of reaction. Topical corticosteroids may be used to control the aggressiveness of the reaction.

**FIGURE 41.3-155.** This patient has a squamous cell carcinoma *in situ* of the glabella and declined surgery. 5-Fluorouracil was applied twice a day for 4 weeks. The patient developed this crust, as expected. After discontinuation of the treatment, complete resolution of the crust occurred. Close monitoring and rebiopsy to confirm the absence of any deeper tumor may be indicated based on the clinical exam.

**FIGURE 41.3-156.** This patient with extensive solar damage treated his scalp with 5-fluorouracil. He had a history of multiple hypertrophic actinic keratoses and squamous cell cancers. However, he was also anticoagulated with coumadin and developed hemorrhagic bleeding at the sites of erosion caused by the 5-fluorouracil.

**FIGURE 41.3-157.** Slightly pink, smooth skin appearance immediately after complete resolution of 5-fluorouracil treatment course. Although many patients obtain a sustained benefit from this treatment, it is not unusual to see the redevelopment of actinic keratoses in 6 to 8 months. In addition, 5-fluorouracil may eliminate superficial actinic keratoses but conceal the development of basal cell cancer or squamous cell cancer under the skin surface. Although this is not a very common occurrence, one must be alert to the possibility.

**FIGURE 41.3-158.** This patient had a large squamous cell carcinoma of the left cheek. After complete removal by Mohs micrographic surgery, it was decided to perform adjuvant radiation therapy. The erythema and swelling is typical at this stage in the radiation therapy course. Discomfort can be controlled with emollients and topical corticosteroids.

**FIGURE 41.3-159.** Large scar on the back of a 70-year-old woman. Previously this patient underwent radiation therapy for a basal cell carcinoma. Note the hypopigmentation, atrophy, scarring, and telangiectasias. This is a common result after radiation therapy. An erosion at ten o'clock required multiple biopsies because of the suspicion that recurrent basal cell carcinoma was present within and under the scar. Biopsies were negative indicating that the erosion was secondary to radiation tissue effects.

**FIGURE 41.3-160.** This patient underwent radiation therapy for a basal cell carcinoma of the left infraorbital cheek. He presented because of a small erosion and retraction five years after treatment. The nodule was present on palpation, but aggressive biopsy failed to reveal the presence of cancer. The scarring, retraction, and pigmentation change are not uncommonly seen after radiation therapy and can complicate the diagnosis of recurrent cancer.

**FIGURE 41.3-161.** This patient underwent Mohs micrographic surgery excision of a large basal cell carcinoma of the nose with subsequent reconstruction using a full-thickness skin graft. The erythema consisting of multiple telangiectasias secondary to new vascular growth is very common and makes the graft more prominent than it otherwise should be.

**FIGURE 41.3-162.** The patient underwent treatment with the pulsed dye laser, a technique used to treat telangiectasias, port wine stains, and other vascular tumors. This simple procedure effectively eliminated the blood vessels and improved the cosmetic result.

## MOHS MICROGRAPHIC SURGERY

**FIGURE 41.3-163. A:** Mohs micrographic surgery is a technique designed to provide maximal cure rate and optimal tissue preservation. In the first stage of Mohs surgery the tumor is debulked with a curette. A thin layer of tissue surrounding the curetted area is then excised in a horizontal fashion. The tumor is then divided into sections and mapped, denoting margins with different colored ink. **B:** The tumor specimen is then prepared for frozen section in the adjacent laboratory specifically designed for this procedure. Using a cryotome, the tumor is then sectioned across the inferior margin including the complete peripheral epidermal margin. Sectioning of the epidermal edge and dermis is made possible by the unique way in which the Mohs specimen is obtained, using a 45-degree beveled incision. **C:** Specimens are then evaluated microscopically and areas of residual tumor are noted on a map by the Mohs surgeon. Residual cancer is then excised according to denoted areas of cancer positivity. **D:** The specimens are then studied again and additional Mohs micrographic surgery stages are excised until the complete tumor has been extirpated. The final defect is then reconstructed or permitted to heal by second intention. (Figs. 41.3-163 A–D courtesy of Neil A. Swanson, M.D.)

**FIGURE 41.3-164. A:** 4-mm nodular basal cell carcinoma on the right lower eyelid margin. Basal cell cancer in this area is at risk for spread along the tarsal plate, resulting in a cancer that is larger than appears on clinical exam. To preserve important structures and obtain the highest cure rate, Mohs micrographic surgery was performed. **B:** Lower eyelid site after excision by the Mohs technique. **C:** The wound was allowed to heal by second intention, yielding an excellent cosmetic and functional result. Note that reconstruction is often not necessary with defects of this size because of the tissue preservation feature of Mohs micrographic surgery.

**FIGURE 41.3-165. A:** An infiltrative basal cell carcinoma of the right ala in a young woman. The area is curetted and then a Mohs micrographic stage is taken under local anesthesia. **B:** Defect following Mohs micrographic surgery indicating the true extent of the basal cell carcinoma. In this region the tissue preservation technique permits minimal destruction of tissue in an area that is challenging to reconstruct. **C:** A full-thickness skin graft is placed to yield the best cosmetic result. **D:** Final result after complete healing of the skin graft.

**FIGURE 41.3-166. A:** A large superficial multifocal basal cell carcinoma of the right upper ear. The patient was concerned that he might lose the upper half of his ear. He pursued Mohs micrographic surgery as an alternative. **B:** Defect following Mohs micrographic surgery indicating preservation of cartilage and ear anatomy. **C:** A full-thickness skin graft is placed at the time of Mohs surgery. **D:** A full-thickness skin graft 4 weeks after surgery indicating complete graft take with preservation of the ear anatomy.

**FIGURE 41.3-167. A:** An infiltrative basal cell carcinoma of the right nose in a 30-year-old woman. **B:** Defect following Mohs surgery resulting in preservation of normal anatomic and functional relationships. **C:** Linear repair of Mohs defect. Complex reconstruction is often not required in smaller lesions excised with Mohs micrographic surgery. **D:** Final result after plastic reconstruction provides a minimally noticeable scar with preservation of anatomic relationships.

**FIGURE 41.3-168.** **A:** Clinically ill-defined skin cancer on the dorsal nose. Mohs surgery is indicated because of the need to achieve the highest cure rate while preserving normal tissue in this cosmetically important area. **B:** Defect following Mohs surgery. **C:** Dorsonasal flap is used to repair the defect with adjacent tissue to provide the best cosmetic result.

**FIGURE 41.3-169.** **A:** Ill-defined infiltrative basal cell carcinoma on the nasal tip of a 33-year-old woman. **B:** Defect following excision indicating true histologic extent of cancer, which is greater than could be appreciated clinically. The tendency of basal cell carcinoma of this type to extend beyond the clinical margins highlights the value of the Mohs technique. **C:** The patient was referred to a plastic surgeon for forehead flap reconstruction of defect. Repair shown is 2 months status post reconstruction. The repair will continue to mature over time, and patients must be reassured of the fact that with time the cosmetic result will improve. The patient underwent several scar revisions. **D:** Several years status post final scar revision demonstrates excellent result. There was no evidence of recurrence.

**FIGURE 41.3-170.** **A:** An ill-defined morpheaform basal cell carcinoma of the left nasal tip and ala. Because of the inability to be certain of the extent of the basal cell cancer, Mohs surgery is indicated. **B:** Defect following Mohs micrographic surgery. The resulting shallow depth of the wound permits a variety of reconstructive options, including healing by second intention, skin graft, and flap. Because of the potential for elevation of the nasal tip, a full-thickness skin graft is performed. **C:** The full-thickness skin graft in place. **D:** Final result after healing of full-thickness skin graft. Note preservation of normal anatomic relationships of the aesthetically complex nasal tip unit.

**FIGURE 41.3-171.** **A:** Morpheaform basal cell carcinoma of the right infraorbital cheek. Repair of defects in this area has the potential for resulting in ectropion. **B:** Defect following excision. Note extent of defect is larger than would have been anticipated from the clinical appearance of the cancer but smaller than would have resulted with standard excisional margins. **C:** Linear repair oriented to minimize inferior traction on lower eyelid.

**FIGURE 41.3-172.** **A:** Recurrent basal cell carcinoma of the right cheek, below the eye. Note contracture resulting from residual scar tissue from previous treatment. In this situation one should anticipate a relatively large extent of cancer unpredictable from clinical exam. **B:** Defect following Mohs excision revealing extension of cancer into subcutis. **C:** Linear repair of defect is designed to conceal the final scar within natural skin tension lines and minimize ectropion. **D:** The final result at 3 months indicating well-healed scar with no ectropion.

**FIGURE 41.3-173. A:** Infiltrative basal cell carcinoma of the right ala. Careful clinical examination of the site failed to reveal significant clinical extension. **B:** Histologic specimen. Infiltrative basal cell carcinoma noted during Mohs excision. **C:** Defect following Mohs micrographic excision of infiltrative basal cell carcinoma of the right nose. Note that cancer extended onto the cheek. The patient was referred for plastic reconstruction.

**FIGURE 41.3-174. A:** Classic morpheaform basal cell carcinoma featuring a scar-like, smooth white appearance. Morpheaform basal cell carcinoma typically extends significantly beyond the clinical margins of the cancer. Its histologic behavior is characterized as aggressive growth. **B:** Defect following Mohs micrographic excision. This defect can be repaired in a simple fashion similar to the procedure used on the patient depicted in [Fig. 41.3-167](#).

**FIGURE 41.3-175. A:** Basal cell carcinoma previously untreated noted in the right nasolabial groove extending under the right ala. Basal cell cancer in this embryonic fusion plane can be expected to be significantly larger than the clinical appearance of the cancer suggests. In addition, extension through the plane, which represents the course of least resistance is thought by some cutaneous oncologists to result in the potential for deeply invasive cancer. **B:** Defect following Mohs micrographic surgery revealing extent of cancer to the vermillion border, and extending superiorly into and under the ala. The patient was referred for plastic reconstruction, and after several scar revisions, underwent laser resurfacing to optimize the appearance of the reconstructed site.

**FIGURE 41.3-176. A:** A long-standing basal cell carcinoma at the angle of the nasolabial fold and the left ala in a woman in her 30s. Palpation of the tumor indicated nodular extension beneath the surface. **B:** Defect following Mohs micrographic surgery revealing extension into the orbicularis oris and into the subcutis of the cheek. **C:** Infiltrative nests of basal cell cancer are noted adjacent to salivary tissue. The patient underwent plastic reconstruction but requires close observation for recurrence of cancer in this region.

**FIGURE 41.3-177. A:** Patient with surgical excision ulcer on right cheek. This patient was referred for Mohs micrographic surgery after intraoperative conventional excision with frozen sections revealed extensive positive margins. **B:** Infiltrating basal cell cancer noted on Mohs micrographic tissue section. **C:** Extensive defect is noted following complete extirpation of cancer by Mohs micrographic surgery.

**FIGURE 41.3-178. A:** Recurrent basal cell carcinoma of right temple. Recurrent cancer often involves extension of cancer cells throughout pre-existing scar tissue. It appears that the scar tissue planes permit broader extension of cancer than would otherwise occur. **B:** Defect following excision revealing the extent of cancer. Injury to the temporal branch of the facial nerve is a significant risk in this region but is unavoidable if cancer involves the nerve.

**FIGURE 41.3-179. A:** This patient had a lesion on the nose and cheek for at least 15 years. Because of the long-standing nature of the lesion and the likelihood of extensive disease, Mohs micrographic surgery was indicated. Complete cancer extirpation, as well as tissue preservation, is especially important when cancer is present in the central facial area. In addition, proximity to the embryonic fusion plane is another indication for controlled microscopic excision. **B:** Extensive defect following Mohs micrographic surgery. Although repair with complex flaps and other forms of tissue rearrangement may result in a good cosmetic result, despite the very high cure rate associated with the Mohs technique, there is a risk of recurrence. Minimizing complex repairs can permit recognition of recurrence at the earliest stages. The patient developed recurrent skin cancer under a forehead flap several years after the original surgery.

**FIGURE 41.3-180. A:** Long-standing basal cell carcinoma of the nasal tip. Following Mohs micrographic surgery, the complete nasal tip, including cartilage, was removed. Basal cell cancer infiltrated between the nasal cartilages. **B:** Forehead flap repair 2 months after reconstruction. The patient was referred to plastic surgery for reconstruction. The forehead flap option permitted repair of cosmetic unit with full-thickness tissue to compensate for extent of nasal loss due to cancer. Further revision of the flap under local anesthesia will achieve an improved cosmetic result.

## WOUND MANAGEMENT AND RECONSTRUCTION AFTER MOHS MICROGRAPHIC SURGERY

Following excision of skin cancer, whether using the Mohs micrographic surgery technique or conventional frozen section methods, reconstruction of the defect must be addressed. Options usually include plastic reconstruction ranging from simple linear closure to skin grafts and skin flaps. This series demonstrates a range of procedures that represent reconstructive options for defects resulting from relatively large skin cancer excisions. In most cases reconstruction can be performed in the office setting under local anesthesia. Key guidelines to follow include reconstruction within cosmetic units, minimization of repair, and an understanding of the long-term management implications of a particular solution with respect to the possibility of recurrent cancer. In general, the simplest approach that yields the best aesthetic results is preferred. Healing by second intention may often result in a cosmetic result superior to that of plastic reconstruction depending on the location, depth, and breadth of the defect. In cases in which the cancer has been removed using Mohs micrographic surgery, reconstruction is usually performed at the same time as a separate and distinct procedure. Alternatively the wound may be allowed to heal by second intention. In another strategy, the team approach is employed. Mohs micrographic surgery can be performed on one day, and reconstruction can be performed by a reconstructive surgeon at any point thereafter, including the same day. If adjuvant radiation therapy is anticipated, it is usually not initiated until the wound or plastic reconstruction has healed completely, most commonly at 6 weeks.

**FIGURE 41.3-181. A:** This nasal tip defect resulting from excision of a basal cell carcinoma is especially difficult to reconstruct, because it involves the soft triangle of the nose. Of the many available options, reconstruction using a bilobed transposition flap is chosen. **B:** Immediately after transposition of the flap into the wound, there is evidence of excellent blood flow ensuring the likelihood of flap viability. This procedure takes approximately 30 minutes under local anesthesia. Patients who smoke, diabetics, and others with compromised blood supply are at a greater risk of flap failure. **C:** Side view of the original defect site at 4 weeks, demonstrating healing flap and preservation of alar rim. **D:** Frontal view of repair indicating matching texture of flap tissue with that of adjacent skin. Patients must be advised that the healing process takes approximately 12 months, and fullness and bulkiness of any flap will resolve with time. Early scar revision is usually not indicated. The alar rim is contiguous, and there has been successful reconstitution of the soft triangle of the nose.

**FIGURE 41.3-182. A:** Large defect involving part of the nasal ala, upper lip, nasolabial fold, and cheek. This defect can be repaired in a variety of ways, but there must be special attention paid to the fact that it traverses several cosmetic units. In general the simplest approach that yields the best cosmetic result is preferable. **B:** An island pedicle advancement flap was incised inferior to the defect and advanced superiorly. It survives on a vascular pedicle including muscle and subcutis. Once advanced into the defect, the flap is sutured in place. **C:** Reconstruction as it appears at 3 months postoperatively. Note preservation of natural facial skin lines. This will continue to improve over time and, because of the simplicity of the repair, permit identification of any recurrence of skin cancer in this critical embryonic fusion plane.

**FIGURE 41.3-183. A:** Large nasal defect on the side of the nose. This would heal well by second intention. The process would take approximately 4 weeks until the wound filled with granulation tissue and closed with epidermal resurfacing. Further wound contraction would result in a final scar approximately one-third of the original defect. Because of the desire to obtain the best cosmetic result, reconstruction was selected. **B:** A transposition flap was created borrowing skin from the nasolabial fold and transposing it into the defect. Lateral cheek skin was advanced into the nasolabial fold to close the secondary defect. Sutures will be removed in approximately 1 week, and continued improvement can be expected.

**FIGURE 41.3-184. A:** A very large defect of the nasal bridge involving the nasal cartilages. The reconstructive options include a delayed pedicle forehead flap, skin graft, and healing by second intention. The patient did not want to undergo the extensive surgery involved in a forehead flap. A skin graft would have resulted in an unsatisfactory cosmetic appearance. Healing by second intention would have been similarly unsatisfactory. A further option was explored. **B:** A bilateral transposition flap was performed borrowing skin from the cheek on each side of the nose. This procedure, performed under local anesthesia, permitted positioning of adjacent tissue, which closely matched nasal skin in color and texture. **C:** The appearance of the repair 4 months following surgery. Note minimal appearance of scar lines and preservation of natural contours of the nose. It should be noted that patients with fair skin and good facial blood supply tend to heal extremely well. This simple repair is an excellent alternative to more complicated reconstructive procedures when the patient prefers a simple approach.

**FIGURE 41.3-185. A:** This large defect involved removal of much of the left nasal ala and extended into the cheek and nasolabial fold. The patient had a history of cardiac disease and was not considered a candidate for surgery under general anesthesia. Allowing the wound to heal by second intention might have resulted in deformity and possible closure of the nostril with limited airflow. The decision was made to reconstruct the defect with local tissue. **B:** A combined repair involving a nasolabial transposition flap and island pedicle flap to re-create the lining and floor of the nose was performed. **C:** Final result at 6 months. Although the ala does not match that of the other side, it is functional and cosmetically acceptable to the patient. No evidence of recurrence is noted.

**FIGURE 41.3-186. A:** Large defect of right temple following excision of a large basal cell cancer by Mohs micrographic surgery. Reconstructive options included full-thickness skin graft, split-thickness skin graft, and healing by second intention. Because of the relative extent of the cancer and the patient's lack of desire to

undergo further surgery, the wound was allowed to heal by second intention. **B:** Granulation tissue has completely filled the wound by 4 weeks. In another 2 weeks, the wound will heal over with epidermis. In the subsequent 6 to 12 months, contraction of the wound will result in a final scar that will be approximately 30% of the original wound diameter. Wound contraction is an impressive feature of healing by second intention and must be anticipated when considering allowing a wound to heal in this fashion. For example, certain defects surrounding the eye can result in ectropion if allowed to heal by second intention.

**FIGURE 41.3-187. A:** A large defect of the scalp extending into the periosteum. This patient had multiple medical problems and elected not to undergo flap reconstruction. Moreover, flap reconstruction may be problematic if recurrence develops and cancer spreads under the galea. Healing by second intention was not an option because of exposure of the outer table. Human skin allograft was placed as illustrated here. **B:** The same patient at 10 to 14 days postoperatively demonstrating vascularization of human skin allograft. This approach minimizes wound care and stimulates normal healing. In the vast majority of circumstances, the human skin allograft will be rejected at 2 to 4 weeks, revealing well-granulated base that subsequently heals by second intention. **C:** Final wound result after sloughing of human skin allograft and complete healing by second intention. This scar will continue to improve in texture and color over many months. In addition any recurrence of cancer should be easily noted.

## RECURRENT SKIN CANCER

While most nonmelanoma skin cancers are easily managed with a range of approaches, if recurrence develops the tumor can behave in an aggressive fashion. This series depicts the clinical behavior of recurrent nonmelanoma skin cancer and highlights the advantages of achieving the highest cure rate when the cancer presents as a primary lesion. Recurrence of skin cancer relates not only to the thoroughness of the original treatment but also to the intrinsic biologic behavior of the cancer. Often, second cancers will develop near the site of previous treatment and in fact do not represent recurrent tumor. A patient who has had one basal cell cancer has a 40% chance of developing a second new skin cancer.

**FIGURE 41.3-188. A:** Recurrent basal cell carcinoma on the tip of the nose. **B:** Defect following Mohs micrographic surgery reveals extension onto columella and into the soft triangle of the nose. A wound such as this can heal by second intention or with a skin graft. Extension of the cancer beyond the clinical margins is typical for recurrent basal cell cancer.

**FIGURE 41.3-189.** Recurrent basal cell carcinoma developing within the scar line of a previous skin cancer excision. The presence of basal cell cancer within the scar line is an indication of recurrent cancer probably resulting from incomplete removal at the time of the original excision. Although the literature suggests that incomplete basal cell carcinoma will frequently not recur, these studies do not take into account the histologic subtype of the basal cell cancer.

**FIGURE 41.3-190. A:** Multiply recurrent basal cell carcinoma of the left forehead. Of note are a depressed skin graft and an area that appears shiny and white. The patient was referred for Mohs micrographic surgery because of the recurrent nature of the cancer. **B:** Defect following Mohs micrographic excision with extension of the wound down to periosteum. **C:** Following reconstruction with a full-thickness skin graft. Although not cosmetically optimal, this repair permits monitoring for recurrence in this large infiltrative basal cell carcinoma.

**FIGURE 41.3-191. A:** Recurrent basal cell carcinoma of the forehead. This patient underwent multiple previous procedures for removal of the basal cell carcinoma. **B:** Defect following Mohs micrographic surgery demonstrating extension of cancer into the upper eyelids. In many cases, recurrent basal cell cancer may develop squamoid features and demonstrate more aggressive behavior with recurrence. **C:** Full-thickness skin graft in place. This cancer is at a very high risk for recurrence despite the Mohs technique. Recurrence will result in extension of cancer along the medial canthus. **D:** Wound is healing well with complete take of graft at 6 weeks. Central crust will resolve with normal grafted skin underneath. Close monitoring, including palpation in the periorbital area, is essential.

**FIGURE 41.3-192. A:** Multiple scars indicating previous adjacent tissue transfers. The patient had undergone multiple excisions for basal cell carcinoma in the past, and each time residual cancer was noted. The patient was advised by his physician that basal cell carcinoma is not serious and there is no need to re-excise. The patient presented for evaluation because of the crust located in the scalp area. **B:** Defect following Mohs micrographic surgery performed under local anesthesia in the office setting. **C:** Infiltrating basal cell carcinoma noted tracking along the galea. **D:** Full-thickness skin graft in place at 1 year. **E:** The patient continued to traumatize the scalp and developed erosions on a regular basis. Clinically, the distinction had to be made whether this represents a recurrent basal cell cancer or simply poor healing due to trauma in a full-thickness skin graft.

**FIGURE 41.3-193. A:** Eighty-year-old woman with multiple basal cell carcinomas of the forehead. Previously, the patient had superficial basal cell carcinomas, which were treated with dermabrasion. Because of our current knowledge of the biology of basal cell cancer, this approach would not be considered optimum. **B:** Microscopical example of superficial basal cell carcinoma demonstrating extension into dermis. Elimination of this cancer by dermabrasion is not feasible and can result in the creation of multiple bands of scar in which recurrent skin cancer can develop. **C:** Defect following Mohs excision of recurrent basal cell carcinoma. Note extension of cancer down to periosteum. The patient was referred for reconstruction.

**FIGURE 41.3-194.** Recurrent basal cell carcinoma of the left upper lip. This cancer developed at the site of previous cryotherapy. The scar created by previous treatment provided sanctuary for cancer cells to extend. The defect can be expected to be larger than the clinical lesion.

**FIGURE 41.3-195. A:** Recurrent basal cell carcinoma on the right cheek surrounding previous site of electrodesiccation and curettage. Electrodesiccation and curettage are appropriate for small superficial skin cancers but are not as effective as excision at removing basal cell carcinoma that is infiltrative, nodular, or large. **B:** Defect following Mohs micrographic surgery reveals extensive nature of cancer that spread through scar tissue bands. In this region, extension into the parotid gland and injury to CVII are risks.

**FIGURE 41.3-196.** **A:** Recurrent basal cell cancer in right preauricular region. **B:** Extensive defect similar to that in Figure 41.3-195 but extending onto the ear and towards the ear canal.

**FIGURE 41.3-197.** Marginal recurrence of basal cell carcinoma at site of previous excision of basal cell cancer. The patient underwent multiple previous conventional excisions of the skin cancer, each time developing marginal recurrence. It is conceivable that the Mohs micrographic surgery may have limited the number of recurrences in this situation. Alternatively it appears that certain basal cell carcinomas have an aggressive behavior and may recur independent of the surgical technique used.

**FIGURE 41.3-198.** Recurrent basal cell carcinoma on the chest. Note the white scar indicating the previous site of electrodesiccation and curettage.

**FIGURE 41.3-199.** Recurrent basal cell carcinoma on the neck. This widespread multifocal superficial basal cell carcinoma on the neck surrounds a site of previous electrodesiccation and curettage. Excision by Mohs micrographic surgery is indicated.

**FIGURE 41.3-200.** Multiple recurrent areas of basal cell carcinoma surrounding a cryosurgery scar. Excision is indicated because of the tendency of the cancer cells to extend beneath the scar tissue and the clinical difficulty in determining the true extent of the cancer.

**FIGURE 41.3-201.** Recurrent basal cell carcinoma on the upper extremity of a young woman. Note the previous electrodesiccation and curettage scar and the recurrence of basal cell carcinoma at the margin. Recurrence of basal cell carcinoma at the margin in this as in [Fig. 41.3-198](#), [Fig. 41.3-199](#), and [Fig. 41.3-200](#) suggests the incomplete nature of electrodesiccation and curettage at the peripheral edges.

**FIGURE 41.3-202.** Recurrent basal cell carcinoma at the right lateral canthus. Note retraction of the lower eyelid and the large nodule. This cancer is very large and requires Mohs micrographic surgery for adequate excision.

**FIGURE 41.3-203.** Recurrence of basal cell carcinoma in the right nasolabial fold had been treated multiple times by conventional excision and recurred each time despite the report of negative margins.

**FIGURE 41.3-204.** Defect following Mohs micrographic surgery indicates deep extension into the nasolabial fold. It is believed that this embryonic fusion plane provides low resistance to deep tracking of the tumor.

**FIGURE 41.3-205.** Histologic features of infiltrative basal cell carcinoma as noted in the patient of [Fig. 41.3-204](#).

**FIGURE 41.3-206. A:** Multiply recurrent basal cell carcinoma on the nose and medial canthus of a 68-year-old man. **B:** Following Mohs micrographic surgery, the defect extends into the medial canthus, onto the cheek, and over the midline of the nose. Over the subsequent 8 years, the patient underwent repeat excisions because of recurrence, despite the use of Mohs micrographic surgery. The tumor had an infiltrative histology. Eventually cancer tracked under the floor of the orbit and an orbital exenteration was performed. **C:** The patient 1-year status post exenteration of the orbital contents and contiguous facial soft tissue. **D:** The orbital prosthesis is in place. **E:** Orbital prosthesis. The technology is available now to create very acceptable prostheses. Reconstruction in this patient would have been unacceptable because of the high risk of recurrence and the need to monitor for the development of new cancer, which, in this case, could be life threatening because of extension into the brain.

**FIGURE 41.3-207. A:** This patient underwent multiple excisions of basal cell carcinoma in the left nasolabial fold over the course of 10 years. Repair with a forehead flap had been done most recently. **B:** She presented with recurrence of skin cancer on the left upper lip. Mohs micrographic surgery combined with intraoperative conventional excision resulted in complete removal of the nose and medial canthus. The cancer extended into the glabella and tracked under the base of the flap and its origin on the forehead. This highlights the tendency of recurrent cancer to track under flap reconstruction without evidence of recurrence until there has been widespread cancer growth. **C:** Same patient with nasal prosthesis in place.

**FIGURE 41.3-208. A:** Recurrent basal cell carcinoma of the left upper lateral eyebrow. Previously, the patient underwent radiation therapy to this site and developed recurrence at multiple foci. **B:** Defect following Mohs micrographic surgery with removal of cancer in its entirety.

**FIGURE 41.3-209. A:** Basal cell carcinoma of the nasal tip. Previously this patient underwent radiation therapy for a basal cell carcinoma in this area and received treatment to the whole nose. Note cutaneous changes of telangiectasias, hypopigmentation, and atrophy. **B:** Defect following Mohs micrographic surgery. Extensive cancer invaded the cartilage and extended onto the cheeks. The patient underwent reconstruction.

**FIGURE 41.3-210.** Basal cell carcinoma at the site of a previous scar. The patient was unaware of any previous trauma or skin cancer treatment at this site. Basal cell carcinoma is known to develop at the site of long-standing scar.

**FIGURE 41.3-211. A:** This patient had multiple recurrences of basal cell carcinoma of the back starting many years earlier with treatment by electrodesiccation and curettage. Each time the cancer recurred, it appeared to invade more deeply and become more aggressive. He underwent Mohs micrographic surgery. **B:** Defect

following Mohs micrographic surgery indicating extension deep into muscle of the back. **C:** Histologic specimen indicating deep infiltration of basal cell carcinoma. **D:** Despite successful healing by second intention, the patient developed recurrent basal cell carcinoma, and the decision was made to perform radiation therapy. This treatment failed as well. Long-standing, aggressive, large basal cell carcinomas that undergo squamous differentiation have the potential to metastasize, but this is extremely rare. When it does occur, treatment options are limited.

## RARE SKIN TUMORS

While the vast majority of skin cancers are basal cell carcinoma and squamous cell carcinoma, other nonmelanoma skin cancers do occur and, because they present on the skin, can be diagnosed by biopsy at presentation.

**FIGURE 41.3-212.** Dermatofibrosarcoma protuberans (DFSP) noted on the dorsum of the left hand of a 35-year-old woman. The patient first noted the lesion around the time that she received an intravenous infusion at that site. It grew slowly over time. DFSP is a slow-growing sarcoma of skin that may initially be confused with a benign dermatofibroma. Complete excision is indicated, and Mohs micrographic surgery is now considered the treatment choice. Because of the irregular growth pattern, conventional excision with standard wide margins may not completely remove the tumor. Metastasis is rare and usually occurs in circumstances where the cancer has recurred multiple times.

**FIGURE 41.3-213.** Recurrent DFSP in a skin graft adjacent to the clavicle in a 30-year-old man. This cancer had been present for some time prior to initial excision. At that time the cancer extended into the region of the brachial plexus and further surgery was deferred because of the risk. Margins remained positive at the time of the completion of the initial surgery. A skin graft was placed, and this small nodule was noted several years later. Mohs micrographic surgery was performed, and the cancer was removed in its entirety. Close monitoring is essential, because the lesion, with a history of deep positive margins, is at risk for recurrence.

**FIGURE 41.3-214.** Dermatofibrosarcoma protuberans on the nose of a young child. This lesion had been excised with the clinical diagnosis of a cyst. The pathology revealed dermatofibrosarcoma protuberans, and further excision was indicated. This cancer does occur in children, although it is not as common as in older patients.

**FIGURE 41.3-215.** Two lesions are noted. On the left there is a linear scar from the excision of a lesion that was considered to be a dermatofibroma. There are forms of dermatofibroma that may be hard to distinguish histologically from dermatofibrosarcoma protuberans. In this case evaluation by a skilled pathologist is necessary. The use of special stains such as CD-34 is usually helpful. Inferior and to the right of this lesion is a classic dermatofibroma which is represented by an 8-mm, dome-shaped tan nodule. A complete biopsy was performed of this lesion because of the patient's history, but there is nothing about the clinical appearance of this lesion that is concerning, nor is biopsy normally indicated for dermatofibroma.

**FIGURE 41.3-216.** Leiomyosarcoma is noted on the right outer arm of a 50-year-old man. This patient presented because of continued growth of the lesion, which he had been told was scar tissue. Several years earlier a similar lesion was excised, and the patient was advised that it was not malignant. Review of the original's lines confirmed that it was not possible to make a diagnosis of malignant tumor at that time. However, excision of this lesion down to fascia and careful examination of the pathology revealed that it was a leiomyosarcoma.

**FIGURE 41.3-217.** Merkel cell carcinoma on the leg of an elderly man. This large cancer can behave much like a melanoma, with potential for metastatic spread. Wide local excision and radiation therapy are indicated. Mohs surgery is advocated by some.

**FIGURE 41.3-218.** Microcystic adnexal carcinoma of the cheek on a 45-year-old man. The lesion had been present for many years prior to seeking treatment. A microcystic adnexal carcinoma is believed to originate from the sweat gland apparatus. Although it tends not to metastasize, it can behave aggressively and demonstrate perineural invasion. If this occurs, cure rate is diminished.

**FIGURE 41.3-219.** Microscopical example of microcystic adnexal carcinoma indicating structures similar to sweat glands and the infiltrative nature of the cancer.

**FIGURE 41.3-220. A:** A microcystic adnexal carcinoma of the nose demonstrating infiltration of the nasal bridge, distortion the soft triangle of the nose, and erosion in that region as well. This had been a long-standing lesion. **B:** Following Mohs micrographic surgery, which is the treatment choice for this condition, partial rhinectomy resulted. Cancer infiltrated between the nasal cartilages. Reconstruction was performed using a forehead flap.

**FIGURE 41.3-221.** Microcystic adnexal carcinoma of the chin highlighted by a small area of white papules on the right lateral inferior chin area. Surrounding erythema is identifiable and approximates the true extent of the cancer, which involved most of the lower chin area.

**FIGURE 41.3-222.** Angiosarcoma of the scalp. The cancer appears as a hemorrhagic patch that does not blanch on compression. This patient progressed to develop nodules and erosions requiring extensive surgery. Angiosarcoma is extremely difficult to treat with chemotherapy, and radiation therapy does not provide consistent results. In addition, the histologic nature of the cancer is such that there are often skip lesions, and negative histologic margins are no indication of complete eradication of the cancer.

**FIGURE 41.3-223. A:** This patient has multiple small papules, noted for several years. A biopsy was done to rule out basal cell carcinoma. Histology revealed angiosarcoma. The patient underwent Mohs micrographic surgery and reconstruction. Subsequently, and not surprisingly, the cancer recurred in noncontiguous areas. The patient received radiation and several cycles of chemotherapy. **B:** Same patient after multiple excisions and reconstruction. In addition the patient received radiation therapy to the central facial area, which resulted in breathing complications. Because of the metastatic potential of this cancer, routine monitoring with CT scan and full physical examination is necessary. **C:** Patient developed a new nodule of angiosarcoma in the glabellar area. He had already completed multiple courses of chemotherapy, and the decision was made to treat this lesion symptomatically. It was excised with margins down to the periosteum, which was involved by angiosarcoma. Overall this patient has done well during the 7-year course of his disease without any evidence of metastatic disease.

**FIGURE 41.3-224.** Purplish nodule on the nose of a 30-year-old woman. This lesion was an angiosarcoma. Wide excision was successful in eliminating the lesion.

**FIGURE 41.3-225.** The violaceous plaque with erosion on the scalp of a woman in her 60s. This patient had this lesion for several years before it became darker and thicker. Physicians had treated it with laser, assuming it was a benign vascular tumor. When biopsy was performed, angiosarcoma was identified. In this case the changes of angiosarcoma were very subtle and required consultation with multiple dermatopathologists. Excision was performed initially with Mohs micrographic surgery, but eventually multiple areas of recurrence required complete removal of the scalp tissue with full-thickness skin grafting. The patient did well for approximately 5 years until she presented with a lytic lesion of the posterior parietal scalp. Imaging studies revealed a large infiltrating mass compressing the dura and infiltration of the calvarium by angiosarcoma.

**FIGURE 41.3-226.** Atypical fibroxanthoma of the arm. This sun-induced tumor is normally seen in elderly men. It has a low potential for metastasis but can behave aggressively and requires excision. Mohs micrographic surgery is the treatment choice.

**FIGURE 41.3-227. A:** A young patient demonstrating a tumor of the right lower eyelid. **B:** The same patient many years later demonstrating the effect of neglecting basal cell carcinoma. This cancer must be considered incurable. (Photograph courtesy of Israel Dvoretzky, M.D.)

**FIGURE 41.3-228.** Long-standing infiltrative basal cell carcinoma of the right cheek in a 95-year-old man. The patient was unable to undergo surgery, and the family declined radiation therapy. A course of intralesional interferon was unsuccessful. This cancer is at high risk for extension into the parotid gland and involvement of the facial nerve.

## PIGMENTED LESIONS

Pigmented lesions include benign moles or nevi, atypical nevi, melanoma, and a range of benign epithelial tumors. This series depicts a range of pigmented lesions, highlighting those that should arouse a high index of suspicion for malignancy. Melanoma is most curable when it is diagnosed in its earliest stages. A melanoma that is up to 1 mm in depth has a 96% cure rate with simple local excision. Any lesion that is suspicious for melanoma or an atypical nevus should be promptly biopsied. The clinical photographs represent the spectrum of pigmented lesions with which patients present to their dermatologist.

**FIGURE 41.3-229. A:** Seborrheic keratosis of right cheek. This very common pigmented lesion has a rough, greasy surface and may often be confused with a melanoma by the patient because of the pigmentation. The visit to the doctor provides an opportunity to perform a full body skin examination. **B:** Multiple seborrheic keratoses of the trunk. These lesions are very common and accumulate with age. They are benign proliferations of epidermis and do not transform into malignancy.

**FIGURE 41.3-230.** Compound nevus. This normal mole is slightly darker than the surrounding skin color. The papillated surface is not uncommon. Note the regular border.

**FIGURE 41.3-231.** Several nevi are noted in this picture. The central lesion is slightly irregular with darker pigmentation in the center surrounded by a rim of tan coloration. These features suggest that this mole may be atypical, especially in comparison to the surrounding nevi. Biopsy of the central lesion is indicated.

**FIGURE 41.3-232. A:** Two nevi are noted. The one on the right is approximately 2 mm in diameter and is regular in coloration. There is no indication of atypicality. The larger lesion is approximately 5 mm in its longest diameter and has irregular pigmentation. These atypical features are concerning, and biopsy is indicated. A tangential biopsy is sufficient to determine whether further excision is needed due to the degree of atypicality of the nevus. **B:** This large nevus has irregular pigmentation, a notched border, and a relative lack of symmetry. It is difficult to identify from the photograph, but one must be concerned about the possibility of an atypical nevus at the least and melanoma at the worst. Biopsy is required.

**FIGURE 41.3-233.** Congenital nevus of the right neck. This lesion has been present since birth. It has slightly irregular pigmentation that has been unchanged during the life of the patient. Close monitoring is indicated, but biopsy at the earliest sign of any change is necessary.

**FIGURE 41.3-234.** Slightly irregular dark nevus. Note how the dark pigmentation is different from surrounding pigmented lesions in this fair-skinned individual. Biopsy is indicated to rule out melanoma.

**FIGURE 41.3-235.** Nevus of the left lateral dorsal foot. Nevi on the extremities can occur. If there is any suspicion of melanoma or atypical nevus, biopsy is required.

**FIGURE 41.3-236.** Multiple nevi on a patient who is being followed for a history of atypical moles. Note the central irregular mole that has a notched border and irregular pigmentation. Careful monitoring of patients with multiple moles may be accomplished with serial photography. Biopsy should be performed on any lesion that demonstrates a change when compared to photographs, or in the opinion of the patient or physician.

**FIGURE 41.3-237.** A congenital mole characterized by large size, brown pigmentation, regular border, and normal skin surface markings. Opinion varies about whether congenital nevi smaller than 1 cm need to be removed. In general any congenital mole smaller than 1 cm may be monitored.

**FIGURE 41.3-238. A:** Large congenital nevus on the anterior shin of a patient with a history of melanoma. Because of this history it is judicious to ensure that the congenital nevus is removed in its entirety. Therapeutic options include excision with skin grafting or staged excision. The author prefers the latter in this situation, as it causes minimal discomfort and provides a superior cosmetic result. In the first excision the majority of the lesion is excised in an elliptical fashion to permit linear approximation of wound edges. **B:** Healed nevus after first stage of excision. **C:** Final result after second excision of residual nevus. This was performed approximately 3 months after the first excision. Note well-healed scar with no evidence of residual nevus.

**FIGURE 41.3-239.** Large congenital nevus of the trunk with areas of irregular pigmentation. The risk of transformation to melanoma over time increases with the size of the congenital nevus. Excision in this situation would help minimize the need to monitor for malignant transformation.

**FIGURE 41.3-240.** Labial lentigo in an 18-year-old with a history of sun exposure. This lentigo has regular pigmentation and a well-circumscribed border. The risk that this represents a malignant lesion is very low, but biopsy may be performed without complication. When multiple lesions of this sort are noted, Peutz-Jeghers syndrome must be considered.

**FIGURE 41.3-241.** Blue nevus is noted on the cheek of a middle-aged woman. The blue nevus represents pigment cells located within the dermis. The blue coloration is due to the Tyndall effect, light reflecting off pigment deep within the dermis. The differential diagnosis must include melanoma. Common blue nevi are benign, although cellular blue nevi have the potential for malignant transformation.

**FIGURE 41.3-242.** Lentigo maligna, also called melanoma *in situ*, noted on the right cheek of a man with severe solar damage. Lentigo maligna can transform over many years into invasive melanoma. Treatment is often complicated by its large size. Atypical melanocytes are confined to the epidermis, and there is no risk of metastasis as long as the lesion has not transformed into invasive lentigo maligna melanoma. Lentigo maligna was historically referred to as *Hutchinson's melanotic freckle*. The treatment of choice is excision with 5-mm margins. This approach can be complicated by the fact that at the periphery of the lesion, it is sometimes difficult to distinguish sun-damaged melanocytes from truly malignant cells. In addition, the occurrence of these lesions on the face sometimes limits the margin of tissue that may be taken.

**FIGURE 41.3-243.** Recurrent lentigo maligna on the nose of a 75-year-old woman. This patient underwent excision of extensive lentigo maligna on the nose with skin graft placement. Note recurrent lentigo maligna resulting from migration of malignant cells from marginal skin.

**FIGURE 41.3-244. A:** Lentigo maligna, which is most commonly seen in elderly patients, can be extensive. Often, the broad extent of the malignancy precludes surgical excision. This patient was not a surgical candidate but had extensive long-standing lentigo maligna. On an experimental basis, the Q-switched ruby laser was used to treat the lesion with the concern that although the pigment may be removed, amelanotic malignant cells may persist. This presents a theoretical risk of developing invasive melanoma that might not be identified because of the absence of pigmentation. This approach is considered experimental and necessitated by the unique clinical challenge presented by this case. **B:** The patient underwent several treatments with the Q-switched ruby laser, and clinical elimination of lesion was achieved. Most notable was the complete elimination of labial lentigo maligna. Follow-up biopsy failed to reveal any malignant cells. Further rigorous studies are needed to determine the role of laser in the management of inoperable lentigo maligna.

**FIGURE 41.3-245.** Lentigo maligna of the left jaw. This patient presented for laser treatment of this liver spot because of cosmetic concerns. Because of the size of the lesion, biopsy was performed, which confirmed the presence of lentigo maligna. In this case surgical excision is feasible, and laser was not indicated.

**FIGURE 41.3-246.** Tan, slightly irregular pigmented lesion of the shin in a patient with extensive solar damage. Although this lesion has the appearance of a melanoma *in situ*, the scale that is noted confirms that clinically this is most likely a seborrheic keratosis.

**FIGURE 41.3-247. A:** Long-standing irregularly pigmented patch on the cheek of a 65-year-old woman. The patient presented for cosmetic treatment of this lesion. Biopsy revealed lentigo maligna. **B:** The extent of the lesion was identified using ultraviolet light, which highlights areas of epidermal pigmentation. Those margins were marked as shown, and excision was performed with 3 to 5 mm beyond the identified area. Rush permanent histologic sections permit identification of residual areas of lentigo maligna that require further excision. Once all of the lentigo maligna is removed, the patient may undergo reconstruction. Careful monitoring is required because of the tendency of this type of lesion to recur in sun-damaged skin.

**FIGURE 41.3-248.** Irregularly pigmented nodular lesion. Note asymmetry, irregular border, variegated color, and diameter greater than 5 mm. This is a melanoma until proven otherwise by biopsy.

**FIGURE 41.3-249.** A regularly pigmented dark nodule. The differential diagnosis includes melanoma and seborrheic keratosis.

**FIGURE 41.3-250.** Superficial spreading melanoma in the radial growth phase. Neglect of this lesion or aggressive behavior will result in transformation into the vertical growth phase, thus increasing the risk of metastasis. Early diagnosis of melanoma is the single best approach to obtaining the highest cure rate. The role of sentinel node biopsy is currently under study but is increasingly recommended for intermediate- and some early-stage melanomas.

**FIGURE 41.3-251.** Nodular malignant melanoma. The dark coloration, size, and nodularity make the diagnoses obvious.

**FIGURE 41.3-252.** Microscopical example of nodular melanoma with atypical melanocytes extending into the dermis.

**FIGURE 41.3-253.** Irregular pigmentation under the nail. The differential diagnosis includes hemorrhage and melanoma. Often a clear history of trauma is helpful in clarifying the diagnosis. If the lesion is not obvious hemorrhage, biopsy is necessary to rule out melanoma.

**FIGURE 41.3-254.** Pigmented band in the thumbnail of a 70-year-old man. The lesion had been present for many months. The diagnosis in this fair-skinned individual is melanoma until proven otherwise. A biopsy was performed following avulsion of the nail under local anesthesia, and the histology revealed a simple lentigo.

**FIGURE 41.3-255.** Lightly pigmented band extending from the proximal nail fold to the distal toe at the medial edge of the nail plate. This long-standing lesion had begun to change in color. After the nail was avulsed, a biopsy was performed of the nail matrix, and melanoma *in situ* was identified. Further excision with margins was performed and the wound was allowed to heal by second intention.

**FIGURE 41.3-256. A:** Irregular growth of the nail plate associated with a nodule under the medial aspect of the great toenail raised the suspicion of an amelanotic melanoma. **B:** After avulsion of the nail, a digital fibroma was identified and removed. Biopsy confirmed the benign nature of this growth.

**FIGURE 41.3-257.** Irregular black pigmented lesion on the sole of an African American. This represents an acral lentiginous melanoma. The development of melanoma on the sole is the reason why full body skin examination must include a careful examination of that area, including the interdigital web spaces.

#### INTRODUCTION

The normal human melanocyte adheres singly to the basement membrane of the epidermis with five to six keratinocytes between each cell. Despite normally resting, melanocytes maintain a lifelong proliferation potential. With their dendrites, they reach to keratinocytes in the upper layers of the epidermis to distribute the pigment melanin. Melanin is packaged in melanosomes and provides protective coloration against the damaging effects of ultraviolet (UV) irradiation. Developmentally, melanocytes arise from pluripotent cells of the neural crest. Their survival, migration to the skin, and differentiation is related to spatial and temporal expression of molecules, not only on the migrating cells, but also on juxtaposed other cell types and the extracellular matrix. Defects during development in genes associated with melanocyte migration lead to complete or partial loss of pigment-producing cells in the skin, whereas defects in genes of the pigmentation pathways lead to presence of melanocytes but absence of pigmentation.<sup>1</sup> Genes specific for either melanocyte development or pigmentation are potentially important determinants for melanoma, but a causal relationship has not yet been established. Growth factor receptor genes such as c-kit or endothelin receptor-B (EDNRB) could have a potential role in the pathogenesis of melanoma. Stem cell factor, the ligand for c-kit, is a strong mitogen for normal melanocytes, but has little effect on melanoma cells because expression of c-kit is down-regulated through as yet unknown mechanisms.

The type of pigment, eumelanin versus pheomelanin, present in the melanosomes appears to be related to susceptibility for development of melanoma.<sup>2,3</sup> Those individuals who produce pheomelanin instead of eumelanin are at higher risk for developing melanoma. Preliminary investigations have revealed mutations in the gene for the receptor for melanocyte-stimulating hormone (MC1R). Apparently specific point mutations in the MC1R gene correlate with high susceptibility for melanoma,<sup>4</sup> but not all studies came to the same conclusions.<sup>5,6</sup>

The incidence of melanoma has increased in the United States from 3 cases per 100,000 in 1950 to 13 cases in 2000 with annual increases of 2.5%. This yearly increase is among the highest of all human cancers. In 1999, 44,000 new cases are expected in the United States, with approximately 9000 deaths from the disease. There are no indications that the rate of increase will be slowing in the near future. Fortunately, diagnosis of melanoma in more recent years occurs at an earlier stage, resulting in higher cure rates than two decades ago. Thus, mortality has not increased as steeply as incidence rates.

#### ETIOLOGY OF MELANOMA

Knowledge of the etiology of melanoma comes predominantly from epidemiologic, less from genetic, studies. UV exposure at the ultraviolet B (UVB) (290 to 320 nm) and ultraviolet A (UVA) (320 to 400 nm) range is the most important, if not the only, causative agent for sporadic melanoma development. Predisposition for poor tanning in combination with high sun exposure provides the largest accumulative risk factor for melanoma development. Risk factors for melanoma development over a lifetime are, in decreasing order from less than tenfold to less than twofold: presence of over ten dysplastic nevi, presence of over 100 common acquired nevi, fair skin (types I and II), red hair, and high intermittent sun exposure (i.e., blistering sunburns as a child).<sup>7,8,9</sup> and <sup>10</sup> Excessive intermittent sun exposure is more prevalent in individuals from higher socioeconomic classes.

The melanoma-inducing effects of UV light have been demonstrated in experimental animal systems. Irradiation with UV light sources in the B range induced melanomas in *Xiphophorus* fish and *Monodelphus domestica*.<sup>11,12</sup> and <sup>13</sup> UVA could also transform melanocytes in the highly susceptible *Xiphophorus* fish.<sup>14</sup> Preliminary experimental evidence of melanoma induction by UVB comes also from a human skin/mouse chimera model, in which the human skin was grafted to severe combined immunodeficient (SCID) or recombinaase activating gene (RAG) knockout mice and then treated with the carcinogen 7,12-dimethylbenz[a]anthracene followed by chronic UVB irradiation over 9 months.<sup>15,16</sup> In this model, which comes closest to the conditions in humans, melanocytic hyperplasia is seen after 4 to 5 months, followed 2 to 3 months later by atypia in lentiginous lesions. Human melanomas have developed but rarely.

#### GENETICS OF MELANOMA

Cytogenetic analyses over the last two decades have identified in melanoma cells at least six different chromosomes with loci showing nonrandom deletions, translocations (rarely), or amplifications (rarely). Extensive research efforts in the late 1980s and early 1990s focused on chromosomes 1, 6, 7, 9, 10, and 11 ( [Figure 42.1-1](#)). The severe aneuploidy of melanoma cells has made it difficult to identify specific regions because each chromosome showed several affected regions. Whereas few laboratories have continued their efforts on the cytogenetic analysis of melanoma cells, most are currently concentrating on screening specific loci or on genome-wide scans. Cytogenetic studies have helped to identify the 9p21 locus, which is frequently affected in melanoma. Intensive research efforts have identified mutations in the p16<sup>INK4a</sup> gene, which localizes in this region. The p16<sup>INK4a</sup> is affected through germline mutations or deletions in patients with familial melanoma,<sup>9</sup> which represent 8% to 10% of all melanoma cases. Approximately 50% of familial melanoma patients have germline abnormalities at chromosome 9p21,<sup>17</sup> making this the most frequently abnormal locus. Of these, approximately 50% have mutations or deletions in the p16<sup>INK4a</sup> gene. Thus, p16<sup>INK4a</sup> abnormalities represent approximately 5% of all melanomas. They are also significant in sporadic melanomas, in which 25% to 40% of all lesions have mutations or deletions or in which the gene is functionally silenced ( [Table 42.1-1](#)). Besides p16<sup>INK4a</sup>,<sup>9</sup> only the cyclin-dependent kinase (CDK4) gene has been found mutated in familial melanoma, but only two families have been identified to date.<sup>18</sup>

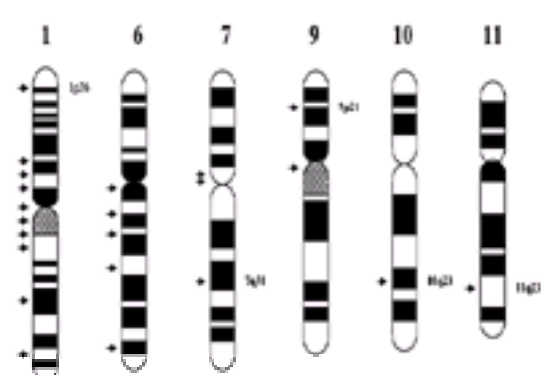

FIGURE 42.1-1. Identification of regions in human chromosomes with melanoma-specific abnormalities.

Gene	Abnormalities	Frequency (%)
p16 <sup>INK4</sup>	Mutation/deletion/silencing	25-40
Ras	Mutation	5-25
PTEN	Mutation/deletion	6
p53	Mutation	5
β-Catenin	Mutation	3
Fas	Mutation	3
Others		<1
PKC-α	Mutation	
c-myc	Mutation	
CDK4	Mutation	
NF-1	Mutation/deletion	
EWS-ATF	Translocation	

**TABLE 42.1-1.** Gene Abnormalities in Lesions of Patients with Sporadic Melanomas

Among sporadic melanomas, mutations have been found in ras genes with the frequency ranging between 5% and 25%. The wide range is due to differences in the site of the lesions among the studied patients' cohorts. Melanomas in the sun-exposed face have relatively higher proportions of ras mutation than those in sun-protected areas.<sup>16</sup> p53, phosphatase and tensin homologue deleted on chromosome 10 (PTEN) and b-catenin mutations are each around 5% of melanoma cases.<sup>2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23</sup> and <sup>24</sup> Further studies are needed to determine for each lesion the relative frequency of each of the six major genes listed in [Table 42.1-1](#). Some lesions may accumulate several abnormalities to account for a lower overall percentage of melanomas with defined genetic aberrations. Little is also known about the sequence of gene defect accumulations in melanomas. With the exception of ras mutations, all abnormalities appear to occur in late stages of progression. Nevertheless, the aberrations have important biologic implications for melanoma progression.

## FUNCTIONAL SIGNIFICANCE OF SPECIFIC GENE MUTATIONS IN MELANOMA

### CELL-CYCLE-REGULATING GENES IN MELANOMA

Proliferation in melanocytes is tightly controlled in the late G<sub>1</sub> phase of the cell cycle through a number of checkpoint-modulating proteins. These include cyclins (cyclins A, B, D, and E),<sup>25</sup> CDKs such as CDK2, CDK4, CDK6, CDC2, CDK8,<sup>26</sup> CDK inhibitors such as p16<sup>INK4a</sup>, p15<sup>INK4b</sup>, p21<sup>WAF1/CIP1</sup>, p27<sup>KIP1</sup>,<sup>27,28</sup> and <sup>29</sup> pocket proteins of the retinoblastoma (Rb) family (p107, p130, p105),<sup>30</sup> E2F transcription factors (E2F 1 through 6),<sup>31</sup> and other regulatory proteins ([Figure 42.1-2](#)). A clear definition of the restriction point in the cell cycle has enabled further characterization of each protein in relation to its effects on the cell cycle. Separation of pre-S phase G<sub>1</sub> cells from postmitotic G<sub>1</sub> phase by the restriction point relays the mitogenic signals from growth factors to cell-cycle regulatory proteins. In melanoma, growth factors such as basic fibroblast growth factor (bFGF) and insulin-like growth factor-1 (IGF-1) can stimulate the cells to progress from the restriction point interface to the pre-S phase. Combined with their ability to act as survival and maintenance factors, growth factors can stimulate the expression of positive regulators such as cyclins and CDKs or suppress CDK inhibitors and pocket proteins.

**FIGURE 42.1-2.** Cell cycle regulatory proteins in melanoma. Regulation by p53, Rb, cyclins, cyclin-dependent kinases (CDKs), and CDK inhibitors during the melanoma cell cycle. MDM2, murine double minute 2.

D-type cyclins (D1, D2, and D3) are induced in response to the presence of growth factors and, unlike other cyclins, do not oscillate during cell-cycle.<sup>32</sup> This growth factor-sensing ability allows the cells to synthesize D-type cyclins and interact with their CDK partners such as CDK4 and CDK6, and initiates autonomous cell-cycle entry. The main function of cyclin D-dependent kinases is phosphorylation of Rb in mid G<sub>1</sub> phase and at least cyclin D is required for the import of CDK4 into the nucleus. Subsequently, cyclin E-CDK2 becomes active and phosphorylates Rb on other sites. The main role of cyclins A and B-dependent cdc2 kinase appears to be the maintenance of Rb in its hyperphosphorylated form during the cell division before its hypophosphorylation during the next G<sub>1</sub> cycle. Hyperphosphorylated Rb in late G<sub>1</sub> phase does not associate with the various E2F family members, thereby allowing efficient transcription of a number of target genes, especially those involved in DNA synthesis during S phase of the cell cycle.<sup>28,33</sup>

The CDK inhibitors belong to two classes: the Cip/Kip and INK4 families. The most prominent protein among Cip/Kip family proteins is p21<sup>WAF1/CIP1</sup>; others include p57<sup>KIP2</sup> and p27<sup>KIP1</sup>. p21<sup>WAF1/CIP1</sup> is able to associate primarily with CDK2, in addition to other CDKs, and can interact with proteins involved in DNA repair and replication. It also has been identified as a protein induced by the p53 tumor suppressor protein. On DNA damage, p53 is stabilized and acts as a transcription factor, which, in turn, stimulates expression of p21<sup>WAF1/CIP1</sup>. This induction of p21<sup>WAF1/CIP1</sup> inhibits cell-cycle progression by inhibiting cyclin-CDK complexes and by inhibiting DNA synthesis through proliferating cell nuclear antigen.<sup>34,35</sup> The INK4 family members consist of p16<sup>INK4a</sup>, p15<sup>INK4b</sup>, p18<sup>INK4c</sup>, and p19<sup>INK4d</sup>. The hallmark of this group of proteins is that they are able to inhibit specifically the assembled cyclin D/CDK4/6 activity, and expression directly correlates with the Rb phosphorylation status. Another protein is encoded from the same p16 gene but from a different reading frame, p19<sup>ARF</sup>, which acts as a tumor suppressor for the p53 pathway by inhibiting the effect of MDM2 (murine double minute 2) on p53. At this time, there are no known abnormalities in the p19<sup>ARF</sup> gene in melanoma or other cancers.<sup>36</sup>

### b-CATENIN PATHWAY

b-Catenin is a multifunctional protein that is involved in cell-cell adhesion during tissue morphogenesis and tumor growth.<sup>37,38</sup> Its expression levels and subcellular localization are tightly regulated.<sup>39</sup> In the absence of a Wnt signal or when not associated with adherens junctions, b-catenin is present as a large multiprotein complex that consists of glycogen synthase kinase 3b (GSK3b), adenomatous polyposis coli (APC), and axin ([Figure 42.1-3](#)). Phosphorylation in this complex targets b-catenin for proteolytic degradation by the ubiquitin-proteasome system.<sup>40,41</sup> When the Wnt signaling pathway is activated via ligand binding to *frizzled* receptors, GSK3b function is inhibited. b-Catenin then accumulates, interacts with TCF/LEF-1 (T-cell factor/lymphoid enhancer factor-1) transcription factors, and activates transcription of promoters of genes containing TCF/LEF-1 binding sites.<sup>42</sup> Posttranscriptionally, b-catenin's fate is regulated by at least two proteins that control GSK3b. Akt/protein kinase B (PKB), which is activated by growth factor receptors and integrins through phosphoinositide 3 kinase (PI3), phosphorylates GSK3b, thereby inhibiting its ability to phosphorylate b-catenin, leading to its degradation.<sup>43,44</sup> *Dishevelled*, which is a predominantly cytoplasmic protein, is regulated by *frizzled*.<sup>44</sup> *Dishevelled* contains an axin-like domain, a PDZ (three proteins) domain (involved in protein interactions), and the DEP domain (implicated in G protein regulation)<sup>45,46</sup> and it interacts with axin to regulate GSK3b, thereby influencing b-catenin. In addition, overexpression of axin can suppress the effect of b-catenin in

cells. Mutations in the b-catenin gene in melanoma would lead to an endogenous activation without degradation.

**FIGURE 42.1-3.** b-Catenin pathways in melanoma. Differences between normal and transformed melanocytes for cadherin signaling. APC, adenomatous polyposis coli; mut.b-cat., b-catenin mutation.

### PHOSPHATASE AND TENSIN HOMOLOGUE DELETED ON CHROMOSOME 10 PATHWAY

PTEN has emerged as a major component in regulating survival of tumor cells through its involvement in intricate cascading pathways for growth and adhesion signaling. Both the growth factor and the adhesion receptor (integrin) signaling pathways work in tandem, and signaling is initiated from PI3 kinase, which acts as a relay station (Fig. 42.1-4).<sup>47</sup> PI3 kinase activity is associated with the transformation ability of oncoproteins and stimulation by growth factors. Akt/PKB, an oncogene initially discovered in retroviruses, binds to phosphatidylinositol 3,4-diphosphate (PtdIns-3,4-P<sub>2</sub>), and phosphatidylinositol 3,4-triphosphate (PtdIns-3,4,5-P<sub>3</sub>), and is then transported to the membrane where it activates PI3 kinase. Activation of Akt/PKB in melanoma cells by IGF-1 provides survival signal by phosphorylating Bad and caspase 9. PTEN dephosphorylates PtdIns phosphates, thereby depriving the PI3 kinase of its substrate. Thus, a mutated PTEN can constitutively activate Akt/PKB to influence downstream genes. Cells accumulate in the G<sub>1</sub> phase of the cell cycle through up-regulation of p27. However, it is unknown whether the phosphatase activity is involved in this process and whether it is necessary for dephosphorylation of FAK leading to inhibition of integrin-mediated signaling of cell spreading.

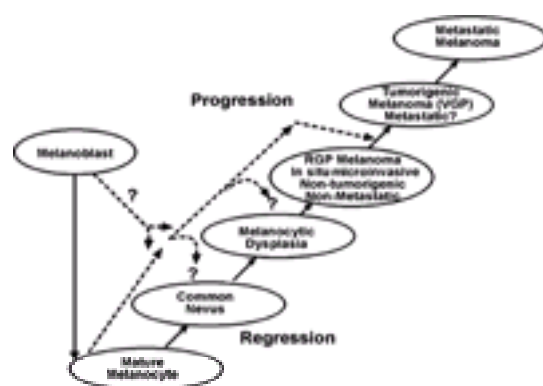

**FIGURE 42.1-4.** PTEN (phosphatase and tensin homologue deleted on chromosome 10) pathways in melanoma. Schematic representation of PTEN as a central molecule influencing PI3 kinase-dependent Ras and Akt signaling.

It is not yet clear how the PTEN may signal to regulate the ras pathway.<sup>48,49</sup> One evidence is the involvement of Shc phosphorylation, which affects its association with Grb2. Shc and Grb2 interactions are necessary for subsequent activation of the ras/raf/MEK1/MAPK pathways, providing a central role for PTEN in controlling cellular responses to growth factor- and integrin-mediated signaling.

## BIOLOGY OF MELANOMA DEVELOPMENT AND PROGRESSION

### PROGRESSION MODEL

Clinical and histologic studies have resulted in defining distinct steps of melanoma development and progression ( Fig. 42.1-5): step 0, melanocytes; step 1, common acquired and congenital nevi with structurally normal melanocytes; step 2, dysplastic nevi with structural and architectural atypia; step 3, radial growth phase (RGP), nontumorigenic primary melanomas without metastatic competence; step 4, vertical growth phase (VGP), tumorigenic primary melanomas with competence for metastasis; and step 5, metastatic melanoma.<sup>50,51</sup> and <sup>52</sup> A refinement by Elder et al. of this classification of nevi and primary melanomas<sup>51</sup> divides lesions into three classes: class I represents precursor nevi; class II lesions are intermediates, confined to the epidermis or with microinvasion into the dermis and represented by *in situ* and microinvasive RGP melanomas; class III are VGP tumorigenic melanomas. As in any neoplastic system, individual melanomas can skip steps in their development, appearing without identifiable intermediate lesions. It remains to be experimentally verified that melanoma cells can develop from a melanocyte precursor cell, which appears to be present not only in murine but also in human skin.

**FIGURE 42.1-5.** Melanoma development and progression. The model implies that melanomas develop and progress in a sequence of steps. However, malignancy can also develop *de novo*. RGP, radial growth phase; VGP, vertical growth phase.

The progression from each stage to the next is associated with specific biologic changes, which are based on experimental models and clinical and histopathologic observations (Fig. 42.1-6). The transition from the mature melanocyte to the formation of a nevus is characterized by a disruption of cell-cell cross-talk between melanocytes and keratinocytes, which leads to an escape of the melanocyte from the regulatory control of keratinocytes. Nevus cells show limited proliferation because common acquired nevi have no apparent chromosomal aberrations. Thus, nevi can develop not just through a stimulatory event, but also through loss of

control of keratinocytes over melanocytes.

**FIGURE 42.1-6.** Biologic events during melanoma progression. Each transition is marked by characteristic changes in the cells. RGP, radial growth phase; VGP, vertical growth phase.

Progression from the melanocyte or common acquired nevus cell to a dysplastic nevus or RGP melanoma most likely involves the beginning of genetic aberrations. The cells show cytologic atypia, they can separate from the basement membrane without undergoing apoptosis, and the entire lesion shows architectural atypia. Cells from RGP lesions have biologic properties *in vitro* that are intermediate between benign and malignant. They require several growth factors for proliferation, do not grow anchorage independently in soft agar and are nontumorigenic in mice. At this time, a local immune response is observed, which could be critical for long-term disease outcome. Specificity and nature of infiltrating lymphocytes in dysplastic nevi or RGP melanoma have not yet been determined. Surgical excision of dysplastic nevi and RGP melanomas leads to a cure from the disease. The histologic diagnosis of both dysplastic nevi and RGP primary melanomas is still controversial because of a lack of molecular markers. For example, in the diagnosis of 37 lesions by eight pathologists, disagreements in diagnosis were noted in 40% of the cases.<sup>53</sup>

VGP primary melanomas are characterized as expanding nodules that invade deep into the dermis. Lesions show increased blood vessel infiltration and a decreased host response. Approximately 35% of VGP lesions have already disseminated at the time of surgical excision of the primary lesion. Besides the classical criteria of Clark's level of invasion and Breslow's measure of tumor thickness, several additional attributes have been defined that determine disease outcome: (1) mitotic activity (i.e., the higher the number of mitoses, the lower the survival rate); (2) lymphocyte infiltration (i.e., the higher the better for survival); and (3) minor attributes such as sex (i.e., male worse than female subjects), site (i.e., trunk worse than extremity), and regression (i.e., presence worse than absence).<sup>54</sup>

Cultured VGP melanoma cells grow independently of exogenous growth factors with the exception of IGF-1. They readily grow anchorage independently in soft agar and all form tumors when injected into immunodeficient mice. VGP primary melanomas are highly aneuploid, which has hampered their cytogenetic and molecular genetic characterization. Biologically, the cells are relatively plastic, and selective pressure over a few weeks can render cells independent of all exogenous growth factors<sup>55</sup> or they become highly invasive.<sup>56,57,58</sup> and <sup>59</sup> Some also acquire metastatic competence.

The metastatic phenotype of melanoma cells isolated from metastatic lesions of patients is unstable. Injection of these cells into an immunodeficient host rarely produces metastases. Metastatic cells also show a high level of phenotypic plasticity, depending on the environment and any selective pressure placed on the cells.

## BIOLOGIC BASIS OF MELANOMA PROGRESSION

Monoclonal antibodies have been used for the last 20 years to characterize molecules expressed by melanoma cells ( Fig. 42.1-7). They have particularly aided in biologic and biochemical analyses of melanoma-associated antigens. Each group of molecules is represented by 5 to 20 members. Thus, melanoma cells are among the best studied of all human tumors. Most intensely studied are adhesion receptors and their ligands, and growth factors with their receptors.<sup>60</sup> In the following discussion, we focus on the biologic significance of adhesion receptors and growth factors for melanoma survival, growth, motility, and invasion.

**FIGURE 42.1-7.** Expression of defined molecules on melanoma cells. Each group, which was defined with monoclonal antibodies, represents 5 to 20 different molecules.

## ADHESION RECEPTORS

Melanoma cells express all major groups of adhesion receptors: integrins, cadherins, and cellular adhesion molecules of the immunoglobulin supergene family. Expression of most adhesion receptors increases with progression ( Fig 42.1-8). There is a dynamic shift as others decrease. Only few remain unchanged. This shift in adhesion receptor expression between normal and malignant cells is most obvious among the cadherins. Melanocytes express E-cadherin, whereas melanoma cells express N-cadherin. The expression of E-cadherin by melanocytes allows them to adhere to keratinocytes and develop gap junctions through connexin 43 ( Fig. 42.1-9). Melanoma cells cannot establish gap junctions with keratinocytes. Instead, melanoma cells, which all express N-cadherin, adhere to either fibroblasts or endothelial cells, which both express N-cadherin. Neither fibroblasts nor endothelial cells can establish gap junctions to keratinocytes. The biologic consequences of gap junction formation are not clear.

**FIGURE 42.1-8.** Dynamic shifts in the expression of adhesion receptors and their matrix proteins by melanoma cells. The increase or decrease in expression may already start in nevi or only in vertical growth phase melanomas.

**FIGURE 42.1-9.** Melanocyte and melanoma cell interactions with juxtaposed cells in their environment. Adhesions occur through either E-cadherin (E-cad) or N-cadherin (N-cad) and gap junctional communication is mediated through connexin 43 hexamers.

Keratinocytes can control the phenotype of normal melanocytes but not melanoma cells. They can regulate melanocyte growth and the expression of cell surface adhesion receptors. [Figure 42.1-10](#) illustrates that melanocytes in culture in the absence of any other cell (monoculture) express melanoma-associated antigens. However, the expression of these molecules disappears within 3 to 4 days when the cells are cocultured with normal keratinocytes to allow cell-cell contact. Melanoma cells are refractory to keratinocytes. However, if the melanoma cells are transduced with E-cadherin, they can adhere to keratinocytes and establish gap junctions. At this time, cell surface molecules are down-regulated, gap junctions are established with keratinocytes, and growth of cells is controlled by keratinocytes. Highly metastatic melanoma cells are no longer invasive. [56,61,62](#) Little is currently known about the signaling mechanisms between keratinocytes and E-cadherin-expressing melanoma cells.

Besides N-cadherin-mediated interactions, melanoma cells can adhere through other adhesion receptor systems (see [Fig. 42.1-10](#)). Most notable is adhesion through Mel-cellular adhesion molecules and a yet unidentified ligand, also found on melanoma cells. Melanoma cells and activated endothelial cells share a number of adhesion molecules that allow heterophilic adhesion between these two cell types in a similar manner as homophilic adhesion between the malignant cells. The similarities in adhesion receptor expression could have functional consequences ([Fig. 42.1-11](#)). Maniotis and coworkers demonstrated that melanoma cells could establish tubule-like structures for blood flow, which can connect to bona fide blood vessels. [63](#)

**FIGURE 42.1-10.** Expression of tumor-associated antigens on melanocytes and melanoma cells is dependent on the presence of E-cadherin (E-cad.) and adhesion to keratinocytes. Keratinocytes can regulate antigen expression on melanoma cells only when E-cadherin is expressed by melanoma cells.

**FIGURE 42.1-11.** Melanoma-melanoma and melanoma-endothelial cell adhesion. Both cell types use similar molecules for cell-cell adhesion.

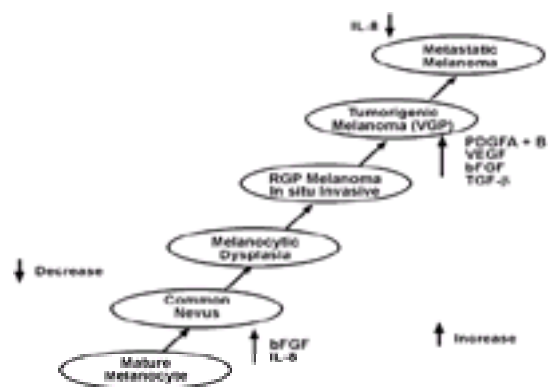

$b_3$  is present on almost all VGP primary and metastatic melanomas, but not on cells of earlier stages of progression. One of the most specific markers that characterizes VGP and metastatic cells is the  $b_3$  subunit of the vitronectin receptor  $\alpha_v b_3$  ([Fig. 42.1-12](#)). When the  $b_3$  gene was transduced to RGP melanoma cells, there were no changes in growth properties *in vitro*.[64](#) On the other hand, the cells became highly invasive in a skin reconstruction model and were now tumorigenic in mice, two attributes of VGP melanoma cells. Apparently,  $b_3$  integrin expression triggers the up-regulation of a variety of genes associated with invasion and tumor growth. The  $b_3$  integrin subunit is also up-regulated by tumor-infiltrating endothelial cells, and several clinical studies have been initiated to target  $b_3$  on endothelial cells, melanoma cells, or both for therapy.

**FIGURE 42.1-12.** Expression of the integrin subunit  $\beta_3$  of the  $\alpha_5\beta_3$  vitronectin receptor in melanocytic cells from different stages of tumor progression. Expression was tested with monoclonal antibodies on both frozen and fixed tissue sections. RGP, radial growth phase; VGP, vertical growth phase.

## GROWTH FACTORS

With progression, melanoma cells show an increase in production of growth factors and cytokines ( Fig. 42.1-13). Normal melanocytes are relatively inactive in growth factor production, even after stimulation. Nevus cells may produce bFGF and chemoattractive cytokines such as interleukin-8 or MCP-1 (monocyte chemoattractant protein-1). The strongest increase in growth factor expression, most notably a further increase in production of bFGF, and of expression of platelet-derived growth factor (PDGF) and transforming growth factor- $\beta$ , can be found in VGP melanomas. Vascular endothelial growth factor (VEGF) can be triggered in VGP and metastatic cells by hypoxic growth conditions or by chemokines and growth factors. bFGF, PDGF, and VEGF act in concert with each other (see Fig. 42.1-13). bFGF is the most significant autocrine growth factor in melanoma. Blocking of bFGF production with antisense oligonucleotides stops melanoma cell proliferation. <sup>65</sup> Despite its lack of a signal sequence, it can be released from cells through yet unknown mechanisms. When released from cells, bFGF binds to matrix proteins such as heparan sulfate proteoglycan, and it can then stimulate both fibroblasts and endothelial cells. bFGF is not only a survival factor and a growth stimulator for melanoma cells but also a motility factor. Its role in invasion comes from up-regulation of serine proteinases (urokinase and plasminogen activator), and metalloproteinases (gelatinase A and B). Potentially, a variety of other genes are activated as well, which still need to be identified.

**FIGURE 42.1-13.** Dynamic up-regulation of expression of growth factors and cytokines during melanoma progression. Whereas initial increases occur after the transition from normal melanocyte to nevus cells, most changes occur between the radial growth phase (RGP) and vertical growth phase (VGP) of primary melanomas. Metastatic cells generally show the highest production levels. bFGF, basic fibroblast growth factor; IL-8, interleukin-8; PDGFA + B, platelet-derived growth factor-a and-b; TGF- $\beta$ , transforming growth factor- $\beta$ ; VEGF, vascular endothelial growth factor.

The biologically most significant stimulating growth factor for tumor-infiltrating fibroblasts is PDGF ( Fig 42.1-14). Melanoma cells produce both A and B isoforms. PDGF is not only mitogenic for fibroblasts, but it also induces the production of matrix proteins such as fibronectin and collagen, which provide the melanoma cells a scaffolding to which to adhere. Activated fibroblasts produce IGF-1, one of the most significant exogenous growth factors for melanoma cells because they do not produce it on their own. IGF-1 is highly mitogenic for melanoma cells but is also a motility factor and stimulates survival by stabilization of b-catenin. Melanoma cells are strong producers of chemoattractive proteins such as interleukin-8 (neutrophil attractant) or MCP-1 (monocyte attractant). In early malignant lesions, infiltrating neutrophils and monocytes may have a stimulatory role for tumors by producing angiogenic cytokines such as tumor necrosis factor- $\alpha$  or by inducing stroma formation. High production of these chemokines can lead to a strong infiltration of the inflammatory cells, which then kills the malignant cells. Thus, tumor cells must maintain a fine balance of chemokine production for biggest growth advantage. Inflammatory cell infiltrates diminish with metastasis apparently due to a breakdown of the gradient when the chemokine levels are increased to be elevated in serum.

**FIGURE 42.1-14.** Melanoma to stroma cross-talk. Production of growth factors and cytokines by melanoma cells that affect normal host cells in the environment. A positive feedback may also occur, when the stromal cells produce stimulants for the malignant cells. bFGF, basic fibroblast growth factor; IGF-1, insulin-like growth factor 1; IL-8, interleukin-8; MCP-1, monocyte chemoattractant protein-1; PDGF, platelet-derived growth factor; SF, scatter factor; TGF- $\beta$ , transforming growth factor- $\beta$ ; TNF- $\alpha$ , tumor necrosis factor- $\alpha$ ; VEGF, vascular endothelial growth factor.

## INTRODUCTION

Cutaneous melanoma is a readily curable neoplasm, with 85% of diagnosed patients enjoying long-term survival following simple surgical excision. In its disseminated state, however, it is a devastating illness with limited effective treatment options prompting the evolution of efforts designed to identify metastatic disease early and to develop novel biologic therapies.<sup>1</sup> The application of immunotherapy has so far provided benefit to only a small percentage of patients. In the majority of patients with metastatic disease, many in their youth, treatment with chemotherapy or biologic therapy is unsuccessful, and they ultimately succumb to their disease. In the United States, melanoma is diagnosed in at least 47,000 people a year, more than double the reported incidence in 1970. There has been a steady increase in melanoma incidence over the last century. In 1935, for example, the incidence of melanoma in the United States was approximately 1 in 100,000. Now, the incidence approaches 15 in 100,000. Although the basis for this increase is incompletely understood, the localized degradation of the ozone layer, the increase in solar exposure as a recreational activity, and the immigration of fair-skinned populations into equatorial latitudes each appears to play some causative role. Because of the effectiveness of early surgical treatment, the international community has focused extensively on preventive measures and screening efforts with some success. The diagnosis of the majority of melanoma occurs at thin and easily cured depths of invasion.

Large prospective, randomized, multicenter trials have answered some basic management questions, improved the care of melanoma patients, and expanded our understanding of the disease. However, many aspects of the treatment of melanoma, such as the therapeutic role of sentinel node dissection, isolated limb perfusion (ILP), and cytotoxic, biologic, or both therapies remain controversial and inconclusive. The field of melanoma is rapidly evolving with new techniques and therapeutics becoming standard care, even before substantial evidence of benefit exists. Not surprisingly, many physicians still find the enormous amount of conflicting data confusing. The changing framework of surgical, radiologic, and even pathologic assessment demands additional randomized, prospective, controlled trials to arrive at meaningful conclusions to serve as the foundation for future progress. Many of these are currently ongoing without results available at the time of preparation of this chapter.

Melanoma has been one of the most successful targets for immunotherapy, especially as biologic therapies. Interleukin-2 (IL-2) and interferon (IFN) therapy have now become routine and new peptide or protein vaccines as well as cellular and genetic therapies are being aggressively developed. Melanoma has attracted the attention of immunotherapists for many reasons. Spontaneous regression of melanoma associated with evidence supporting a specific cellular immune response occurs more frequently in patients with melanoma than with other solid tumors. The lack of effective alternatives has allowed the implementation and evolution of new treatments since, as yet, no systemic therapy has been shown to prolong survival significantly for treated cohorts in properly randomized studies. The identification of tumor rejection antigens recognized by CD4 and CD8 T cells as well as prognostically significant roles of antibody response to melanoma antigens has spawned a renaissance of immunotherapy. Occasional patients with advanced disease have been apparently *cured* by immunotherapy, surviving as long as 15 years without disease, something essentially unheard of for systemic therapy of metastases of any other major solid tumor.

The advances made in melanoma treatment have moved into other areas of oncology. Sentinel node biopsies are increasingly applied in the treatment of breast and

colon cancer. The rapid advances in understanding melanocyte biology and the immunologic community's interest in studying the disease has propelled the development of novel biologic therapies for other tumors. Melanoma trials have demonstrated the importance of multidisciplinary approaches in confronting the difficult problems faced in the treatment of cancer patients.

## EPIDEMIOLOGY

In 1956, Lancaster observed an association between sun exposure and the development of melanoma. He described the relationship between disease incidence and latitude among people of European background. The closer to the equator, the greater the rate of melanoma mortality and incidence of melanoma in whites.<sup>2</sup>

Since 1973, the Surveillance, Epidemiology and End Results (SEER) program has sampled hospital-based cancer registries in 11 different regions accounting for a total of 10% of the U.S. population. Even with this surveillance system, underreporting is common as numerous thin melanomas are treated in an office setting and not reported in this hospital-based system. For example up to 19% of melanomas were not reported in the Massachusetts Cancer Registry. Using national surveys of community practices, some believe the incidence of melanoma in the United States to be 2.5 times SEER estimates.<sup>3,4</sup>

In 2000, an estimated 7700 Americans will die of malignant melanoma.<sup>5</sup> The incidence of melanoma in the white U.S. population has increased alarmingly from 1 per 100,000 in 1935 to 15 per 100,000 in 1996 (Fig. 42.2-1).<sup>6</sup> In 2000, at least 47,000 cases are expected. However, the overall melanoma mortality has not increased nearly as dramatically over the last several decades (Fig. 42.2-2). Since 1973 the mortality only increased from 1.6 to 2.3 per 100,000 individuals in the 1996 survey (Fig. 42.2-3).<sup>7</sup> During the same time period, overall 5-year survival in patients with melanoma has increased significantly, possibly due to the thinner depth at diagnosis of lesions and the adoption of improved surgical techniques (Fig. 42.2-4). The increase in melanoma mortality over the last 50 years has only recently shown signs of slowing.<sup>8</sup> Some argue that the increased incidence of melanoma may be secondary to the detection of neoplasms that never would have acquired metastatic potential and were destined for regression. Others question whether a lead-time bias may account for the relative differences in rates of mortality and incidence changes. However, one analysis demonstrates rather clearly that the increase in incidence is only partly associated with earlier detection.<sup>9</sup>

**FIGURE 42.2-1.** Age-adjusted incidence of melanoma in the United States from 1973 to 1996. The incidence has increased for the white population substantially and is rising faster in male than female subjects. This increase in melanoma incidence has not discernibly affected the black population. (Data from the Surveillance, Epidemiology and End Results program, 2000.)

**FIGURE 42.2-2.** The incidence of melanoma has increased disproportionately faster than mortality. This is at least in part due to the increase in superficial lesions diagnosed relative to thicker ones. (Data from the Surveillance, Epidemiology and End Results program, 2000.)

**FIGURE 42.2-3.** Age-adjusted U.S. mortality from melanoma from 1973 to 1996. Note the increasing mortality among white male subjects. (Data from the Surveillance, Epidemiology and End Results program, 2000.)

**FIGURE 42.2-4.** Five-year survival rates after the diagnosis of melanoma in the United States. These have improved from 1960, the earliest time period for which reliable data are available. The difference between the earliest and latest time periods are statistically significant. This increase in survival may be due to the increase in thinner melanomas compared with thicker ones. (Data from the Surveillance, Epidemiology and End Results program, 2000.)

Currently, melanoma is the sixth and seventh most common cancer in American men and women, respectively. The lifetime risk for developing melanoma among white Americans is 1 in 85. The risk of melanoma increases with age and the median age at diagnosis ranges between 45 and 55 years, but people of all ages are at risk.<sup>10,11</sup> Melanoma commonly afflicts young, productive members of society. One-fourth of melanoma cases identified in the United States occurs in individuals before the age of 40. In women 20 to 35 years old, it is the second most common tumor after cervical cancer<sup>12</sup> and in women aged 25 to 30 it is the leading source of cancer death. The years of productive life lost to melanoma exceed those of all other solid tumors. In the United States, melanoma is more common among higher socioeconomic classes, but the case fatality is highest among lower socioeconomic groups.<sup>13</sup> The highest mortality from melanoma occurs in the state of Vermont and the lowest in Washington, DC. Although there is some increased distribution of melanoma mortality by latitude, other factors such as race are additionally important (Fig. 42.2-5).

**FIGURE 42.2-5.** Substantial geographic variation in the incidence of melanoma. Interestingly, the U.S. mortality for melanoma is highest in Vermont (3.2 per 100,000) and lowest in Washington, DC (0.8 per 100,000) and Hawaii (1.2 per 100,000). Factors other than latitude, such as ethnic background, significantly influence the geographic risk of overall melanoma mortality. (Data from the Surveillance, Epidemiology and End Results program, 2000.)

Racial differences in susceptibility are apparent, and melanoma is most prevalent among white, European populations. For example, the incidence of cutaneous melanoma among African Americans is approximately 1/20 that of the U.S. white population and behaves differently at presentation. Among African Americans, melanoma occurs predominantly in acral sites rather than in areas of pigmented integument.<sup>14</sup> The worldwide incidence of melanoma varies considerably as well (Fig. 42.2-6). Rates of 0.2 per 100,000 in parts of Japan to nearly 40 per 100,000 in Queensland have been reported. Despite these wide variations, the increase in overall melanoma incidence has increased globally.<sup>15</sup> Worldwide, race is the predominant risk factor for the development of melanoma, with white populations having the highest risk and Asian the lowest risk.

**FIGURE 42.2-6.** Worldwide incidence of melanoma. Note the wide variation in incidence depending on race, sex, and latitude. (Data from refs. 549 and 550.)

In the United Kingdom, trends have been similar to those in the United States. The incidence and mortality of melanoma has increased 50% during the last decade.<sup>12</sup> In Australia, where the incidence rates are the highest in the world, the increase in mortality is only now showing signs of slowing. However, mortality is increasing in many countries that had not previously reported increases such as France, Italy, Spain, and Hungary.<sup>16</sup>

## RISK FACTORS, PREVENTION, AND SCREENING

With the increase in melanoma incidence over the last 40 years, effective screening strategies have become increasingly important.<sup>17</sup> The biologic and clinical behavior of melanoma supports the broad pursuit of screening programs. Effective screening for melanoma can be accomplished using noninvasive skin examinations since 93% of all primary melanomas are grossly visible. The remaining balance arises in mucosal, ocular, and unknown primary sites.<sup>18</sup> Many primary cutaneous lesions have a distinct radial growth phase that may persist for months to years, giving physicians, family, and patients ample opportunity for early recognition and appropriate excision before progressive vertical tumor invasion.<sup>19</sup> As melanomas less than 0.76 mm deep have a 10-year survival rate of more than 95%, the goal of screening is to identify lesions before the development of the so-called vertical growth phase associated with a worsened prognosis.<sup>20</sup> Furthermore, screening for melanoma can be accomplished in just minutes by trained physicians, and diagnostic biopsies are relatively inexpensive and simple to perform in the office setting.

### RISK FACTORS FOR THE DEVELOPMENT OF MELANOMA IN POPULATIONS AT HIGHEST RISK FOR DEVELOPING MELANOMA

Education and screening programs should especially focus on populations that are at high risk for the development of melanoma. Many known risk factors can be used by physicians to improve the efficiency of screening programs (Table 42.2-1). Typical risk factors associated with carcinogenesis such as use of tobacco, alcohol, and estrogens do not affect the risk of melanoma. Instead, factors such as patient phenotype (hair, skin, and eye color), sun exposure, family history, and genetics play key roles.

Congenital nevi >5% body surface area
Previous melanoma
Family history
Dysplastic nevi syndrome
Dysplastic nevi
5 nevi >2 mm diameter
5 nevi <5 mm diameter
Sunburns during childhood
Poor tanning ability
White race
Red hair
Blond hair
Blue eyes
Freckles
Entering sunbath
Equatorial latitudes
Psoriasis maculosa
Nevus of Ota

\*Many risk factors have been identified for the development of melanoma. Patients with a previous history of melanoma, a family history of melanoma or dysplastic nevi, or large congenital nevi are at highest risk. Although all patients should be screened for melanoma by a trained physician, identifying risk factors can allow physicians to focus on especially high-risk patients.

**TABLE 42.2-1.** Known Risk Factors for the Development of Melanoma<sup>a</sup>

### Common Nevi

The role of moles or melanocytic nevi in the genesis of melanoma has been suspected since Norris' first description of melanoma in the English language in 1857. Small, common nevi are pigmented lesions that are often raised, symmetric in outline, and delimited with discrete regular borders. Clearly, the number of moles is an important predictor of melanoma risk and is surprisingly genetically determined, with monozygous twins having almost identical mole counts in contrast with dizygotic twins.<sup>21</sup> A threefold increase in melanoma risk is associated with the presence of five nevi more than 5 mm in diameter, or for those patients with more than 50 nevi greater than 2 mm in diameter.<sup>22</sup>

### Atypical Nevi

Atypical melanocytic nevi that exhibit histopathologic features of dysplasia were initially described by Reimer et al. in the setting of familial melanoma.<sup>23</sup> These lesions when clinically defined but not pathologically examined are classified as *atypical nevus*,<sup>24</sup> and lesions defined histologically with specific architectural and cytologic features are called *dysplastic nevus*.<sup>25</sup> An atypical nevus is defined clinically as a flat macule greater than 5 mm. At least two of the following features are also necessary to distinguish atypical nevi from banal nevi: variable pigmentation; irregular, asymmetric outline; and indistinct borders.<sup>26</sup> Atypical lesions in patients without familial syndromes are more commonly found on sun-exposed areas.

The majority of melanoma is sporadic, and in this setting, the role of atypical nevi has become more clearly apparent. Atypical nevi among patients with sporadic melanoma are clinically indistinguishable from those of patients with familial melanoma. Atypical nevi occur in 2% to 7% of the white population and can be identified in 25% to 40% of patients with melanoma.<sup>22,25,27,28</sup> and <sup>29</sup> Atypical nevi are a significant risk factor for the development of melanoma. Their presence may indicate a general instability in melanocyte growth. Estimating the risk incurred by the presence of atypical nevi has been difficult and ranges widely in the literature. The risk of new primary melanoma among individuals with atypical nevi was calculated according to the presence of a family or personal history of prior melanoma by Kraemer et al.<sup>27</sup> This risk relates both to the presence of atypical nevi, melanoma, or both in the balance of the family of a given individual. In cases in which atypical nevi are isolated in an individual, the risk is lowest (27 times population risk). When atypical nevi are found in multiple members of a family or there is a history of melanoma in additional members of the family, the risk rises. Those patients with multiple family members exhibiting atypical nevi and a having a history of melanoma have the highest risk (148 times population risk).<sup>27,30,31</sup> Unfortunately, the history of atypical nevi and of melanoma itself is often difficult to elicit. Crijns et al. reported that more than one-half of patients without an elicited history of melanoma or atypical nevi on initial family history are later found to have familial patterns of atypical nevi, melanoma, or both.<sup>32</sup> Still the identification of atypical nevi even among skilled clinicians and pathologists is problematic, and some find the distinction from conventional nevi unconvincing.<sup>33</sup>

The risk incurred by the presence of atypical nevi has been difficult to accurately establish. In one series, 716 patients with melanoma were compared with a group of matched controls. In the absence of atypical nevi, increased numbers of small nevi were associated with an approximately twofold elevated risk of melanoma, and increased numbers of both small and large nonatypical nevi were associated with a fourfold greater risk. The presence of a single clinically atypical nevus was associated with a twofold greater risk, while ten or more conferred a 12-fold greater risk of developing primary melanoma.<sup>26</sup> Another smaller series suggested the risk of developing melanoma might be as high as 37 times greater in those individuals who have atypical nevi.<sup>34</sup>

### Congenital Nevi

Childhood melanomas are rare, but even infants have been reported with the disease, especially in association with giant congenital nevi.<sup>35</sup> Patients with large congenital melanocytic nevi, those that appear at birth or during early childhood, are at high risk for developing melanomas ( Fig. 42.2-7). The lesions are elevated, with discrete borders and stippled pigmentation.<sup>26</sup> Large congenital nevi occur in 1 in 1000 to 1 in 20,000 newborns, and giant nevi involving large body surfaces (i.e., the entire trunk) occur in 1 in 500,000 newborns.<sup>36</sup> One-half of all cases of melanoma within large congenital nevi occur in the first decade of life so screening, surgical excision, or both should be planned early.<sup>37</sup> In a series of 265 patients with congenital nevi, patients with congenital nevi that covered more than 5% of their total body surface area had a risk of developing melanoma 1000-fold higher than the general population. No patients with congenital nevi that involved less than 4% of their total body surface area developed melanomas, but the study size could not exclude a small increase in risk.<sup>38</sup> In another series of 46 patients with large congenital nevi, two individuals developed three melanomas arising from nevi after a mean of 7.3 years of routine screening. Although the study was small, it confirms that these patients are a high-risk population.<sup>39</sup> Furthermore, detecting early melanoma in these lesions is difficult since malignant transformation usually evolves in the deeper layers of the nevus, and visible surface alterations are late manifestations.

**FIGURE 42.2-7.** Giant congenital nevus with malignant degeneration. This melanoma developed on the shoulder of a patient with a giant congenital nevus. Patients with large congenital nevi have a 1000-fold increased risk for developing melanoma. Frequent surveillance is necessary to diagnose these lesions early. For nevi that encompass more than 5% of total body surface area, resection may prevent the development of melanoma.

### Spitz Nevi

Spitz nevi are benign lesions that occur in children, and their importance stems from the difficulty in distinguishing them from melanoma. Whereas Spitz nevi are usually under 1 cm in diameter and may resemble verrucae or small hemangiomas, melanomas in children tend to be larger and quite striking clinically.<sup>40</sup> All children diagnosed with melanoma or Spitz nevi should have the lesions reviewed by experienced pathologists. Parameters suggesting malignancy are age of diagnosis greater than 10 years, presence of ulceration, diameter greater than 1 cm, involvement of subcutaneous fat, and a mitotic activity of at least 6/mm<sup>2</sup>.<sup>41</sup>

### Familial Atypical Nevus Syndromes

Melanoma is divisible into familial and sporadic patterns. Our understanding of the role of melanocytic precursor lesions in the genesis of melanoma has been clarified over the past 30 years based on pioneering studies involving familial clusters of patients with melanoma, many of whom are observed to have nevi exhibiting atypical features.<sup>42,43</sup> and <sup>44</sup>

Patients with the dysplastic nevus syndrome, a disease of autosomal dominant inheritance with incomplete penetrance, are at increased risk for developing melanoma.<sup>22</sup> In familial syndromes, the atypical moles of patients with the familial atypical mole-melanoma syndrome were named according to the initials of the probands (B-K nevus syndrome).<sup>23,43</sup> These atypical nevi were also notable for their location on the skin of the trunk that was not necessarily sun-exposed. The presence of atypical nevi identifies patients with a high risk of melanoma among family members with this syndrome.<sup>44</sup> The risk conferred by the presence of multiple atypical nevi in such individuals approaches 100% by age 70.<sup>30,44,45</sup> and <sup>46</sup> This risk is more complex than that of a discrete precursor lesion that progresses stepwise into malignancy. Although many melanomas have been identified to arise within atypical nevi, most occur in areas of skin that show neither gross nor histologic

evidence of an antecedent atypical nevic lesion. This observation suggests that removal of atypical lesions is not akin to the reduction in carcinoma risk after resection of adenomatous polyps of the colon as most melanomas arise *de novo*. In patients with familial melanomas, it is clear that atypical nevi may serve as nonobligate precursors and markers of melanocyte dyscrasia.

Careful molecular, genetic, and pathologic studies in patients with familial atypical mole-melanoma syndrome may define the molecular basis of progression and identify markers for adequate surveillance and ultimate disease prevention. A few apparently important genetic mutations have already been identified in the cyclin-dependent kinase genes, some of which serve as inhibitors of cell-cycle progression. An enhanced incidence of melanoma is associated with a single mutation in CDK4 (12q14) as well as mutations in the CDKN2A (9p21) and CDKN2B genes.<sup>47</sup> There is a correlation between CDKN2A mutations in family members with atypical nevus syndromes. Clinical findings associated with this germline mutation involve nevi in abnormal locations and abnormal numbers. These include nevi on the buttocks, nevi on the feet, total nevi greater than 100, and two or more atypical nevi.<sup>48</sup> Germline mutations of CDKN2A have been identified in approximately 20% of melanoma-prone families, and CDK4 has been described in three families.<sup>49</sup> Polymorphisms occurring in the melanocyte-stimulating hormone receptor predict skin coloration, risk of developing nevi, and independently and synergistically with p16 mutations, ultimately the development of melanoma. Although familial melanoma provides important insights into the disease, the number of cases of familial melanoma are limited. They represent an estimated 10% of patients with melanoma.

### **History of Previous Melanoma**

A significant number of patients with a past history of melanoma develop a second, metachronous lesion.<sup>22</sup> A study of 3310 patients from a prospective database with stage I and II melanoma showed that 3.4% developed a second primary melanoma. The 5- and 10-year risk of developing a second primary melanoma was 2.8% and 3.6%, respectively.<sup>50</sup> Patients with a past history of melanoma should undergo frequent cutaneous examinations to screen for such metachronous lesions. Patients who are at especially high risk for metachronous lesion are those with atypical nevi or family history.<sup>51</sup>

### **Transplant and Other Immunosuppressed Patients**

Patients who have had a solid organ transplant are at increased risk for developing melanoma, and the risk is directly related to the degree of immunosuppression. Although the risk for nonmelanomatous cutaneous tumors is estimated at approximately 65-fold that of the general population, the risk for developing melanoma is increased by a more modest threefold.<sup>52</sup> Children who have had a renal transplantation demonstrate higher benign nevus counts than controls, and the duration and degree of immunosuppression correlates positively with these counts. Such nevi are found most commonly on the back and acral sites.<sup>53</sup> Interestingly, in normal adults, nevus counts increase in number, peaking in the early 20s and then progressively decreasing with time.<sup>54</sup> Children with genetically determined immunodeficiencies have a three- to sixfold risk of developing melanoma.<sup>55</sup> Of the few patients reported to have melanoma and human immunodeficiency virus in the literature, approximately one-third had metastatic disease at the time of initial examination, and systemic symptoms correlate with decreased CD4+ cell counts. Melanomas among patients with human immunodeficiency virus infection are often atypical in appearance, multiple, and metastatic.<sup>56</sup> The number of nevi less than 5 mm in diameter was found to be greater in patients with human immunodeficiency virus than in the general population. Immunodeficiency may promote or permit the development of nevi and raises the question of whether sun-induced immunosuppression plays a role in the development of nevi.<sup>57</sup> The development of melanoma may relate directly to the suppression of cellular immunity. Melanoma in immunosuppressed patients may evolve from precursor nevi that are unable to elicit cellular immune recognition. The detection of dysplastic nevi offers an opportunity to identify those immunosuppressed patients who are at greatest risk of melanoma.<sup>58,59 and 60</sup>

### **Phenotypic, Solar, and Other Risk Factors**

Risk factors for melanoma apart from the presence of acquired and congenital melanocytic nevi include easily identifiable phenotypic characteristics of pigmentation such as pale skin, poor tanning ability, light hair and eyes, and the presence of freckles. Compared with individuals with brown and black hair, the relative risk for developing melanoma for those with blonde and red hair is 1.8 and 2.4, respectively. Individuals with blue eyes have a risk 1.2 times that of individuals with brown eyes.<sup>22,61</sup> Episodic exposure to intense sunlight and a history of blistering sunburns, especially in childhood (ages 10 to 19), is strongly associated with the development of melanoma.<sup>51,62</sup> Childhood sunburn with blistering is also associated with increased numbers of atypical nevi.<sup>22,63</sup> Unlike other nonmelanoma skin cancers, recreational intermittent exposure to sunlight is more strongly associated with risk of melanoma than lifetime continuous exposure.<sup>64</sup>

One might expect a much higher incidence of melanoma in patients with albinism since they have minimal natural solar protection and the development of melanoma is dependent on the presence of melanocytes, not on melanin. However, only 23 cases of melanoma have been documented in the literature in patients with oculocutaneous albinism. They were all, of course, amelanotic.<sup>65,66</sup> Patients with xeroderma pigmentosum are another group that have little natural solar protection; however, 5% of patients develop melanoma at a median age of 19 years. They are a rare high-risk subgroup that needs close screening for cutaneous malignancies.<sup>67</sup>

Ultraviolet (UV) exposure is the most easily modified risk factor for the development of melanoma, but a causative role of UV exposure only partially explains observational data. Exposure to UV radiation is not obligatory for the development of melanoma. Melanomas are commonly found on the soles of the feet and in mucosal areas that never are exposed to daylight, and geographic susceptibility to melanoma does not consistently increase with the amount of UV exposure. Melanoma occurs in children and young adults who frequently have had relatively little sun exposure. UV radiation frequently initiates the development of melanoma either directly or indirectly, but patient susceptibility is a much more important risk factor.

### **Role of Pregnancy and Estrogens in Melanoma**

As pregnancy is associated with an increase in melanocyte-stimulating hormone levels and an increase in pigmentation in some patients, the theoretical concern for stimulation of melanoma has prompted concern. Although various case reports initially suggested an adverse outcome in pregnant patients with melanoma, six well-controlled studies have evaluated the effect pregnancy has on survival. No difference in survival between patients diagnosed during pregnancy and controls has been substantiated.<sup>68,69,70,71 and 72</sup> Interestingly, one study implied that prior pregnancy was in fact protective by demonstrating improved survival in women under 50 who had more than five children before the diagnosis of melanoma.<sup>73</sup> Neither is there evidence that pregnancy occurring after the diagnosis of melanoma worsens prognosis.<sup>70,74</sup> In women with a history of melanoma, it may be reasonable to suggest waiting 2 years after initial diagnosis before becoming pregnant since two-thirds of recurrences occur within this time period. However, the stage and depth at diagnosis and the age and desires of the mother factor heavily into these decisions.

There is no evidence that estrogen use increases the risk of melanoma. Much of the confusion concerning estrogens results from the expression of estrogen receptors on some melanomas. The presence or absence of these receptors neither predicts prognosis nor hormone responsiveness. Tamoxifen has been suggested to have effects on melanoma; however, its actions may be indirect, through the potentiation of the cytotoxic chemotherapy or enhancing natural killer (NK) function, rather than directly affecting melanoma.<sup>74,75</sup> More recent randomized controlled trials failed to corroborate a significant benefit of tamoxifen with dacarbazine or multidrug therapy. Well-designed epidemiologic studies have not shown an increased rate of melanoma in patients who have used exogenous estrogens.<sup>76,77</sup> No studies have specifically examined the risks of hormonal replacement therapy in postmenopausal women with melanoma, but no data exist to suggest that hormonal replacement therapy is harmful.<sup>74</sup> The well-characterized beneficial effects of hormonal replacement therapy likely outweigh any theoretical, unsubstantiated risks of estrogens.

## **DIAGNOSIS: CHARACTERISTICS OF MELANOMA**

Identification of features that may mark lesions suspicious for melanoma can be simply recalled using the mnemonic ABCDE. *A* stands for asymmetry, *B* for borders that are irregular or diffuse, *C* for color variegation, *D* for diameter more than 5 mm, and *E* signifies enlargement or evolution.<sup>78</sup> Bleeding and ulceration occurs in 10% of localized melanomas and 54% of late melanomas and is a poor prognostic finding.<sup>79</sup>

### **Morphotypes**

Although specific morphotypes of melanoma have been used for prognostic information, the Breslow depth of the lesion and presence or absence of ulceration are the most significant predictors of biologic behavior of the primary lesion. Morphology does not predict prognosis independently of these well-defined risk factors. The classic morphotypes now serve as descriptive tools that aid in the recognition of these lesions and as historic references ( [Fig. 42.2-8](#), [Fig. 42.2-9](#), [Fig. 42.2-10](#), [Fig. 42.2-11](#), and [Fig. 42.2-12](#)). Physicians should recognize that many less dangerous (and more common) skin lesions may exhibit features similar to melanoma such as

seborrheic keratosis, pigmented basal cell cancer, solar lentigines, and atypical nevi. <sup>80</sup>

**FIGURE 42.2-8.** Lentigo maligna melanoma. These lesions commonly occur on the face in older patients. These lesions may require considerable planning for reconstruction.

**FIGURE 42.2-9.** Nodular melanoma. The second most common melanoma morphotype. It is associated with the so-called vertical growth phase, manifesting a more aggressive biologic phenotype and worsened prognosis.

**FIGURE 42.2-10.** Superficial spreading melanoma. This typical example exemplifies the most common melanoma morphotype. Note the irregular borders, large size, color variegation, and asymmetry. Radial growth at the dermal-epidermal junction for prolonged periods is associated with a better prognosis.

**FIGURE 42.2-11.** Subungual melanoma. All nail bed lesions that have grown or remained unchanged over 4 to 6 weeks should undergo an incisional biopsy and removal of the nail.

**FIGURE 42.2-12.** Acral lentiginous melanoma. These lesions, located in the extremity, are more common in Asians and African Americans.

Superficial spreading melanoma presents as an asymptomatic, flat macule or barely raised plaque with color variations that may include shades of black and brown. Areas of regression (depigmentation) are common. It is the most common growth pattern and accounts for 60% to 70% of all melanomas.<sup>81,82</sup> These lesions may exist for years before a rapid growth phase is identified.<sup>22</sup> Notching and scalloping are common, with enlargement during the radial growth phase of melanoma. They can

occur at any site, although they most commonly can be seen on the lower extremities of women and on the trunk of men.<sup>79</sup>

Nodular melanoma typically presents as a uniform lesion that is dark black-blue or bluish-red, although 5% are amelanotic.<sup>22,79</sup> This is the second most common morphotype, occurring in 15% to 30% of patients, and usually exhibits a more rapid onset.<sup>82</sup> Nodular melanomas are associated with deeper Breslow depths because they quickly establish a vertical growth phase. Most commonly, nodular melanomas are located on the trunk or head and neck and are observed in men more frequently than women.

Lentigo maligna melanomas (LMM) are typically located on the face and are generally large, flat lesions that are tan colored, with differing shades of brown. Rarely, LMM can be amelanotic. Up to one-half of lentigo maligna (LM), a precursor lesion that is characterized by atypical melanocytic proliferation, degenerate into melanoma over a period of many years. The diagnosis requires the presence of sun-related changes in both the epidermis and dermis. They are found in approximately 5% of patients with melanoma.<sup>82</sup>

Acral lentiginous melanomas are uncommon and typically occur on the palms, soles, or beneath the nail (subungual). However, not all lesions in these locations are acral lentiginous melanomas. Melanoma in the hands or feet account for less than 5% of all melanomas, but they are much more common in dark-complexioned individuals.<sup>83,84</sup> These lesions tend to present late and thus are associated with a poorer prognosis. They represent up to 70% of melanomas in African Americans and up to 46% in Asians.<sup>79</sup> They are usually tan, brown to black macular lesions with variegation in color and an irregular border.<sup>22</sup> In a Japanese series of 62 plantar melanomas, 82% were acral lentiginous, 3% were superficial spreading, and 14% were nodular. The lesions most commonly affected the heel. Acral melanomas are strongly associated with high total body nevus counts [relative risk (RR) = 6.3] and with nevi on the soles. There is also an association with penetrating injuries to the feet or hands (RR = 5.0) and heavy exposure to agricultural chemicals (RR = 3.6).<sup>85</sup> Subungual melanomas account for only 1% to 3% of all melanomas. They commonly are diagnosed late because of their close resemblance to many benign lesions of the nail. If a nail bed lesion has not changed significantly in 4 to 6 weeks, a biopsy should be performed, accompanied by removal of the nail. Some clinical parameters that should arouse suspicion of subungual melanoma are lesions occurring in patients greater than 50 years old, a width greater than 3 mm with variegated borders, extension of pigment into the lateral or proximal nail fold, and lesions occurring in individuals of African American, Asian, or Native American ancestry.<sup>86</sup> Seventy percent occur on the great toe or thumb. These tumors are associated with a 5-, 10-, and 20-year median survival of 59%, 44%, and 29%, respectively. One-half have associated nail destruction and 70% ulcerate. Twenty-five percent present with metastases and 74% are greater than 1.5 mm thick.<sup>87</sup>

Desmoplastic melanoma is a rare and locally aggressive variant of malignant melanoma that is difficult to diagnose clinically and microscopically. It represents approximately 1.7% of melanomas. The majority of these tumors occur on the head and neck of elderly patients and one-half are amelanotic.<sup>88</sup> Desmoplastic tumors are aggressive locally and behave more like mesenchymal neoplasms. These tumors stain intensely with S-100. The most reliable and characteristic histologic features of an early lesion of desmoplastic melanoma are aggregates of lymphocytes, tumor cell cytologic atypia, stromal myxoid change, and poor circumscription of the dermal infiltrate.<sup>89</sup> The risk of local recurrence increases when neurotropism is present.<sup>90</sup>

## PREVENTION

With the assumption that the prime modifiable risk factor in the development of melanoma is UV radiation, prevention strategies focus on reducing the public's excessive exposure to sunlight. The American Cancer Society and the Skin Cancer Foundation recommend that the general population employ "sun-smart" practices. This includes the avoidance of direct midday sun exposure between the hours of 10 a.m. and 4 p.m. and the use of sunscreens, protective clothing, and appropriate shade (e.g., sun umbrellas). The increased risk of melanoma incurred through sun exposure is strongly associated with blistering sunburns between the ages of 10 and 19; thus, special attention should be focused on teaching children these sun-smart practices. While the use of sunscreens of sun protection factor (SPF) of at least 15 is recommended, sunscreens have been largely shown to reduce the nonmelanoma skin cancer incidence. There is much controversy regarding the effectiveness of sunscreen for prevention of melanoma, with the epidemiologic data inconclusive at present.<sup>91</sup>

### Sunscreens and Sunlight

Claims of a reduction in melanoma risk from the use of sunscreens have been controversial and difficult to substantiate. In fact, most studies show an increased risk for the development of melanoma with the use of sunscreens, probably because of their ability to delay or avoid sunburn episodes, which may allow prolonged exposure to unfiltered UV radiation (Table 42.2-2). Many criticize these epidemiologic studies, for many confounding factors may contribute to these negative results. Individuals who sunbathe frequently are more likely to use sunscreens. In addition, many studies had focused on older preparations that were either less effective at blocking UVB light (low SPF) or contained psoralens, potent tanning activators. People with a poor tanning ability who have used psoralen sunscreen in the past have a risk of developing melanoma 4.5 times that of regular sunscreen users.<sup>15</sup> The risk reduction from newer, high SPF sunscreens is difficult to assess due to the long latency from sun exposure to the development of melanoma.<sup>92,93</sup> However, increases in benign nevus counts are clearly associated with the use of sunscreens. In a large, randomized, placebo-controlled study of more than 600 European children, the number of nevi increased in those who used sunscreens even when controlling for factors such as skin type and eye color.<sup>91</sup> A theoretical basis exists for the lack of efficacy of sunscreens. Most sunscreens offer greater protection from UVB (290 nm) than UVA (375 nm) radiation, thereby reducing the risk of sunburn while not blocking UVA radiation, which efficiently induces tanning. However, UVA penetrates more deeply and causes more DNA damage than UVB. Although the ozone layer filters UVA more effectively than UVB light, approximately 1000 times more UVA than UVB bathes the earth's surface.<sup>94</sup> Thus, the depletion of the ozone layer may significantly affect the incidence of melanoma. An estimated 1% increase in melanoma incidence occurs with each percentage decrease in the ozone layer.<sup>15</sup>

<sup>a</sup>Many studies paradoxically show an increased odds ratio for the development of melanoma with the use of sunscreens. These data, although interesting, are hard to interpret because of the difficulty in controlling multiple patients variables, the long latency between sun exposure and melanoma occurrence, and the changing formulations of sunscreens over the last decades. The American Academy of Dermatology strongly recommends sunscreens that has a more certain effect on development of solar-driven skin lesions.

TABLE 42.2-2. Relationship between Melanoma and Sunscreen Use: Case-Controlled Studies <sup>a</sup>

Several studies show that the excessive use of tanning salons is associated with an increased risk of developing melanoma. No study demonstrates that tanning is protective against subsequent sunburns or melanoma.<sup>95,96</sup> Long-term use of tanning salons is associated with premature skin aging, cataract development, and nonmelanoma skin cancers. Prevention strategies should discourage the use of tanning salons.

### Self-Examination

Patients at increased risk of melanoma should be informed how to perform regular self-examinations of their skin. Most patients who develop melanoma would have alerted their physicians much earlier if they had used a simple checklist that helps identify high-risk lesions.<sup>97</sup> Self-examination is currently underused even in high-risk populations. Only one in five patients with melanoma practices self-screening and only 6% of patients follow recommendations for self-examination, sun protection, and yearly professional examinations.<sup>98,99</sup> Screening by trained physicians currently cannot be replaced by self-screening until national efforts at public education are more broadly undertaken.

### Excision of Nevi

Evidence supports the removal of atypical nevi in patients with a prior history of melanoma as a preventative strategy. The excision of atypical lesions decreases the expected incidence of melanomas in high-risk cohorts, but it is unclear whether a broader population-based strategy supporting the excision of these nevi can be extrapolated.<sup>100</sup> Wholesale removal of unsuspecting nevi should be condemned as a surgical practice. Indiscriminant excisions are associated with unnecessary scarring and little effect on the development of melanoma. Most melanomas, even in patients with familial atypical mole-melanoma syndrome, arise *de novo*; thus, the excision of all atypical lesions may not eliminate the risk of developing melanoma. Large congenital nevi should be excised if feasible, and frequent screening should be performed in these patients until excision is performed. If the lesion is too large for excision, surgery may be limited to biopsies of the most worrisome sites in combination with observation and photographic documentation. Dermabrasion and other superficial excisions may not decrease the risk of developing melanoma and are not recommended.

## SCREENING

Prevention and screening for melanoma are reasonable objectives to restrain the rising incidence of this silent epidemic. Cancer screening for melanoma fulfills many of the requirements necessary for effectiveness. First, early detection appears to result in improved outcomes. Second, the screening process is easy to perform by primary care physicians, and third, the screening is cost effective.

### Efficacy

Randomized trials to determine efficacy and cost effectiveness of screening programs would require thousands of people and prolonged (greater than 10-year) follow-up; however, there is sufficient evidence to assume the validity and efficacy of current screening programs, especially in high-risk populations. Although the true effectiveness of screening programs can only be determined by noting an increased survival in screened populations, many reports demonstrate that thinner lesions are found in screened compared with unscreened cohorts. Since the thickness of the melanoma correlates linearly with survival in stage I and II patients, screening programs can measure their effectiveness through this intermediate end-point instead of waiting 10 years (or more) for survival data.<sup>101</sup> Numerous studies have been published from Australia, Europe, and the United States demonstrating the effectiveness of screening programs. Many have focused on high-risk populations in order to attain a high number of events with much fewer patients.

Many of the published screening trials studied high-risk populations with either a strong family history of melanoma, a previous personal history of melanoma, or a diagnosis of the dysplastic nevus syndrome. In one series of 555 high-risk patients, screening reduced the average thickness of diagnosed melanomas to 0.52 mm compared with an average tumor thickness of 1.44 mm before the screening program was instituted. None of the 138 patients diagnosed with melanoma on screening developed metastatic disease.<sup>102</sup> In another series from the Netherlands, in which high-risk patients were screened, the thickness of primary lesions decreased from 1.75 mm before the screening process to 0.8 mm at the start of the screening process and then to 0.54 mm during routine follow-up.<sup>103</sup>

In Australia, the incidence of melanoma is the highest in the world due to an equatorial climate, a fair-skinned immigrant population, and localized depletion of the ozone layer. The decrease in average tumor Breslow depth in Australia has been attributed to extensive screening. In 1960 the average thickness of melanoma lesions was greater than 2.5 mm. By 1986, after the establishment of a comprehensive screening program in the 1960s, the mean tumor thickness dropped to 0.80.<sup>104</sup> In France, a unique situation exists as occupational medicine specialists examine the entire working population yearly. In a study involving 65,000 people, 273 patients examined by occupational medicine specialists were thought to have suspicious lesions. Of these patients only 172 followed up with their primary care physicians and five melanomas were found. This translates to an incidence of 7.7 per 100,000, close to the 9 per 100,000 found in the general French population.<sup>105</sup>

The American Academy of Dermatology has provided more than 1 million free skin cancer screenings from 1985 to 1997. Of all the biopsies performed for suspicious lesions, 17% were found to be melanomas on histology. More than 90% of histologically confirmed melanomas were less than 1.5 mm thick, and the median thickness of all melanomas was 0.30 mm. The 8.3% of cases with advanced melanoma is a lower proportion than that reported by the 1990 SEER registry. The rate of thickest lesions (greater than 4 mm) and late-stage melanomas among all participants was 2.83 per 100,000 population. Thirty-nine percent of screened patients who had melanoma claimed they would not have sought examination otherwise and more than 30% of these melanomas were located on areas not readily visible on self-examination.<sup>106</sup>

### Examination

Although dermatologists have superior accuracy compared with nondermatologists in the diagnosis of melanoma and dysplastic nevi, there are too few dermatologists for all routine screening.<sup>107</sup> Dermatologists are generally more qualified in identifying these lesions. Screening for melanoma by a dermatologist has a sensitivity and positive predictive value of 89% to 97% and 17% to 75%, respectively.<sup>108</sup> The use of epiluminescence microscopy by an experienced dermatologist can greatly increase the sensitivity and specificity of the examination.<sup>109</sup> Further, only 12% of nondermatologists were able to correctly identify five out of six melanomas, whereas 69% of dermatologists did.<sup>101,110</sup> A viable health strategy for reducing the mortality of melanoma involves educating primary care providers to incorporate skin examinations as part of their routine physical examinations. With education, primary care physicians should successfully incorporate skin screenings in their physical examinations as they have with breast examinations, digital examinations, and fecal occult blood testing.

Screening examinations are quick, painless, inexpensive and readily accepted by patients. Complete examination of the skin should be performed systematically, with the patient fully undressed. Care should be taken not to ignore the scalp, nails, palms, soles, ears, and beneath the breasts. Since most melanomas occur on the trunk and lower extremities in women and on the trunk and proximal upper extremities in men, these areas should be carefully examined. Lesions of the perineum are uncommon and may be excluded unless the patient has a specific lesion in question. Problems do exist with screening protocols as some melanomas may have an uncharacteristically benign appearance and a radial growth phase shorter than the screening interval.

### Cost-Effectiveness

The cost of screening includes practitioner time spent with patients and the cost of biopsy and pathology. Since the ratio of positive to negative biopsy results ranges from 1:70 to 1:250, the number of biopsies subsequent to mass screenings may be considerable.<sup>105,106</sup> In a cost-effectiveness model of screening high-risk patients, \$29,000 would be spent per year of life saved. This is less than what is currently spent on prostate-specific antigen testing, Pap smears, or annual mammography.<sup>111</sup>

## STAGING OF MELANOMA

The staging of cutaneous melanoma involves segregation by local, regional, or distant disease and strongly correlates with survival ( [Fig. 42.2-13](#)). The vast majority of patients who present with primary melanoma have localized tumors, and for this reason stage I and II have been used to designate early (low-risk) and later (intermediate-risk) tumors, even though both represent localized disease. The features of melanoma that influence the risk of relapse are encapsulated in current and proposed staging systems of the American Joint Committee on Cancer (AJCC) ([Table 42.2-3](#) and [Table 42.2-4](#)). The last formal edition of this system (1992) is currently in revision, so the features of the prior system will be contrasted to those of the proposed new system of 2000.<sup>112</sup> In both systems, distant metastases (M1) define stage IV disease, whereas regional lymph node metastases (N1 to N3) define stage III disease and are cardinal prognostic variables for patients with melanoma of the skin. Most patients present with neither distant nor regional disease apparent, so the features of local prognostic significance assume a predominant role in defining the prospect for relapse-free survival and overall survival in patients with melanoma.

**FIGURE 42.2-13.** Melanoma survival correlates strongly with stage. Fifteen-year survival results are shown for over 4000 melanoma patients. (From Ketcham AS, Balch CM. Classification and staging systems. In: Balch CM, Milton GW, eds. *Cutaneous melanoma: clinical management and treatment results worldwide*. Philadelphia: JB Lippincott, 1985:55, with permission.)

**TABLE 42.2-4.** American Joint Committee on Cancer Tumor (T), Node (N), Metastasis (M) Stage Grouping for Cutaneous Melanoma<sup>a</sup>

### STAGE I MELANOMA

The microstage or Breslow depth and presence or absence of ulceration are the most important variables in those without regional or distant metastases.<sup>113</sup> Patients with localized disease apparent only at the primary site make up by far the largest category of those presenting with melanoma. The division between stages I and II has been arbitrary, in part reflecting an effort to separate low-risk from intermediate-risk disease.<sup>114,115,116 and 117</sup> The staging system adopted by the AJCC in 1992 moved from a dependence on prognostic assessment based on the levels of skin through which a tumor had penetrated, to a duality of thickness measured in millimeters according to Breslow, and levels according to Clark.<sup>118,119</sup> The role of the Breslow thickness has been recognized as more predictive of prognosis. A secondary importance of the Clark level, especially in thinner tumors, has been identified. The Breslow depth is the primary predictor of prognosis, even when it predicts a more favorable prognosis than the level of invasion. Although the AJCC 1992 system allowed for either thickness or level (whichever was worse) to be taken as the basis for risk assessment, thickness appears to be considerably more reproducible in predicting prognosis than the Clark level.<sup>112,118,120,121</sup> Thus, in the proposed new classification system<sup>112</sup> stage I and II melanoma prognostic assessment will be based on Breslow thickness and ulceration. The Clark level of the primary lesion enters multivariate analyses only as a secondary feature when the Breslow depth is less than 1 mm. Patients with T1 lesions and a Clark stage of IV or more have a 10% chance of nodal disease compared with only a 2% risk in those with T1 lesions and Clark stages less than IV. Because of the importance of Clark stage in thin tumors, lesions less than 1 mm in Breslow depth that are level IV or V are designated as T1b lesions.

#### Breslow Depth

The Breslow depth of a primary melanoma is the cardinal prognostic factor for clinically localized disease (stages I and II).<sup>119</sup> The risk of relapse and death due to melanoma rises incrementally with each millimeter of depth (Breslow thickness) for primary melanoma, and the relationship between primary tumor thickness and the relapse rate is linear between 1 and 6 mm (Fig. 42.2-14). Beyond 6 mm of depth, the incremental risk of relapse and death for each millimeter of invasion is less than for lesions below that thickness.

**FIGURE 42.2-14.** The relationship between primary melanoma thickness and survival is nearly a linear function. The American Joint Committee on Cancer breakpoints between T stages is not based on defined biologic mortality differences, but for convenience and general prognostic grouping.

Melanoma thickness is therefore a continuous variable, for which there are no natural breakpoints, so the choice of dichotomization between stages I and II (and within stage I between substage A and substage B, or in stage II between substages A and B) is somewhat arbitrary. The designation of T1/stage IA (less than 0.76 mm), T2/stage IB (from 0.77 to 1.50 mm), T3/stage IIA (1.51 to 4.00 mm), and T4/stage IIB (greater than 4.0 mm) has been based in part on data from early series in which it appeared there might be biologically determined breakpoints at these depths. The risk for patients in these categories rises in direct relation to the Breslow depth, without any evident breakpoints, to justify the previous divisions at 0.76 and 1.50 mm. The staging system proposed for adoption by AJCC in 2000 therefore adopts integer breakpoints at 1, 2, and 4 mm in place of the previous 0.76, 1.50, and 4 mm. <sup>112,116,118,122,123</sup>

### **Ulceration**

Ulceration is found in 21% to 60% of localized primary melanomas. <sup>115,117</sup> The presence of ulceration reduces the 5- to 10-year relapse-free survival by more than one-third and is important in both univariate and multivariate analyses. Ulceration is more common with deeper tumors, although melanomas of any depth can ulcerate. The median thickness of nonulcerated melanomas is 0.8 mm whereas that of ulcerated melanomas is 2.6 mm. Ulceration independently predicts local recurrence, regional disease, and worse overall survival. <sup>122</sup> In tumors with associated ulceration, the risk of regional lymph node dissemination is increased by 10% compared with nonulcerated tumors. <sup>112,116,118,123</sup> Adding back the depth of an ulcer crater does not correct for the decrease in survival associated with ulceration, and the width of ulceration is more significant than the depth in predicting prognosis. <sup>124</sup> The AJCC revision of melanoma staging for 2000 proposes the incorporation of ulceration as the major independent factor for prognostic assessment of stage I and II melanomas after the Breslow depth. The suffix *a* will indicate nonulcerated and *b* ulcerated primary melanoma.

### **Morphotype**

The morphotype of the primary melanoma historically was used to predict prognosis. Nodular melanomas have a higher risk and shorter latency than superficial spreading melanomas because of their tendency toward a vertical growth pattern. The less frequent acral lentiginous melanoma similarly has been associated with increased risk when compared with that of LMM. The latter morphotype is distinctive in its occurrence at a median age of more than decade later than that of the more common superficial spreading and nodular, as well as acral lentiginous, morphotypes. The site of origin is also distinctive for LMM, which is typically found on the chronically sun-exposed areas of the head and neck, and for acral lentiginous melanoma. These descriptive terms, although helpful in pattern recognition for clinicians, are less frequently used based on more modern staging systems.

### **Lymphoid and Dendritic Cell Host Response**

Infiltration of the primary melanoma site by lymphocytes has been correlated with an improved outcome in studies performed over the past several decades. The Boston Collaborative Melanoma Study has demonstrated a more favorable prognosis of melanomas infiltrated densely with lymphocytes. <sup>125</sup> The immunologic target of the lymphoid response frequently observed in primary melanomas, and less often in metastatic sites of disease, has led to intense efforts with each of the emerging therapeutic tools of immunology. There has also been a correlation with the infiltration of other immune mediators and prognosis. Dendritic cells (DC), potent antigen-presenting cells, are also found in melanoma specimens, and DC infiltrate is inversely related to tumor thickness in melanoma. DCs mediate several biologic roles including regulation of angiogenesis and the active uptake of apoptotic tumor, processing of nominal antigens and migration to local nodal basins where a specific T-cell response is capable of being stimulated. <sup>126,127</sup>

### **Regression**

Historically, lesional regression characterized by the histologic presence of fibrosis and centralized depigmentation has been suggested as an ominous sign. Many interpret regression as an invalidation of the Breslow depth because the tumor may have once extended deeper than measured at the time of excision. Thus, actual prognosis would be worse than predicted since the patient would be understaged. The studies of the University of Alabama and Sydney Melanoma Unit have not borne this out; in fact, complete regression of primary as well as metastatic lesions has been well documented, and rarely, spontaneous cures occur. <sup>128,129</sup> Melanomas with undetermined primary sites presumably originate from regressed lesions. These patients have the same if not a slightly better prognosis than equally matched patients whose primary is known. Other evidence suggests that melanoma regression is not a negative prognostic factor. Gershenwald et al. reported that no patient with melanomas less than 1 mm thick with evidence of regression had a positive sentinel node. <sup>130</sup> Tumor regression indicates an active specific tumor response may have beneficial systemic effects. Tumor immunologists have tried to augment this immune response through various vaccine strategies to treat melanoma.

### **Site of Origin**

Patients with melanoma of acral, subungual, and head and neck sites have a worse prognosis than those with melanoma arising on the extremities. Multivariate analysis from one mature series from the University of Pennsylvania (n = 488) and a multicenter German database (n = 5246) have shown that the site of tumor origin is an independent and significant prognostic variable. <sup>131,132</sup> and <sup>133</sup> In general, patients with primary lesions of the extremities have a significantly better prognosis than those with primary lesions of the trunk and head. Lesions of the upper and lower extremities do not differ in prognosis, but those found distally on the hands and feet fare worse than those with more proximal lesions. <sup>10,131,134</sup> The use of a model that incorporated four variables (i.e., site of origin, gender, age, and Breslow thickness) has been reported; the prognostic variables increased prediction of survival by up to 50%. <sup>131</sup> In patients with positive regional lymph nodes, the site of origin, gender of the patient, and age become unimportant in predicting prognosis.

## **STAGE II**

A large and relatively heterogeneous population is the group previously designated as stage II, composed of stage IIA (T3) melanomas between 1.5 and 4.0 mm in depth, and stage IIB (T4) melanomas of more than 4 mm in depth. Relapse risk for this group lies between 10% and 40% and is directly related to the primary Breslow depth. Beyond the Breslow depth in this category, the most consistent and powerful prognostic factor identified over the past 20 years has been the presence or absence of ulceration. The presence of ulceration is significantly associated with an increase in the likelihood of nodal metastasis and reduces the prognosis for relapse-free survival by nearly 10% for any given Breslow depth.

Elective lymph node dissection (ELND) has previously been the only available means to demonstrate the presence of regional lymph node involvement and proved to be positive in 20% of these patients with lesions greater than 1 mm in depth. The development of more precise techniques of lymph node mapping has significantly affected the ability to predict prognoses for this group of patients. Many large adjuvant trials have been conducted in patients for whom the pathologic status of the regional draining lymph nodes has either not been assessed at all, or in whom this has only been assessed using anatomically guided elective regional lymphadenectomy, not isotopically or dye-guided sentinel lymph node (SLN) mapping. Thus, the surgical and pathologic assessment of melanoma at the primary site has now been coupled with techniques that have demonstrated improved precision at the regional lymph node basin(s). Consequently, the assessment of relapse and mortality risk for primary melanoma patients with intermediate risk is in substantial flux. In patients for whom SLN mapping is not feasible, the previously defined risk algorithms and factors are still of use. For those in whom SLN mapping is appropriately performed and whose results are negative, the prognosis appears to be substantially improved. <sup>135</sup> The series of patients that have been assessed by SLN mapping have to date less than 5 years of median follow-up. The limited follow-up in these series qualifies interpretation of the data at this time, since it is possible that the identification of nodal disease using refined pathologic, immunohistochemical, and in some cases, molecular [reverse transcriptase-polymerase chain reaction (RT-PCR)] assays for melanosomal antigens such as tyrosinase may simply have improved lead time for the diagnosis of metastatic disease.

## **STAGE III**

In patients with nodal disease, only three variables independently affect overall prognosis: the number of lymph nodes, the presence of ulceration of the primary tumor, and whether the nodal disease is macroscopic or microscopic. In patients with macroscopic disease, more than one positive lymph node, and an ulcerated primary lesion, the 5-year survival is only 16%. In patients with only one microscopically positive node and without ulceration in the primary tumor, the overall 5-year survival is 71%. This large difference in survival demonstrates the inadequacies of previous staging systems and the heterogeneity of supposedly matched patients in previous clinical trials. <sup>136</sup>

## Sentinel Lymph Node Mapping

The detection of lymph node metastases previously relied on crude clinical or regional ELND, which has not improved survival in several large randomized controlled trials. Currently, SLN mapping and selective lymphadenectomy directed by isotopic lymphoscintigraphy or blue dye lymphography has been shown to identify lymph node metastases more precisely and with less surgical morbidity, hospitalization time, and cost than elective dissection. <sup>135,137,138</sup> All of the observations reported from series attempting to refine the prognostic assessment of patients based on Breslow depth and Clark's level, with or without ulceration, has been in many ways supplanted by the availability of pathologic assessment of SLNs mapped using isotopic and dye techniques. A study of 580 patients whose sentinel draining lymph nodes localized using dye and scintigraphic techniques (e.g., SLN) and found to be pathologically negative has demonstrated that the status of the SLN is the single most powerful prognostic factor after Breslow depth ( $P < .00001$  for each). <sup>135,137,139</sup> Sentinel node status remains a significant prognostic factor in multivariate analyses of disease-specific survival in this model after adjustment for other previously identified prognostic factors. Once SLN status is accounted for, a number of factors that have previously been considered as independent prognostic factors lose their significance. The primary site of origin, age of the patient, and sex of the patient are all nonsignificant after incorporation of SLN status in a prognostic model for outcome of stage I and II patients. <sup>135,139</sup> The multidisciplinary procedure of SLN evaluation requires attentive radiology and meticulous pathology as well as expert surgery for optimal outcome. <sup>140,141</sup> Whether the information attained from SLN biopsy allows treatment decisions that alter outcome remains a question currently being addressed in a number of prospective trials. Even though it has been widely adopted by most centers in the United States, it is less widely applied elsewhere and the results of seminal prospective studies should be available within the next few years to assess its utility in improving patient outcome. It is conceivable that strategies to quantitatively identify tumor in the peripheral blood using molecular analysis or serologic assays may supplant this surgical staging procedure.

## Number of Nodes

Regional lymph node involvement defined stage III in the AJCC system in 1992 as it does currently. The size of involved lymph nodes had previously served as the basis for characterization of patients within stage III (TNM N1, N2, N3). Multiple studies have been performed using Cox regression analysis to identify the most important predictors of outcome for patients with stage III disease. <sup>116</sup> In all of these studies, the number of lymph nodes found to be involved with tumor (whether macroscopic or microscopic) has been the cardinal factor identified ( Fig. 42.2-15). The advent of sentinel node mapping has increased the precision with which regional lymph node dissemination can be identified, but even in studies that have patients evaluated by SLN mapping, the number of involved lymph nodes has been a significant prognostic factor. <sup>135,142</sup> The prognosis for patients with one involved regional lymph node is significantly better than for patients with two or more involved regional lymph nodes. <sup>112,116,143,144</sup> and <sup>145</sup> The recommended AJCC 2000 staging system will adopt the number of nodes involved with tumor as the principal basis for prognostic assessment of patients with regional disease. N1 will signify one node involved, N2 will signify two to three nodes involved, and N3 will signify four or more nodes involved with tumor. N3 includes matted nodes and ulcerated melanoma with any number of metastatic lymph nodes. A secondary criterion for classification of patients with nodal metastatic disease is that of nodal bulk of disease (microscopic versus macroscopic). The former is invisible to the gross surgical or pathologic evaluation, nonpalpable, and designated (a). The N1(a)/N2(a) category of microscopic involvement represent a significant and increasing fraction of patients identified through sentinel node mapping procedures, for whom the prognosis appears to be improved. Previous data suggested a more favorable prognosis of patients with microscopic disease identified at ELND as compared with those with clinically manifest recurrence subjected to therapeutic node dissection. <sup>146,147</sup> Although the sentinel node is meticulously examined using immunohistochemistry and fine sections, for practical reasons, nodes from the completion lymphadenectomy specimen are not. The prognostic importance of rigorously characterizing the number of sub-micrometastatic positive nodes after completion lymphadenectomy using thin sections and immunohistochemical staining is unclear.

**FIGURE 42.2-15.** Survival for stage III patients according to the number of nodal metastases. Survival correlates strongly with increasing numbers of positive lymph nodes. (From ref. 222, with permission.)

## Satellitosis and In-Transit Disease

The stage III category has also been designated for patients with forms of regional extranodal disease. Satellite involvement, *satellitosis*, is a form of tumor extension that may be manifested by deep or aggressive primary melanomas, often with intervening areas of apparently tumor-free skin. Satellite involvement signifies a poor prognosis for patient outcomes; prognosis has been shown to resemble that of patients with regional lymph node involvement. A second category of metastatic melanoma that has long been recognized to have a more ominous prognostic significance than localized primary disease is known as *in-transit disease*. In-transit melanoma does not differ from more typical nodal metastatic disease. The more indolent course of in-transit melanoma, particularly when associated with paraneoplastic hypopigmentation, has led to substantial immunologic interest in this form of melanoma, and its location has lent itself to regional isolated perfusion chemotherapy and biologic therapy. <sup>148,149</sup> For these reasons, both satellite involvement in the region of the primary, and in-transit melanoma between the primary and regional nodal basin have been assigned to a category N2C. Patients with both manifestations of satellite involvement or in-transit involvement with regional lymph node metastases have been assigned to the N3 category, due to their more ominous prognosis, regardless of the number of involved regional lymph nodes. <sup>112,116,118,147,150</sup>

## STAGE IV: M1

Distant disease that has spread beyond the regional draining lymph nodes is generally denoted as M1 in the TNM system and stage IV in the AJCC and Union International Contra le Cancrum systems. The prognosis of patients with stage IV M1 disease is poor, with median survivals of less than 1 year. <sup>151</sup> The AJCC Subcommittee on Melanoma has reviewed criteria for this disease category, which represents the smallest fraction of patients of any stage at presentation, but a significant fraction of the patients with melanoma who will die each year. For these patients, the identification of important prognostic factors may guide treatment selection or decisions whether to pursue therapy. An analysis of the clinical factors associated with a favorable prognosis in patients with stage IV disease entering therapeutic trials of the Eastern Cooperative Oncology Group (ECOG) has demonstrated that patient factors including a normal appetite, absence of nausea and vomiting or fever, unimpaired performance status, and female gender are significant. Disease-related factors of prognostic importance included limited numbers of sites of disease, disease limited to soft tissues and lymph nodes, a time interval more than 1 year to therapy for metastasis, and the occurrence of a clinical response to treatment. <sup>152</sup> A current reassessment of important factors in 1325 patients with stage IV melanoma treated in eight clinical trials over 25 years in ECOG has identified many of the same factors to be significant, including the number of metastatic sites, unimpaired performance status, and female gender. A number of multivariate analyses of factors that bear on survival in stage III or IV have been reported. <sup>153,154,155,156</sup> and <sup>157</sup> The median survival in all studies has been 6 to 8 months, except for one case record analysis of the European Organization for Cancer Research and Treatment Group of Cancer (EORTC). <sup>158</sup> In a large metaanalysis of patients with disseminated melanoma that included 83 studies and 6322 patients, the median survival for patients diagnosed after 1985 was 8.9 months. The 2-, 3-, and 5-year survival rates were 13.6%, 9.7%, and 2.3%. Survival for patients before 1985 was 5.9 months. The study provides important information that will allow survival results from current and future trials to be compared with expected survival. <sup>158</sup> The number of sites or organs involved with metastatic disease appears to be of significance in most models and is unquestionably important in determining prognosis. However, the AJCC has presently chosen not to incorporate a measure of the number or volume of tumor metastases, due to the variability of imaging techniques employed to assess the presence of metastatic disease, and the state of flux of radiologic assessment for melanoma at present. The 1992 formulation of stage IV disease dichotomized metastatic disease according to its location in nonvisceral (M1a) or visceral (M1b) locations. A review of data from JWCI (John Wayne Cancer Institute), <sup>157</sup> the ECOG, <sup>159,160</sup> and other series has shown that metastatic disease

involving the lung but no other viscera has a prognosis that is intermediate between that of nonvisceral distant metastasis and other visceral sites of metastasis. The proposed reformulation of the AJCC for 2000<sup>112,118</sup> proposes classification of nonvisceral metastatic disease limited to skin, soft tissue, and nodes be designated as M1a, and that involvement of lung sites be considered as M1b, with the M1c category left to designate all other visceral sites of disease.

### **Biochemical and Serologic Markers**

Many studies have evaluated biochemical, immunologic, or other quantitative blood assays that might reflect the prognosis of patients with melanoma. One of the earliest was the level of the enzyme lactic dehydrogenase (LDH), assessed as a marker of metastatic disease, particularly within the liver.<sup>161</sup> Several multivariable proportional hazards models have evaluated the importance of an elevated LDH level (either elevated above the mean value for a laboratory or above the upper limit of normal for the laboratory). In each case in which LDH was assessed, it proved to be a significant prognostic factor. Additional factors included melanoma inhibitory activity (MIA)<sup>162</sup> and the level of the polypeptide S-100b.<sup>163</sup> The AJCC Subcommittee for Melanoma has taken a significant step in a new direction in the proposed 2000 revision of the melanoma staging system<sup>112,118</sup> by including LDH measurement as a factor to be employed to define a more ominous prognosis and to downstage patients with known metastatic disease who have an elevated LDH value, assigning these patients with stage IV disease to stage IV M1c.

A number of studies have proposed the prognostic utility of S-100b measured by radioimmunoassay or a more recent luminometric immunoassay.<sup>164</sup> A prospective, observational study evaluated the clinical and prognostic value of S-100 protein in patients with metastasis-free disease versus patients with newly occurring lymph node, visceral, brain metastases, or all three. In this series that included 570 patients and 52 normal controls, the sensitivity and specificity of S-100 measured by an immunoluminometric assay was 64% and 91%. False-negative results occurred in those with amelanotic melanoma. The negative predictive value was 99%, but the positive predictive value was only 65%.

S-100b was examined prospectively in the peripheral blood of patients undergoing surgical procedures for resection of high-risk primaries or lymph node metastases. Of the patients who were S-100b positive by luminometric immunoassay, 47% developed metastatic disease after at least 2 years of follow-up. Kaplan Meier analysis showed that patients who were S-100b positive had approximately 2.7 times shorter disease-free survival than patients negative for S-100b. This difference was statistically significant, and multivariate analysis showed that S-100b was an independent prognostic determinant of disease-free survival.<sup>164</sup>

RT-PCR has also been used to gain prognostic information by attempting to detect small numbers of blood-borne melanoma cells. The technique is generally limited by its extreme sensitivity. The use of tyrosinase has been somewhat problematic because tyrosinase is also present in nonmalignant cells including melanocytes in the dermis picked up by phlebotomy. Up to 10% of healthy people may have blood tyrosinase-positive cells in this assay.<sup>165</sup> However, tyrosinase has been used to detect circulating melanoma cells in patients with melanoma with intriguing results. Positive tyrosinase results are seen in stage I, II, III, and IV melanoma patients at a frequency of 11%, 18%, 31%, and 67%, respectively. In stage IV patients, median overall survival was 8 months compared with 12 months in those patients with a negative test result.<sup>166</sup> Tyrosinase is present in a proportion of long-term clinically disease-free melanoma patients, and the late presence of circulating melanoma cells predicts a subsequent high risk of relapse and death. Some studies have correlated tyrosinase positivity with increasing stage, survival, presence of visceral metastases, and higher LDH levels.<sup>167,168</sup> Actuarial 2-year survival is 97% for the tyrosinase-negative patients versus 72% for the tyrosinase-positive patients.<sup>169</sup> The use of true real-time quantitative PCR (Taqman) may improve on the prognostic utility of these melanoma assays.

MIA, a novel molecular marker, has been examined as a potential prognostic marker. One hundred sixty-six patients with melanoma were examined for expression of MIA. A correlation between positive blood sample results and tumor burden in stage III and IV patients was detected and 73% of stage I and II patients were negative for the MIA RNA. Five of 24 patients who were RT-PCR positive progressed to systemic disease within the follow-up period of 6 months. The predictive values were low and the study was too small to deduce prognostic significance.<sup>165</sup> MIA, as currently examined, is limited in its utility as a prognostic marker.

Immunosorting of melanoma cells using magnetic cell separation has been used to isolate, in a specific fashion, viable melanocytes from patient's blood. This technique does not have suitable sensitivity for early detection of metastasis, but may prove a valuable tool in the isolation and identification of circulating autologous melanoma cells. No patients with stage I primary melanoma were found to have circulating melanoma cells, whereas 13.6% and 15.2% of patients with stage III and IV disease were found to have them. The prognostic significance of these circulating cells is unknown.<sup>170</sup>

### **IMAGING OF MALIGNANT MELANOMA**

Conventional evaluation of the patient with primary melanoma involves chest radiography for all patients with primary lesions deeper than 1 mm. In the setting of established stage II or III disease, radiologic evaluation may be indicated with the use of magnetic resonance imaging of the brain and computed tomography (CT) of the chest, abdomen, and pelvis. In the setting of known metastatic disease, thorough evaluation may be required to allow the participation in clinical trials and in planning therapy. Advances in imaging techniques have improved the ability to identify and localize primary and metastatic melanoma. The most notable advances have been positron emission tomography (PET), radionuclide agents with affinity for melanoma, and the resurgence of lymphoscintigraphy. Lymphoscintigraphy can provide valuable assistance in localizing SLNs for biopsy.<sup>171</sup> It is particularly helpful for tumor locations with variable lymphatic drainage and has identified previously unsuspected drainage patterns for some regions.<sup>171</sup>

Improvements in PET have made it a valuable staging study for melanoma. Rinne et al. prospectively compared whole body <sup>18</sup>F-fluorodeoxyglucose PET with conventional imaging (CT, magnetic resonance imaging, and so forth) in 100 consecutive patients (52 at diagnosis, 48 at follow-up).<sup>172</sup> At initial staging, PET was 100% sensitive and 94% specific, whereas conventional imaging did not identify any of the nine lymph node metastases and was 84% specific. In the 48 follow-up patients, the sensitivity, specificity, and accuracy of PET per metastasis was 92%, 94%, and 92%, respectively, compared with 58%, 45%, and 56% with conventional imaging. While PET was better at detecting cervical lymph node metastases (100% vs. 67%) and abdominal metastases (100% vs. 27%), CT was better for small lung metastases (87% vs. 70%). With the exception of brain imaging, where magnetic resonance imaging is superior, these authors suggested that a single whole body PET scan could replace all other imaging performed in melanoma patients. This will need to be evaluated in other series.

Other imaging techniques that show promise in melanoma are technetium 99m (<sup>99m</sup>Tc)-sestamibi (MIBI), <sup>99m</sup>Tc-tetrofosmin, and iodine 123 iodobenzamide (for melanotic tumors).<sup>173,174</sup> and <sup>175</sup> Of these, <sup>99m</sup>Tc-MIBI has undergone the most thorough evaluation and appears to be a reasonably inexpensive substitute for whole body PET scans in staging melanoma patients.

### **RADIOBIOLOGY OF MELANOMA**

Early experiences with conventional radiotherapy of melanoma led some clinicians to believe that this tumor was so radioresistant that radiotherapy was of little use. This erroneous deduction was based on experience with treating melanomas with conventional low-dose fractions (approximately 2 Gy per fraction) and moderate total overall doses. Radiobiologic studies of melanoma have subsequently altered the clinical approach to treating melanoma. Some investigators identified wide *shoulders* for *in vivo* cell survival curves for melanoma, suggesting a large capacity for repair of sublethal damage that prompted a number of investigators to treat patients with malignant melanoma with large-dose fractions.<sup>176,177,178,179,180,181</sup> and <sup>182</sup> There is some intrinsic variability within various melanoma cell cultures, and these models differ in many respects from tumors found in patients. Analyses of clinical experiences with various radiotherapy treatment schedules provided important data. Melanoma can be responsive to radiotherapy when large-dose fractions are used.

An important study of the clinical radiobiology of melanoma is the analysis by Bentzen et al. of tumor control in 121 patients with 239 histologically proven recurrent or metastatic malignant melanomas.<sup>179</sup> They identified an alpha to beta ratio of 0.57 (95% confidence interval, -1.07 to 2.5 Gy). The rationale for standard fractionation is that small-dose fractions preferentially spare late reacting normal tissues with lower alpha to beta ratios (1.8 for subcutaneous) than malignant tumors, which usually have alpha to beta ratios closer to 10.<sup>183,184</sup> With melanoma, these clinical data indicate the reverse situation. In cases in which the larger individual dose fraction is used, more normal tissue is spared the effects of radiation compared with tumor. There is little treatment time effect (negligible repopulation during a treatment schedule) indicating that treatment may be administered with large-dose fractions twice a week rather than conventional application five times per week schedule. The subsequent protraction of the overall treatment time allows normal cell populations that determine acute radiation reactions (such as moist skin erythema and mucositis) to repopulate to a greater degree between fractions to minimize acute side effects. The dose response is markedly influenced by tumor size in radiotherapy of melanoma. [Figure 42.2-16](#) shows the estimated total doses necessary for 80% control probability in tumors of different sizes with different dose fractions derived from their data. In contrast with these findings, the Radiation Therapy Oncology Group trial 83-05 found largely identical responses in 137 patients with measurable melanoma lesions randomized between 32 Gy in four weekly 8-Gy fractions (24% complete response, 35% partial response) compared with 40 Gy

with daily 2.5-Gy fractions (23% complete response, 34% partial response).<sup>185</sup>

**FIGURE 42.2-16.** Radiosensitivity of melanoma. Total dose (Gy) necessary to control 80% of malignant melanoma tumors as a function of tumor size and dose per fraction as estimated from 239 tumors in 121 patients. (Redrawn by permission from ref. 179.)

Several factors have been postulated to contribute to the relative radioresistance of melanoma including tumor hypoxia, loss or dysfunction of the p16 DNA locus, and decreased cell membrane gangliosides.<sup>186,187,188</sup> and <sup>189</sup> A number of different innovative techniques are being investigated to improve radiotherapy of malignant melanoma. Hypoxic cell sensitizers such as tirapazamine and gadolinium texaphyrin show promise in preferentially killing radioresistant hypoxic cells within melanoma tumors.<sup>190</sup> Hyperthermia combined with radiotherapy is another approach to optimize killing of hypoxic tumor cells.<sup>191,192</sup> Approaches that combine radiotherapy with radiosensitizing chemotherapy such as topoisomerase I targeting drugs (topotecan, camptothecin) or taxanes, which arrest cells in the most radiosensitive phase ( $G_2/S$ ), also could improve radioresponsiveness.<sup>188,193</sup> Boron neutron capture therapy, which depends on selective drug uptake in tumor (as does gadolinium texaphyrin), also holds potential in treatment of melanoma.<sup>194</sup> Gene therapy including application of N-Ras or Myc transfection is another promising approach to increase radiosensitivity.<sup>194a</sup> The specific use of radiotherapy on primary tumors, in-transit disease, recurrences, and metastatic disease are discussed in the following sections.

## STAGE I AND II DISEASE: MANAGEMENT OF PRIMARY MELANOMA

All lesions with characteristics suggestive of melanoma should be biopsied. Suspicious lesions may have irregular raised surfaces; ulceration, bleeding, or both; variegations; or recent changes in color or size. As sampling error may occur with incisional biopsies, a full-thickness excisional biopsy is the preferred diagnostic technique since the depth of the lesion determines the extent of resection. Shave biopsies are contraindicated since they may not encompass the full depth of the lesion and make pathologic interpretation of Breslow depth impossible.

### PREOPERATIVE WORKUP

The most important staging information obtained from patients with melanoma is the Breslow depth, presence of ulceration, and nodal status. The 1992 National Institutes of Health Consensus conference indicated that asymptomatic patients with T1 lesions do not appear to benefit from any diagnostic staging including computed tomography, magnetic resonance imaging, or nuclear scans. A chest radiograph is performed in patients with stage IB disease or greater.<sup>195</sup> Liver function tests, especially LDH, and other radiologic tests are indicated in stage III and IV disease or otherwise symptomatic patients.

### EXCISIONAL BIOPSY

Performing an excisional biopsy is preferable over an incisional biopsy. Sampling error may limit the reliability of assessing the Breslow depth of incisional biopsies. In most instances, a biopsy can be done in an office setting under local anesthesia with minimal morbidity. An excisional biopsy removes the lesion *en toto*. No effort is made to obtain a wide margin, but a small margin (1 to 2 mm) of normal skin is taken with the elliptical specimen and primary closure performed on most lesions. The specimen is sent to pathology for permanent section. Some surgeons suggest that a single-stage procedure is possible using frozen sections to characterize tumor depth, but this has not been validated.<sup>196</sup>

### INCISIONAL BIOPSY

Wide excision after incisional biopsy was initially thought to be associated with a higher recurrence rate. Those studies were poorly designed and retrospective, and no evidence in the recent literature suggests a worse outcome from incisional biopsy. However, incisional biopsy has a higher rate of inaccurate microstaging<sup>197</sup> and should be reserved for large or subungual lesions to confirm diagnosis. Incisional biopsies may be used in areas such as the face where cosmesis and skin coverage are an issue. The biopsy should be a wedge of tissue including normal skin, the center of the lesion, and subcutaneous fat.

### SURGICAL MARGINS OF RESECTION

The depth of melanoma resection does not require inclusion of the underlying muscular fascia, although this was initially suggested. Biopsies should go down to, but not include the fascia.<sup>198</sup> For years, no clear standard existed that guided the amount of margin to resect around the primary tumor. The margin is defined as the radial distance from the visible edge of the lesion or scar. Only relatively recently have randomized trials examined the width of surgical margin in relation to local recurrence and overall survival. Pathologists have long observed malignant cells separated by some distance from the primary lesion. Wide excisions minimize the risk of leaving behind these cells that may locally recur or metastasize. Rests of malignant cells can be found distances of 1 cm from the visible edge of the tumor, and their presence outside 1 cm is directly proportional to the depth of the primary lesion.<sup>199,200</sup> Some histopathologic data show morphologically bizarre melanocytes in normal skin upward of 5 cm from the primary site.<sup>201</sup> The extent of excision necessary should depend of the thickness of the primary tumor. Since large resections risk functional deficits, disfigurements, and increased cost, determining the minimal excision margin has been extensively studied.

Appropriate initial resection remains crucial in the management of primary melanoma since almost all patients with a local recurrence die of metastatic disease. Locally recurrent disease may be just a surrogate for more aggressive biologic behavior, but an adequate surgical resection should never be compromised.<sup>202</sup> Local recurrence, defined as tumor relapse within 3 to 5 cm of the primary closure or skin graft, is a relatively rare event, making the design of trials difficult. In a retrospective series of 3569 patients, local recurrences were found in only 3.2% of patients.<sup>203</sup> Some factors have been identified that are associated with the probability of local recurrence. One large study found that the probability of local recurrence depends on only ulceration of the primary tumor (1.5% without ulceration vs. 10.6% with ulceration) and tumor thickness (2.3%, 4.2%, 11.7% for 1 to 2 mm, 2 to 3 mm, 3 to 4 mm lesions, respectively).<sup>204</sup> Another large prospective series found that the site of primary tumor also predicted recurrence. In the 10-year reassessment of the Intergroup trial, multivariate analysis showed that the only variables that predicted local recurrence were ulceration and a head and neck primary site. The proximal extremity was least likely to have a local recurrence, followed by the trunk, distal extremity, and head and neck. When ulceration was present, the relative risk of local recurrence was 6.3 compared with nonulcerated melanomas. In patients with head and neck primaries, the relative risk for local recurrence was 9.4 compared with all sites. Both of these risks were highly significant.<sup>136</sup>

Although the risk of recurrence increases with more narrow margins, wide incisions can be quite morbid. A more radical excision is associated with the morbidity of cosmetic defects, functional losses, and the need for skin grafting. Wide excisions for melanoma were first popularized by Handley in 1907 who described a 1-inch skin margin with further undermining of 2 more inches laterally.<sup>205</sup> In 1947 Urteaga and Pack compared radiation therapy to surgical excision with an 8-cm margin and found resection to have a superior 5-year survival.<sup>206</sup> Others proposed routine amputations or huge 15-cm margins with *en bloc* lymphadenectomy. Until more recent randomized trials, a 3- to 5-cm excision, which frequently required skin grafting, was the standard treatment. Even as late as the 1980s, there were no national guidelines for the extent of excision necessary and much variation between surgeons existed. Although the rate of recurrence was known to depend on tumor depth, there was no correlation between the extent of operation and tumor thickness.<sup>207</sup> Three well-designed, randomized prospective trials and various retrospective trials

supports the use of a 1-cm margin for melanomas less than 1 mm thick and a 2-cm margin for deeper lesions deeper ([Table 42.2-5](#)).

Stage	Margin
Melanoma in situ	0.5 cm
T1 (<1 mm)	1 cm
T2 (2-3 mm) or greater	2 cm
Subungual	Amputation just proximal to distal interphalangeal joint

**TABLE 42.2-5.** Current U.S. Recommendations for Excision of Primary Melanoma

### **Thin and Intermediate Thickness Lesions**

Breslow and Macht first questioned the need for excessively wide (3 to 5 cm) resection margins for thin melanomas in 1970.<sup>119</sup> The World Health Organization (WHO) designed a trial to answer the question of resection margins in thin lesions (less than 2.0 mm). In the WHO trial, 612 patients with melanomas less than 2 mm thick were randomly assigned to either receive wide excision (3 cm) or narrow excision (1 cm). The results, reported in 1988, showed that the 12-year survival rates were not significantly different at 87.2% and 85.1%, respectively. There was a 1.8% recurrence rate in the 612 patients. There were four local recurrences in patients with lesions 1.1 to 2.0 mm deep who received a narrow excision and none of the patient who had had the 3-cm excision. Although this difference was not statistically significant and there was no difference in survival between the two groups, the WHO reserved judgment on the safety of narrow excisions for intermediate-thickness lesions. They concluded that in melanomas less than 1.0 mm in depth, a 1-cm margin is to be recommended.<sup>208</sup>

The Melanoma Intergroup trial was designed to examine intermediate-thickness lesions and reported its initial data in 1993. The Intergroup trial entered 468 patients with lesions 1 to 4 mm in thickness and randomized patients to undergo either a 2-cm or a 4-cm wide local excision. After a median follow-up time of 8 years, the overall survival rates were 79.5% and 83.7%, respectively (no significant difference). The local recurrence rates were not significantly different at 0.8% and 1.7% in patients with 2- and 4-cm margins, respectively. With a narrow margin, the rate of skin grafting decreased from 46% to 11%, with a resultant decrease in hospital stay and cost.<sup>209</sup> In 1996, the Swedish Melanoma Study group subsequently reported their series of 769 randomized patients with thin and intermediate-thickness melanoma to a 2- versus a 5-cm margin. Again, there was no difference in local or regional recurrence or survival.<sup>210</sup> The current standard of care for lesions between 1 and 4 mm is a margin of 2 cm.

### **In Situ and Thick Melanomas**

For treatment of patients with melanoma *in situ*, retrospective data supports the use of 0.5-cm margins. There have not been any reported local recurrences using this as a guideline.<sup>195</sup> For thick primaries, no randomized trial exists comparing different resection margins; however, a retrospective review of 278 patients compared excisions greater than 2 cm with excisions less than 2 cm in thick lesions. With a median tumor thickness of 6 mm, no correlation between the width of marginal resection and local recurrence or overall survival was found. The local recurrence rates were 11% and 13% in the less than 2-cm and greater than 2-cm excision groups, respectively.<sup>211</sup> Thick tumors do not require a margin greater than 2 cm since patient outcome is dictated more by the presence of regional and systemic disease. Currently, a prospective trial is accruing patients with melanomas greater than 2 mm thick and randomizing them to 1-cm versus a 2-cm margin. Outside of this trial, resection margins of 2 cm are recommended for all lesions greater than 1 mm deep.

### **Technique**

The surgeon should mark the appropriate resection margin from the visible edge of the tumor or scar. If primary closure is desired, an elliptical incision should be performed. The minor axis of the ellipse should encompass the resection margins and the major axis should be approximately three times the minor axis. The long axis of the ellipse should be parallel to the axis of the extremity, or, if on the trunk, along Langers' lines. Care must be taken not to bevel the dissection inward, and the excision should not include the fascia. Generous undermining of the lateral flaps allows for a tension-free closure. Rotational flaps may be required for large lesions or lesions on the face.

## **SPECIAL SITES**

### **Subungual Tumors**

If a nail bed lesion has not changed significantly in 4 to 6 weeks, a biopsy should be performed accompanied by removal of the nail. An incisional biopsy, taking a representative wedge that includes the middle of the lesion, is recommended to establish a diagnosis and prevent needless amputation. The biopsy should include the nail plate and should be oriented longitudinally.<sup>84</sup> The level of amputation does not seem to affect the incidence of recurrence or patient survival, so especially in lesions of the thumb, maintenance of function is important. For disease confined to the nail bed, amputation through the distal interphalangeal joint is recommended, and for bulky disease, a more proximal amputation through the base of the phalanx may be required.<sup>212,213</sup> Toe amputations should be performed more proximally as the loss of a toe at the metatarsal-phalangeal joint does not result in decreased function. Some surgeons advocate ILP, sentinel node biopsy, or both in patients with these high-risk lesions. There are few data showing a survival benefit in any patient with melanoma using adjuvant ILP.

### **Acral and Lentiginous Melanoma**

Due to functional concerns, there is a tendency to use smaller margins, perhaps accounting for the two- to fivefold higher incidence of local recurrence in this area.<sup>214</sup> Excisions often require split-thickness skin grafting for closure or tissue transfer, especially in wounds involving weight-bearing areas such as the heel of the foot that may require flap transfer.<sup>215</sup> In most instances, skin grafts may be applied successfully to weight-bearing areas.<sup>216</sup>

### **Head and Neck**

Melanoma of the face and scalp represent sites where local recurrence, nodal, and in-transit disease occur more frequently perhaps due to the extensive lymphatic drainage. Melanoma of the head and neck usually occurs in an age group 10 years older than truncal and extremity melanoma. The lesions most commonly involve the face ([Table 42.2-6](#)). LMM, a common morphotype of head and neck melanomas, is historically associated with an improved prognosis. However, appropriate excision margins for Breslow depth should not be compromised solely on cosmetic bases.<sup>217</sup> LM, a benign precursor lesion, can be treated through a number of techniques that do not require a wide margin of resection. Since up to one-half degenerate into malignancy, the treatment of these lesions is warranted. Multiple techniques have successfully been used to treat these lesions including excision, micrographic Moh's surgery, cryosurgery, radiotherapy, electrodesiccation and curettage, 5-fluorouracil, azelaic acid, and retinoic acid.<sup>218</sup> A Wood's lamp examination often helps to define the extent of pigmentation better than room light.<sup>219</sup> Full-thickness wedge resections are indicated for melanomas arising on helix of the ear ([Fig. 42.2-17](#)).

Region	No.	Age (Median) (y)
Face	316	68
Eyelid	15	66
Auricle	54	66
Neck	88	58
Scalp	23	58

\*The mean age at diagnosis of head and neck melanoma is 15 years older than those found at other sites. These melanomas should be excised without compromise of appropriate margins. Head and neck melanomas tend to have a higher recurrence rate, have a more complicated nodal drainage, and often require tissue transfer for closure. The most common site of these melanomas is on the face.<sup>187</sup>

**TABLE 42.2-6.** Mean Age at Diagnosis for 496 Patients with Melanoma of the Head and Neck <sup>a</sup>

**FIGURE 42.2-17.** Melanoma of the external ear. These patients should be treated by a full-thickness wedge excision of the helix. Primary, three-layer closure can easily be performed with good cosmetic results. (Courtesy of H. Edington, M.D., University of Pittsburgh Cancer Institute.)

### MOHS MICROGRAPHIC SURGERY

Mohs micrographic surgery (MMS) has been used for some time by dermatologists for nonmelanomatous lesions. The technique reduces scarring and may spare normal tissues by shaving involved tissues until a histologically negative margin. MMS employs repeated shallow (3-mm) resections, each examined histologically by frozen section. Some specialized centers have proposed the use of Mohs surgery in melanoma to minimize loss of normal tissue, especially in areas such as the face, hands, and feet. Margins are generally taken somewhat less than the WHO and Intergroup trials found appropriate, which has generated much criticism from most melanoma experts. There have been no randomized trials comparing the standard surgical excision with MMS, but in some uncontrolled centers, rates of local recurrence and overall survival have not been found to be inferior to matched historic controls. Interesting differences exist between traditional surgical resection and micrographic surgery. For instance, the diameter and location of the primary tumor are prime determinants of the expected extent of excision in the MMS literature. Proponents of Mohs surgery claim that repeated frozen sectioning is accurate and saves normal tissues. Opponents cite the fact that satellite lesions may be missed using the Mohs technique and that pathologists do not generally examine the specimens. Critics also claim that frozen section is notoriously inaccurate for identification of melanoma.<sup>220</sup> Appropriate controlled multicenter trials are essential before this technique can be accepted by the surgical community for the treatment of melanoma.

### RADIOTHERAPY OF PRIMARY SKIN TUMORS

Radiotherapy is rarely indicated in the management of primary invasive melanoma except in patients who refuse surgical excision or who are poor medical candidates. Treatment is usually administered with 6- to 9-MeV electron beams or 100- to 280-kilovolt (peak) x-rays using wide margins. Seegenschmiedt et al. reported tumor control in all 11 patients with residual (n = 6) or recurrent (n = 4) stage IIB melanoma (one patient with primary disease refused surgical excision).<sup>180</sup> They found better tumor control in these patients compared with control achieved through radiotherapy in patients with skin and lymph node metastases. Radiotherapy is a noninvasive alternative to surgical resection in the management of LM. This therapy may be appropriate for patients who cannot undergo or refuse surgery. Harwood reported 40 cases of LM and LMM managed with radiotherapy alone at Princess Margaret Hospital.<sup>175</sup> Radiotherapy doses were 45 to 50 Gy in 10 to 15 fractions with orthovoltage beams. Fourteen of 17 patients with LM and 34 of 37 with LMM were alive without tumor progression after 1 month to 7 years. Four patients with local recurrent or persistent tumor (two LM and two LMM) were salvaged by surgery (one LM, two LMM) or further radiotherapy (one LM). One LM patient died of intercurrent illness. Lesions can take up to 2 years to disappear after radiotherapy and the follow-up of available series remains short.<sup>175</sup>

### STAGE I AND II DISEASE: EXAMINATION OF THE LYMPH NODE BASIN

Although prophylactic nodal dissection has never clearly been demonstrated to be of survival value in any other tumor, the Halstedian belief of radical lymphadenectomy has, and still dominates the treatment of melanoma. Physicians have believed that a survival benefit exists after the early removal of nodes that are subclinically involved with tumor compared with removal once obvious nodal disease develops because the longer melanoma grows in the lymphatics, the more likely it is to metastasize systemically. This concept was tested in numerous trials by comparing ELND, a complete lymphadenectomy (LND) in those at risk for nodal disease but without clinical evidence, with therapeutic lymph node dissection (TLND), LND in those with clinically positive nodes. Although no clear survival benefits have yet been demonstrated by ELND, many confounding factors may have contributed to the generally negative results. After years of controversy surrounding the potential benefit of elective nodal dissection and numerous trials, it is ironic that, regardless of the conclusions reached, the new technique of sentinel node mapping, has cast a shadow on all the answers recently obtained. The complexity of nodal drainage, the relatively low frequency of nodal disease, inadequate staging, and slight, if any, therapeutic benefit are clear obstacles in attempting to demonstrate any benefit of elective nodal dissection for melanoma. In previous texts, a detailed discussion of ELND was mandatory. Now the wholesale removal of entire nodal basins that may harbor metastatic disease based on inadequate descriptions of drainage patterns, and insensitive pathologic techniques should no longer be performed. With the advent of sentinel node mapping, ELND is only discussed as an historic reference. Regardless of possible therapeutic benefit, sentinel node biopsies efficiently predict prognosis with low morbidity. Current trials are assessing therapeutic benefit of selective nodal dissection. Unlike in breast cancer, there is no clearly beneficial adjuvant therapy available for high-risk patients, but as various new melanoma therapies are being developed, risk stratification by nodal status will become increasingly important. In the future sophisticated assays such as quantitative PCR (Taqman), which can measure melanoma antigens in the peripheral blood, may prove more important than nodal status for predicting prognosis and obviate the need for invasive procedures.

### ELECTIVE LYMPH NODE DISSECTION

ELND has been an extremely controversial subject and its theoretical value hinges on the biology of melanoma metastasis. Does melanoma spread stepwise through the draining lymph nodes before reaching other more distant sites, or, as in breast cancer, does a Fisherian theory of nodal disease exist in which positive nodes are only a marker for systemic disease? Selecting patients who may be candidates for ELND has been based on the depth of the primary tumor. Patients with tumor less than 1 mm deep have a 98% cure rate and would not benefit from a relatively morbid operation. Patients with thick lesions (greater than 4 mm) at the time of diagnosis did not undergo ELND. Initial studies of ELND in this group of patients could not show any benefit and data erroneously suggested that this was due to a high percent (70%) of patients with occult metastatic disease.<sup>221</sup> Numerous trials have tried to understand the role of nodal dissection for intermediate-thickness lesions, but, unfortunately, many of the data are conflicting. Although sentinel node mapping has not yet proven therapeutic, the knowledge gained has helped elucidate the reasons for failure in multiple ELND trials and given much insight to the biology of nodal disease in melanoma.

Proponents of ELND advocate the use of ELND for its prognostic information since, in patients with regional disease, the actual number of nodes involved is the most important predictor of overall survival.<sup>222</sup> Advocates also cite retrospective studies that demonstrate a 5-year survival rate increase of up to 10% to 27% when patients

with clinically occult disease have their nodal basins resected compared with delayed resection of gross disease. <sup>223</sup> As well, regional node disease may determine candidacy for adjuvant treatment such as IFN- $\alpha$ .

Opponents point out the morbidity of the operation, the lack of clear therapeutic benefit of ELND, and a controversial advantage to IFN- $\alpha$  treatment. One of the most important criticisms was that up to 80% of patients had negative nodes on pathology. This large percentage of patients received no benefit from the procedure. Many believe that lymph node metastases are a manifestation rather than a predecessor of distant spread. In a retrospective review of 4682 patients, only 16% of patients had positive nodes at ELND. Ten percent of metastases were positive in the contralateral node, and 6% were positive in nodal basins not classically predicted. At Breslow depths of less than 0.76 mm, 0.76 to 1.5 mm, 1.5 to 2.5 mm, 2.5 to 4.0 mm, and greater than 4 mm, the regional nodal basin was positive in 0%, 5%, 16%, 24%, and 36% of cases, respectively. <sup>224</sup> LND has substantial potential morbidity that includes chronic lymphedema, pain, paresthesias, cosmetic deformity, and, especially in the groin, wound complications. Lesions of the head and neck are especially problematic. As is true for squamous cell cancers of the head and neck, evidence arising from randomized prospective trials is not available to confirm the value of prophylactic nodal dissection for melanoma arising in the head and neck. <sup>225,226</sup>

The usefulness of ELND has been debated for decades because of conflicting trials of various quality ( [Table 42.2-7](#)). Multiple trials suggest that TLND does not jeopardize the probability of cure and prevents the need for difficult toilet operations. Most trials are retrospective and mixed in conclusions. In one from Duke University and another from the Sydney Melanoma Unit, initial analysis showed a survival advantage in patients with intermediate-thickness lesions, but both, after 10 years of further data accrual, showed no advantage to ELND. This demonstrated the lack of reliability of retrospective trials and the length of time needed for adequate data accrual.

Trial	Design	Results
Memorial Sloan-Kettering, 1970	Retrospective	Benefit for intermediate thickness
University of Michigan, 1982	Retrospective	Benefit for intermediate thickness
Duke University, 1983	Retrospective	Benefit for intermediate thickness
Memorial Sloan-Kettering, 1985	Retrospective	Benefit for intermediate thickness
University of Pennsylvania, 1985	Retrospective	No benefit
Doggett, 1986	Retrospective	Benefit for intermediate thickness
Duke University, 1986	Retrospective	No benefit
Kang, 1987	Retrospective	Benefit for intermediate thickness
Memorial Sloan-Kettering, 1988	Retrospective	No benefit
NIH Health Organization, 1977	Prospective	No benefit
Mayo Clinic, 1986	Prospective	No benefit
Intergroup Melanoma, 1986	Prospective	No benefit overall benefit for 1/2 mm and patients <60
NIH Health Organization, 1988	Prospective	No benefit

NIH Health Organization has been repeatedly questioned for benefit with mixed results. Most prospective trials show no benefit, but there have been exceptions. The Intergroup trial showed overall benefit in part for patients under the age of 60 and with lesions between 1 and 2 mm. Regardless of trial outcome, with the advent of sentinel node biopsy, patients overall no longer routinely undergo lymph node dissection.

**TABLE 42.2-7.** Results of Elective Lymph Node Dissection Trials <sup>a</sup>

Two prospective trials from the WHO in 1977 and Mayo Clinic in 1986 showed no benefit of ELND. <sup>227,228</sup> Both these trials included what we now recognize as many low-risk patients and their negative results have been criticized. Both the Intergroup and WHO trunk trials are contemporary prospective randomized trials that were developed to address much of the conflicting information. Although long-term data are still accruing, results have been published.

In 1998, the WHO published a series of 252 patients randomized to immediate or delayed node dissection. All patients had truncal melanoma of at least 1.5 mm thickness. The 5-year survival observed in patients who had delayed node dissection was 51.3% compared with 61.7% in patients who had had immediate resection ( $P = .09$ ). Multivariate analysis showed that routine use of immediate node dissection had no effect on survival. <sup>229</sup> The WHO study, in contrast to the Intergroup Melanoma trial, was much smaller in patient accrual, assessed patients who generally had thicker melanomas, and did not use lymphoscintigraphy to determine the appropriate drainage basins to resect.

In 1996, initial results of the Intergroup Melanoma trial were reported. The trial randomized 740 patients with intermediate-thickness lesions to ELND, and, although there was no difference in survival for the entire group, an apparent survival benefit was seen in a post hoc analysis of a subgroup of patients. Male patients younger than the age of 60, with tumors 1.1 to 2.0 mm thick, and without ulceration had a significant improvement in 5-year survival of 96% versus 84% ( $P = .007$ ) which was confirmed in multivariate analysis. The subgroup of patients with tumor thickness 1.1 to 2.0 mm of any age who underwent an ELND also had a significantly better 5-year survival compared with the observation group (92 vs. 84%,  $P = .05$ ). <sup>230</sup>

Cascinelli et al. suggest a role of prophylactic dissection in a randomized study of patients with trunk melanoma comparing elective versus delayed dissection, noting that only patients with positive lymph nodes benefited from lymphadenectomy. <sup>229</sup> These data become important with the advent of sentinel node biopsy and subsequent selective nodal dissection. Now a large percentage (80%) of patients who may not benefit from LND may be spared the procedure while identifying patients who may most benefit. SLN biopsy followed by dissection in patients with positive nodes eliminates the indications for prophylactic dissection, and future studies can focus on a homogenous group of patients in order to establish the true therapeutic role of lymphadenectomy.

## SENTINEL NODE BIOPSY

Even before the results of the WHO and Intergroup Melanoma trials, the use of sentinel node biopsy was widely adopted as a means to minimize procedural morbidity of LND. The sentinel node is the most likely lymph node to contain metastatic disease. The concept of sentinel node biopsy is based on the presumption of an orderly progression of disease through the lymphatic system. A negative SLN would suggest more upstream metastatic disease has not occurred, whereas a positive SLN would indicate potential involvement of other nodes in the same basin. <sup>231</sup> A lymphadenectomy after intraoperative lymphatic mapping and sentinel node biopsy has been termed a *completion lymph node dissection*. <sup>232</sup> The importance of a positive sentinel node is underscored by multivariate analyses, which show that the SLN status is the most important prognostic factor influencing disease-free and distant disease-free survival in patients with stage I and II melanoma. <sup>233</sup>

SLN biopsies have clarified the natural progression of melanoma metastasis. <sup>234</sup> The data from initial trials using sentinel node mapping demonstrate an apparent orderly progression of disease with failure to observe lymph node metastases in nodes adjacent to a negative sentinel node. <sup>235</sup> Cabanas was the first to describe the technique of sentinel node biopsy for penile cancer as a means to prevent the morbidity of bilateral inguinal LND. <sup>236</sup> This concept is that discrete areas of skin drain initially to specific node(s) within lymph node basin(s) that may or may not be proximate anatomic basins. The identification of such initially draining nodes allows for pathologic assessment in far greater detail than is possible otherwise.

Although many surgeons believe SLN biopsy is the current standard of care, the true role and benefit of sentinel node mapping is still to be determined. Undoubtedly, sentinel node status is extremely valuable in staging. Clinical trials of melanoma have been hampered by the heterogeneity of patient populations due to suboptimal staging. Accurate knowledge of the lymph node status (macroscopic, microscopic, immunohistochemical, and molecular) enables appropriate comparisons to be made between treatment groups. There is still debate whether a positive sentinel node biopsy with subsequent lymphadenectomy of clinically negative basins and adjuvant therapy is efficacious. Data suggest that the early removal of positive lymph nodes may improve survival. The Intergroup trial suggests that the benefit of elective LND may be meaningful in patients whose tumors are nonulcerated, extremity primaries, of thickness between 1 and 2 mm, and whose age is less than 60 years. Current trials are attempting to determine the efficacy of early LND guided by sentinel node mapping. Although the efficacy of adjuvant treatment for melanoma is less than desired, the ongoing studies of IFNs, chemotherapy, vaccines, and combinations will be improved by a greater precision in prognostic assessment.

## Lymphoscintigraphy

In 1977 Robinson et al. described the use of cutaneous lymphoscintigraphy in the nodal basin for truncal melanomas using colloidal gold scanning. <sup>237</sup> In 1985, Morton began the first clinical trials using both lymphoscintigraphy and vital dye injection for the identification of sentinel nodes in melanoma patients. In 1993, Alex introduced the use of technetium 99m sulfur colloid, a radioactive tracer, injected intradermally around a primary melanoma site, followed by imaging and subsequent intraoperative use of a gamma probe to localize the sentinel node. <sup>238</sup>

The day before the operation, lymphoscintigraphy is performed using <sup>99m</sup>Tc (0.5 to 0.8 mCi), which is injected around the tumor site ( [Fig. 42.2-18](#) and [Fig. 42.2-19](#)).

The colloidal isotopes are phagocytosed by macrophages within the lymph node. This keeps tracer in the draining node and prevents further passage through the nodal basin.<sup>239</sup> Immediately afterward, dynamic images are obtained, and after 2 hours static scintigrams are taken. Dynamic imaging helps differentiate between multiple sentinel nodes and spillover to nonsentinel node. The choice of tracer is also important. The <sup>99m</sup>Tc sulfur colloid has a particle size in the micrometer range, and transport may be too slow to be suitable for dynamic imaging. <sup>99m</sup>Tc colloidal albumin and technetium 99m human serum albumin appear to be the most favorable as the sentinel node becomes positive within 20 minutes in 97% of patients and is retained for up to 24 hours without an increase in the number of sentinel nodes.<sup>240</sup> <sup>99m</sup>Tc human serum albumin demonstrated faster washout rates from injection sites and better definition of lymph channels than either particulate agent, whereas particulate agents were retained longer in nodes and demonstrated more nodes in delayed images than in early images. Early dynamic imaging is important, as sentinel nodes cannot be distinguished reliably from nonsentinel nodes in delayed images alone.<sup>241</sup> The radiologist should mark the position of the sentinel node on the skin, although the surgeon must be wary that relaxation during surgery and positioning may change the position of the lymph node relative to the skin marker.

**FIGURE 42.2-18.** Lymphoscintigram. This patient had a biopsy-proven melanoma on the right hand (note the high area of radioactive tracer around the injection site) and was noted to have an epitrochlear sentinel node. Five percent of patients with distal extremity lesions have popliteal or epitrochlear nodes. Using classical guidelines for lymphadenectomy, a potential positive lymph node may be overlooked, which may result in incorrect staging.

**FIGURE 42.2-19.** Lymphoscintigram. This patient had a primary tumor on the nose. Sentinel node mapping in the head and neck can be difficult secondary to the increased number of nodes (3.8 vs. 1.3), the overshadowing of pertinent lymph nodes by the primary injection site, the difficult dissections, and cosmetic concerns. Note, the multiple sentinel nodes suggested during early imaging. In this patient, no sentinel nodes in the parotid gland were identified. (Courtesy of H. Edington, M.D., University of Pittsburgh Cancer Institute.)

The surgeon should reexamine the SLN in the operating room with the hand-held gamma counter and make the skin incision directly over the most radioactive point. As only 1% of the injected dose of radioactive colloid reaches the SLN, a primary site close to the nodal basin may preclude effective use of the gamma probe, even if the primary site is excised initially.<sup>242</sup> This shadowing becomes especially important in head and neck melanomas where nodes and the primary site overlap. After the sentinel node is removed, the wound is explored with the gamma probe for additional *hot*, blue nodes.

Sappey had originally injected mercury into the skin of cadavers and showed that a line drawn just above the umbilicus would differentiate inguinal versus axillary drainage. Lesions within 2 cm of this line had bidirectional drainage. With the use of these techniques, lymphatic drainage not predicted by Sappey's original description of the cutaneous watershed of lymph drainage has been frequently observed.<sup>243</sup> Only more recently, with the use of lymphoscintigraphy, has Sappey's guide to lymphatic flow been modified by modern means of assessment.

Discordance from classical drainage patterns is especially common in the head, neck, and trunk. Sixty percent of head and neck and 32% of the trunk tumors drain in unpredicted sites. Operative intervention is changed in almost one-half of patients when lymphoscintigraphy is used.<sup>244,245</sup> Lymphoscintigraphy may also identify patients with lymphatic drainage in two separate basins. Patients who have positive nodes in two basins have a worse prognosis when compared with patients with nodal disease in one basin, even when controlling for the total number of positive nodes.<sup>246</sup> Even in distal extremity lesions in which lymphatic drainage is seemingly obvious, lymphoscintigraphy may identify popliteal or epitrochlear nodes.<sup>247</sup>

The unpredictability of lymphatic drainage based on anatomic guidelines basins, especially in the head, neck, and trunk, make the use of routine ELND based on classic anatomy inappropriate without preoperative lymphoscintigraphy. The examination of incorrect lymphatic basins, the lack of appropriate immunohistochemical techniques, and the inclusion of patients with a relatively low likelihood of nodal involvement accounts for the difficulty in interpreting the various results of prior trials studying the role of ELND.

### Vital Dye

After induction of anesthesia, vital blue dye (1.0 mL of isosulfan blue or patent blue V) is injected intradermally around the primary tumor or scar ( Fig. 42.2-20). The gamma counter is more accurate than vital dyes in locating sentinel nodes, especially in the axilla or in deep fatty tissue. Techniques using dye alone require a longer learning curve to achieve success rates of only 80%. The blue dye is still helpful in visual confirmation of a hot node ( Fig. 42.2-21 and Fig. 42.2-22), but up to 15% of radiolabeled sentinel nodes lack any blue dye. Conversely, 8% of blue nodes are not hot, and some of these nodes will be the only site of metastasis.<sup>248</sup> Complications of the technique are infrequent and minor including dye-stained urine and prolonged tattooing of the skin lasting several months.

**FIGURE 42.2-20.** Vital blue dye injected around a primary melanoma. The patient had undergone lymphoscintigraphy before injection of the vital blue dye. (Courtesy

### Results of Sentinel Lymph Node Biopsy

After nodal mapping, regional recurrence rates are acceptably low and the sensitivity and specificity are quite high. Reintgen, in 1997, reported that after 600 mappings and 5 years of follow-up, no patient developed a recurrence in any basins not predicted at risk by lymphoscintigraphy.<sup>242</sup> In another series, the sensitivity of lymphatic mapping and SLN biopsy for extremity melanoma was 100% and the specificity was 97%. Only 3% of patients with histologically negative SLNs developed inguinal nodal metastases during a mean 2-year follow-up.<sup>249</sup> Lenisa et al. described their series of 580 sentinel node biopsies, 15% of which had nodes involved with tumor. Positive cases were distributed according to thickness as shown in Table 42.2-8. In 77% of the patients, only a single positive node was identified after completion LND. Only eight patients (1%) had a local relapse after a negative sentinel node biopsy.<sup>250</sup> Using multivariate analysis, the probability of a positive sentinel node depends only on tumor thickness, ulceration, and truncal location. Although tumor thickness and ulceration influenced survival in SLN-negative patients, they provided no additional prognostic information in SLN-positive patients. Sentinel nodes are positive in 15% to 26% of patients in various series.<sup>234,248,251</sup> Of patients with positive sentinel nodes, 24% to 33% demonstrate lymph nodes to be involved at completion lymphadenectomy. A single SLN is found in 59% of patients, two SLNs in 37%, and three SLN in 3%.<sup>240</sup> The median number of sentinel nodes found in several series ranges from 1.3 to 1.8.

Thickness (mm)	No.	Percentage Positive Sentinel Lymph Node
1.0-1.99	27	5
2.0-2.99	97	18
>3.0	146	27

<sup>a</sup>The probability of a sentinel node demonstrating metastatic disease depends on tumor thickness. Careful selection is necessary before the use of sentinel node mapping in patients with T1 melanomas. Even in patients with thin ulcerated tumors, the chance of nodal disease is less than 10%. A positive sentinel node in multivariate analysis is the single most important variable in determining long-term survival.<sup>250</sup>

**TABLE 42.2-8.** Thickness of Melanoma and Sentinel Lymph Node Positivity<sup>a</sup>

Essner et al. were the first to show that sentinel node biopsy followed by completion lymphadenectomy did not decrease survival compared with patients undergoing ELND. They described a series of 534 matched patients with clinical stage I melanoma; one-half of the patients were treated with lymphatic mapping and sentinel lymphadenectomy and the other half were treated with ELND. The overall incidences of nodal metastases and survival were no different between the sentinel node and ELND groups, but the incidence of occult nodal disease was significantly higher among patients with intermediate-thickness primary tumors who underwent sentinel node mapping instead of ELND.<sup>240a</sup> Essner et al. showed that sentinel node mapping is therapeutically equivalent but prognostically more accurate than ELND.<sup>252</sup>

Whether previous wide excision affects the ability to map the sentinel node by changing local lymphatic drainage has been debated. The likelihood of appropriate dye uptake is decreased by one-half if a wide excision has been previously done.<sup>234,253</sup> Most surgeons strongly recommend the use of lymphoscintigraphy before wide local excision to avoid disruption, artifactual drainage of the lymphatic drainage, or both.<sup>254</sup> Morton et al. retrospectively examined 47 patients who had SLN mapping after wide local excision and concluded that SLN biopsy can be cautiously performed in patients who have undergone previous wide local excision if the primary resection margin was no greater than 2.0 cm and the primary was not in a region of ambiguous drainage. Another retrospective review of 142 patients concluded that previous wide excision does not affect the reliability of sentinel node biopsy unless a rotational flap has been used.<sup>255</sup> Further study is needed before firm conclusions can be made on the timing of SLN biopsy.

SLNs of the head and neck behave somewhat differently. Sentinel node biopsy has been less consistently successful in the head and neck due to the frequent alterations in lymphatic draining; likewise, prophylactic nodal dissection has not proven useful. Series reports between a 90% and a 95% success rate in identifying the sentinel node, somewhat less than the success rate for sentinel nodes at other sites.<sup>226,250,256,257,258</sup> and <sup>259</sup> Many differences in head and neck lesions make sentinel node biopsy more difficult. Whereas most patients with extremity melanomas have a median of 1.3 to 1.8 SLNs, a median of 3.8 sentinel nodes is found in patients with intermediate-thickness head and neck lesions. Difficulties in mapping strategies are seen in nonclassical and especially parotid nodes, which may be shadowed by the radioisotope injected in the primary site. Furthermore, only 67% of lesions stain with vital dyes. One-half of sentinel nodes are located in nonadjacent nodal basins. One-fourth are in nonclassical sites and one-half in the parotid gland. Often, a functional node dissection with *ex vivo* dissection using the gamma probe is

necessary to find small sentinel nodes.<sup>260</sup> Furthermore, the patients must be warned that prolonged tattooing may occur from injected dyes in cosmetically sensitive areas of the face.

In 1994, the Multicenter Selective Lymphadenectomy Trial was begun to evaluate the therapeutic role of lymphatic mapping and SLN biopsy with and without wide excision in patients with localized melanoma. This trial has just closed with 1800 patients accrued, and long-term results are awaited. The Multicenter Selective Lymphadenectomy Trial has a 99.1% success rate in obtaining sentinel node(s) using both dye and radiolabeling.<sup>232</sup> In centers participating in the Multicenter Selective Lymphadenectomy Trial, a minimum of 30 procedures must be performed before patients can be entered. After performing 30 cases, there was no difference in success of sentinel node biopsies between any of the centers.<sup>261</sup>

### **Pathologic Interpretation**

Frozen sections do not have a place in sentinel node mapping because micrometastatic disease cannot be determined, and thus permanent pathologic interpretation is crucial to success of sentinel node staging. Hematoxylin-eosin (H&E) staining is performed with negative samples undergoing immunohistochemical staining with the antibodies reactive with melanoma including S-100 and HMB-45. Ninety percent of melanomas are positive for S-100. HMB-45 is more specific but less sensitive than S-100, which also stains neurons, melanocytes, and DCs.<sup>22</sup> The importance of immunostaining is exemplified in a study by Gershenwald. Of 243 patients with a histologically negative SLN on routine H&E staining, 27 (11%) developed local, in-transit, regional nodal, distant, or both nodal and distant metastases after a median follow-up of 35 months. Ten patients (4.1%) developed a nodal recurrence in the previously mapped basin. Reexamination of the original cassettes using S-100 and HMB-45 demonstrated that 80% of these patients had evidence of occult metastases by serial sectioning or immunohistochemical staining.<sup>141</sup> In another large series of 357 patients and 838 sentinel nodes, 45% of positive nodes were only positive by S-100 staining, again confirming the importance of immunostaining for H&E-negative nodes.<sup>262</sup> At a minimum, all negative SLNs should undergo immunohistochemical staining for melanoma markers.

The Multicenter Selective Lymphadenectomy Trial uses strict guidelines in handling nodal tissue. The Trial recommends cutting the lymph node in two halves through its longest diameter and fixing the specimen. Ten serial 8- to 10- $\mu$ m sections are then made. Sections 1, 3, 5, and 10 are used for H&E staining, section 2 for S-100, section 4 for HMB-45, and sections 6 and 7 are negative controls for immunoperoxidase studies. Sections 8 and 9 are used to repeat any needed studies.<sup>248</sup>

The use of RT-PCR, or potentially in the future, Taqman analysis to examine nodes for mRNA of melanosomal proteins may be valuable as this could reduce sampling error and increase sensitivity. Its extreme sensitivity, however, may result in the inappropriate upstaging of patients and overtreatment of patients falsely termed positive. In one study of RT-PCR of 124 patients, 58% of patients with histologically negative nodes were upstaged. This group of patients had a worse overall prognosis than patients who were RT-PCR negative and histologically negative. Twenty percent of these patients developed either locoregional or systemic disease, whereas only 5% of the PCR-negative patients developed signs of disease. One melanoma cell in 1 million background cells can be detected.<sup>263</sup> Since approximately 80% of sentinel nodes will be negative, a quick screening of H&E-negative nodes using PCR may identify patients in whom the more labor-intensive immunostaining may be performed.<sup>264</sup> One aim of the current Sunbelt trial is to examine the importance of PCR-positive lymph nodes and the effect of adjuvant therapy in patients with histologically negative nodes. The introduction of Taqman analysis may allow more accurate antigen quantitation and further insight.<sup>265</sup>

### **SENTINEL LYMPH NODE RESULTS IN THIN AND THICK MELANOMAS**

Only rarely are sentinel nodes found positive in patients with thin melanomas (T1). The use of sentinel node biopsy is controversial in this group of patients, and many have looked for risk factors that may predict a higher incidence of nodal metastases. Less than 2% of patients with nonulcerated primary lesions less than 1 mm (T1) and less than Clark level IV have positive sentinel nodes. No lymph node involvement has been reported in lesions less than 0.73 mm. Thus, there is no role for sentinel mapping in these patients. The two most significant risk factors for positive sentinel nodes in thin primary lesions are ulceration and Clark level greater or equal to IV. Even in patients with T1b lesions, the risk for nodal disease is less than 10%. Patients with T1b tumors have the same risk for nodal disease as T2a patients. In a series of 254 patients reported by Gershenwald, no patient with T1 lesions and a positive sentinel node had positive nodes on completion lymphadenectomy. Regression by itself was not found a risk factor for nodal disease in thin lesions.<sup>130</sup> Careful selection and patient education is necessary before the employment of SLN biopsies in these patients with thin lesions.

No trial has shown benefit for elective nodal dissection in patients with tumors greater than 4 mm, and, in fact, ELNDs were not performed in this group of patients. However, many centers perform sentinel node mapping in this group of patients. Perhaps the subgroup of patients that has deep lesions and negative sentinel nodes may have improved survival compared with stage III patients and would be spared adjuvant therapy.

### **STAGE III DISEASE: MANAGEMENT OF THE CLINICALLY POSITIVE NODAL BASIN**

#### **THERAPEUTIC NODE DISSECTION**

The development of clinically palpable nodes in the draining basins of a primary melanoma requires TLND to control local disease. Although there are no randomized trials clearly demonstrating a survival difference after TLND, a significant number of patients attain 5-year survival. Furthermore, the palliative benefits of TLND are considerable. Untreated nodal metastasis can be expected to ulcerate, impinge on neural structures, and cause pain in patients whose life expectancy is more than 1 year. Even in some patients with metastasis to distant nodal regions, TLND has a role in palliation. In addition, prognostic information is obtained after TLND since the number of positive nodes correlates with survival and may guide adjuvant therapy.<sup>143</sup>

In patients with a prior history of melanoma but without evidence of infection, 90% of lymphadenopathy is associated with tumor.<sup>266</sup> Tumor-involved nodes tend to be firm and spherical. Five-year survival rates following TLND range from 19% to 38% in retrospective series.<sup>222,266,267,268,269,270 and 271</sup> In one series of 133 patients undergoing iliac and inguinal nodal dissection, those with one, two, three, or more than four lymph nodes positive for tumor had median survivals of 90, 78, 49, and 15 months, respectively. The median survival was significantly worse for those with deep nodes positive with survival of 53, 42, 14, and 9 months, respectively.<sup>272</sup>

#### **Inguinal Dissection**

The extent of surgical management in patients with clinically palpable inguinal nodes is a controversial topic in the treatment of melanoma. An inguinal groin dissection can be either superficial, including all nodes below the inguinal ligament, or complete, including the deep iliac and obturator nodes accessed through retroperitoneal exposure. The superficial dissection is carried out through a longitudinal incision with the removal of subcutaneous tissues, lymphatics, and the anterior portion of the femoral sheath. A sartorius muscle flap is used in closure to protect the femoral vessels and decrease wound complications.<sup>273</sup>

Of patients with palpable inguinal nodes, up to 37% have histologically positive deep iliac nodes. Some believe that the routine removal of all deep nodes in patients with palpable inguinal disease is indicated, whereas others believe patients with radiologically positive pelvic nodes should not undergo TLND given the likelihood of distant disease. There are currently no randomized data comparing complete and superficial LND. Case series suggest that performing a deep inguinal dissection increases the morbidity of the operation and does not offer an obvious survival advantage in a radiologically negative pelvis. In comparing patients who undergo deep TLND for known positive iliac disease with those who have no apparent pelvic disease and only positive inguinal disease, overall survival is equivalent. For some, this is evidence that pelvic dissections are beneficial. They argue that those with grossly positive pelvic nodes should have a predictably worse prognosis since those patients had significantly more positive lymph nodes of generally larger size.<sup>274</sup> There is some suggestion that the probability of a groin recurrence decreased with the inclusion of a deep iliac dissection.<sup>272</sup> In a retrospective review of 362 therapeutic groin dissections, 20% had positive deep inguinal nodes. The 5- and 10-year survival for those patients was 24% and 20%, respectively, with the number of positive iliac nodes an independent prognostic factor. The authors suggest that deep lymph node dissection may be of benefit as up to 20% of patients are long-term survivors who would otherwise would have had residual disease if treated only by a superficial dissection.<sup>275</sup> A prospective trial is currently testing the value of deep iliac dissection in patients who will all have superficial dissection.

#### **Axillary Dissections**

Therapeutic axillary nodal dissection for melanoma involves the complete removal of levels I and II nodes, and some advocate the removal of level III nodes including skeletonizing the axillary vein and brachial plexus. Rarely, in patients without evidence of distant disease and with positive supraclavicular nodes, a lower cervical node dissection may be performed by resection of the middle third of the clavicle.<sup>273</sup> As with inguinal dissections, survival after axillary dissection correlates with the number of positive nodes. The 5-year survival rate is 80% in patients with histologically negative nodes. With one, two, three, or more than four nodes, the 5-year

survival was 62%, 51%, 28%, and 5%, respectively. Patients with recurrent lymph nodes or nodes that are fixed have a 5-year survival of 13%.<sup>276</sup>

### Neck Dissections

A functional neck dissection is indicated with the preservation of the jugular vein, sternocleidomastoid, and spinal accessory nerve unless directly involved with tumor. Modification of the extent of dissection is appropriate relative to the site of the primary tumor.<sup>273</sup> Patients treated with node positivity in head and neck cancer have a substantially lower survival than in patients with truncal or extremity melanoma. Superficial, nerve-sparing parotidectomy is indicated for palpable metastatic lesions for local tumor control.<sup>277</sup> These parotid nodes should be removed by superficial parotidectomy. Although controversial, some advocate the use of adjuvant radiotherapy for high-risk lesions because of the higher rate of recurrence in head and neck lesions.<sup>260</sup> This is the topic of an ongoing randomized controlled trial, E3697, by ECOG.

### Popliteal and Antecubital Nodal Dissection

Infrequently, the popliteal nodes become involved with metastatic disease and cause palpable enlargement. The popliteal nodes only drain a small area of skin of the posterior calf. In the absence of distant unresectable disease, popliteal nodal dissection should be performed through an S-shaped incision. There are no data demonstrating survival benefit of this operation as there are only small case series in the literature.<sup>273,278</sup> Epitrochlear node involvement occurred in 18% of patients with forearm or hand lesions, and only when the primary melanoma was within 5 cm of the elbow or in the ulnar distribution.<sup>279</sup>

### Complications of Nodal Dissection

In inguinal dissections, necrosis of the skin flap occurs to some degree in 7% of patients. Wound infection occurs in 10% of patients.<sup>280</sup> The most devastating long-term complication is lymphedema. This occurs in up to 24% of patients and may be upward of 40% with prolonged follow-up. A strict regimen of daily leg elevation and routine use of elastic stockings decreases the severity of symptoms. The lateral femoral cutaneous nerve is commonly sacrificed with resultant numbness of the lateral thigh. The Intergroup Melanoma Trial reports a 50% wound complication rate in inguinal lymphadenectomies. In 112 patients there were 23 wound breakdowns, 24 cases of lymphedema, one deep vein thrombosis, and one pulmonary embolism.<sup>230</sup>

Necrosis is rare in axillary dissection. Neuropraxia secondary to brachial plexopathy is also a rare event that is usually resolved within 3 to 6 months. Proper positioning, careful placement of retractors and careful dissection minimize this event. Lymphocele rates are 7%, and the incidence of arm edema is much lower than nodal dissection for breast cancer.<sup>281</sup> Mobilization after axillary dissection should be limited until after surgical drains are removed.<sup>282</sup>

### MELANOMA OF UNKNOWN PRIMARY SITE

Melanomas presenting as regional or distant disease without an obvious primary site occur uncommonly and may represent a completely regressed primary tumor. A vigorous search for suspicious lesions is mandatory in these patients with a low threshold for biopsy. In a large series of more than 84,000 patients with melanoma, 2.2% of all melanoma presented without signs of a primary lesion. In patients with unknown primary melanomas, the distribution of metastases as localized to a region or multiple sites at presentation was 43% and 57%, respectively.<sup>283</sup> These patients are younger than other melanoma patients and tend to be male. The most common presenting nodal site is the axilla.<sup>284</sup> In patients with lymph node metastasis without a known primary site, survival is equal or better than for patients with known primaries. The clinical disease course of patients with metastatic melanoma of unknown primary origin is similar to that of patients with primary cutaneous melanoma when the same clinical stages of the disease are compared, and they should be treated accordingly.<sup>285</sup>

### MANAGEMENT OF LOCOREGIONAL DISEASE BY RADIOTHERAPY

Radiotherapy may be useful in the management of unresectable lymph node metastases from melanoma and possibly as adjuvant therapy after repeat resection in patients with recurrent lymph node metastases. The role of adjuvant radiotherapy to regional lymphatics is presently being investigated in an ECOG protocol that randomizes patients with high-risk disease between IFN- $\alpha_{2b}$  with or without regional radiotherapy to 30 Gy in five biweekly 6-Gy fractions. This study was undertaken because of the favorable experience with adjuvant radiotherapy reported by Ang et al.<sup>176,182</sup> For 118 previously untreated patients with melanomas greater than 1.5 mm in thickness or Clark's level IV and V, with no palpable nodes managed with wide local excision and adjuvant radiotherapy to 30 Gy in five fractions, 5-year local regional control was 86% and survival was 63%. In 39 patients with clinically positive nodes and 67 patients with recurrent local regional tumor who received postoperative local regional radiotherapy, 5-year local regional control rates were 92% and 88%, respectively, while survival rates were 41% and 45%, respectively. Arm or leg edema and brachial neuropathy associated with radiation fibrosis are concerns with high-dose fraction radiotherapy of lymph node regions. Ang et al. reported mild to moderate late radiation sequelae in only 3 of 224 patients.<sup>181,182</sup> Arm or leg edema is managed with limb compression therapy. Radiation fibrosis with or without extremity edema appears to improve with treatment following therapy with pentoxifylline (400 mg twice a day) and vitamin E (500 IU twice a day) for 6 months.<sup>286</sup>

### STAGE III DISEASE: MANAGEMENT OF IN-TRANSIT DISEASE

*In-transit disease* is defined as dermal or subcutaneous recurrent melanoma located in the skin or subcutaneous tissue of the lymphatic drainage of the primary tumor and found greater than 5 cm from the origin of the primary tumor (Fig. 42.2-23). If observed surrounding the site of the primary tumor, the term *satellitosis* is sometimes used. In-transit disease occurs in an estimated 2% to 10% of all melanoma patients. The probability of developing locoregional cutaneous relapse is highly associated with histologic evidence of lymphatic invasion seen in the initial primary lesion.<sup>287</sup> Seventy percent of in-transit disease occurs in the lower extremity, the majority originating from thick primaries.<sup>288</sup> The lower extremity has the highest incidence of in-transit disease perhaps due to the higher density of lymphatics. Regional nodal metastases are common and seen in up to two-thirds of patients with in-transit disease.<sup>289</sup> Patients with in-transit disease without regional lymph node involvement have similar disease progression as patients with two to four positive nodes, thus the proposed stage designation of N2C. Patients with nodal involvement and in-transit disease will be designated N3. The 5-year survival rate following locoregional recurrence of melanoma of the extremities is approximately 20%. Treatment options are not standardized, and until more effective systemic therapy is developed, aggressive local treatment is indicated for this group of patients.

**FIGURE 42.2-23.** In-transit disease most often is found between the primary lesion and the draining lymph nodes but in advanced instances is able to track beyond these sites, presumably through lymphatic connections.

### SURGICAL EXCISION

Resection is indicated for small, easily excised recurrent tumors and patients with a limited number of in-transit lesions. Simple resection may delay or even eliminate the need for ILP. Wide excisions are unnecessary and excessively morbid in patients whose lymphatics are already contaminated. Amputation should only be considered if the limb is nonfunctional or hygiene cannot be maintained. When amputations are necessary, they should be performed as either a hip disarticulation or

hemipelvectomy as distal amputations usually fail locally. The 5-year disease-free survival after amputation in older series is approximately 20% to 35%. <sup>290</sup>

## ISOLATED LIMB PERFUSION

ILP for the introduction of chemotherapeutic agents to control regional malignant disease was first described in 1958 by Winblad. Approximately 50% of primary melanomas occur in the extremities, and approximately 10% of those patients have a recurrence as in-transit disease. <sup>291</sup> As only rare patients respond to systemic therapy, ILP was developed as a means of limb salvage that would enable the delivery of cytotoxic drugs locoregionally at doses many-fold higher than would be tolerable systemically. No clear agreement exists on which patients benefit most from ILP and which regimens are most active. Prospective randomized trials that examine regimen, toxicity, dosage, and response are in development. Currently, melphalan is the gold standard reagent for use in ILP. Melphalan can be safely delivered locally at doses ten times higher than systemically tolerated. <sup>292</sup> One-half of patients exhibit a complete response and 75% at least have a partial response to melphalan. <sup>293</sup> Melphalan delivered at maximal systemic doses has negligible activity against melanoma. The use of hyperthermia has also become standard during ILP since Stehlin, in 1969, described improved response rates using perfusate at temperatures of 38.8 to 40°C. <sup>294</sup> Current randomized studies seek to demonstrate that combination therapy using melphalan and TNF is superior to melphalan alone in treatment of patients with in-transit disease and the combination has been reported to have a 100% response rate. <sup>295</sup>

### Indications

ILP is useful in two groups of patients. Those with locoregionally advanced melanoma such as satellitosis and in-transit metastasis and those in need of palliation who have bulky regional disease and limited systemic metastasis. Prophylactic ILP for use as an adjunct to wide local excision in patients with a high-risk primary or recurrent melanoma cannot be recommended since no improvement in survival can be shown in prospective trials.

### Prophylactic (Adjuvant) Isolated Limb Perfusion

A well-designed multiinstitutional prospective trial of ILP with melphalan was conducted by the consortium of the EORTC, the WHO, and the North American Perfusion Group. In 1998, the results of this multicenter randomized phase III trial of ILP in patients with primary cutaneous melanoma greater than 1.5 mm in thickness were published. A total of 832 patients were randomized to have wide local excision or wide local excision plus ILP with melphalan and hyperthermia. Median follow-up was 6.4 years. There was no difference in survival. Patients who had not undergone ELND had a nonsignificant trend for a longer disease-free interval. In a subset of patients with melanoma of 1.5 to 2.99 mm thickness, in-transit metastasis was reduced from 6.6% to 3.3% and regional lymph node metastasis was reduced from 16.7% to 12.6%. In thicker lesions, patients succumbed to distant disease. <sup>296</sup>

Other retrospective series demonstrate the lack of benefit for prophylactic ILP. A series of 111 patients compared with 111 historical controls with subungual melanoma demonstrated no difference in survival after ILP with melphalan alone. <sup>297</sup> Prophylactic ILP with melphalan cannot be recommended as an adjunct to standard surgical therapy in high-risk melanoma patients.

### Therapeutic Isolated Limb Perfusion

The role of ILP in prolonging overall survival has some support in the literature. Multiple randomized studies suggest improved survival in a subgroup of patients that undergoes ILP. ILP also is quite effective at ameliorating symptoms from bulky disease such as pain, edema, decreased mobility, and skin breakdown. <sup>298</sup> Numerous nonrandomized series claim survival advantages with melphalan-based ILP, but only two prospective randomized trials, with unfortunately conflicting and criticized results, exist in the literature (Table 42.2-9, Table 42.2-10, and Table 42.2-11).

Author	No.	Isolated Limb Perfusion	Control
Sequeira, 1970 <sup>292</sup>	199	88	88
Jones, 1982 <sup>293</sup>	122	81	35
Rege, 1987 <sup>294</sup>	30	31	63
Martijn, 1987 <sup>295</sup>	120	65	40
Franklin, 1988 <sup>296</sup>	227	77	77
Reijnen, 1992 <sup>297</sup>	11	95	75

<sup>a</sup>These studies are nonrandomized patients compared with historical controls. Although these trials generally show an improved 5-year survival, randomized prospective trials have shown mixed results.

**TABLE 42.2-9.** Five-Year Survival after Isolated Limb Perfusion Compared with Historic Controls <sup>a</sup>

Author	No.	Isolated Limb Perfusion		
		Stage I	Stage II	Stage III
Ghans, 1987 <sup>298</sup>	33 (treatment)	14	13	23
	34 (control)	23	14	28
Makino, 1987 <sup>299</sup>	36 (treatment)	17	17	17
	35 (control)	19	21	25

<sup>a</sup>The significant results of the earlier trial have not been replicated. The later study was able to demonstrate an improved disease-free survival, but no overall survival benefit was established. Isolated limb perfusion should be performed in the setting of randomized trials before it can be widely recommended.

**TABLE 42.2-11.** Tumor Response after Isolated Limb Perfusion with Melphalan Alone

Ghussen et al. reported results in 107 patients in which wide excision and regional lymph nodes dissection were compared with hyperthermic (42°C) perfusion with melphalan at a mean follow-up period of 554 days. The recurrence rate in the control group was 27.8% in stage I, 31.6% in stage II, and 58.8% in stage III compared with 5.6% in stage I, 5.5% in stage II, and 12.5% in stage III, suggesting improved survival for stage II and III patients. However, there has been wide skepticism regarding the results of this small study.<sup>299</sup> Hafstrom et al. reported a prospective randomized trial in 69 patients testing application of regional hyperthermic perfusion with melphalan after surgery to one-half of patients following excision. Median disease-free survival was 17 months in the perfusion group and 10 months in the control group. There were 15 locoregional recurrences in the perfusion group and 24 in the control group. The disease-free survival was better for the perfusion group than for the control group, but no significant difference in overall survival was noted.<sup>300</sup> Of note, Hafstrom et al. used a lower dose of melphalan than currently standard. Patients developing recurrence after ILP may undergo repeat ILP, but there is a high limb recurrence rate and diminished response and disease control interval with increased toxicity.<sup>301</sup>

Patient factors that have been associated with therapeutic benefits include minimal total tumor surface area, absence of regional node involvement, number of lesions, and lack of previous recurrence.<sup>301a</sup>

### Technique and Dosing

ILP of the lower extremity is performed via cannulation of the external iliac artery and vein through a suprainguinal retroperitoneal dissection. All venous and arterial branches including the hypogastric artery are ligated to prevent systemic leak syndrome.<sup>302</sup> Cannulation of the upper extremity is similarly performed through the axillary vessels. A proximal tourniquet aids in limiting systemic exposure to the perfusate. The extracorporeal perfusion circuit is primed with 700 mL saline, 1 U of packed red blood cells, and 1500 U of heparin, and flow is maintained in the range of 50 mL/L limb volume per minute ( Fig. 42.2-24). The amount of systemic leak is measured using <sup>131</sup>I radiolabeled albumin or <sup>99m</sup>Tc-labeled red blood cells with the gamma counter over the precordium.<sup>303,304</sup>

**FIGURE 42.2-24.** Operating room setup of isolated limb perfusion. Note the cumbersome apparatus. If clinical trials are performed demonstrating similar efficacy using isolated limb infusion, the simplification of the treatment of regional disease may enable a more widespread treatment.

Melphalan is an alkylating agent that is the mustard derived from phenylalanine, an essential precursor used in melanin synthesis by melanocytes. Weiberdink developed a regional toxicity scoring system to grade the reaction based on actual measurement of limb volume ( Table 42.2-12). Based on this dosing regimen, a dose of 10 mg/L for the lower extremity and a dose of 13 mg/L for the upper extremities were developed to limit severe toxicities and optimize response.<sup>305</sup>

Grade I	No subjective evidence of reaction
Grade II	Slight erythema, edema, or both
Grade III	Considerable erythema, edema, or both with some blistering; slightly disturbed motility permissible
Grade IV	Extensive epidermolysis, obvious damage to the deep tissue, or both; causing definite functional disturbances; threatening or manifest compartment syndromes
Grade V	Reaction that may necessitate amputation

(From ref. 538, with permission.)

**TABLE 42.2-12.** Wieberdink Grading System for Regional Tissue Toxicity after Isolated Limb Perfusion

The use of hyperthermia has become standard with the use of ILP, as it seems to augment tissue concentrations of melphalan.<sup>306</sup> True hyperthermia is defined as greater than 41.5°C, mild hyperthermia as 38.5° to 41.5°C and controlled normothermia as 36° to 38°C. Temperatures above 42°C are directly cytotoxic to tumor but result in excessive adverse effects.<sup>307</sup> Stehlin suggested an improvement in the 5-year survival rate from 22% to 76% after introduction of hyperthermia to ILP, but others have demonstrated conflicting data. In one series of 136 patients with recurrent extremity melanoma, a minimum temperature of 41.5°C was an independent factor predictive of complete response.<sup>308</sup> By contrast, hyperthermia was not a significant factor related to complete response in an equally large series (n = 120).<sup>309</sup> The optimal duration of therapy, which has ranged from 45 minutes to 2 hours, is unknown.

### Other Agents

A number of other agents in addition to melphalan have been administered by ILP including cisplatin, etoposide, actinomycin D, dacarbazine, thiotepa, mitoxantrone, IL-2, IFN-g, TNF- $\alpha$ , and lymphokine-activated killer (LAK) cells alone or in various combinations.<sup>309a,309b</sup> Although dacarbazine requires systemic hepatic conversion to its active metabolite, it has been shown, when administered by ILP, to generate an overall response rate of 76%.<sup>310</sup> Cisplatin has an overall response rate of over 50%, but the median response duration is only 5 months.<sup>311</sup> ILP using drugs other than melphalan and TNF is less effective and often associated with increased toxicity.<sup>312</sup>

In murine systems, TNF is capable of significant antitumor effects with a single intravenous injection, but effective doses cannot be achieved systemically in patients because of hemodynamic collapse. Immunohistochemical analysis of biopsies from patients treated with ILP with TNF demonstrates intravascular platelet aggregation, endothelial activation, and neutrophil invasion. Specific tumoral vasculature destruction with sparing of the normal vessels is also seen.<sup>313</sup>

The initial study of regional administration of high-dose TNF in conjunction with melphalan and low doses of IFN-g was reported in 1992, demonstrating a complete response rate of 90%.<sup>295</sup> Many other case series corroborate the apparently enhanced activity of combination therapy ( Table 42.2-13). IFN-g induces the up-regulation of TNF receptors on tumor cells and has *in vitro* synergism with TNF in antitumor activity.<sup>314,315</sup> A randomized trial comparing TNF and melphalan alone or in combination with IFN-g has shown no benefit with the addition of IFN-g.<sup>316</sup>

<sup>b</sup>Note: No randomized survival data exist directly comparing melphalan and tumor necrosis factor with melphalan alone.

**TABLE 42.2-13.** Tumor Response after Isolated Limb Perfusion with Tumor Necrosis Factor and Melphalan <sup>a</sup>

A dose of 4 mg of TNF, more than ten times the maximal tolerable systemic dosage, is well tolerated during perfusion, and adverse effects are reportedly no greater than with melphalan alone. Subsequent clinical trials demonstrate no benefit for doses above 4 mg. <sup>317</sup> The melphalan and TNF regimen has been successfully applied in patients who historically do not respond to melphalan ILP treatment alone. Patients with bulky disease, who historically are less likely to respond to melphalan alone, may have an improved outcome with the addition of TNF. <sup>317</sup> In addition, those who have failed treatment or had recurrences after prior ILP with melphalan or other chemotherapeutics are candidates for TNF therapy. <sup>318</sup> Phase III randomized studies evaluating ILP and melphalan with or without TNF in patients with localized, advanced, extremity involvement are currently underway.

### Toxicity

Perioperative toxicity is common but generally tolerable and reversible. Acute regional toxicity after ILP includes pain within the first 48 hours and edema that usually resolves within 14 days. Erythema associated with the procedure fades over a period of 3 to 6 months. Melanomatous lesions soften and flatten, and biopsies show melanin pigment within macrophages without evidence of melanoma cells. Patient age is not an absolute contraindication for perfusion as adverse effects do not appear to be significantly greater in patients greater than 70 years of age. <sup>319</sup> Vroenenraets et al. evaluated 425 patients for treatment-related toxicities after ILP, finding grade I and II toxicities in 85%, grade III and IV toxicities in 15%, and grade V toxicities in 0.5% ( [Table 42.2-14](#) ). The degree of limb toxicity, since it has no correlation with tumor response, should be avoided. <sup>320</sup> Creatinine kinase levels greater than 1000 U after the first postoperative day and temperatures higher than 40°C are both strongly associated with development of severe toxicities. <sup>321</sup> Although some centers recommend prophylactic fasciotomies during ILP, many surgeons simply monitor compartment pressures postoperatively. Renal failure secondary to myoglobinuria can be prevented by maintaining adequate urine output (greater than 4 L/d) and alkalization (pH greater than 7.5) during the first 2 to 3 postoperative days. <sup>322</sup> Serious long-term sequelae of ILP are uncommon. Mild neuropathies are noted in up to 20% to 40% of patients (possibly from the tourniquet) after perfusion ( [Table 42.2-15](#) ). <sup>323,324</sup> Some advocate the use of drugs other than melphalan to prevent wound complications and edema. The use of dacarbazine, cisplatin, or carboplatin may have less adverse effects but no trial has directly compared the therapeutic and toxic effects of these various regimens. <sup>325</sup> Some evidence suggests that nonmelphalan regimens have more rapid recurrence rates. The incidence of wound complications increases significantly in patients who undergo concurrent lymphadenectomy. <sup>326</sup> Some surgeons opt to perform a lymphadenectomy as a staged procedure after 6 to 8 weeks, whereas others routinely perform them in order to avoid a difficult operation in a previously explored site.

Almost all patients develop hypotension and tachycardia during ILP with TNF. Furthermore, patients undergoing ILP with a TNF with measured leaks of greater than 1% develop mild and transient postoperative hypotension. Prevention of systemic leak and fluid loading before tourniquet release may help prevent the need for vasopressors. The use of a perioperative Swan-Ganz catheter is strongly recommended. <sup>327</sup> Disturbances in pulmonary function are common with TNF but resolve to baseline in 8 weeks. <sup>328</sup> Fever, nausea, and reversible hepatic toxicity are also common with TNF protocols. <sup>329</sup> Acute vascular complications are rare (2.1%) and consist mainly of arterial thrombosis for which urgent embolectomy is required. <sup>330</sup>

### ISOLATED LIMB INFUSION

Thompson et al. have reported an alternative approach called *isolated limb infusion* with the percutaneous insertion of venous and arterial catheters in the axial vessels followed by proximal tourniquet limb vessel occlusion. The procedure is performed under normothermic and hypoxic conditions for 30 minutes without an oxygenator, thus avoiding much of the cost and complexity of ILP. Long-term survival results are still pending, but complete response rates comparable with ILP are reported. <sup>331</sup> More investigation of this technique is necessary before wide acceptance.

### INTRAARTERIAL THERAPY

Intraarterial cisplatin combined with systemic therapy has been used with only modest success. Fifteen patients treated with systemic vinblastine and dacarbazine and intraarterial cisplatin were observed to have a 67% response rate. Only 45% were complete responses and one was pathologically positive at subsequent biopsy.

Given the significant toxicities of this regimen, it is necessary to have more experience before any recommendations can be made. <sup>332</sup>

## LOCAL ABLATION

Hill and Thomas reported the use of the ablation of multiple melanoma nodules using a CO<sub>2</sub> laser. Their initial series had a surprising recurrence rate of only 2%. <sup>333</sup> Another small series treated 19 patients with CO<sub>2</sub> laser ablation. After a mean follow-up of 15 months, five patients died from the disease. Among the 14 survivors, 8 have had no limb recurrence and the remaining required further treatments to control disease. <sup>334</sup> In larger European trials, higher recurrence rates with this technique are reported. The use of electrical pulses directly applied to cutaneous metastases after administration of local or systemic bleomycin may have activity against melanoma. In one series, a 91% response rate was noted without any significant reported side effects. <sup>335</sup> The use of photodynamic therapy may have some use in the treatment of patients with in-transit disease. Photodynamic therapy can specifically ablate malignant cells at depths up to 1 cm. There are yet no series of melanoma patients using this technique. <sup>336</sup> These treatments may offer reasonable local control using a minimally invasive approach of nonbulky regional disease.

## LOCAL IMMUNOTHERAPY

Local injection of bacille Calmette-Guérin (BCG), <sup>337</sup> IFN- $\alpha$ , and other agents has been occasionally locally effective, but has not shown systemic effect on noninjected metastases and has been occasionally associated with significant toxicity (e.g., Pott's disease with systemic BCG infection). <sup>338,339</sup> For those reasons, BCG is little used at present for local therapy.

## RADIOTHERAPY

Radiotherapy can be useful in managing in-transit metastases that are too extensive for surgical resection and as an adjuvant therapy after resection of recurrent in-transit disease. Treatment techniques and outcome are similar to those for management of lymph node metastases and remote subcutaneous metastases and are discussed in the sections [Stage III Disease: Management of the Clinically Positive Nodal Basin](#) and [Stage I and II Disease: Management of Primary Melanoma](#).<sup>180,181 and 182,340</sup>

## SYSTEMIC THERAPY

The use of dacarbazine and other systemic chemotherapy, biologic agents, or both benefits patients with in-transit disease at rates equivalent to patients with systemic disease. Immunotherapies including IFN and IL-2 have shown benefit in a small number of patients. Patients with in-transit disease may be ideal candidates for immunobiologic intervention because of their low tumor burden. The use of IL-2 and other novel immunotherapies such as IL-12, IL-18, peptide, or DC-based vaccines may prove effective in the future to control in-transit disease. Morton from the John Wayne Cancer Institute has used the CancerVax vaccine for patients with in-transit disease, and in nonrandomized patients suggests an approximate 50% 5-year survival.

## ADJUVANT MEDICAL THERAPY

The prognosis of melanoma predicted from staging information allows the designation of low-, intermediate-, high-, and very high-risk groups that serve as guideposts for the potential consideration of adjuvant therapy. Patients previously enrolled in trials of adjuvant therapy have been those at high risk, in whom relapse and mortality risk exceed 50% at 5 years. The entry criteria for patients in high-risk trials has previously included both locally advanced, surgically curable (AJCC stage IIB), and regionally metastatic node-positive melanoma.

The adjuvant therapy of melanoma using IFN and other related agents is here considered separately under the previously defined categories of high-risk for recurrence melanoma (AJCC stage IIB and III), and with intermediate-risk melanoma (AJCC stage IIA). Patients with AJCC stage I disease have a low relapse risk and an excellent overall and relapse-free survival. For this reason, stage I patients are unlikely to benefit from such therapy and have not been the focus of any adjuvant therapy trials.

## IMMUNOSTIMULANTS

A number of approaches for postsurgical adjuvant therapy have been tested since 1970. These have included systemic chemotherapy, immunostimulation with crude microbial agents such as BCG,<sup>341</sup> *Corynebacterium parvum*,<sup>342,343</sup> and picibanil, derived from *Streptococcus pyogenes*.<sup>344,345</sup> The antihelminthic chemical immunomodulator levamisole has undergone intensive evaluation.<sup>346,347,348,349 and 350</sup> Unfortunately, randomized controlled trials have not demonstrated reproducible increases in relapse-free or overall-survival with any of these modalities.

## INTERFERONS

More recently, the use of individual cytokines obtained and partially purified from human cells or synthesized by recombinant DNA technology have demonstrated an effect on the natural history of this disease. The IFNs have been the most intensely studied agents for the adjuvant therapy of intermediate- and high-risk melanoma. Results of randomized controlled clinical trials in the United States National Cooperative Groups have now yielded both positive and negative results using high- and low-dose IFN- $\alpha_{2b}$ . A summary of IFN trials for the adjuvant treatment of melanomas is shown in [Table 42.2-16](#).

	European Organization for Research and Treatment of Cancer 18952

TABLE 42.2-16. Summary of Interferon Trials for Adjuvant Therapy of Melanoma

The IFNs are a complex family of proteins with diverse functions that are divided into type I (IFN- $\alpha$ , IFN- $\beta$ , IFN- $\tau$ , IFN- $\omega$ ), type II (IFN- $\gamma$ ) and type III (IL-10, IL-19, IL-20, and IL-21). The IFNs have shown potent immunomodulatory effects *in vivo* and *in vitro* including induction of major histocompatibility antigen expression of both class I (ABC) and class II (DR, DP, and DQ) molecules. Modulation of the number and function of effector cells (NK cell, T cells, monocytes, and DCs) have been well defined, and their function in responding to nominal tumor antigens is now under intense study. <sup>351</sup> The type I IFNs are structurally related species derived from genes on chromosome 9 that are classically induced by exposure of cells to virus or nucleic acids. Type II IFN is produced mainly by T lymphocytes and NK cells, bears little homology to type I IFN, and is coded for by genes located on chromosome 12. The type III members of this family are produced by several lymphoid and myeloid cell types and appear to modify immunity by promoting a humoral immune response, enhancing cytolytic activity, and in some instances, having direct antitumor effects. The types of IFN differ in terms of the receptors with which they interact. IFN- $\alpha$  and IFN- $\beta$  share a common receptor distinct from the receptor that binds IFN- $\gamma$  and induce a unique intracellular signal transduction cascade. Mixed results of trials examining IFN- $\alpha$  may be due to frequent down-regulation of IFN receptors and responsiveness to IFN after prolonged IFN- $\alpha$  administration. Recombinant DNA technology has allowed the production of virtually unlimited quantities of recombinant IFN, which has facilitated their testing both in the laboratory and in the clinic. In melanoma, IFN- $\alpha_{2b}$  has been the most extensively evaluated agent, of which three subspecies are commercially available: IFN- $\alpha_{2a}$  (Hoffman LaRoche), IFN- $\alpha_{2b}$  (Schering Plough), and IFN- $\alpha_{2c}$  (Boehringer Ingelheim) that differ minimally in amino acid

sequence and apparent biologic effects.

### Adjuvant Therapy for High-Risk (American Joint Committee on Cancer Stage IIB and III) Melanoma

IFN- $\alpha$  has been widely tested for the adjuvant therapy of melanoma, and the most extensively evaluated IFN- $\alpha$  subspecies has been IFN- $\alpha_2$ . Other agents currently undergoing evaluation in randomized trials include the chemically defined ganglioside vaccines: GM2, keyhole limpet hemocyanin, plus QS 21 (Progenics) and allogeneic whole tumor cell–derived vaccines for which trials are incomplete or inconclusive [Melacine (Corixa) and CancerVax (John Wayne Cancer Institute)]. Regimens using IFN- $\alpha_2$  for high-risk melanoma can be divided into high-dose regimens given for 1 year, high-dose regimens given for periods of shorter duration (3 months), and low-dose regimens given for longer intervals (of 2 to 3 years). Results of adjuvant IFN trials are shown in [Table 42.2-17](#).

Ref	Year	No.	Age	Site	Treatment	Outcome
1684	1984	287	50-70	Primary	IFN- $\alpha_2$ vs. observation	OS: 38% vs. 45% RFS: 26% vs. 37%

TABLE 42.2-17. Trials for Adjuvant Interferon- $\alpha_2$  for Melanoma

### High-Dose Interferon- $\alpha_2$ for 1 Year: Eastern Cooperative Oncology Group Trial E1684

The ECOG initiated a trial in 1984 (1684) for patients with melanoma at high risk for relapse following surgical resection of primary tumor, regional lymph node metastasis, or both. Twenty-nine centers contributed 287 (280 evaluable) patients who were randomized to treatment with IFN- $\alpha_{2b}$  or observation. Eligibility criteria included the presence of a T4 primary lesion with or without regional lymph node involvement or primary lesions of any depth with pathologically proven regional lymph node involvement. Patients with cutaneous melanoma of any thickness, but with the regional lymph nodes as the site of initial and only relapse were also eligible. All patients underwent regional lymph node dissection and were stratified with respect to clinical and pathologic stage of disease. Maximally tolerable doses of IFN- $\alpha_{2c}$  were used: an initial induction phase of 20 MU/m<sup>2</sup> intravenously daily for 5 to 7 days for 4 weeks was followed by a maintenance phase at 10 MU/m<sup>2</sup> subcutaneously, three times a week for 48 weeks (total treatment duration of 52 weeks). The rationale for the initial high-dose intravenous treatment phase was to provide maximal dose intensity and minimize the induction of anti-IFN antibodies. At a median follow-up of 7 years, a significant improvement in both median relapse-free survival (1.72 vs. 0.98 years) and overall survival (OS) (3.82 vs. 2.78 years) was noted in an intent-to-treat analysis. Patients with established lymph node involvement, *de novo* or recurrent, appeared to derive the greatest benefit from treatment. Only a limited number of patients (31) who were clinically and pathologically node-negative (T4 pN0) entered the study, and an imbalance in the distribution of the important prognostic variable, ulceration, made it difficult to draw firm conclusions for this subset. At five years the 40% improvement in relapse-free survival (26% vs. 37%) and 25% improvement in overall survival (37% vs. 45%) led the Food and Drug Administration to approve the use of IFN- $\alpha_{2b}$  given for 1 year by this intravenous and subcutaneous schedule for patients with stage IIB/T4-N0 and stage III node-positive disease in 1995.

As expected, this regimen was associated with substantial toxicity, and grade 3 and 4 (ECOG toxicity scale) events were noted in the majority of recipients. Dose-modification or delays were required at least once in 50% of patients during the intravenous induction phase and in 48% of patients during the subcutaneous maintenance phase. Most treatment delays occurred in the first 4 months of the regimen. A retrospective quality-of-life (Q-TWiST) analysis revealed a mean gain of 8.9 months without relapse ( $P = .03$ ) and 7 months of overall survival time ( $P = .02$ ) for the IFN-treated patients after 84 months of follow-up as compared with the observation group.<sup>352,353</sup> The treated group experienced severe treatment-related toxicity for an average of 5.8 months. The net result was that the IFN-treated group had more quality-of-life-adjusted survival time than the observation group, regardless of the relative valuations placed on time with toxicity and time with relapse. An economic analysis of the E1684 regimen was also published.<sup>354</sup> The incremental cost of IFN per life-year gained ranged from \$13,700 after a projected 35 years to \$32,600 at 7 years (the median follow-up of E1684). The benefits of IFN projected over a lifetime yielded incremental cost per life-year or quality-adjusted life-year that are less than \$16,000. This compares favorably with the rigorous Canadian benchmark of \$20,000 per quality-of-life-year gained and is comparable with other accepted adjuvant therapies of breast and colorectal cancer.

To evaluate the observations regarding the results of trial E1684 and to evaluate concurrently the high-dose regimen and a low-dose IFN- $\alpha_{2c}$  regimen against observation, Intergroup trial E1690 was initiated in 1991. This trial was designed and implemented before the availability of mature data from the E1684 trial. Eligibility criteria for E1690 were similar to those for E1684 but dropped the requirement for regional lymphadenectomy for patients with deep (T4, greater than 4 mm) primary lesions. Six hundred forty-two (95% eligible) patients were randomized to either high-dose IFN- $\alpha_{2c}$  as in E1684, low-dose IFN- $\alpha_{2b}$  for 2 years (IFN- $\alpha_{2c}$  3 MU subcutaneously, TIW), or observation. At a median follow-up of 52 months, the 5-year estimated relapse-free survival for high-dose IFN- $\alpha_{2c}$ , low-dose IFN- $\alpha_{2b}$ , and observation were 44%, 40%, and 35%, respectively. High-dose IFN- $\alpha_{2b}$  showed a significant effect on relapse-free survival as compared with observation in a Cox analysis ( $P_2 = .03$ ), prolonging median time to relapse by 10 months. There was no significant effect of low-dose IFN- $\alpha_{2b}$  on relapse-free survival, and neither high-dose IFN- $\alpha_{2c}$  nor low-dose IFN- $\alpha_{2b}$  demonstrated a benefit in overall survival.

Of note, the median overall survival for patients assigned to observation in E1690 was 6 years as compared with only 2.8 years for observed patients on E1684. The question has arisen whether the use of systemic IFN- $\alpha_{2b}$  among one-third of patients who relapsed ( $n = 38$ ), who were originally assigned to observation, may have been in part responsible for the large gain in postrelapse survival seen in E1690. The postrelapse survival for patients originally assigned to observation who subsequent to relapse received IFN, versus those who never received IFN, was significantly prolonged (median 2.2 years vs. 0.8 years;  $P = .0024$ ). Other factors that could potentially account for the improved outcome for patients on this trial randomized to observation include the use of more accurate staging techniques or more modern surgical intervention at initial treatment, subsequent relapse, or both.

### High-Dose Regimens of IFN- $\alpha$ of Intermediate Duration

The North Central Cancer Treatment Group (NCCTG) performed a randomized trial of high-dose IFN- $\alpha_{2a}$  given for 3 months (intramuscular, TIW) versus observation in 262 patients with primary melanomas of thickness greater than 1.69 mm deep or with presenting or recurrent regional lymph node involvement. The dose of IFN- $\alpha_{2a}$  used was 20 MU/m<sup>2</sup> given intramuscularly TIW for 12 weeks and reached a total dose approximately one-half that of the E1684 high-dose regimen. At a median follow-up of 6.1 years, the median relapse-free and overall survival were not significantly different for the two arms of the study. For patients with regional lymph node involvement, the improvement in median recurrence-free survival was significant by Cox analysis ( $P_2 = .03$ ) for the IFN- $\alpha_{2a}$ -treated patients (17 months vs. 10 months), without a significant difference in overall survival. The limited number of patients in this subset does not permit a firm conclusion regarding the benefit of this regimen on either relapse-free or overall survival or the treated population as a whole.

### Low-Dose Interferon- $\alpha_{2a}$ for 2 to 3 Years

The use of lower, nontoxic doses of IFN- $\alpha_{2a}$  for high-risk melanoma has been studied both in the United States and in Europe. Between 1990 and 1993, the WHO Melanoma Program entered 444 patients to a randomized trial comparing 3 years of treatment with IFN- $\alpha_{2a}$  (3 MU subcutaneously, TIW) or observation. This trial differed from the ECOG and NCCTG trials in regard to eligibility: Only patients with regional lymph node metastases were eligible for randomization after lymphadenectomy. One-half of the patients studied had extracapsular extension with lymph node involvement, a feature that was excluded from ECOG studies 1684, 1690, and the NCCTG 837052 trials. A preliminary report at 22 months median follow-up suggested prolongation of recurrence-free survival among women younger

than 50 years and men older than 50 years, while a somewhat more mature interim report at 39 months median follow-up revealed no durable benefit in terms of either relapse-free interval or overall survival; a final publication is pending. <sup>355,356</sup> The negative results of the low-dose arm of the Intergroup trial E1690 discussed previously <sup>357</sup> confirm the results of WHO 16, both in terms of recurrence rates and overall survival for patients with high-risk melanoma.

The EORTC Trial 18952 is currently testing two intermediate doses of IFN- $\alpha_{2b}$  in high-risk melanoma patients. The study design incorporates two treatment arms and an observation arm. Treatment comprises a *modified induction* phase of IFN- $\alpha_{2b}$ , 10 MU subcutaneously injected, five times per week, followed either by 10 MU subcutaneously injected three times per week, for 1 year or 5 MU subcutaneously injected, TIW for 2 years. This study will accrue 1200 patients with high-risk resected melanoma, including patients with nodal disease with or without extracapsular extension, of whom 200 will be randomized to observation and 400 to each of the IFN arms (1:2:2 unbalanced assignment) to evaluate the role of dose intensity. The Nordic Melanoma Trial group are investigating the efficacy of two intermediate dosages of IFN- $\alpha_{2b}$  administered for 2 years, using a similar subcutaneous daily induction treatment. While the induction phase and the maintenance phase are modeled on the pivotal E1684 trial, it is important to note that the peak levels of IFN- $\alpha_2$  attained by the intravenous administration of 20 MU/m<sup>2</sup>/d are orders of magnitude higher than the levels that can be detected following the administration of 10 MU/d, especially when given by the subcutaneous route (10,000  $\mu$ /mL vs. less than 100  $\mu$ /mL peak).

### **Vaccines in the Adjuvant Therapy of Stage IIB and III Melanoma**

A number of vaccine approaches are being evaluated in the adjuvant treatment of patients with melanoma. Biochemical analysis has shown the presence of gangliosides of several series in melanoma, including GD3, GM1, GM2, and GM3, among others. In general, the purified gangliosides have not been shown to be immunogenic, and it has been difficult to induce antibody responses to these molecules with the exception of the ganglioside GM2, to which antibody responses have been detected spontaneously in up to 5% of patients with melanoma. Two studies have demonstrated that the presence of anti-GM2 antibodies confers a relapse-free survival advantage for patients with melanoma. <sup>358,359</sup> This led to the conduct of a randomized controlled trial of GM2 plus BCG versus BCG alone (both with cyclophosphamide pretreatment) in 122 patients with AJCC stage III melanoma, at the Memorial Sloan-Kettering Cancer Center in New York. GM2 antibody was detected in 50 of 58 patients treated with GM2/BCG and in only 7 of 64 patients treated with BCG alone. Patients with anti-GM2 antibodies, either preexisting or induced by treatment, had a significantly longer relapse-free survival than antibody-negative patients. A nonsignificant increase in disease-free interval (18%) and overall survival (11%) was found for the GM2/BCG-treated group as a whole. However, exclusion of patients with preexisting anti-GM2 antibodies from the analysis suggested a benefit in terms of disease-free interval for those who developed an antibody response to GM2.

A range of efforts to improve the immunogenicity of the GM2 molecule were tested, including conjugation to immunogenic carrier molecules, and admixture with potent new immunologic adjuvant agents. These have subsequently been found to induce more frequent and higher titer antibody responses to the GM2 molecule. The most potent combination tested uses the GM2 molecule coupled with a carrier protein derived from the keyhole limpet hemocyanin with an immunoadjuvant, QS21, a potent immunologic adjuvant of the saponin class. This vaccine induces qualitatively improved antibody responses of the IgG as well as IgM isotype, of higher titer than obtained by GM2 plus BCG. The GM2, keyhole limpet hemocyanin, plus QS21 vaccine has been developed for clinical evaluation (Progenics, New York, NY; Bristol Myers Squibb) and is currently being compared with high-dose IFN- $\alpha_{2c}$  in the Intergroup U.S. Trial E1694 for patients with AJCC stage IIB and III melanoma. This trial initiated in 1996 completed accrual of 880 patients in 1999, and its results have recently been unblinded due to the significant relapse-free interval and overall survival advantage of HDI, substantially confirming both RFS ( $P = .007$ ) and OS ( $P = .009$ ) benefits of HDI observed in E1684.

The John Wayne Cancer Institute has performed a series of phase II trials employing cultured tumor cell-derived vaccines (CancerVax) administered with the immunostimulant BCG for patients with metastatic disease as well as intermediate- and high-risk resected melanoma. <sup>138,360</sup> Encouraging phase II results have led to the initiation of two ongoing phase III randomized trials of adjuvant therapy for high-risk melanoma and resected metastatic disease patients believed to be at very high risk of recurrence. The first of these is comparing CancerVax plus BCG to BCG alone for the postsurgical treatment of AJCC stage III melanoma. The second is a randomized trial of CancerVax versus placebo for patients with stage IV melanoma rendered clinically disease free with surgery. Firm conclusions will only be possible regarding the therapeutic benefit of these vaccines as these first randomized controlled trials are completed and mature.

On the basis of evidence that cellular immune responses to melanosomal antigens may be of therapeutic value, peptide antigens that represent the immunodominant and subdominant melanosomal antigens have been brought into multicenter adjuvant trial for patients with resectable stage IV (M1) or advanced stage III melanoma in an ECOG study E4697. E4697 will investigate treatment with a multiepitope three-peptide vaccine composed of Melan-A/MART-1, gp100, and tyrosinase antigens that have been studied previously in the National Cancer Institute Surgery Branch and the University of Pittsburgh Melanoma Center/Biologics Program. <sup>361,362</sup>

### **Adjuvant Therapy for Intermediate-Risk Melanoma**

Patients with T3, Breslow depth 1.5 to 4.0 mm (S1992 AJCC stage IIA) melanoma account for a substantial fraction of patients at presentation and represent a heterogeneous group with 5-year survival greater than 72%. This category is historically twice as frequent as the stage III category, representing 31% of new melanomas. With 47,000 new cases of melanoma in the United States, approximately 19,000 represent stage II melanoma and from this group 5400 deaths are anticipated. This group of patients has been the focus of several completed European and newly initiated North American cooperative group studies.

### **Low-Dose Interferon- $\alpha$ for 18 Months**

Adjuvant therapy trials for high-risk melanoma have generally excluded patients with stage IIA melanoma, although a subset of patients in the NCCTG trial 83-7052 (100 patients) had stage II disease. Austrian, French, and Scottish trial groups have evaluated the low-dosage regimen tested in E1690 and WHO 16 in regimens of IFN- $\alpha$  administered for shorter periods of 12 to 18 months for patients with stage II melanoma (defined by clinical examination alone). The results of these trials are therefore difficult to apply to patients for whom more precise staging, by means of sentinel node mapping, is available.

The French Cooperative Group on Melanoma randomized 499 patients with AJCC stage II melanoma to IFN- $\alpha_{2a}$ , 3 MU subcutaneous TIW injections for 18 months, or observation. After a median follow-up of 5 years, a significant improvement in relapse-free survival ( $P = .038$ ) but not in overall survival ( $P = .059$ ) was noted. <sup>363</sup> The Austrian Malignant Melanoma Cooperative Group has reported a smaller trial that is somewhat less mature, at a mean follow-up of only 41 months. <sup>364</sup> Three hundred eleven patients were randomized to observation or treatment with IFN- $\alpha_{2a}$ , 3 MU subcutaneous daily injections for 3 weeks, followed by 3 MU subcutaneous TIW injections for 1 year. The prolongation of relapse-free survival noted in this trial ( $P = .02$ ) must be qualified given the short follow-up period; and the absence as yet of any overall survival data for this trial. <sup>365,366</sup>

Patients entering these trials included those with stage IIA and stage IIB, but neither elective lymph node staging (as in E1684) nor sentinel node mapping were pursued in any participants. This stage grouping therefore represents a heterogeneous population for which multicenter sentinel lymphadenectomy trials suggest that SLNs would be positive in 20% to 28% of patients with T3, T4 melanomas, respectively. The sentinel node mapping technique has had its greatest effect in refining the prognosis for these nominal stage II patients. Sentinel node mapping is an established method for staging these patients, which defines node-negative subgroups at lower risk. These results of the reported studies of low-dose IFN- $\alpha_{2a}$  show prolonged relapse-free interval for patients with intermediate-risk melanoma during treatment, with loss of this benefit over time following discontinuation of therapy. These results differ from the results of the high-dose regimens described previously in showing no durable effect on continuous relapse-free survival. Indeed, one of the conclusions that may be drawn from the Austrian and French experience, is that indefinite therapy may be required to achieve durable relapse-free benefit with low dosage IFN- $\alpha_2$ .

### **High-Dose Interferon- $\alpha$ for 4 Weeks**

The high-dose IFN regimens used in E1684 and E1690 were unique in their incorporation of an induction phase of intravenous therapy for the initial 4 weeks, at maximal tolerable dosages. The rationale for the induction phase was to provide peak levels of IFN- $\alpha_{2c}$  sufficient to inhibit tumor growth directly, as well as antivascular, and immunomodulatory effects on antigen-presenting and T-cell responses against melanoma antigens while avoiding the potential for induction of anti-IFN antibodies. The relative importance of the induction phase is suggested by the early effect of E1684 and E1690 regimens, in which hazard functions for relapse-free survival demonstrate early suppression of relapse risk with high-dose IFN- $\alpha_{2b}$  that is sustained for years after discontinuation of treatment. This has led to the hypothesis that peak dose exposure during induction may represent the critical component of the E1684/1690 regimens. Patient acceptance and tolerance for the intravenous induction phase is excellent. Dose modifications were required in one-half of patients during this phase (a fraction equivalent to the portion requiring dose modification during the subsequent maintenance phase). Removal from treatment was rarely necessary during this interval.

To help clarify the role of high-dose induction intravenous therapy, the ECOG and National Cancer Institute of Canada are currently conducting a randomized trial of intravenous therapy for 4 weeks alone, for patients with intermediate-risk stage IIA and IIB or microscopic nodal stage III N1A disease. Pathologic staging with SLN mapping and biopsy (or ELND) is encouraged but not mandatory, and patients are stratified according to the method of staging. Patients are randomized to receive either the intravenous induction therapy administered as in the first month of E1684 (IFN- $\alpha_{2b}$  20 MU/m<sup>2</sup> 5/week) or observation. To demonstrate a 7.5% improvement in relapse-free survival for the treated population with 80% power will require 1420 patients in this trial.

### **Sunbelt Trial**

A multicenter adjuvant trial that has been designated the Sunbelt Trial tests the role of high-dose IFN- $\alpha_{2a}$  in patients who are staged by SLN mapping procedures and in which both routine (H&E and immunohistochemical) and molecular assays (RT-PCR for multiple markers including tyrosinase, MAGE, and gp100) are conducted. One goal is to assess the significance of molecular markers in contrast to immunohistochemistry and standard H&E. This study will require 3000 patients to have a power to assess its multiple goals.

### **Vaccine Trial for Intermediate-Risk Melanoma**

A commercial vaccine preparation from cultured tumor cell lines (Melacine, Corixa) given together with the proprietary adjuvant agent Detox (monophosphoryl lipid A) has also been shown to induce antitumor responses in patients with metastatic melanoma.<sup>367,368 and 369</sup> A pilot experience suggests improved responses in recipients who have been administered IFN- $\alpha_{2b}$ . The Melacine-cultured melanoma tumor cell vaccine administered with the monophosphoryl lipid A adjuvant Detox has been tested by the Southwest Oncology Group for the adjuvant therapy of patients with T3 melanoma (SWOG 9035). This trial was conducted between 1990 and 1996, with 700 patients having received either the vaccine with Detox, or observation, after primary melanoma resection. Results of this trial have been preliminarily reported, showing no significant prolongation of relapse-free and overall survival in a primary efficacy analysis, but a significant effect in an intention-to-treat analysis that has yet to be clarified.<sup>370</sup>

## **TREATMENT OF STAGE IV DISEASE**

Metastatic melanoma has a median survival of only 6 to 9 months and current systemic therapy has been shown to induce complete durable responses in only a small minority of patients.<sup>371</sup> Most common sites of initial presentation with metastatic disease are the skin, lungs, liver, brain, and bone. Chemotherapy agents, biologic agents individually and in various combinations, and surgery have been used in the treatment of these patients.

### **RADIOGRAPHIC ROLE IN THE DIAGNOSIS OF STAGE IV DISEASE**

Weiss et al. performed a retrospective study on 261 malignant melanoma patients with resected local (greater than or equal to 1.69 mm) and regional nodal disease. Follow-up consisted of physical examination, complete blood cell count, blood chemistry panel, and chest radiography and was performed every 2 and 4 months for the first 1 and 2 years, respectively, followed by every 6 months for the subsequent 3 years. Out of 145 evaluable patients with recurrent disease, 32% were asymptomatic. Physical examination detected 37 of 45 (82%) of the asymptomatic recurrences. Chest radiography detected the other 9 of 45 (22%) recurrences, while no recurrences were detected by blood tests alone.<sup>372</sup> Bassares et al. studied 115 relapses in follow-up of 528 stage I melanoma patients. History and physical examination detected 90% of relapses, with chest radiography and abdominal ultrasound detecting the rest. Only two recurrences were resectable.<sup>373</sup> Roth et al. evaluated bone, brain, and liver scans in the follow-up of 58 patients with node-positive melanoma. Only one patient with a true positive bone scan was found, thus calling into question its utility in patients with melanoma.<sup>374</sup>

### **METASTASECTOMY AND RADIOTHERAPY**

Surgical treatment of asymptomatic, distant metastatic lesions remains controversial because of the likelihood of widespread disease at other sites. However, a subgroup of patients exists that may benefit from surgical resection of metastatic lesions, and some surgeons have advocated the more widespread application of surgery in stage IV disease. Unfortunately, no randomized trials exist to support the use of metastasectomy. Retrospective reviews, largely from single institutions, have reported a survival difference in selected operated melanoma patients compared with historic controls. Although, metastatic melanoma has a worse prognosis (by a factor of two) after resection than other carcinomas, prolonged 5-year survival in some patients has been reported following complete resection of melanoma metastases of the lung, soft tissue, and even gastrointestinal tract.<sup>375,376,377,378,379 and 380</sup> Metastasectomy in melanoma has also been advocated because of the absence of a demonstrable survival effect with currently available systemic therapies in more rigorous randomized controlled trials. However, the rigor with which systemic therapy has been tested is far greater than that with which surgical approaches have been evaluated to date. Although numerous series show survival benefits for metastasectomy compared with historic controls, selection bias may account for these differences. Unfortunately, randomized trials to determine the efficacy of surgery in this setting are not likely.

Metastasectomy should be considered in the absence of locoregional disease and when metastatic disease is confined to a single site that is amenable to complete resection. Before the application of metastasectomy with therapeutic intent, patients must be able to tolerate the operation and have appropriate staging studies demonstrating limited disease. The paradigm for optimal staging includes the use of brain magnetic resonance imaging, whole body CT, and PET scanning. The use of immunotherapy following metastasectomy may afford a more suitable setting for demonstration of the potential benefits of vaccine immunotherapy, as researchers at the John Wayne Cancer Institute are attempting to demonstrate.<sup>381</sup>

### **Nonvisceral Metastasis**

More than one-half of patients who have recurrent melanoma manifest disease initially at nonvisceral sites, and one-half of these lesions may be solitary.<sup>382,383</sup> Adequate data predicting prognosis in patients with nonvisceral metastasis range wildly, making the assessment of metastasectomy's efficacy difficult. Following complete resection, median survivals of 8 to 50 months have been reported with 5-year survival between 10% and 61% of patients.<sup>382,384,385,386,387 and 388</sup> Radiotherapy is an alternative to surgery for managing symptomatic skin metastases not responding to systemic therapy. Impending skin breakdown and pain at the tumor site are relative indications for local ablative therapy. Lesions may respond to radiotherapy using high-dose fractions and high total doses. Commonly used fractionation schemes are 20 Gy/5 fractions and 30 Gy/10 fractions given in conventional daily fractions, or by means of hypofractionated schedules such as 21 Gy/3 fractions and 30 to 36 Gy/5 to 6 fractions.

### **Pulmonary Metastasis**

The lung is the sole site of initial recurrence in 7% to 21% of melanoma patients and is the most common initial visceral site of metastatic disease. Lung metastases are usually detected as asymptomatic lesions on screening chest radiographs.<sup>376,389</sup> Up to one-third of these are benign or represent a new primary neoplasm, suggesting the importance of biopsy and pathologic confirmation.<sup>390,391</sup> There is conflicting information concerning prognostic factors such as rapidity of tumor growth, the disease-free interval, the number of lesions, and survival after metastasectomy. One factor that clearly correlates with median survival after resection is the ability to completely remove all metastatic disease.

The rapidity of tumor growth may affect survival after metastasectomy. The average melanoma has a tumor-doubling time of 30 days. Patients with a tumor-doubling time of greater than 60 days have a median survival of 23 months with a 5-year survival rate of 16%. Patients with a tumor doubling time less than 60 days had a median survival of 16 months and no 5-year survivors were reported. In a multivariate analysis, the number of pulmonary lesions, bilateral location, disease-free interval before diagnosis of pulmonary metastases, and size of the nodules did not significantly affect survival.<sup>390,392</sup>

Five-year survival after pulmonary metastasectomy is 20% to 27%.<sup>375,376</sup> Historic data suggest a median survival of 10 months in patients with disease confined to the lungs alone who were treated with dacarbazine, and the 1-year survival rate for patients receiving nonsurgical treatment was reported to be 36%.<sup>382,393</sup> In a retrospective study, improved survival was found when a second resection was performed after localized recurrence from a previous metastasectomy. Twenty percent of patients who had a second complete metastasectomy for melanoma were alive at 5 years.<sup>394</sup>

Although no randomized trials exist, the resection of pulmonary metastases has been suggested in patients with melanoma whose preoperative radiographic workup showed no evidence of extrapulmonary disease. Almost all of these resections can be done using minimally invasive techniques, and even bilateral procedures can be undertaken with low morbidity. Following patients' chest radiographs serially for a sufficient period may be a reasonable option in order to measure tumor-doubling time and reassess tumor burden when such therapy is considered. The rationale for such heroic surgical approaches may increase if adjuvant trials with IFNs, vaccines, or combinations are found to have a benefit in operable stage IV disease. These resected patients are ideal candidates for adjuvant immunotherapy trials as patients with limited tumor burden may respond better.

### Gastrointestinal Metastasis

Only 5% of all patients who die of melanoma develop symptoms from gastrointestinal disease.<sup>389</sup> Most have multiple lesions and the goal of surgery has been palliation of obstruction, perforation, or bleeding. Median survival after palliative surgery is only 10 months.<sup>395</sup> The diagnosis of a solitary gastrointestinal lesion is quite uncommon; nonetheless, after resection of solitary gastrointestinal lesions, 5-year survival rates have been reported to be as high as 28% to 41% from some centers.<sup>377,378</sup>

There is no evidence that invasive procedures for the treatment of hepatic metastasis benefits patients. There are occasional case reports of long-term survival after resections of isolated hepatic melanoma metastasis, but no substantial series exists in the literature. Hepatic metastasectomy cannot be recommended outside an investigational protocol setting.<sup>396</sup> A series examining the use of isolated hepatic perfusion for hepatic melanoma metastasis has also only reported limited response rates in a small number of patients.<sup>397</sup> At the University of Pittsburgh, hepatic metastasis from ocular melanoma demonstrates no advantage for cisplatin via hepatic artery administration and embolic occlusion of the hepatic artery over systemic administration, even with doses beyond the limits of systemic tolerance.

### Adrenal Metastasis

Isolated adrenal metastases are uncommon; however, a large retrospective series of 83 patients suggested a benefit for surgical excision. Twenty-seven patients underwent surgical exploration and 18 were rendered clinically free of disease at surgery. There was a median survival of 25.7 months for patients rendered disease free compared with only 9.2 months after a palliative resection. Removal of resectable lesions is a reasonable option if other approaches are unavailable, although there is a substantial likelihood of selection bias rather than surgery *per se* accounting for the suggested benefits.<sup>398</sup>

### Bone Metastasis

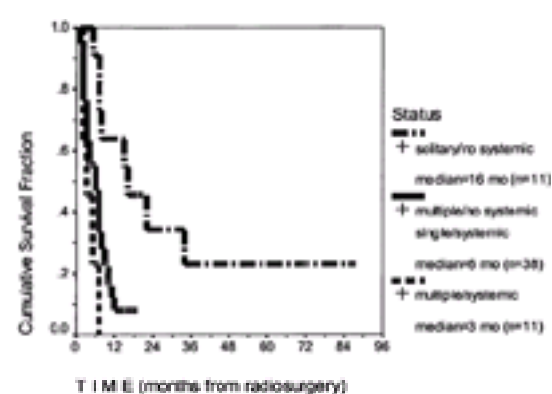

Melanoma metastasizes to the bone relatively late in the disease course. Median survival is just 4 months after diagnosis. Truncal melanomas have a higher percentage of bony metastases compared with melanomas found at other sites.<sup>399</sup> Of those with bone metastases, 67% responded to palliative radiotherapy or decompression with good pain relief.<sup>400</sup> Bone metastases from melanoma respond in a similar fashion to bone metastases from other tumors, with doses of 8 Gy/1 fraction, 20 Gy/5 fractions, or 30 Gy/10 fractions.

### Brain Metastasis

Brain metastases are detected clinically in 8% to 46% of patients and at autopsy in 55% to 75% of melanoma patients.<sup>401,402 and 403</sup> Brain metastases usually require treatment to relieve symptoms, and available options depend on the number and location of lesions. Corticosteroid treatment often reduces symptoms by ameliorating swelling in many patients and may provide palliation. Melanoma metastatic to the brain is reasonably treated by gamma knife irradiation or surgically, if the lesion is solitary, symptomatic, and can be treated without major neurologic injury.

A series of patients with symptomatic, solitary, intracranial lesions showed a median survival after craniotomy of only 10 months.<sup>404</sup> Patients who responded to previous immunotherapy and subsequently relapsed with intracranial disease seem to enjoy more significant benefit after craniotomy. Forty patients with melanoma or renal cell cancer metastasis involving the brain were reported in a study by the NCI. Thirty-six were rendered free of disease after resection of a single metastasis. The median survival after craniotomy for patients exhibiting complete response, partial response, and no response to previous immunotherapy was 23, 17, and 7 months, respectively. Of the ten patients who had achieved a prior complete response, eight remained disease free in the brain at last follow-up and some have had long-term survival. Twenty-five patients experienced neurologic symptoms before craniotomy, and all had complete resolution of their symptoms after surgical excision. The benefits of resection include palliation of symptoms and the potential for a prolonged disease-free interval in the brain.<sup>405</sup>

The role of conventional radiation for multiple lesions or unresectable disease is controversial.<sup>406</sup> Possibly, because of the sensitivity of the brain to large-dose fractions, studies of whole brain radiotherapy with high-dose fractions have shown little survival improvement.<sup>407</sup> Whole brain radiotherapy (30 Gy/10 fractions) is standard therapy for multiple brain metastases with initial radiosurgery beneficial for cases with two to four metastases.<sup>408</sup> Radiosurgery alone is recommended for patients with solitary brain metastases less than 3 cm in diameter (Fig. 42.2-25 and Fig. 42.2-26). Resection followed by whole brain irradiation is recommended for larger lesions with significant mass effect unrelieved by corticosteroids. The local control rates with stereotactic radiosurgery employing single-fraction minimum tumor doses of 16 to 20 Gy are excellent. Mori reported the University of Pittsburgh experience with gamma knife radiosurgery (median marginal dose, 16 Gy; range, 10 to 20 Gy) in 118 brain melanoma brain metastases (median volume, 2.95 mL; range, 0.1 to 25.5 mL) in 60 patients.<sup>409</sup> Median survival was 7 months after radiosurgery and 10 months after the initial diagnosis of brain metastasis, with a 90% local control rate. Local tumor progression developed in seven patients and subsequent remote brain metastases developed in 14 patients. Multivariate analysis demonstrated improved survival was associated with solitary brain metastases and for patients with no other active systemic disease.

**FIGURE 42.2-25.** Actuarial survival curves for 60 patients with malignant melanoma treated by gamma knife radiosurgery. Survival is compared for patients with solitary brain metastasis and no active systemic disease (solitary/no systemic) at radiosurgery (n = 11), multiple brain metastases and active systemic disease (multiple/systemic) at radiosurgery (n = 11), and the remaining patients with either solitary brain metastasis and active systemic disease (single/systemic) or multiple brain metastases without active systemic disease (multiple/no systemic) at radiosurgery (n = 38). Some patients with limited brain disease and no systemic disease are able to enjoy prolonged survival. (From ref. 409, with permission.)

Temozolomide is a nonclassical prodrug of MTIC (5-(3-N-methyltriazene-1-yl)-imidazole-4-carboxamide), the alkylating agent that is the active metabolite of dacarbazine. Temozolomide spontaneously converts into its active metabolite and in several trials has shown antitumor activity against melanoma that is at least equivalent to that of dacarbazine. A randomized phase III study of temozolomide versus dacarbazine was published in which patients with advanced melanoma were randomly assigned to receive either oral temozolomide at a starting dose of 200 mg/m<sup>2</sup>/d for 5 days every 28 days or intravenous dacarbazine at a starting dose of 250 mg/m<sup>2</sup>/d for 5 days every 21 days. Median survival was 7.7 months for patients treated with temozolomide and 6.4 months for those treated with dacarbazine. No major differences in toxicity were seen. Systemic levels of the active metabolite MTIC were higher than with the intravenous dosing of dacarbazine, and overall quality of life was improved with temozolomide.<sup>422</sup> Temozolomide also has been examined in phase I trials for use in conjunction with cisplatin and has been shown to be safe at the studied dosages.<sup>423</sup> The most attractive advantage of temozolomide is the well-documented penetration of third spaces such as the central nervous system (CNS) and ascites fluid. Approximately one-half of the circulating levels in the blood has been documented in the CNS, and temozolomide has been shown to be an active agent against CNS melanoma, as well as glioblastoma multiforme. Failure to demonstrate improvements in survival has led to denial of licensure for melanoma, although this agent has been licensed by the U.S. Food and Drug Administration for glioblastoma multiforme.

## IMMUNOTHERAPY OF METASTATIC DISEASE

Although immunotherapy currently is effective in only a small percentage of patients, the results can be quite dramatic. Six percent of patients have a complete response to IL-2, but two-thirds of patients with complete responses are disease-free survivors at a median follow-up of more than 5 years ( Fig. 42.2-27 and Fig. 42.2-28).<sup>424</sup> These infrequent responses suggest that with a better understanding of the immune mechanisms of IL-2, a greater proportion of patients might be benefited and perhaps serve as a more effective model for developing therapies for patients with other neoplasms.

**FIGURE 42.2-27.** Complete response in a patient with disseminated melanoma using high-dose interleukin-2. Chest radiograph (A) and abdominal computed tomographic scan (B) showing complete regression of disease.

**FIGURE 42.2-28.** Partial response in a patient with multiple cutaneous metastatic lesions after interleukin-2 (before, left; after, right). In general, partial responses are limited in their duration to 6 to 18 months, but some can be sustained for prolonged periods (greater than 10 years).

One fascinating aspect of melanoma is the evidence of tumor regression at the primary tumor site, and less commonly, at regional or distant metastatic sites. One of the hallmarks of primary melanoma is the appearance of subjacent lymphocytic infiltrate and pigment phagocytosis in monocytes associated with lesional depigmentation. Some patients develop patches of cutaneous depigmentation, remote from the primary lesion: This is known as leukoderma or paraneoplastic vitiligo, presumably secondary to a specific immune response directed toward melanocyte antigens.<sup>425,426</sup> Some patients who develop responses after immunotherapy, and in particular after IL-2, IFN- $\alpha_{2b}$ , or vaccines composed of melanosomal proteins or peptide therapy, develop marked paraneoplastic vitiligo. The presence of vitiligo predicts response to immunotherapy.

IL-2, originally termed *T-cell growth factor*, was first identified in 1976 and the first human trials of its antitumor effects were published in 1985.<sup>427,428</sup> and <sup>429</sup> IL-2 has no apparent direct cytotoxic or cytostatic effect on melanoma. IL-2 promotes T-cell proliferation and, in high doses, like IL-4, IL-7, IL-10, IL-12, and IL-18, induces LAK cells from NK precursors. These LAK cells can nonspecifically lyse tumor *in vitro*, and in particular, those failing to express class I molecules. In some instances, IL-2 can promote apoptotic death of T cells and its targeted deletion (or that of its alpha and beta chain receptors) is associated with inflammatory bowel disease. Typical high-dose IL-2 protocols involve the administration of 600,000 to 720,000 IU/kg IL-2 every 8 hours up to a maximum of 15 doses. This is administered in two cycles of up to 5 days separated by a 10-day rest period. Numerous single-institutional case series have been published on the efficacy of IL-2 ( Table 42.2-20). The NCI published the largest series of 283 consecutive patients with melanoma and renal cell carcinoma treated with high doses of IL-2 (720,000 IU/kg). A 7% complete response rate and 10% partial response rate was observed. Complete responses tended to be prolonged with many free of disease 15 years following therapy. An update of these patients published in 2000 demonstrated response durations ranging from 1.5 to greater than 122 months and a median response duration of at least 59 months. Disease progression was not observed in any patient responding for longer than 30 months.<sup>430</sup>

Author	No.	Response Rate (%)	Duration (mo)
Rosenberg, 1989 <sup>429</sup>	42	24	2 to >41
Thatcher, 1989 <sup>428</sup>	31	5	NR

Atkins, 1999 <sup>430</sup>	283	17	1.5 to >122

NR, not reported.  
<sup>a</sup>These trials have shown variable response rates and durations of response; in general, patients with the highest doses have enjoyed the highest response rates. Some patients with diffusely metastatic disease enjoy complete responses and prolonged (greater than 15-year) survival.

**TABLE 42.2-20.** Clinical Trials Using Interleukin-2 as Monotherapy for Melanoma <sup>a</sup>

Relapse after IL-2 usually occurs within 1 to 2 years (97%) in partial responders but much less frequently (41%) in complete responders. In patients who relapse, repeat administration of IL-2 is rarely effective following IL-2 treatment.<sup>431</sup> Surgical resection following recurrence following IL-2 therapy is associated with a rapid relapse with a median time of 5 months before progression, and resection in such patients should be used only as palliative therapy.<sup>432</sup>

Considerable toxicity from IL-2 administration is observed since IL-2 is given in each patient to maximally tolerated doses on the basis of evidence that efficacy is directly related to dose intensity. Capillary leak syndrome resulting in pulmonary edema as well as renal and cardiac dysfunction, hypotension, fever, and malaise are all common side effects of administration. In these early studies, a 1% mortality was reported, although more recent reports, with careful selection of patients, suggests mortality of less than 0.1%. There has been considerable debate concerning the dosage and regimen of IL-2 necessary to optimize response and minimize toxicity. A large experience supports the application of three daily IL-2 doses of 720,000 IU/kg or as more commonly applied outside of the NCI, 600,000 IU/kg of IL-2.<sup>433</sup> Low-dose IL-2 appears to be markedly less effective.<sup>434,435</sup> Identification of patients most likely to respond to IL-2 therapy has generally not been effective, although good performance status, low pretreatment serum IL-6 levels, postinfusion thrombocytopenia, and expression of certain HLA antigens have been suggested to be helpful.<sup>436,437</sup>

IL-2 has been used in numerous trials alone, in combination with other cytokines, with the infusion of autologous immune effector cells, with other chemotherapeutic agents, and with radiation therapy (Table 42.2-21 and Table 42.2-22).<sup>438,439</sup> and <sup>440</sup> None of these combinations has been associated with enhanced survival. The enhanced toxicity and absence of long-term survival advantage compared with IL-2 alone has led to their discontinuation.<sup>441,442</sup> The Extratumoral IL-2 Working Group also failed to demonstrate improved response rates of high-dose IL-2 and IFN- $\alpha$  over IL-2 alone in patients with melanoma in which the response rates were 10% and 5%, respectively.<sup>443</sup> The EORTC evaluated IFN- $\alpha$  and IL-2 with or without cisplatin in 138 patients with advanced metastatic melanoma. The overall response rate was 18% for patients receiving IFN- $\alpha$  and IL-2 and increased to 35% with the addition of cisplatin. In a subset analysis considering patients with normal pretherapy LDH levels, the response rate was 23%, and with cisplatin improved to 38%. Overall survival was 9 months without any significant differences between the various groups. Although results are still early to determine the true effect IL-2 has on survival, a 5-year survival rate of 13% has been shown in patients receiving IL-2 and IFN- $\alpha$  regardless of the inclusion of chemotherapy.<sup>444</sup> Efforts to reduce toxicity associated with IL-2 administration, including the use of corticosteroids and anti-TNF antibodies, have generally been ineffective or limited the antitumor effects of IL-2.<sup>445</sup>

TABLE 42.2-22. Phase III Trials of Biochemotherapy for Stage IV Melanoma

A prospective randomized trial in patients with metastatic melanoma, comparing treatment with chemobiotherapy in relation to chemotherapy was carried out at the NCI. One hundred two patients with metastatic melanoma were prospectively randomized to receive chemotherapy consisting of tamoxifen, cisplatin, and dacarbazine or this same chemotherapy followed by IFN- $\alpha$ <sub>2b</sub> and IL-2 using a schedule that has not been explored by others. No increase in survival was seen with the addition of immunotherapy and toxicity was increased. From previous patients treated with immunotherapy alone it was suggested that the chemotherapy might have negatively affected the efficacy of the immunotherapy component of the regimen.<sup>446</sup>

The addition of immune effectors such as LAK cells, tumor-infiltrating lymphocytes (TILs), or activated T cells combined with IL-2 has not improved response or survival rates substantially over IL-2 alone and greatly increases cost and complexity. TILs can be demonstrated to contain some cells that are specific for known melanosomal lineage antigens of melanoma, as well as the patient's own autologous tumor. It has been suggested that the major targets of T cells in melanoma patients may be unique to each individual. Concomitant infusion of IL-2 may act as a survival factor for the infused TILs, may enhance the recruitment of T cells into the tumor site, and augment the specific cytotoxic T-cell response. In one study, 86 consecutive patients were treated with a combination of TILs and IL-2. An objective response was observed in 34% of patients, including some patients who had previously failed treatment with high-dose IL-2 alone. These T cells were also demonstrated to localize to the site following radiolabeling.<sup>447,448</sup> From both TILs as well as T cells derived from the peripheral blood and sensitized *in vitro*, genes encoding target antigens as well as the major histocompatibility complex (MHC)-specific peptide epitopes derived from them have been identified. These peptides are being used as vaccine antigens to enhance T-cell response and function against melanoma. Numerous clinical protocols have been initiated based on these new findings.<sup>449</sup> Other therapies applying cytokines that have been tested in this disease including IL-1, IL-4, IL-12, TNF, IFN- $\gamma$ , and FLT3L have not been successful. In the future, they may play a role in combination with IL-2 or IFN- $\alpha$ .<sup>450,451,452,453,454</sup> and <sup>455</sup>

### MANAGEMENT OF MELANOMA IN THE PREGNANT PATIENT

Appropriate surgical management should not be delayed in a pregnant patient with melanoma. The cornerstone of fetal viability is maternal health, and a delay in surgery only jeopardizes the lives of both the mother and the child. Adjuvant treatment such as high-dose IFN- $\alpha$ , an abortifacient, should be delayed until after delivery. Patients who have been treated with IFNs while pregnant also have had babies of low birth weight. Only rarely do situations arise in which a woman with melanoma should be advised to terminate pregnancy. In patients with stage IV disease, fetal termination should only be considered for the use of chemotherapeutic or biologic agents with the understanding that only a few percent may experience a survival benefit. Managing a pregnant patient with disseminated melanoma can be difficult, but because the prognosis is so poor in these patients and treatment options are lacking, the patient may reasonably decide to attempt a full-term gestation without therapy. Cases of women receiving chemotherapy and focused spinal radiation without subsequent harm to the fetus have been reported. Uncommonly, melanoma can pass through the placenta, but usually in only far-advanced disease. Melanomas account for only 8% of the cancers that affect pregnant women but for 46% of fetal tumors acquired transplacentally.<sup>456</sup> In a gestational patient with melanoma, the placenta should be specifically examined histologically for occult melanoma metastasis.<sup>457</sup>

## FUTURE PROSPECTS FOR THE BIOLOGIC THERAPY OF PATIENTS WITH MELANOMA

Some of the goals of the tumor immunologist are (1) the development of a specific T cell response to tumor, (2) delivery of T cells across the endothelial barrier to the tumor, (3) maintenance of the T-cell survival within the tumor microenvironment, (4) the induction of long-lasting immune memory to an individual's tumor, and (5) regulation of the local angiogenic response mediated by development of a T-cell response in concert with tumor resident DCs. Future directions in immunotherapy promise more directed stimulation of a specific immune response using vaccines derived from autologous tumor, DCs, and application of known tumor antigens.

### ANTIGENS OF MELANOMA

Specific cellular immune responses to melanoma antigens classically occur through the recognition of a foreign peptide on a self-MHC molecule by the T-cell receptor.<sup>458</sup> These peptides, generated through the processing of either exogenous (extracellular) or endogenous (intracellular) antigens, are presented by DCs to specific T cells in regional lymph nodes. Proteins are cleaved to short amino acid sequences of 8 to 10 aa for MHC class I molecules and 13 to 18 aa for MHC class II molecules. MHC class I molecules interact with CD8 cells to stimulate a cytotoxic T-cell response to melanoma, whereas MHC class II molecules activate appropriate helper CD4 cells to induce a humoral immune response.<sup>459</sup> Single amino acid differences in these small peptides have enormous effects on this interaction as alterations in the anchoring of the peptide in the MHC groove may occur and recognition by the T-cell receptor of the MHC/peptide complex may no longer occur with minute changes in spatial conformation and charge.<sup>460</sup> Escape from immune recognition can occur in a variety of ways, but evidence for defects in the peptide transporter into the endoplasmic reticulum, loss of expression of individual melanoma antigens, and loss of class I molecules (limited to single alleles or globally, often due to loss of  $\beta_2$  microglobulin expression) has been associated with progression of this tumor.<sup>461</sup>

DCs are uniquely required for priming naive T and B cells and probably play a major role in driving the effector phase of the immune response. DCs, which express high levels of costimulatory molecules and efficiently secrete Th1 cytokines, select, activate, and expand specific T cells. Through positive and negative selection of T cells during maturation, autoreactivity should be minimized. Proteins produced from tumor cells that induce a specific T-cell response are called *tumor-associated antigens*. Those that are sufficiently potent at stimulating reactivity, demonstrated by a clinical rejection of tumor, are called *tumor-rejection antigens*. As cancer is a genetic disease, the production of mutated proteins occurs, and these proteins were thought to be prime candidates for the development of peptide vaccines. Of course, this concept is much more complicated as T cells are, in fact, quite capable of recognizing self, and, conversely, are able to develop tolerance or anergy to foreign peptides. In fact, although some mutated self-proteins have been identified in patients that can stimulate an antitumor T-cell response, most peptides thus far identified derive from normal proteins either overexpressed in melanoma or restricted to cells of melanocytic lineage.<sup>462</sup> Understanding the mechanisms of tolerance and the means to stimulate enhanced self-reactivity has been a goal of the tumor immunologist. By identifying antigens present in tumors (the processed epitopes express in concert with MHC class I and II molecules, which can bind with sufficient affinity to the T-cell receptor), therapeutic vaccines may be developed that induce a long-lived antitumor response.

#### Unique Tumor Antigens

Unique antigens, those expressed usually as a result of mutation, only occur in a single patient's melanoma and not in other patients; those may be the most important target. Techniques to sample the antigenic repertoire of autologous tumors and to express them on autologous DCs have been developed. Several sources of antigen have been applied to DCs, including the use of synthetic peptides, peptides stripped from the surface of the tumor cell by means of acid elution, and cDNA or cRNA preparations encoding genes expressed by the tumor. The creation of antigen-presenting cells by fusing autologous DCs with tumor, incubating with tumor lysates or apoptotic bodies, also has been shown to elicit an antitumor response in murine and some human studies.<sup>463</sup>

#### Shared Tumor Antigens

A number of proteins providing a source of peptide epitopes, some of them synthetically altered to improve MHC binding, have been identified and used in clinical trials. These epitopes bind either to class I (Table 42.2-23) or class II (Table 42.2-24) MHC molecules. One technique that enabled the rapid detection and identification of antigens of cancer was the technique known as serologic expression cloning.<sup>464</sup> This has been now shown to detect both antibody-recognized and T-cell-recognized antigens of melanoma.

#### Differentiation Antigens

A broad group of antigens is known as the *cancer testis* group was initially identified in melanoma as MAGE 1, 2, and 3.<sup>465</sup> These antigens are now known to be expressed in cancers of different histologic types, but also in only normal testis and occasionally ovary of adults. The cells in the testis expressing these antigens are immunologically privileged by their anatomic localization and their frequent lack of HLA class I molecules. Thus, cancer testis antigens are restricted to malignant cells in the adult. The identification in melanoma and melanocytes of the cancer testes MAGE genes,<sup>466</sup> which occur naturally in several human cancers, were the first identifiable tumor antigen in human solid tumors. Many more such antigens have been subsequently described.

#### Melanocyte and Melanoma Tumor Antigens

The predominant melanocytic antigens include Melan-A/MART-1, tyrosinase, and gp100. These gene products are expressed in both normal and malignant melanocytes, and immune responses against these targets have been associated with the development of autoimmune reactions against normal melanocytes.<sup>467</sup> However, these genes are not expressed in tumors derived from other cell types. Therefore, vaccination against these targets should allow a relatively tissue-specific response to be elicited.

## CLINICAL APPLICATIONS

### Active Immunotherapy

**CELLULAR ADJUVANTS.** DCs are specialized APC that have the unique ability to stimulate naive T cells.<sup>468,469</sup> They are also capable of presenting exogenous antigens either by the MHC class I or II pathways.<sup>470,471,472,473,474,475,476,477</sup> and <sup>478</sup> DCs can per se mediate antitumor effects<sup>479</sup>; however, current trials use DCs that have been manipulated through various techniques to express tumor antigen on self-restricted MHC molecules ( [Table 42.2-25](#)). For example, animal studies using synthetic<sup>480</sup> or stripped<sup>481</sup> peptides pulsed onto DCs have shown potent inhibition of tumor growth. DCs can be generated easily from peripheral blood monocytes,<sup>482</sup> CD34+ progenitors,<sup>483,484</sup> or by direct purification from blood<sup>485</sup> and have entered clinical trials in a variety of malignant diseases including melanoma.<sup>486,487,488</sup> and <sup>489</sup>

TUMOR DELIVERED INTO DCs
DCs "fed"
Agonistic bodies
Tumor lysates
Kreom recombinant tumor antigens
RNA encoding known tumor antigens
DNA encoding known tumor antigens
RNA subtraction library
Tumor DC fusion heterocouplings
Tumor peptide-pulsed DC-derived exosomes
DC DELIVERY INTO TUMOR
Migration of DC in vivo using
Granulocyte-macrophage colony-stimulating factor and IL-4
FLT3L ligand
Autologous DC injection into tumor
Adoptive transfer of autologous DCs
DCs transfused with
IL-2
Granulocyte-macrophage colony-stimulating factor
IL-18

DC, dendritic cell; IL, interleukin.  
 Significant T cell response requires stimulation by dendritic cells in order to activate and proliferate. By loading dendritic cells with tumor antigens, a specific antitumor response can be induced.

**TABLE 42.2-25.** Uses of Dendritic Cells in Immunotherapy<sup>a</sup>

Nestle et al. performed a clinical trial involving 30 patients with melanoma in which DCs were used to mediate vaccination.<sup>487,490</sup> Patients of HLA serotype HLA-A1 were treated with appropriate peptides derived from the MAGE-1 and MAGE-3 antigens; those who were HLA-A2+ were treated with peptides from Melan-A/MART-1, gp100, and tyrosinase; and those who expressed HLA-B44 received treatment with peptides derived from MAGE-3 and tyrosinase. Clinical responses were noted in 27% (8 of 30) of patients, including three complete remissions and five partial remissions. This study is the most mature of current DC and peptide studies in melanoma and has indicated the feasibility, safety, as well as the tolerance of such therapy. The meaningful clinical responses induced in a group of patients with poor prognosis disease is encouraging but needs further evaluation.

A University of Pittsburgh Cancer Institute trial initiated in 1996 has also shown encouraging evidence of activity in 23 patients.<sup>491</sup> The first patient treated exhibited a relapsing and remitting course of her melanoma over several years and multiple trials. After DC vaccination, this patient developed a complete remission and has remained free of disease for more than 20 months. Another patient on this study attained a complete remission sustained for over 3 years, and a third has had a partial remission.

New adjuvants are also becoming available. Cytokines of great potential interest are FLT3L and CD40L, which preferentially expands or activates DC in the peripheral blood and many tissues.<sup>492,493</sup> and <sup>494</sup> A major difficulty in conducting trials of cancer immunotherapy is the selection of appropriate end points. Most patients on such studies are heavily pretreated and immunosuppressed. It is logical to apply these treatments to patients with a much lower burden of disease such as in the adjuvant setting, where all obvious disease is removed, but there is a high chance of relapse due to microscopic residual or metastatic disease. Performing such studies using the clinical end points of time to tumor progression or survival involves studying large numbers of patients over a long period. This is justifiable if phase II studies in patients with advanced disease indicate that there is significant clinical activity, but for most strategies, this has not yet been shown to be the case.

**CYTOKINE ADJUVANTS.** Granulocyte-macrophage colony-stimulating factor (GM-CSF) is an important cytokine promoting survival and expansion of DCs.<sup>482,483,495</sup> In gene transfer models, GM-CSF gene transfer into poorly immunogenic tumors leads to rejection of those tumors in animal models<sup>496</sup> or to clinical and immunologic responses in humans.<sup>497,498</sup> Direct injection of GM-CSF into subcutaneous melanoma metastases may also lead to regression of injected and noninjected tumor deposits.<sup>499</sup> A study using GM-CSF together with peptides derived from Melan-A/MART-1, tyrosinase, and gp100 in HLA-A2 melanoma patients was reported in 1996.<sup>500</sup> Immunologic responses were observed, consisting of development of skin reactions to intradermal injections of peptide, infiltration of injection site by CD4 and CD8 lymphocytes, and detectable cytotoxic T lymphocytes in peripheral blood without apparent toxicity. Three patients were reported in whom tumor regressions were seen despite having progressive melanoma at the time of entry into the study: One patient showed complete regression of tumor and the others displayed partial regressions. In a study using modified gp100 HLA-A2 peptides, 13 of 31 patients receiving the peptide plus systemic IL-2 showed regression of metastatic melanoma, with an additional four patients showing minor or mixed responses. Immunologic responses could be generated in 91% of patients using blood lymphocytes stimulated *in vitro* before assay.<sup>501</sup>

Another approach to the enhancement of immune response to tumor cells consists of introducing genes encoding costimulatory molecules or alloantigens. In human clinical trials, tumor cells (autologous or allogeneic) or normal cells such as fibroblasts, have been transfected with individual cytokine gene(s) and have been used to induce tumor immunity. So far, only early toxicity results from phase I trials have been reported using this approach in advanced disease patients. Current efforts are underway involving the evaluation of IL-4 or IL-12 gene therapy in patients with melanomas. A human clinical trial using this approach was reported using IFN-g gene modified and irradiated autologous melanoma cells. The preparation was given every 2 weeks for a total of six doses. Twenty stage III and IV melanoma patients were treated. Two complete responses were observed and two patients had a decrease in the size and number of their subcutaneous nodules. The vaccinated population showed an increased IgG response dominated by IgG-2, suggesting the development of an effective T-helper cell response.<sup>502</sup> Palmer et al. reported on 12 patients who were treated with autologous irradiated tumor engineered to secrete IL-2 by infection with recombinant retrovirus. No clinical responses were seen, but three patients had stable disease for 7 to 15 months.<sup>503</sup>

Arienti et al. reported the vaccination of 12 patients with metastatic melanoma with an allogeneic human melanoma line genetically modified to release IL-4. Only two mixed responses were recorded, without objective clinical responses by conventional criteria. However, induction of a specific immune response was demonstrated by *in vitro* studies. Antibodies to alloantigens could be detected in 2 of 11 patients tested. A significant increase in IFN-g release was detected in 7 of 11 cases when postvaccination lymphocytes were stimulated by the untransduced allomelanoma cells. However, induction of a specific recognition of autologous melanoma cells by peripheral blood lymphocytes was obtained after vaccination in only one of six cases studied. This response involved the melanoma peptide Melan-A/MART-1<sup>501,504,505,506,507,508,509,510</sup> and <sup>511</sup> that was recognized in an HLA-A2-restricted fashion. These results, although modest, show that the induction of a specific immune response is possible in a few patients through novel vaccination strategies.<sup>451</sup>

The feasibility of using melanosomal proteins for the immunotherapy of patients with melanoma is now being addressed. Immunization using peptides or recombinant viruses containing genes encoding the melanosomal antigens MART-1 or gp100, with or without coadministration of cytokines such as IL-2, IL-12, or GM-CSF, are ongoing at the National Institutes of Health, as well as in the ECOG.<sup>512</sup>

**PEPTIDES ALONE.** Initial studies using melanoma peptides were performed using peptides alone. One of the first involved the use of a MAGE-3 HLA-A1-restricted peptide without of any immunologic adjuvant.<sup>355</sup> In this study, 6 of 19 patients with melanoma displayed tumor regression, and toxicity was minimal. In one patient, tumor regression occurred several months after completing peptide vaccination, although the tumor had progressed while on treatment, leading to the initiation of vaccination. Eventually four of five lung metastases in this patient disappeared entirely.<sup>513</sup> This initial study demonstrated that synthetic peptides derived from

self-tumor antigens were safe and that clinical responses could be obtained in some individuals in the absence of any other adjuvant. Cytotoxic T-lymphocyte responses against melanoma differentiation antigens correlate inversely with expression of the antigen in melanoma tissues: Patients with progressing disease have been shown in several experiences to display antigen-loss variants, implying *in vivo* immunoselection under the pressure of peptide vaccination.<sup>513a,513b</sup>

A series of studies was performed at the NCI involving peptides derived from the melanoma differentiation antigen gp100.<sup>501,506,507</sup> Initially, HLA-A2+ patients were treated with the native peptide, and subsequent patients were treated with a version of this peptide containing a single modified amino acid.<sup>507</sup> This substituted peptide has a higher binding affinity for HLA-A\*0201 than the native peptide and has been pursued in the hopes that there will be correspondingly greater induction of *in vivo*, as well as *in vitro* cytotoxic T lymphocytes.<sup>507</sup> Patients treated with the substituted peptide developed cytotoxic T lymphocytes recognizing both native and modified peptide-pulsed target cells, as well as HLA-A2+ tumor cell lines expressing gp100 in almost all cases. Following administration of IL-2 many of these T cells were not found in the peripheral blood, but a substantial number of patients were observed to respond. Presumably, reactive T cells migrated to the site of antigen.

Considerable work has been done in relation to several HLA class I subtypes to map binding pockets and to determine preferential anchor residues for binding peptides.<sup>509</sup> To improve the stability of the class I complex, some investigators have produced modified class I peptides with amino acid variations designed to introduce residues that improve the binding to individual class I molecules. This has enhanced the generation of cytotoxic T lymphocytes with specificity not only for the modified peptide-pulsed target cells, but also for unmodified peptide and for naturally processed peptide.<sup>507,510</sup> Vaccination using modified peptides has now entered evaluation in clinical trials, and cytotoxic T lymphocytes have clearly been demonstrated in patients vaccinated in these studies.<sup>501</sup>

Allogeneic tumor vaccines are based on the presumption that same cell type tumors from different individuals share several common antigens that are capable of inducing an immunologic response. One vaccine based on this approach, CancerVax, has been developed at John Wayne Cancer Institute. CancerVax is a whole cell irradiated vaccine developed from three allogeneic melanoma cell lines that were subsequently demonstrated to express several known immunogenic tumor-associated antigens. Phase II nonrandomized trials have shown impressive results in a select group of patients. Stage IV patients received CancerVax after resection of all evident metastatic disease and were compared with a matched set of controls. The 5-year overall survival and median survival for patients who received the vaccine appears to be improved, but it is well recognized that historic controls have great liabilities. Forty-two percent of patients who received the vaccine were alive at 5 years and the median survival was 42 months. The historic reference had a 19% 5-year survival and an 18-month median survival. After multivariate analysis, CancerVax therapy was suggested to be a significant predictor of survival.<sup>360</sup> It is believed that prior surgery enabled success of the vaccine by reducing tumor load and identifying a better group of patients. Prospective randomized studies are now needed, and underway, to appropriately evaluate this therapy in patients with resected stage III and stage IV melanoma.<sup>514</sup> Use of peptides fused to heat-shock protein hsp70 has been shown to be rapidly taken up by DCs and to bypass the need for T-cell help in murine models.<sup>515</sup> *In vivo* immunization with these hybrid peptides caused rejection of tumors expressing antigen and may represent important strategies to be taken into clinical trials.

Lysate vaccines are produced by mechanical disruption of whole tumor cells. Vaccine preparations have been evaluated in which nonpathogenic viruses such as vaccinia virus and Newcastle disease virus, are used to lyse cells to enhance their immunogenicity (viral melanoma oncolysate). They contain multiple tumor-associated antigens and are capable of stimulating a polyvalent immune response. Wallack et al. compared a vaccinia melanoma oncolysate with vaccinia virus alone in AJCC stage III melanoma patients. This phase III, randomized, multicenter trial demonstrated no significant difference in either disease-free or overall survival at a median follow-up of 46 months.<sup>516</sup> Similar studies by Hersey from Australia have also failed to show either relapse-free survival or overall survival benefit.<sup>517</sup>

## CELLULAR ADJUVANTS

### Passive Immunotherapy

*Passive immunotherapy* is a term generally applied to agents that are thought to have direct antitumor activity themselves. Most specifically, this would include the adoptive transfer of cells or antibodies. Application of the adoptive transfer of T cells and LAK cells has been discussed previously (see [Immunotherapy of Metastatic Disease](#), earlier in this chapter). Although responses have been observed in conjunction with delivery of IL-2, the general sense is that these responses are inferior in quality and duration to those of IL-2 alone and provide no long-term benefit. With an improved understanding of the so-called central (CCR7+ vs. CCR7-) memory T cells that could provide long-term benefit, it would be worthwhile to reevaluate these approaches with these cells as opposed to the effector memory T cells (CCR7+), which are most likely to provide only short-term responses.<sup>518,519</sup> Application of gene therapies using gene-marked TILs, IL-4, or IL-12 may also enhance induction of a melanoma-specific immune response.<sup>520,521 and 522</sup>

The application of antibodies in melanoma was first evaluated with the notion that such antibodies could confer complement or antibody-dependent cellular cytotoxicity on tumor cells.<sup>523,524</sup> The subsequent genetic engineering of monoclonal antibodies (MAB), resulting in human molecules, and successes with antibodies targeting breast cancer and lymphoma in clinical trials has led to a reevaluation of these reagents alone or in combination with molecularly defined cytokines and growth factors for the immunotherapy of melanoma. The development of a human IgG anti-mouse antibody (HAMA) has been observed in virtually every patient and limited the effectiveness of these early approaches in treated patients. However, first-generation murine MABs have been developed that have been used to effectively map melanosomal, melanocyte, and melanoma antigens.<sup>525</sup> One of these antibodies, R24, an IgG3 murine monoclonal antibody that recognizes GD3, a ganglioside present on melanoma cells and a subset of T cells, was reported initially to mediate 3 of 12 responses in patients with melanoma.<sup>526</sup> Evidence of immune reactivity with inflammatory reactions (urticaria, pruritus, erythema, subcutaneous ecchymoses) were observed at tumor sites in some patients treated at doses greater than or equal to 80 mg/m<sup>2</sup>. Tumor biopsies during and after treatment showed lymphocyte and mast cell infiltration, mast cell degranulation, and complement deposition. Subsequent studies with this antibody have failed to confirm this level of response.<sup>527</sup> As a single agent, R24 induced responses in 10 of 103 patients two of which were complete. Combining R24 with cytotoxic drugs or cytokines did not increase the response rate. An alternative approach was to develop strategies to immunize with the antiidiotype (so-called Ab2) to induce a host immune response to the original antigen (Ab3).<sup>528,529</sup> BEC2, an antiidiotypic MAB mimics GD3 has been tested with two immunologic adjuvants, BCG and QS21, administered with BEC2 in melanoma patients free of disease after surgical resection. All patients developed high-titer IgG antibodies against BEC2. Anti-GD3 antibodies were induced in 3 of 14 patients immunized with BEC2/BCG; no patient immunized with BEC2/QS21 developed such antibodies. Conjugation of BEC2 to keyhole limpet hemocyanin did not increase the immunogenicity of BEC2 when administered with BCG. Prolonged disease-free intervals were noted in a majority of treated patients in these adjuvant studies. Two clinical trials with the mouse antiidiotypic MAB MF11-30, which is an Ab2 of human high-molecular-weight melanoma-associated antigen was administered subcutaneously to patients with advanced melanoma.<sup>530,531</sup> In the first phase I trial in 16 patients, minor responses were observed in three patients. In a second clinical trial MAB MF11-30 was administered to 21; 17 of 19 evaluable patients had increased levels of anti-mouse Ig antibodies and 16 developed antibodies that inhibit the binding of antiidiotypic MAB MF11-30 to the immunizing anti-high-molecular-weight melanoma-associated antigen MAB 225.28. One patient had increased levels of anti-high-molecular-weight melanoma-associated antigen antibodies. One patient achieved a complete remission with disappearance of multiple abdominal lymph nodes for a duration of 95 weeks. Minor responses were observed in three patients. These collective results suggest that such antiidiotype antibodies may be useful in patients with melanoma. Additional antibodies including those directed against the cell surface high-molecular-weight antigen or a transferrin-like molecule have been used in experimental studies of imaging or therapy with cytokines including IL-2.<sup>527,532,533,534 and 535</sup> MABs with tumor specificity are able to enhance the immunologic specificity of IL-2-activated LAK cells. MAB 3F8 and 14.G2a, which are specific for neuroblastoma and melanoma and recognize ganglioside GD2, were able to mediate antibody-dependent cell-mediated cytotoxicity with fresh effector cells and antibody-binding targets. Use of cross-linked antibodies or humanized antibodies has yet to be clinically explored in this disease but may represent promising approaches.<sup>536</sup>

## INTRODUCTION

Melanomas are the most common primary intraocular malignancy in whites. They arise from uveal melanocytes (i.e., mature melanin-producing and melanin-containing cells) residing in the uveal stroma and originating from the neural crest. Whereas reactive or neoplastic proliferations of pigmented cells can occur in the epithelia of the iris, ciliary body, and retina, forming adenomas or adenocarcinomas, this chapter deals exclusively with uveal melanomas. A particular emphasis is given to the current therapeutic concerns and issues since (1) the appropriate treatment of the primary tumor remains in many instances controversial and (2) management of metastatic disease is essentially palliative.

## EPIDEMIOLOGY

The annual age-adjusted incidence of nonskin melanomas as reported in the Surveillance, Epidemiology, and End Results program during 1973 to 1977 was 0.7 per 100,000 population in the United States. Similar figures were reported from epidemiologic studies conducted in New England (0.65 per 100,000 residents from 1984 to 1985), the Swedish west coast (0.72 per 100,000 over the period 1956 to 1975), and Iceland (0.7 per 100,000 in male patients and 0.5 per 100,000 in female patients over the period 1955 to 1979). In the Third National Cancer Survey, conducted from 1969 to 1971, the annual age-adjusted incidence in the United States was estimated at 0.6 per 100,000. The precise anatomic origin of ocular melanomas was unspecified in approximately 25% of cases. Seventy-three percent of the tumors arose within the globe (mainly from the choroid), and 2% developed from the conjunctiva. Melanoma accounted for 70% of all primary ocular malignancies, followed in frequency by the childhood tumor retinoblastoma (13%). In persons older than 20, melanoma was the reported diagnosis for 80% of all primary ocular cancers. Data from the Missouri Department of Health; China; the Surveillance, Epidemiology, and End Results program; New England; Iceland; Finland; and the Ocular Melanoma Task Force are similar to those reported by the Third National Cancer Survey.<sup>1</sup> A French study in 1992 provided accurate data on the incidence of this condition in the French population: 0.73 per 100,000.<sup>2</sup> The annual age-adjusted incidence of ocular melanomas is approximately one-eighth that of skin melanomas in the United States. The recently observed increase in the incidence of cutaneous melanomas has not been observed for uveal melanomas.<sup>3</sup>

Although the incidence increases steadily by decade, with a peak in the seventh decade, uveal melanoma cases occur before the age of 20, as illustrated by 101 of the 6359 cases on file at the Registry of Ophthalmic Pathology at the Armed Forces Institute of Pathology (AFIP), 40 of 3706 consecutive patients seen at Wills Eye Hospital, and by several other reports. Most studies show a median age at diagnosis of approximately 55, with rates dropping after age 70.<sup>3,13</sup>

## RACE

The lower incidence of uveal melanoma in African Americans has been noticed in several large series. Only 10 African American patients were identified among more than 3586 patients with uveal melanoma (0.39%) from the oncology service at Wills Eye Hospital between 1974 and 1989.<sup>3</sup> Findings from the Florida Cancer Data System showed a 32-fold greater risk of uveal melanoma in whites than in African Americans.<sup>4</sup> White men had 72 times the risk of developing uveal melanoma as compared with that of African American men. For white women, this risk was 22 times that of African American women.<sup>4</sup> According to the Florida Cancer Data System, the risk of uveal melanoma in Hispanics is 62% less than that of white non-Hispanics. These findings may support at least in part the hypothesis that the sunlight effect on the causation of melanoma is primarily a direct one, since this is not found for visceral melanomas.<sup>5</sup> A study of the initial clinical manifestations and pathologic characteristics in Hispanic patients enucleated for choroidal melanomas showed an earlier onset, a larger tumor diameter, and a heavier pigmentation in this population than in other groups.<sup>6</sup> An epidemiologic study of posterior uveal melanoma in Israel over the period 1961 to 1989 shows that the incidence rates have been stable over this 30-year period. The incidence rate is lowest in Jews from Asia and Africa (2.2) and in non-Jews (1.5) and is highest in Jews born in Israel (6.8), Europe, and the Americas (7.5). The significance of these figures with regard to the role of constitutional factors and timing of sunlight irradiation remains conjectural.<sup>7</sup>

## GENDER

Although Scotto et al. found that the overall risk of ocular melanomas did not vary by gender, Jensen, Gislason et al., and others noted a predominance of male patients.<sup>8,9</sup> and<sup>10</sup> Ocular and skin melanoma show similar age patterns, with more women affected at younger ages and more men later in life. The Third National Cancer Survey indicated a left-sided excess of 18% for ocular melanomas in men and a right-sided excess in women.<sup>1</sup>

## MORTALITY

As emphasized by Markowitz et al.<sup>11</sup> in a review of mortality from choroidal melanoma, very few reports are complete enough to be informative. Diener-West et al.,<sup>12</sup> using selected data published during the period from 1966 to 1988, performed a pooled analysis (metaanalysis) of 5-year mortality rates among enucleated patients, providing weighed estimates of 5-year mortality after enucleation: 16% for small tumors [95% confidence interval (CI), 14% to 18%], 32% for medium-size tumors (95% CI, 29% to 34%), and 53% for large tumors (95% CI, 50% to 56%). The most complete long-term survival studies after enucleation were performed in Denmark by Jensen<sup>9</sup> et al. and in Finland by Raivio.<sup>13</sup> In the Finnish study, the 5-, 10-, and 15-year survival rates were 65%, 52%, and 46%,<sup>13</sup> respectively. In the Danish study, survival rates were similar; at the end of the 25-year period, 51% patients had died from metastasis.<sup>9</sup> A French study of survival of patients with uveal melanomas treated by enucleation with a long-term follow-up reported similar figures.<sup>14</sup> Rates of survival after radiation therapy appear comparable in the short term and mean term. Yet, as the following discussion shows, both the validity of these data and the long-term predictability of prognosis after conservative treatment remain a matter of controversy. The median survival of patients with metastatic disease is reportedly very short: 2 to 5 months.<sup>11,12</sup>

## ETIOLOGY AND HISTOGENESIS OF OCULAR MELANOMAS

As is the case for most human cancers, the specific causes of ocular melanomas are unknown. However, epidemiologic, electron-microscopical, and experimental data allow characterization of risk factors, predisposing conditions, and hypothetical genetic or oncogenic causes.

### GENETICS AND IMMUNOHISTOCHEMISTRY

There is now considerable evidence that, like many cancers, a subset of uveal melanomas is caused by an inherited predisposition. The familial occurrence of uveal melanomas was first mentioned by Silcock<sup>15</sup> in 1892 and reported since several times.<sup>16,17</sup> and<sup>18</sup> Despite the rare occurrence of uveal melanoma in a family and the presence of many skips in these pedigrees, the occurrence of familial uveal melanoma is not caused by fortuitous familial aggregation of sporadic cases.<sup>18</sup> Because of an insufficient number of families with more than two affected individuals, it is impossible to distinguish between polygenic inheritance, single-gene inheritance with reduced penetrance, and the role of environmental factors as causes of this familial aggregation. A few cytogenetic studies argue for the putative role of a recessive oncogene on chromosome 2, 3, or 6q<sup>19,20</sup> and showed abnormalities again on chromosomes 6 and 8q.<sup>19,21,22</sup> and<sup>23</sup> Other studies emphasize the possible relationship of monosomy 3 and multiplication of chromosome 8q to uveal melanoma,<sup>24,25</sup> suggesting monosomy 3 as an early, if not primary, event and supporting a role for chromosome 8q multiplication in the proliferation of cloned tumor cells *in vitro*. A role for the *c-myc* oncogene, located in the region 8q2.1-qter, in uveal melanoma formation and progression, probably linked to the regulation of cell proliferation, has been hypothesized. This is partly supported by cytogenetic<sup>21</sup> as well as immunohistochemical studies.<sup>26</sup> Abnormalities of the p53 gene have also been demonstrated.<sup>27,28</sup> The coexistence of ocular and cutaneous melanoma in some patients suggests a predisposition to both types and may imply mutations in the CDKN2A gene on chromosome 9 in a proportion of these cases.<sup>29</sup> An association between ocular melanoma and breast or ovarian cancer (or both) has also been reported, and BRCA2 on chromosome 13 may also be involved.<sup>29</sup>

Additional molecular genetic studies are necessary to understand the pathogenesis of familial uveal melanoma. In several studies,<sup>30,31,32</sup> and<sup>33</sup> investigators have demonstrated a close link between oncogenesis and the cell-cycle machinery. Progression through the cell cycle is orchestrated by sequential activation of a series of cyclin-dependent kinases (CDKs). The CDKs' activity is primarily dependent on the association with their activating cyclin subunits (D<sub>s</sub>, E, G<sub>1</sub>). CDK activity is counterbalanced by a variety of CDK-inhibitory proteins (CKIs), such as p21, p27, p16, and the like. Deregulated expression of G<sub>1</sub> cyclins p21, p27, p16 CKIs, and alteration in the interaction of CKIs with CDKs may be implicated in the neoplastic transformation of human ocular melanocytes to malignant melanoma cells.<sup>30,31,33</sup>

MDR1 gene and its gene product, P glycoprotein, which are known to cause drug resistance in cancer cells, are expressed in ocular melanoma.<sup>32</sup> Dunne et al.<sup>32</sup> reported a statistically significant association between MDR1 expression by tumor cells and shorter survival times, which was most striking at grade III.<sup>32</sup> Whether P glycoprotein is a marker for tumor aggressiveness, for clinical chemotherapy resistance, or perhaps for both remains to be clarified.

### PREDISPOSING CONDITIONS

Ocular and oculodermal melanocytosis (i.e., nevus of Ota) predispose to the development of uveal melanomas. In 4.6% of reported cases of nevus of Ota, malignant transformation was reported<sup>34</sup> and, except for a single anecdotal case, the melanoma occurred in the pigmented eye. In the vast majority (90%) of patients with oculodermal melanosis and uveal melanoma, the uveal melanoma was diagnosed between the ages of 31 years and 80 years.<sup>34</sup> Rare cases of uveal melanomas have been reported in patients with type 1 neurofibromatosis,<sup>35</sup> a neurocristopathy. The tumor cells in neurofibromatosis have their origin in the neural crest, in common with melanocytes.<sup>35</sup>

Evidence that nevi are the origin of most choroidal melanomas has been provided by Yanoff and Zimmerman.<sup>36</sup> Yet a nevus-like configuration associated with choroidal melanoma may, in some cases, be explained by other mechanisms, such as (1) flattening of normal uveal melanocytes or of tumor cells, (2) a secondary proliferative effect of the malignancy, or (3) common oncogenic stimuli. The last two mechanisms have been postulated in a few cases of bilateral diffuse melanocytic tumors of the uvea in patients with systemic carcinoma.<sup>36</sup>

In some instances (as discussed), a familial increased occurrence of uveal melanoma has been recorded.<sup>16,17,18</sup> Data on the occurrence of uveal melanocytic tumors in patients with the dysplastic nevus syndrome are controversial<sup>36</sup> but generally support the value of periodic ophthalmoscopic examination of patients with atypical nevi.<sup>37</sup> A recent case-control study by Bataille et al.<sup>38</sup> demonstrated that (1) numerous common nevi (i.e., 100) were present in 10% of cases versus 3% of controls; (2) four or more atypical nevi were present in 7% of cases versus 0.4% controls; (3) pigmented iris nevi were significantly more common in cases than in controls (odds ratio, 3.1); and (4) the atypical mole syndrome was a strong risk factor (odds ratio, 7.3).

The association between uveal melanomas and other cancers is still a matter of controversy. Turner et al.<sup>39</sup> showed that the overall prevalence of non-basal cell cancers in uveal melanoma patients was twice the expected prevalence based on an age- and gender-matched population.<sup>39</sup> Anecdotal cases of uveal melanomas associated with various cancers exist, including breast cancer<sup>28</sup> and lymphomas.<sup>40</sup> A link between cutaneous and uveal melanoma was suspected on the basis of the association, in three cases (among 333 patients), of primary uveal and cutaneous melanomas. A family history of cutaneous or uveal melanoma was present in 14 of the primary uveal melanoma patients and 2 of the cutaneous melanoma patients.<sup>41</sup> Bataille et al.<sup>41</sup> reported five cases of primary ocular and cutaneous melanoma occurring in the same individual. Lischko et al. conducted a case-control study among 197 New England cases with 385 matched controls and 337 cases (from the United States) with 800 controls. They concluded that the association of prior malignancies with uveal melanomas is weak.<sup>42</sup> Holly et al., in a similar study of 407 uveal melanoma patients from the western United States with 870 control subjects, found no excess prior cancer.<sup>43</sup>

### ONCOGENIC STIMULI

Certain electron-microscopical and biomolecular studies of ocular melanomas suggest an etiologic role of viruses. Viruses such as the feline sarcoma have been used successfully in the induction of animal ocular melanoma models.<sup>53,54</sup>

In a study of a single population of chemical workers, a statistically significant and higher-than-expected incidence of ocular melanomas was found. Nicotine has been incriminated in the unusual incidence of uveal melanomas in male patients but does not appear to increase the risk for metastasis.<sup>44</sup> Various chemicals, including nickel bisulfamide, platinum, methylcholanthrene, ethionine, N-2-fluorenylacetylamide, radium, and N-methyl-N-nitrosourea have been reported to induce ocular melanocytic tumors in animals.<sup>55</sup> An exploratory study of various occupational associations provided elevated odds ratios for agriculture and farming work, several industrial operations, and exposure to inks, insecticides, gases, radioactive substances, polybromated phenyls, and chemical solvents.<sup>33,45</sup> A possible connection between Parkinson's disease, levodopa therapy, and malignant melanoma has been mentioned. The role of hormonal factors and pregnancy has been suggested in some reports. Hartge et al.<sup>46a</sup> reported a case-control study comparing 238 women with uveal melanoma with 223 matched control women. They showed that women with a history of pregnancy or hormonal substitutive treatment with estrogens had an increased risk, whereas a history of oophorectomy had a decreasing influence on relative risk (risk ratio, 0.6), and oral contraceptives had no influence on relative risk.<sup>46</sup> Seddon et al. and Shields et al.<sup>44a,45e</sup> have documented the role of pregnancy in the growth of uveal melanomas. Whether the growth observed clinically is secondary to cellular growth or other factors (e.g., fluid retention or vascular engorgement) is unclear.<sup>55,57,58</sup> Foss et al.<sup>46</sup> failed to detect any estrogen or progesterone receptors in 27 choroidal melanomas and questioned the role of these hormones in the development or progression of these tumors.

A case-control study lends support to the etiologic role of sunlight exposure.<sup>49</sup> A study of host factors (Northern ancestry, light skin color, 10 or more cutaneous nevi), ultraviolet radiation, and risk of uveal melanoma indicated that personal attributes are strong independent risk factors.<sup>48</sup> Holly et al.<sup>43</sup> showed that light skin color and easily sunburned skin increase by twofold the risk of uveal melanoma, while ultraviolet exposure increases this risk by fourfold, and sevenfold if intensive.<sup>49</sup> These data, contradicting previous studies, confirm the high association between light iris color and the presence of melanocytic lesions.<sup>50</sup> More recent evidence of an association between light iris color and melanocytic lesions has come from cases of melanomas associated with xeroderma pigmentosum<sup>47,48,56</sup> as well as a case-control study of patients with uveal melanoma. It has been suggested that cutaneous freckles (25 or more) or iris freckles and nevi may be risk factors for uveal melanomas.<sup>49</sup> Also, a relationship has been suggested between cutaneous or iris nevi and ocular melanomas.<sup>38</sup> Paraneoplastic uveal melanocytic proliferations have been observed in association with various systemic malignancies, such as ovary and lung.<sup>50,51</sup> These appear as diffuse multinodular infiltration of the uveal tract by predominantly diploid nevoid cells as well as more anaplastic cells; in addition, an association between bilateral uveal melanoma and a proliferation associated antigen (Ki-67) has been described.<sup>52</sup> The pathogenesis of paraneoplastic uveal melanocytic proliferation remains speculative. Hamartomatous paraneoplastic

proliferation or stimulation of a preexisting tumor are possible underlying factors. <sup>50</sup>

## HISTOPATHOLOGY, PROGNOSTIC PARAMETERS, AND NATURAL HISTORY

### CYTOLOGIC AND HISTOLOGIC CLASSIFICATION

Experienced pathologists generally make the accurate microscopical diagnosis of uveal melanoma easily, but it is still occasionally difficult to differentiate between primary and metastatic choroidal melanomas. <sup>71,72</sup> In rare cases, differentiation from metastatic carcinoma may be facilitated by immunohistochemical labeling with monoclonal antibodies to S-100 protein. <sup>72</sup> This technique is not helpful in differentiating other neural crest–derived tumors (schwannomas, neurofibromas, and leiomyomas). <sup>73</sup> The S-100 immunophenotypes of uveal melanomas differ considerably from cutaneous melanomas. <sup>74,75,76</sup> and <sup>77</sup> S-100b is not helpful for distinguishing between primary and metastatic choroidal melanoma. HMB-45 immunostaining appears to be a useful adjunct in the differentiation between nonmelanocytic and melanocytic tumors but serves as a marker of melanocytic activation rather than a tool to differentiate uveal melanomas from nevi. <sup>72,75,76</sup> Studies of the immunocytochemistry of uveal melanomas using antibodies against cutaneous melanomas or anti-HLA antibodies have not yet provided a clinically useful characterization of the ocular tumors. <sup>77,78</sup> Cytometry can phenotype cells in suspension from ocular melanoma tissue. <sup>73</sup> Lawry et al. <sup>73</sup> described antibody binding for MHC antigens, the adhesion molecule ICAM-1, and the oncoproteins c-erb B-2, c-myc, and bcl-2. Further studies should be undertaken to question whether there are any relationships between traditional clinical and pathologic parameters (tumor cell type, volume, location, the tissue origin) and the flow cytometric measurement of cell surface protein or cytoplasmic-nuclear oncoprotein expression in cells taken from samples of primary uveal melanomas.

In 1931, Callender recognized major cell types in the spectrum of cells composing uveal melanomas, and this provided a cytologic classification clearly correlated with prognosis after enucleation. The different cell types are based on cell size and shape, cytoplasmic features, nuclear and nucleolar characteristics, evidence of loss of cohesion, and relative number of various cell types as outlined in [Table 42.3-1](#).

Cellular Cell Type	Cell Size and Description	Cytoplasm	Nucleus	Nucleolus	Other
Spindle A	Elongated spindle or oval cell, round, depending on plane of section; cell boundaries are distinct, may appear more distinct in cross-section	Usually sparse but may be relatively abundant	Diagonal, fine chromatin pattern; chromatin line characteristic but not necessary for diagnosis; pleomorphism in some cells	Indistinct or none	Colony; often extremely rare
Spindle B	Thicker spindle or round depending on plane of section; cell boundaries are typically distinct from spindle, but may be indistinct in the section	Relatively sparse	Larger; pleomorphism than spindle A; coarse chromatin pattern; chromatin clumping	Single distinct, single, small, and round; often eccentric	Less cohesive than spindle A; may form fascicular arrangements; occasional mitoses
Epithelioid	Larger, more pleomorphic, often polygonal; distinct cell borders	Abundant; may be vacuolated	Larger, more pleomorphic; chromatin marginated; often marked, can be nucleolated	Larger, may be multiple; centrally located; distinct	Loss of cohesion; cells readily separate easily in cross-section

**TABLE 42.3-1.** Designation of the Cell Type Based on the Armed Forces Institute of Pathology Modification of the Callender Classification

According to Callender's cytologic characterization, uveal melanomas are divided into three categories:

- Spindle cell melanomas type A, B, or both, accounting for 30% of intraocular tumors, composed of spindle cells
- Mixed cell melanomas, when fewer than one-half of the tumor sections examined are composed of epithelioid cells
- Epithelioid cell melanomas (accounting for 5% of intraocular tumors), when greater than one-half is composed of epithelioid cells

Based on Callender classification, spindle cell tumors carry the best prognosis and epithelioid cell tumors the worst. In the Collaborative Ocular Melanoma Study (COMS) series, <sup>74</sup> large tumors contain more epithelioid cells than small tumors do; small tumors contain a higher percentage of spindle cell types. In their series, a more malignant cell type was observed more commonly in tumors with large size and anterior location.

Paul et al. reviewed 2652 cases accessioned at the AFIP by 1959 and found that 95% of patients with spindle A tumors, 85% of those with spindle B tumors, 60% of those with mixed tumors, and 83% of those with epithelioid tumors were alive 5 years after enucleation. <sup>43e</sup> At 15 years after enucleation, the survival rates were 85% for spindle A, 80% for spindle B, 46% for mixed, and 34% for epithelioid. <sup>74</sup> McLean et al., <sup>79a</sup> in a review of 3432 cases from the AFIP, found that the overall mortality from metastasis 15 years after enucleation was 46%. The mortality of patients with mixed cell melanomas was three times that of patients with pure spindle cell lesions. <sup>74</sup>

In Jensen's series of 302 cases reported from Denmark that had been observed for 25 years, 150 patients (50%) died of metastatic melanoma. Fewer than 1% of patients with spindle A tumors died of metastatic disease; 63% with mixed tumors died of this cause; and the cause of death in 71% with epithelioid tumors was metastatic melanoma. <sup>9</sup>

Works by Sorenson et al. and Gamel et al. <sup>80,81</sup> and others have corroborated the well-documented prognostic value of Callender's classification, especially as to the pejorative significance of a high epithelioid cell content. <sup>82</sup> Yet, the major cell types described by Callender are part of a continuous spectrum, and the pathologist's identification of a particular cell type involves subjective judgment.

In the COMS report number 6, <sup>74</sup> balloon cells were associated with epithelioid tumors but not with tumor size. Metastases containing balloon cells have been reported. These lipid-laden cells are thought to be metabolically less active than spindle or epithelioid cells. <sup>74</sup>

This issue was addressed by Sorenson et al. and Gamel et al., <sup>80,81</sup> who described a more objective method of assessing uveal melanomas histopathologically. This technique uses computed cytomorphometry and entails evaluating the inverse of the standard deviation of the nucleolar area with measurements made of the mean of the 10 largest nucleoli and stereologic estimates produced of the volume-weighted mean nucleolar volume. <sup>79,80</sup> This, in conjunction with tumor size as estimated by largest tumor diameter, is among the best objective cytologic measures of a tumor's malignant potential ( $F > .001$ ). <sup>81</sup> Marcus et al., <sup>84</sup> counting nucleolar organizing regions, reached similar figures.

Folberg et al., <sup>82,83</sup> Pe'er et al., <sup>85</sup> and Rummelt et al., <sup>86</sup> using sections stained with periodic acid–Schiff, described nine vascular patterns that they observed in  $\times 10$  objective fields of uveal malignant melanomas:

- Normal vessels
- Silent-avascular zones
- Straight with randomly distributed vessels
- Parallel-oriented straight vessels without cross-linking
- Parallel with cross-linking between vessels
- Arcs that are incomplete loops
- Arcs with branching
- Loops that represent fibrovascular septa that completely surround lobules of tumor
- Networks that are composed of at least three back-to-back loops

The detection of these patterns in histologic sections is highly reproducible between observers, <sup>87</sup> and more than one pattern can exist in a tumor. <sup>88</sup> Foss et al. <sup>88</sup> showed that the avascular zones contain large numbers of small blood vessels as demonstrated by factor VIII staining.

Two of these microvascularization patterns (networks, parallel with cross-linking) showed a very strong correlation with metastatic disease; two other

microvascularization patterns (silent, parallel without cross-linking) were correlated with a more favorable outcome for the patient. <sup>82,83,85,86,89,90</sup> and <sup>91</sup> The survival rate was 80% at 20 years in the absence of loops, networks, or parallel with cross-linking vascular patterns and only 40% when these patterns were present. <sup>82,83,85,86</sup> The presence of epithelioid cells is associated with the presence of networks, and the absence of epithelioid cells is associated with avascular zones. <sup>87</sup> These microcirculatory patterns of primary uveal melanomas appear also in foci of metastasis, regardless of the site of dissemination. <sup>92</sup>

The Callender classification cell typing is highly subjective because it is based on multiple cytoplasmic, nuclear, and nucleolar features. Loops and mean of the largest nucleoli (MLN) should be less subjective than cell type, because these variables are based on only one feature and MLN is measured objectively. <sup>93</sup>

Several attempts to evaluate the growth and malignant potential of uveal melanomas have been made recently using DNA cell-cycle studies (e.g., bromodeoxyuridine uptake or Ki-67 antibody as a marker of cycling cells, <sup>96</sup> proliferating cell nuclear antigen, <sup>94,95</sup> DNA or RNA content by flow cytometry).<sup>96</sup> Several reports of DNA ploidy analysis in uveal melanomas showed a progressive predominance of diploid over aneuploid tumors moving from spindle to epithelioid cell type and worsening prognosis. <sup>96,97</sup> and <sup>98</sup> The value of this technique as a diagnostic and prognostic tool in combination with fine-needle aspiration biopsy needs further confirmation. <sup>97,99</sup>

After the works of Rosenberg et al. on the prognostic and therapeutic value of tumor-infiltrating lymphocytes (TIL), a reappraisal of the lymphocytic infiltration of some uveal melanomas has been undertaken. <sup>100</sup> Whelchel et al. <sup>101</sup> and other authors <sup>102</sup> unexpectedly showed that T-lymphocytic infiltration is associated with death from metastasis. T cells appear predominant among TIL. Attempts to generate TIL cytotoxic for ocular melanoma cells showed that after interleukin-2 addition, cells expressing natural killer (NK) cells, lymphokine-activated killer cells, and tumor-specific cytotoxic properties were obtained. <sup>100</sup> Moreover, allogeneic melanomas could substitute for autologous tumors in active specific immunotherapy with CD8+ cytotoxic T lymphocytes. <sup>103</sup> A few studies suggest a link between host-immune responses to the tumor and gangliosides profile (e.g., GM3 vs. GD2 and 3). <sup>104,105</sup> The role of infiltrating lymphocytes in the regression of animal models of tumors was shown in nude mice for NK cell-mediated lysis <sup>106,107</sup> and for CD8+ cytotoxic T lymphocytes in the rejection of tumors from transgenic mice. <sup>106,107</sup>

## TISSUE CULTURE AND ANIMAL MODELS OF UVEAL MELANOMAS

Several cell lines of human ocular melanomas have been established and characterized. <sup>53,54,55,56,57</sup> and <sup>58</sup> These vary greatly regarding doubling times or morphology and are mostly used for genetic studies and the development of animal models.

The most commonly used model of uveal melanoma is the Greene melanoma, which represents a transplantable hamster amelanotic melanoma. When injected into a rabbit eye, this tumor grows rapidly with marked spontaneous necrosis and is, therefore, not reflective of the clinical situation. <sup>59,60</sup> Other models of either induced or spontaneous pigmented intraocular tumors are available arising from the retinal pigment epithelium or representing atypical nevi. <sup>61,62,63</sup> and <sup>64</sup> Yet, to date, the most clinically relevant model to the human situation appears to be the heterotransplantation of human uveal melanomas into the choroid of rabbits, <sup>65,66,67,68</sup> and <sup>69</sup> and the newer transgenic mouse models.<sup>70</sup> These transgenic models are based on using the promoter region of the tyrosinase gene to target the expression of oncogenes to pigment-producing cells of different origins. Most of the models have been successful in producing intraocular pigmented tumors, including retinal pigment epithelium tumors, carcinomas, and ocular melanosis. <sup>70</sup> These models might provide better understanding of uveal malignant melanoma pathobiology.

## HISTOPATHOLOGIC EFFECTS OF RADIATION

The histopathology of radiation-treated globes is of value in understanding the therapeutic mode of action. <sup>108,109,110,111,112</sup> and <sup>113</sup> The aim of treatment is to kill all tumor cells or to render them incapable of sustained proliferation. It is postulated that this result can be achieved through indirect tumor necrosis and hypoxia secondary to blood supply damage. <sup>108</sup> Most studies are biased by the small size of the sample and by the complicated nature of cases examined in the pathology laboratory. Changes in eyes enucleated for radiation-induced complications or poor tumor control may not reflect the radiation response of most treated cases. Using conventional light-microscopy methods, it was difficult in most studies to characterize histopathologically the radiation response aside from radiation-induced damage (radiation retinopathy, rubeosis iridis, cataract, vitreous hemorrhage). In the COMS, <sup>74</sup> preenucleation radiation significantly reduced, but did not eliminate, mitotic activity. Not surprisingly, tumor regrowth is correlated with significant mitotic activity, <sup>112</sup> whereas good tumor response is linked with fewer mitotic figures and tumor and blood vessel damage. <sup>113</sup> It seems likely that loss of replicative capacity through DNA damage is a major mode of action of this method. Other significant features of irradiated tumors include necrosis, fibrosis, and balloon cell formation. <sup>109,111,113</sup>

Further studies of the sequence of changes after proton beam treatment of uveal melanomas indicates progressive changes with decreased inflammation and increased fibrosis. In successfully treated tumors, mitotic figures persist only for the first 30 months after treatment. <sup>114,115</sup>

## NATURAL HISTORY

### *Doubling Time*

Little is known about the natural history of uveal melanomas. Until recent decades, all patients underwent enucleation immediately after the diagnosis. <sup>113</sup> Data on the growth pattern of small melanomas from series of patients observed by Gass and others have contributed to our knowledge of the rate of intraocular tumor growth prior to treatment. <sup>50</sup> These findings and other selected reports suggest a gompertzian (exponential) growth curve, as postulated by Manschot et al. <sup>129</sup> The doubling time of uveal tumors may vary from 2 months or less to several years. In rapidly growing tumors, a high mitotic activity and the presence of epithelioid cells have been documented. Spontaneous regression of a choroidal melanoma has been described. <sup>116</sup>

### *Intraocular Spread*

Small melanomas grow from a discoid to a hemispheric shape. They progressively obliterate the choriocapillaris and displace Bruch's membrane and the retina inward. When Bruch's membrane is disrupted, the tumor usually grows in the subretinal space in a mushroom configuration. <sup>118,119</sup> and <sup>120</sup> The retinal pigment epithelium overlying the tumors undergoes early changes called *tumor-associated retinal pigment epitheliopathy*, which includes drusen formation and orange pigment (lipofuscin) accumulation. <sup>120</sup> The neurosensory retina is frequently detached and, in some instances, infiltrated by tumor cells, which can seed into the vitreous. Most often, but not exclusively, this is a late finding.

Anterior tumors are more likely to affect the lens and to involve the posterior chamber. The zonules, lens, iris, anterior chamber, and angle may be affected by the tumor. A secondary glaucoma may result from obstruction of the outflow pathways by tumor cells, cell debris, and phagocytic cells swollen with ingested cell debris (melanomalytic glaucoma). The tumor may infiltrate through the scleral spur into the anterior chamber.

Although the sclera is thought to be an effective barrier against extraocular extension, scleral infiltration by tumor cells along ciliary vessels and nerves and along the vortex veins is frequent (32.3% of large melanomas in a series reported by Shamma and Blodi). <sup>122</sup> Approximately 5% of melanomas grow diffusely in the plane of the uvea or circumferentially along the root of the iris. They induce a slight thickening of the uvea (approximately 3 to 5 mm) and are often unsuspected or diagnosed late when secondary glaucoma or extraocular spread occurs. Extraocular spread may occur adjacent to or within the optic nerve or can occur anteriorly about the limbus. <sup>124</sup>

### *Extraocular Extension*

Although extrascleral extension may be observed with small tumors, it is more likely to occur when the tumor has reached a larger size. <sup>125</sup> In a study by Shamma and Blodi, <sup>122</sup> extrascleral extension was observed in 18% of tumors exceeding 10 mm in diameter. The overall incidence of transscleral extension was determined to be approximately 13% among 1842 malignant melanomas studied by Starr and Zimmerman. <sup>125</sup> Other series arrive at similar data. Starr and Zimmerman noted a tenfold increase in the incidence of postoperative recurrence if the tumor extended to the surgical margin. The depth of scleral extension may have a prognostic significance. Other less common paths of extraocular spread include the optic nerve and the lumen of the vortex veins. <sup>124</sup>

### *Metastases*

Lymphatic spread has not been demonstrated, as would be expected from the absence of lymphatics in the eye. This is in contrast to cutaneous melanomas. Hematogenous dissemination to the liver is a frequent form of metastatic spread. The respective roles of nonspecific trapping and of cell surface antigens in the invasiveness and dissemination of uveal melanomas are not yet fully established.<sup>117</sup> Plasminogen activator function<sup>118</sup> and the epidermal growth factor receptor<sup>119</sup> may play a role in the occurrence and progression of metastases. Metastases to other sites (lung, heart, gastrointestinal tract, lymph nodes, pancreas, skin, central nervous system, bones, spleen, adrenal, kidneys, ovaries, thyroid) generally occur in association with liver metastases.<sup>120</sup> In a survey of metastases from proton beam-treated melanomas, liver involvement was documented in almost all patients (136 of 145); the overall 1-year survival was 13%.<sup>120</sup>

In a series of studies, McLean et al. found that most deaths from metastatic disease occurred in the first 5 years after enucleation, with a peak mortality in the second and third years (approximately 8% per year). They compared these data with the natural course of untreated melanomas<sup>126</sup> and reached a conclusion that remains controversial: McLean et al. incriminated enucleation as a risk factor and suggested two principal mechanisms: (1) dissemination of tumor cells during traumatic operations, as demonstrated experimentally by Fraunfelder et al.,<sup>126,127</sup> and (2) decreased host resistance to disseminated tumor cells. This latter mechanism has been called by Niederkorn et al.<sup>61</sup> the "loss of intraocular induced concomitant immunity" mediated by cytotoxic T lymphocytes. Zimmerman and McLean's assumptions have been challenged by several investigators. Seigel et al.<sup>128</sup> concluded that the statistical data can be interpreted differently and that no evidence suggested that the existing pattern of treatment be altered.<sup>128</sup> Manschot and Van Peperzeel,<sup>129</sup> Kersten and Blodi,<sup>130</sup> and Davidorf<sup>131</sup> pointed out that most melanomas are diagnosed only when they have reached a relatively large size and concomitantly given rise to metastases, and only then are enucleated. The clinical consequences of these controversies are the use of less traumatic techniques for enucleation and new impetus to the search for alternative treatments.<sup>132</sup>

### Multiple Choroidal Malignant Melanoma

It has been estimated that only one person will develop bilateral choroidal melanomas in a population of 50 million.<sup>121</sup> There is no clinical evidence of an inherited genetic predisposition for bilateral primary uveal melanoma, and it may be associated with ocular melanocytosis.<sup>123</sup> Unilateral multifocal intraocular malignant melanoma appears to be even rarer than bilateral intraocular melanoma.<sup>121</sup> To eliminate the possibility of a multinodular tumor, serial sections of the enucleated eye are useful to exclude continuity between the two tumors. Intraocular multifocal melanoma has been associated with ocular melanocytosis, iris melanoma with invasion of the ciliary body, iris or choroidal nevus (or both), and with systemic malignant neoplasm.<sup>121,124</sup> However, other cases of double melanoma do not show any such associations. It is also unknown whether the prognosis for life differs in patients with multiple versus unifocal primary uveal melanoma.

## DIAGNOSIS OF UVEAL MELANOMAS: CHOROIDAL AND CILIARY BODY MELANOMAS

The diagnosis of choroidal and ciliary body melanomas has reached a high degree of accuracy at eye centers where experienced clinicians and modern ancillary testing facilities are available.<sup>134</sup> This is well illustrated by a comparison of the misdiagnosis rates among the eyes on file at the AFIP: 19% (of 529 eyes) until 1962; 20% (of 208 eyes) between 1963 and 1970; and 6.4% (of 744 eyes) between 1970 and 1980. During the 11-year period of the last study, the rate of misdiagnosis declined from 12.5% to 1.4%. Between 1954 and 1977, the misdiagnosis rate was 2.6% (of 224 eyes) at the Mayo Clinic. In the Mayo series, in addition, six clinically unsuspected melanomas were found.<sup>132</sup>

This high rate of correct clinical diagnosis is particularly impressive because only outpatient procedures (including clinical examination, ultrasonography, and fluorescein angiography) were used. No biopsies were performed, as is used for many other tumors. A review of 395 eyes enucleated during a 50-year period, drawn from the pathology files of Ohio State University, revealed a misdiagnosis rate of 10.9% in the period 1931 to 1959 that decreased to 1.7% in the period 1960 to 1981. Nine percent of choroidal melanomas were unsuspected preoperatively; all were in eyes with opaque media. In a series of 400 consecutive patients referred to the oncology unit of the Wills Eye Hospital with an incorrect diagnosis of melanoma (i.e., patients who proved to have a so-called pseudomelanoma), the correct diagnosis was reached through clinical evaluation in 397 cases (99%). In that series, the most commonly encountered conditions mimicking a melanoma included suspicious choroidal nevi (26.5%), peripheral disciform degeneration (11%), congenital hypertrophy of the retinal pigment epithelium (9.5%), and choroidal hemangioma (8%). Most metastatic carcinomas had been correctly diagnosed by the referring ophthalmologists. The diagnostic accuracy of 99.7% in the COMS exceeds previously documented rates.<sup>132</sup> It reflects the value of rigorous and standardized ophthalmic and systemic evaluations.

The cornerstone of diagnosis of posterior uveal melanoma remains clinical examination and, in particular, indirect ophthalmoscopy through a dilated pupil. Fundus contact lens examination and the use of a three-mirror lens can be extremely helpful.<sup>142</sup> Scleral transillumination as advocated by Reese is also a useful aid.<sup>182a</sup> Pigmented conjunctival lesions, such as conjunctival melanoma, staphylomas, scleral ectasia, hematoma, cellular blue nevi, and ocular melanocytosis, may mimic extraocular extension of uveal melanomas. Visual field studies are of little help, especially in distinguishing melanomas from choroidal nevi. Although clinical examination by an experienced observer remains the most important test in establishing the presence of an ocular melanoma, ancillary diagnostic testing can be extremely valuable.<sup>142,143,144 and 145</sup>

Fluorescein angiography and monochromatic photography have proved useful in differentiating subretinal or choroidal hemorrhage and hemangioma from melanoma (Fig. 42.3-1). Although no angiographic pattern is pathognomonic, features of value include early mottling fluorescence, orange pigment over the margin of the tumor, progressive fluorescence of the lesion with late staining, and multiple pinpoint leaks that increase in size. Breaks in Bruch's membrane and retinal invasion can be detected from abnormalities, such as a double or tumor circulation pattern (simultaneous visualization of retinal and choroidal circulation).<sup>134,135,136 and 137</sup> However, this double circulation pattern is often difficult to recognize, particularly when the overlying retinal pigment epithelium is completely intact. An *in vitro* study of endogenous fluorescence<sup>133</sup> emphasized the differences between low tumor autofluorescence and bright retinal pigment epithelium autofluorescence due to lipofuscin deposits.

FIGURE 42.3-1. Fluorescein angiogram showing characteristic pattern of choroidal melanoma.

Indocyanine green angiography was formerly used as a tool to differentiate melanomas from nevi, but early photographs had a rather poor resolution.<sup>134</sup> Since the introduction of videoangiography and high-resolution fundus digital imaging systems, this technique has proven useful in documenting retinal vascular and choroidal diseases.<sup>135,136</sup> It can also be useful to further differentiate amelanotic choroidal tumors, such as some nevi or melanomas from hemangiomas or metastases, the latter appearing almost invariably hyperfluorescent on early or late frames (or both). This imaging system might also better delineate tumor borders. Indocyanine green angiography using a confocal scanning laser ophthalmoscope is superior to fluorescein angiography in imaging microvascularization patterns.<sup>85,90,137</sup> The angiographically seen microvascularization patterns appear to be identical to patterns identified histologically that have prognostic significance in choroidal melanomas.<sup>89,90,138</sup> *In vivo* imaging of these microvascularization patterns may offer the possibility of improving the prognostic assessment of choroidal melanomas.

The combined use of A- and B-mode ultrasonographic techniques is of great value in confirming the clinical diagnosis of choroidal melanoma, especially in the presence of opaque media.<sup>139,140</sup> The B-mode ultrasonographic characteristics useful in differentiating melanomas from metastases or hemangiomas are acoustic hollowness, choroidal excavation,<sup>141</sup> and orbital shadowing (Fig. 42.3-2). Small tumors elevated less than 2 mm to 3 mm cannot be evaluated accurately. In large tumors, ultrasonography provides valuable size data for serial measurements.<sup>146</sup> However, a difference between ultrasonographic and histopathologic measurements of tumor thickness was demonstrated, probably consecutive to tumor shrinkage after laboratory preparation. Extrascleral extension can be detected by contact

B-mode ultrasonography. Ultrasonic tissue characterization and tumor volume determination might bear prognostic information. [141,142,143,144,145,146](#) and [147](#)  
Ultrasonography is also a very important follow-up tool after conservative treatment of uveal melanoma. [145](#)

**FIGURE 42.3-2. A:** Ultrasonographic appearance of choroidal tumor. **B:** Tumor dimensions correspond to schematic drawing showing dimensions.

Three-dimensional ultrasonography is a promising imaging technique for evaluating the accurate position of radioactive plaques secured beneath intraocular tumors. [148](#) It can also be used to observe extrascleral extension of a choroidal melanoma, [149](#) to quantify the tumor volume, and for posttreatment follow-up.

Direct observation by indirect ophthalmoscopy or the use of a three-mirror lens is useful to display the anterior border of these tumors. Clinical transillumination is helpful but is dependent on tumor characteristics and can be more difficult in those patients with amelanotic tumors, [74,150](#) with ocular melanocytosis, and with dark pigmentation, or tumors complicated with paratumoral hemorrhage. Transillumination may provide an inaccurate assessment of the anterior tumor margins of the peripheral choroid. Anatomic features evident on ultrasonographic biomicroscopy before enucleation were correlated with pathologic examination: supraciliary choroidal effusions, ciliary body rotation, anterior tumor margin position, and angle involvement. [150](#)

The clinical need to define the anterior borders of peripheral choroidal melanomas clearly is related mainly to decisions regarding treatment options. Secondly, the pattern of ciliary body involvement can help differentiate tumors of ciliary origin from those of choroidal origin.

Recent reports on the usefulness of color-coded Doppler imaging in the characterization and follow-up of melanomas are promising, particularly for detection of pulsatile ocular blood flow (POBF) at the tumor base. [151,152,153,154,155](#) and [156](#) The tumor blood flow can also be quantified indirectly by ocular blood flow tonography. The higher POBF values observed in eyes with choroidal melanoma indicate that the pulsatile component of choroidal blood flow is increased. [151](#) At present, these techniques must be interpreted with caution. Fundamental studies to validate the theoretically derived POBF values and clinical studies to determine reference ranges are required before any meaningful interpretation of these parameters can be made.

The usefulness of radioactive phosphorus ( $^{32}\text{P}$ ) in determining malignancy remains controversial, and this is little used at present. It has limited indications for use in routine cases in which adequate support for a diagnosis of ocular melanoma can be obtained with less complicated procedures. [157](#)

Radiologic examination, including computed tomography (CT), is useful in evaluating the presence and size of extraocular extension of tumor. It does not, however, add significant information to ultrasonography and implies low doses of radiation. [145](#)

Images of uveal melanoma have been obtained by magnetic resonance imaging (MRI). This imaging modality has become more useful with employment of thin-section imaging, surface coils, and contrast material (gadolinium). Typically, due to the postulated paramagnetic properties of melanin, pigmented melanomas are hyperintense on T1-weighted images with enhancement by gadolinium and hypointense on T2-weighted images when compared to the brightness of the vitreous. [158,159](#) This method is, therefore, promising in the detection and characterization of tumors in difficult cases as well as in the differentiation of associated serous retinal detachments.  $^{31}\text{P}$  magnetic resonance spectroscopy may be helpful in this respect in the near future. [158](#) Nevertheless, to this date, ultrasonography is by far the main diagnostic modality in intraocular melanomas. Ocular ultrasonography is also more sensitive than MRI or CT for the detection of extraocular extension of choroidal malignant melanomas. [160](#) Ultrasonography and fluorescein angiography are together very useful in patients' follow-up ( [Fig. 42.3-3](#)).

**FIGURE 42.3-3.** Angiographic appearance of choroidal melanoma during follow-up.

Immunologic testing does not yet offer reliable results. [161,162](#) Using the indirect immunoperoxidase method, Folberg et al. [162a](#) found that 78% of patients with uveal malignancy had tumor-associated antibodies (TAA), whereas 24% of controls tested positive for TAA. However, TAA assays could not be used to separate primary from secondary uveal tumors. Studies with monoclonal antibodies (discussed earlier in [Cytologic and Histologic Classification](#)) are still in the experimental phase. Radioimmunoassay using technetium 99m-labeled monoclonal antibodies are still too preliminary to be considered as reliable diagnostic tools, even after pretargeting techniques. [161](#) However, surveillance of melanoma-associated antigens and carcinoembryonic antigens may be useful for monitoring recurrence or metastatic disease. [162](#)

In a review of 51 consecutive patients who had undergone enucleation for a choroidal melanoma and 50 patients with simulating lesions, Char et al. found that the ophthalmoscopic examination was the most accurate diagnostic modality, allowing correct diagnosis of choroidal melanomas in all patients with clear media. [163](#) Subretinal fluid, orange pigmentation, and collar-button configuration occurred more often with melanomas than with other lesions. In 63% of melanoma patients, fluorescein angiography was diagnostic; in 82%, A- and B-mode ultrasonography was diagnostic. [163](#)

In some problematic cases, fine-needle aspiration biopsy has been proposed. However, the interpretation of aspirates may be difficult even in the hands of an experienced pathologist, and subsequent tumor cell seeding in the needle track has been reported. Nonetheless, in selected cases, this technique has proven useful in differentiating benign lesions or lymphoid infiltrates from melanoma. Such biopsies obtained through a transocular approach with a 22-gauge needle provided informative specimens in almost 90% of cases, with an accuracy of approximately 98%. [164](#) It should be emphasized that the lack of histologic data prior to conservative treatment of most uveal melanomas represents a major limitation to our understanding of tumor response to radiation, accurate adaptation of conservative approaches, and establishment of prognosis.

Despite ancillary examinations, the differential diagnosis of small tumors may be difficult. Careful follow-up of such patients at short intervals with photography,

fluorescein angiography, and ultrasonography is advocated to demonstrate tumor growth. <sup>165,166</sup> Buttler et al. <sup>165</sup> showed that the presence of symptoms, tumor thickness, orange pigment, acoustic hollowness, and hot spots on fluorescein angiography was a significant predictor of growth.

Patients with suspected intraocular melanoma should undergo a physical examination and metastatic workup. Clinical laboratory studies should include routine blood work, chest radiography, and liver enzyme measurements. CT should be performed if other tests suggest liver involvement. <sup>165,166,167</sup> and <sup>168</sup> Detection of circulating melanocytes using reverse transcriptase-polymerase chain reaction amplification of the tyrosinase gene is a promising approach. <sup>67,167,168</sup> Nevertheless, even though it is known that the detection of melanoma cells in blood cannot automatically be taken as a definitive sign for the presence of metastatic disease, polymerase chain reaction might help in interpreting the result of conventional markers for metastasis in the near future. Haynie et al. <sup>169</sup> noted significant differences in the peripheral blood lymphocytes in two subgroups of patients with clinically less favorable choroidal melanoma; ciliary body involvement was related to reduction in NK cells and, in patients with extrascleral extension, an increased number of activated T cells was noted. Liver ultrasonography, liver-spleen scans, CT of the head, and MRI appear useful in the initial workup and follow-up. <sup>158</sup>

## MANAGEMENT

### PROGNOSTIC ASSESSMENT OF CHOROIDAL AND CILIARY BODY MELANOMAS

The number of epithelioid cells in conjunction with the largest tumor dimension <sup>74,90,91,93</sup> and the microvascularization patterns <sup>14,82,83,84,85</sup> and <sup>86</sup> are the most important histologic prognostic parameters. Despite an early study by Flocks et al., <sup>170</sup> a larger study of small melanomas by Char et al. <sup>163</sup> showed that the largest tumor diameter was the best prognostic parameter for such tumors. The location of the anterior margin of the tumor, invasion of the line of transection, and the degree of pigmentation follow this, according to Seddon et al. <sup>215</sup> Other features that have been associated with prognosis include tumor size, location of the anterior margin of the tumor, and degree of ciliary body involvement. <sup>74</sup> Shamma and Blodi, <sup>122</sup> in a study of 253 choroidal and ciliary body melanomas for which a follow-up of 5 years or more was available, identified nine factors that significantly influenced prognosis: age of the patient enucleation; location of the tumor; location of its anterior border; largest tumor diameter in contact with the sclera, or largest tumor dimension; height of the tumor; integrity of Bruch's membrane; cell type; pigmentation; and scleral infiltration by tumor cells. <sup>171,173</sup>

Char et al., <sup>163</sup> using a multivariate analysis, reached similar conclusions for small melanomas. Parameters that significantly influenced prognosis were cell type, largest dimension, scleral extension, and mitotic activity. A single-factor analysis identified three additional factors of significance: degree of scleral invasion, optic nerve invasion, and pigmentation. In most studies, increased pigmentation has been associated with increased mortality. <sup>174</sup> However, in a multivariate analysis, these last three parameters appear statistically related to cell type and tumor size. <sup>171</sup> Regan et al. <sup>172</sup> described iris color as a prognostic factor in ocular melanoma and concluded that patients with blue or gray irises show light to moderate tumor pigmentation and appear to be at increased risk of metastatic death from choroidal melanoma, independent of other risk factors. Maximum tumor size is believed to be an important predictor of outcome. <sup>74</sup> In the COMS report number 6, <sup>74</sup> anterior location was observed more commonly with large tumor size and more malignant cell type. In many studies, tumors involving the ciliary body have a worse prognosis than those located entirely in the choroid. <sup>74,87</sup> Microvascular networks tend to develop more commonly in the ciliary body relative to the choroid. <sup>87</sup> This observation is important, because deletion of chromosome 3 may be characteristic of ciliary body melanomas and has been associated with their aggressive behavior. <sup>87</sup>

A matter of concern in the present classification of posterior uveal melanomas is the lack of an accurate, consistent, and clinically pertinent size classification. <sup>173</sup> This question is not purely theoretic, since size classification is most often the only available prognostic parameter; a clinically relevant size classification should assign tumors to currently accepted elective treatment modality, or at least to groups of significantly different life prognosis; and a comparison of results using various therapeutic approaches is required. The current TNM staging by the American Joint Committee on Cancer <sup>174</sup> draws boundary lines for small, medium, and large tumors. According to this classification, many tumors considered medium in the current conservative management would belong to the large-tumor category. Whereas a classification according to the largest tumor dimension would appear best suited to predict patient survival, a size classification taking into account tumor thickness and basal diameter is currently in use in most centers and in the COM study ( [Table 42.3-2](#)). <sup>74</sup> Data from retrospective evaluations, <sup>173</sup> as well as recommendations from the COM Study group, <sup>174</sup> tend to classify tumors as in [Table 42.3-2](#). In COMS report number 6, <sup>74</sup> larger tumor size was related more commonly with anterior location and more malignant cell type. Large tumors invaded the retina, the vitreous, and vortex veins and ruptured Bruch's membrane more often than medium tumors. <sup>74</sup>

Type	Apical Height	Largest Basal Diameter
Small	1.0-2.5 mm	5 mm
Medium	2.5-10.0 mm	5-16 mm
Large	10 mm	16 mm

(Adapted from ref. 174.)

**TABLE 42.3-2.** Classification of Tumor Size According to Boundary Lines

It has been shown that certain histologically identified microvascularization patterns are an independent risk factor for the growth and metastatic behavior of choroidal melanomas. The microvascularization patterns that are networked and parallel with cross-linking indicate a high probability for metastatic disease, whereas the presence of microvascular patterns that are silent and parallel without cross-linking indicates a better prognosis. <sup>14,82,83,84,85</sup> and <sup>86,90,91</sup> A Cox proportional hazards model was generated with the conventional prognostic factors (including the largest tumor dimension in contact with the sclera, cell type, tumor-infiltrating lymphocytes, mitotic figures, gender, and location of the tumor within the eye) and the presence or absence of each of the nine microcirculatory patterns. The most important variable was the network pattern (back-to-back loops). Other significant factors in the model include (in decreasing order of importance) largest tumor dimension, mitoses, parallel with cross-linking vascular patterns, age, the presence of tumor-infiltrating lymphocytes, and male gender. <sup>87,175</sup> However, in the Foss et al. series, <sup>88</sup> the parallel with cross-linking pattern did not carry a poor prognosis; in this series, a poor prognosis was associated with absence of the normal pattern and the presence of arcs, arcs with branches, loops, and networks. Foss et al. <sup>88</sup> suggested that the periodic acid-Schiff patterns are based on three underlying factors that have been identified as (1) presence of disordered growth, (2) presence of rapidly growing subclones, and (3) sectioning orientation. The first two of these factors carried prognostic significance in a multivariate Cox model that included tumor size and microvessel density. <sup>88</sup>

Mehaffey et al. <sup>91</sup> observed that larger areas of these microcirculatory patterns (tumors with >2% occupied) imply a worse prognosis than small isolated foci (tumors with <0.5% occupied). This study also showed that it is possible to separate choroidal melanomas into three prognostic groups by cross-sectional area measured from histologic sections: small (tumor area <16.0 mm<sup>2</sup>); medium (tumor area >16.0 mm<sup>2</sup> but <61.4 mm<sup>2</sup>); and large (>61.4 mm<sup>2</sup>).

The estimation of tumor volume was related to outcome, but the relation between estimated volume and outcome did not hold for relatively small tumors (measuring <1.344 mm<sup>3</sup>). <sup>175</sup> In a series of 217 small tumors (measuring <1.400 mm<sup>3</sup>), the largest tumor dimension in contact with the sclera was more strongly associated with outcome than estimated volume, possibly because diffuse melanomas may have a relatively small volume but follow an aggressive clinical course. <sup>169</sup>

Technologic advances have implemented the assessment of nucleolar area, nucleolar organized regions, tumor vascular patterns, and tumor vascular density as potential prognostic factors. Cell type, however, remains the most potent single predictor of outcome. <sup>74,93</sup>

Seregard et al. have shown that the MLN and PC10 immunostaining counts retain a prognostic value in uveal melanoma when adjusting for the effect of the mean of the diverse vascular patterns. <sup>176</sup> In recent studies, <sup>177,178</sup> high expression of HLA-A (and, to a lesser extent, of HLA-B) antigens on the primary uveal melanoma was

strongly correlated with poor patient survival. High HLA-B expression was significantly correlated with the presence of epithelioid cells in the tumor. <sup>172</sup> The primary uveal melanomas showed a high expression of monomorphic and polymorphic HLA-A antigens, while metastases showed a high expression of monomorphic and a lower expression of polymorphic antigens. <sup>173</sup>

In summary, all studies show that the prognosis of a patient with a choroidal or ciliary body melanoma is adversely affected by the following factors:

- Tumor containing loops, networks, or parallel with cross-linking vascular patterns <sup>91,93,172</sup>
- Largest tumor dimension exceeding 10 mm
- Presence of numerous mitotic figures (mean count per 40 high-power field)
- Patient age older than 56 <sup>81</sup>
- Presence of tumor-infiltrating lymphocytes <sup>87</sup>
- Male gender <sup>87</sup>
- Tumor containing epithelioid cells (or related cytologic features, such as nucleolar parameters and vascular architecture, as discussed earlier in [Cytologic and Histologic Classification](#))
- Anterior tumor border anterior to equator <sup>174</sup>
- Tumor extending to the scleral surface

In the COMS report number 4, <sup>174</sup> older patients with a history of diabetes and patients with more anteriorly located tumors were at increased risk for death. Yet a close interval-by-interval analysis of the prognostic value of size and cell type in a series of 3680 patients shows a decline over time after tumor excision. <sup>175</sup> Gamel et al., <sup>179</sup> applying the log-normal survival model <sup>175,179</sup> to 2892 patients treated by enucleation, demonstrated that the probability that the patient is cured by tumor resection is not modulated by the same biologic factors as those determining survival time among patients. Their analysis showed that mixed cell type and advanced patient age are associated only with a short median survival time. In contrast, pleomorphic nucleoli and large tumor size were independently associated with both a low probability of curative resection and short median survival time. Many of these prognostic parameters are lacking in patients treated conservatively. Furthermore, due to a shorter follow-up, bias in patient selection and size of samples, and the use of different survival analysis models, comparison of survival rates between conservative approaches or between conservative approaches and enucleation remains a subject of intense controversy. <sup>163,179,180</sup> and <sup>181</sup> To date, the survival rates in large series after 5 years do not differ significantly. The reported tumor-related mortality 5 years after radiation therapy ranges from 11% to 25%, <sup>181,183</sup> whereas preliminary assumptions based on a log-normal model may indicate a poorer life prognosis after 10 years for patients treated conservatively. The COMS, a prospective multicenter study, should provide answers to this most crucial and controversial issue. <sup>209</sup>

Several studies have established a correlation between rapid tumor regression after radiation therapy and a poorer life prognosis. <sup>175</sup> Rapid regression of tumor height after radiation therapy appears as a risk factor for metastasis. Rapid regression can possibly be correlated with a less differentiated cell type of fast-regressing tumors. However, such a hypothesis is difficult to ascertain for several reasons: (1) Cytologic study of melanomas is rarely performed before radiation therapy; (2) when needle biopsy is obtained, it often does not provide a reliable characterization of the cell type; and (3) study of enucleated eyes after radiation therapy for any reason may not accurately reflect features of the tumor prior to radiation therapy, particularly in mixed or epithelioid tumors.

## PRETREATMENT CLINICAL STAGING

In light of current knowledge, it is useful to discuss the treatment of choroidal and ciliary body melanomas in terms of tumor size, following the size classification discussed previously in Management. In contrast with the Reese-Ellsworth classification <sup>182a</sup> of retinoblastoma, the current classifications are of marginal help in predicting the visual outcome of conservative approaches, since such factors as the distance to the optic nerve and macula are important in estimating final visual acuity.

Another problem is related to the rarity of detectable metastases, particularly lymphatic, at the time of diagnosis. Attempts to detect and treat subclinical metastases should develop in the near future to address appropriately this major clinical problem. Moreover, the lack of histopathologic data in most cases managed conservatively has given emphasis to clinical patterns of tumor growth prior to treatment and histologic analysis of tumor regression after radiation therapy based on enucleated eyes. The results of comparisons of data from retrospective studies have been a source of confusion and controversy.

## TREATMENT OF CHOROIDAL AND CILIARY BODY MELANOMAS

In the late nineteenth century, enucleation became the standard and almost universally accepted treatment for all choroidal or ciliary body melanomas. Even today, early enucleation continues to have its ardent advocates. <sup>181</sup> However, in the last two decades, enucleation has been reassessed as the standard means of treating malignant melanomas of the choroid and ciliary body. This reassessment has resulted from (1) the development of newer and more precise diagnostic tests for recognizing malignant melanomas and the serial documentation of their size; (2) more information about clinical and pathologic features that determine survival; (3) additional observations about the natural course of untreated ciliary body and choroidal melanomas; (4) therapeutic developments other than enucleation to treat these tumors without destroying the eye; and (5) disagreements as to the value and risks of enucleation. <sup>183</sup>

Most authors today agree that the goals of an ophthalmologist treating a uveal melanoma should be to destroy or inactivate the neoplasm, to maintain useful vision in the involved eye, to employ a treatment with as few side effects as possible but, most important, to provide the patient with the best prognosis for life possible. <sup>175,176</sup> Regarding which treatment can best achieve these goals, controversies will continue until results from prospective randomized treatment trials are collected. <sup>183</sup> In the absence of these data, the selection of treatment is based on the specific findings in each case with regard to tumor size, location, and growth rate; the preferences of the ophthalmologist; and the desires of the patient. Recently, Cruickshanks et al. showed that treatment choice does not seem to be associated with large differences in quality of life (as assessed by the Medical Outcome Study Short Form 36 and the National Eye Institute Visual Function Questionnaire). <sup>184</sup>

### Small Melanomas

The choices open to the physician treating a small choroidal or ciliary body melanoma include (1) observation; (2) some method of local treatment, such as radiation therapy, photoradiation, cryotherapy, ultrasonic hyperthermia, or local resection; and (3) enucleation.

**OBSERVATION.** An accumulating body of evidence indicates that the risks in observing most melanomas are generally low. <sup>184</sup> Serial examination every 3 months without intervention seems appropriate if the tumor is asymptomatic and appears *dormant*, the diagnosis is equivocal, and no growth is seen on serial ophthalmoscopic, photographic, and ultrasonographic examinations. Observation is also indicated for elderly or seriously ill patients or for tumors in the patient's only useful eye, particularly where the tumor is growing slowly. If the tumor shows progression, especially rapid growth or an increase in size beyond 10 mm in diameter and 3 mm in elevation, or if the lesion results in significant impairment of vision, treatment is indicated.

**PHOTOCOAGULATION.** In the photocoagulation method, the xenon arc, the argon laser, photoradiation with red light after photosensitization with hematoporphyrin derivatives, or dye laser after phthalocyanine photosensitization can be used. <sup>185</sup> Some success with photocoagulation has been documented histologically in small series. <sup>186,187,188</sup> and <sup>189</sup> The following criteria <sup>188,189</sup> for selecting patients with melanoma for photocoagulation treatment were suggested by Meyer-Schwickerath <sup>188</sup> and Vogel <sup>189</sup> and adapted by Shields <sup>186</sup>:

1. The diagnosis of melanoma and evidence of growth should be documented thoroughly.
2. The tumor should not be greater than 5 diopters in elevation and 6 disc diameters at its greatest diameter.
3. The tumor must be surrounded completely without damaging the fovea or the optic disc.
4. The patient must have clear ocular media and a sufficient mydriasis to enable photocoagulation to be performed.
5. The tumor surface should not have large retinal vessels.

Photocoagulation requires several outpatient treatment sessions and is carried out after mydriasis and, in the case of xenon photocoagulation, use of retrobulbar anesthesia. A double confluent row of heavy coagulation is repeated three times at monthly intervals to encircle the tumor and to obliterate the choroidal vasculature supplying the lesion. The tumor subsequently becomes necrotic, with gray discoloration and a surrounding chorioatrophic scar.

Long-term complications of photocoagulation include retinal vascular obstruction, visual field defect, macular pucker, cystoid macular edema, choroid neovascularization, vitreous hemorrhage, and retinal detachment.<sup>186</sup> Recurrences may appear, usually within 2 years of treatment. In a 20-year follow-up of 54 patients with uveal melanoma, Vogel<sup>189</sup> reported that 63% were alive, although only 46% were considered cured by photocoagulation. Twenty percent of patients subsequently underwent enucleation. Of the 20 patients (37%) who died, 8 did so as a result of metastatic disease, 3 died of other causes and, in 9 patients, the cause of death was undetermined.<sup>166</sup> Shields<sup>186</sup> reported that among 35 patients treated between 1976 and 1979, 25 retained useful vision, 5 had poor vision, and 5 subsequently underwent enucleation. There were no tumor-related deaths. Effects of laser phototherapy are strongly correlated with tumor pigmentation.<sup>185</sup> Comparison of xenon arc and argon laser photocoagulation in 38 consecutive patients with a minimal follow-up of 58 months showed that recurrences were less frequent and appeared later after xenon radiation therapy.<sup>190a</sup> Moreover, primary photocoagulation of small posterior choroidal melanoma with argon laser is not recommended in view of a risk of immediate visual loss.<sup>189</sup>

Photocoagulation seems best suited for small posterior melanomas located within 3 mm of the optic disc or fovea. In such lesions, radiation-induced retinopathy may cause visual loss.<sup>186,187</sup> The patient's wish to avoid radiation therapy or enucleation may be the deciding factor. Phototherapy could also be used as an adjunct to brachytherapy.<sup>190,191 and 192</sup> Photocoagulation can be helpful in the treatment of secondary serous macular detachments. Reports on hematoporphyrin, benzoporphyrin derivative monoacid and phthalocyanine, and indocyanine green-enhanced phototherapy are still preliminary.<sup>191,192 and 193</sup>

Transpupillary thermotherapy is a technique that employs infrared light (diode laser, 810 nm) delivered as heat to induce necrosis in tumor tissues. Transpupillary thermotherapy offers very promising results in the management of retinoblastoma. It also may be an effective treatment for small choroidal melanomas, theoretically reducing radiation-induced complications.<sup>194,195</sup> In a 14-month follow-up of 100 patients with posterior choroidal melanomas, Shields et al.<sup>195</sup> reported tumor control in 94% of the cases but worsening of visual acuity in 42%. A longer follow-up is necessary to assess the actual rate of local recurrence, survival, and visual outcome.

**OTHER LOCAL NONSURGICAL TECHNIQUES.** Lincoff et al. obtained discouraging results with cryotherapy of ocular melanomas in four patients. Anecdotal reports of successful treatments for small peripheral melanomas exist.<sup>196</sup> Even more than with radiation therapy, the efficacy of these alternative approaches lacks unequivocal evidence.

**LOCAL RESECTION.** Peyman et al. developed a technique of local sclerochorioretinal resection for choroidal melanomas.<sup>197,198,199,200 and 201</sup> After a series of photocoagulation treatments around the tumor to create a firm chorioretinal adhesion or an area of bare sclera, the tumor is surgically removed, along with the adjacent sclera and retina. The defect is replaced by a scleral graft. Peyman has suggested that surgical candidates should exhibit the following criteria: (1) no evidence of metastatic disease; (2) the ability to tolerate general anesthesia; (3) a tumor base no larger than 12 mm and tumor location at least 3 disc diameters from the optic disc; (4) exudative retinal detachment no larger than one-third of the fundus; and (5) clear media.

After local resection, one-third of the eyes required enucleation because of complications, including vitreous hemorrhage and retinal detachment. Shields et al.<sup>195</sup> advocate, in selected cases, the use of partial lamellar sclerouvectomy.<sup>200,201</sup> Damato et al.,<sup>202</sup> reporting the large experience of a skilled team, concluded that with a technique combining lamellar scleral flap for eye closure, hypotensive anesthesia for homeostasis<sup>202,203</sup> and, more recently, ocular decompression by pars plana vitrectomy, good visual results can be obtained in nasal tumors and for tumors located more than 1 disc diameter from the optic nerve and fovea. Yet, most authors note that patients treated by local resection are also amenable to radiation therapy and that early visual loss is far more frequent after surgical resection than with radiation.<sup>204</sup> The risk of leaving some viable tumor cells after treatment is also a matter of major concern. Local resection has not been widely adopted. Recently Damato et al.<sup>202</sup> recommended to adjunct systematically <sup>106</sup>Ru brachytherapy to prevent tumor recurrence after local resection.<sup>204</sup>

Iridocyclectomy has proven useful in the treatment of ciliary body melanomas in several series.<sup>205</sup> In the report by Forrest et al.<sup>206</sup> of 107 iridocyclectomies for ciliary body melanoma, 6% of the patients had subsequent enucleation. The majority of problems related to surgical management occurred within 4 years of surgery.<sup>206</sup> Damato et al. have promoted and employed this method for many years with good results.<sup>202</sup> A surprising feature is the low incidence of recurrence even when tumor extends to the margins of the resection. In contrast to resection of choroidal melanomas, iridocyclectomy is widely accepted for the treatment of ciliary body melanomas.<sup>204</sup> Endoresection of choroidal melanoma is technically challenging but may bear some interest for the conservation of central vision after removal of juxtapapillary tumors. Preliminary results are encouraging in terms of visual outcome despite a high rate of complication, including retinal detachment (40%), and cataract (65%).<sup>205,207</sup> The risk of tumor cell release during surgery warrants long-term assessment of this procedure.

**ENUCLEATION.** In the case of patients with a healthy second eye, enucleation is advised if the tumor shows evidence of rapid progression and invasion of the optic nerve or extraocular extension is suspected.<sup>208,209</sup> Other considerations, including loss of central vision, failure of previous conservative treatment, and the patient's desire for complete surgical removal of the tumor, may make enucleation a reasonable choice.

### **Large Melanomas**

There is at present general agreement that it would be inadvisable to treat cases of large melanoma by methods other than enucleation.<sup>208</sup> Possible exceptions include patients with only one sighted eye, rare patients in whom vision can be salvaged, and patients who refuse enucleation. Abramson et al.<sup>182</sup> recommended local radiation therapy in these latter difficult cases. Some authors recommend external radiation therapy prior to enucleation. Only experimental evidence in animal models exists for the usefulness of this therapy. This method is currently being evaluated in the COMS.<sup>174</sup> This randomized trial reported initial mortality findings that showed no survival difference in the preenucleation irradiated group.<sup>208,209</sup>

Zimmerman et al. have suggested that when enucleation is carried out, the "no-touch" technique of Fraunfelder should be considered.<sup>210</sup> This method was designed to minimize the possibility of seeding of tumor cells into the blood vessels during enucleation. The authors claim that this technique avoids intraocular pressure elevations above 15 mm before complete freezing occurs around the tumor. Cryotherapy is used to minimize the flow of fluid and blood to or from the tumor during the manipulation necessary for enucleation. Although most surgeons do not use the no-touch technique, it is increasingly recognized that enucleation should be carried out by a person skilled and experienced in the procedure and that surgery should be done with a minimum of manipulation.<sup>210</sup>

### **Medium-Sized Melanomas**

Treatment of medium-sized tumors is the subject of current controversy. Although general agreement exists that the observation of small melanomas carries little risk and that large melanomas should be treated by enucleation, there is less consensus regarding the treatment of medium-sized melanomas.

### **Nonsurgical Techniques**

**RADIATION THERAPY FOR OCULAR MELANOMA.** Ocular melanomas have been successfully treated by a variety of radiotherapeutic modalities, including external-beam techniques using photons or charged particles (protons and helium ions); stereotactic radiosurgery with modified linear accelerators and multisource cobalt units; brachytherapy (plaque) techniques using a wide variety of isotopes; hyperthermia in combination with brachytherapy; and, at least experimentally, boron neutron capture therapy (BNCT). Techniques with the most widely reported clinical experience to date include charged-particle beam therapy and plaque therapy.

**CHARGED-PARTICLE BEAM THERAPY.** Charged-particle beams (protons or helium ions) have specific dosimetric advantages in the delivery of high radiation dose to very precisely localized targets. Treatment of ocular melanoma requires pinpoint accuracy to limit dose to the adjacent retina, optic nerve, lens, and brain. Charged-particle beams are produced by a cyclotron or synchrotron available at only a few sites around the world. High-energy charged particles travel a fixed distance in tissue that varies with the energy of the particle and the nature of the tissue. Near the end of their path, they deposit the bulk of their energy within a well-defined volume, referred to as the *Bragg peak*. A high and relatively uniform dose can be achieved within a small volume, thereby sparing adjacent normal tissues.<sup>211</sup>

Proton beam therapy is available at only 16 facilities in nine countries and helium and other ion beams at even fewer sites.<sup>212</sup> Charged-particle beam therapy is generally delivered in four or five treatment sessions over 1 to 2 weeks. The treatment requires sophisticated planning techniques, precise tumor mapping, immobilization of the head, and fixation of the eye at a reproducible and verifiable gaze angle. Surgical placement of inert radiopaque rings on the sclera assists in identifying the target volume. Patients are treated in a seated position, with a face mask and bite block to immobilize the head. The correct gaze angle, chosen so that the beam enters the sclera and minimizes radiation therapy of the anterior chamber, is verified by an infrared camera with the patient's vision focused on a fixation

light. The treatment portal (beam diameter) ranges from 1 to 4 cm. Daily setup of the patient is accomplished in 10 minutes, and the duration of radiation therapy is only 1 to 2 minutes.<sup>213</sup> Long-term data on the experience with helium ion therapy for ocular melanoma have recently been updated.<sup>214</sup> Three hundred forty-seven patients were reported, with local tumor control achieved in 96%. Although rare cases of tumor regrowth were identified as late as 5 years after treatment, 85% of local regrowth was detected within 3 years. The total enucleation rate was 19% (3% for local regrowth and 16% for complications of radiation therapy, including neovascular glaucoma). The 10-year overall survival is 76%, with 24% of patients manifesting distant metastasis. Risk of metastasis was related to previously known negative prognostic factors, such as large tumor size or unfavorable location.

Proton beam treatment centers report similar local control rate of 90% to 95%.<sup>213</sup> Risk of distant metastasis also appears comparable to the helium ion–treated patients, approximately 20% at 5 years. Randomized studies comparing proton beam therapy and enucleation have not been reported, and retrospective comparisons are difficult because of the need to balance the known prognostic factors (tumor size, tumor location and ocular structures involved, patient age) between the treatment groups. A large and statistically well-balanced comparison of proton-treated patients with enucleated patients from the same institution has shown no apparent difference in long-term survival.<sup>216</sup>

Visual preservation is one of the goals of eye-conserving therapies for ocular melanoma. Radiation maculopathy and papillopathy are major causes of visual loss after successful treatment of melanoma with charged-particle beams. Although preservation of peripheral vision and ambulatory vision has been satisfactory, visual acuity of 20/100 or better was observed in only 32% of patients treated at one major center for proton radiation therapy<sup>218</sup> and was 20/200 or better in only 36% of patients treated with helium ion therapy.<sup>214</sup> These studies concur in the finding that posttreatment visual acuity is greatly affected by tumor location (in relation to optic disc and fovea), tumor size, pretreatment visual acuity, and treatment parameters. In proton beam–treated patients with tumor edge more than 3 mm from the optic disc and fovea, 67% retained useful vision (20/200 or better); with tumors located within 3 mm of these structures, only 39% maintained useful vision.<sup>213</sup>

**EPISCLERAL PLAQUE RADIATION THERAPY.** Episcleral plaque therapy, a highly specialized multidisciplinary treatment approach, is more widely available than charged-particle beam therapy for ocular melanoma. A concave plaque is constructed to house several small radioactive sources based on preoperative tumor measurements. This requires integration of data from clinical examination, ultrasonography, CT, or MRI scan. The specially designed plaque containing multiple radioactive sources is temporarily sutured to the sclera overlying the tumor under general or retrobulbar anesthesia. Operative localization of the plaque placement is guided by transillumination, ophthalmoscopic observation, or ultrasonography. The plaque remains in place for 2 to 5 days, depending on the type and activity of the radioactive source, and is then removed under similar operative conditions.

Iodine 125 is the most commonly used radioisotope in the United States and is the only isotope permitted in the COMS trial. Ruthenium 106 is frequently used in Europe; other isotopes include cobalt 60 and palladium 103. Isotopes with lower photon and electron radiation (<sup>125</sup>I, <sup>106</sup>Ru, <sup>103</sup>Pd) are more easily shielded to reduce the exposure to adjacent normal tissues in the patient and the potential exposure to medical personnel. The choice of radioisotope has been based historically on availability and experience. Newer isotopes have been used after detailed dosimetric study and computer modeling. <sup>103</sup>Pd has dosimetric advantages based on its lower photon energy as compared to <sup>125</sup>I.<sup>217</sup> Phase I trials of <sup>103</sup>Pd have been favorable.<sup>218</sup> A nonrandomized comparison of <sup>125</sup>I and <sup>106</sup>Ru plaques showed better tumor control with the <sup>125</sup>I.<sup>219</sup>

The COMS group recently completed accrual to a randomized trial comparing standardized <sup>125</sup>I plaque therapy to enucleation for medium-sized melanomas. A review of factors considered in selecting <sup>125</sup>I plaque therapy for this trial has been published.<sup>220</sup> In comparison to <sup>60</sup>Co plaque, <sup>125</sup>I results in a significantly reduced exposure of normal tissue to high radiation dose. Each plaque consists of a flexible inner plastic plaque and a rigid outer gold plaque that is sutured in place. Six different plaque sizes are available, and the size selected covers a 2- to 3-mm margin around the base of the tumor. <sup>125</sup>I seeds are sandwiched between the gold and plastic plaques. The activity and number of seeds are selected to achieve an apical dose rate between 42 and 105 cGy/h. Treatment duration for the plaque therapy is calculated to deliver a total dose of 85 Gy to the prescription point.

Study end points include survival, freedom from melanoma metastasis, as well as useful vision retained. The accrual objective was reached in July 1998, when 43 clinical centers enrolled a total of 1317 patients. Published data will be available when reliable 5-year survival estimates are known. The COMS data will have a major influence on the choice of treatments. No other randomized trial has been published comparing enucleation with any radiotherapeutic approach. As with proton beam therapy, retrospective comparisons between plaque therapy and enucleation require careful analysis and balancing of prognostic factors. A large retrospective series comparing <sup>60</sup>Co plaque therapy to enucleation identified no significant difference in long-term survival.<sup>221</sup>

Table 42.3-3 summarizes some of the retrospective data available for a variety of plaque therapies. Survival rates at 5 years range from 80% to 88%. The rate of metastatic disease is approximately 10% at 5 years but appears to increase to close to 20% for studies reporting 10-year data. Enucleation has been required for either tumor progression or severe radiation complication (neovascular glaucoma, vitreous hemorrhage) in 10% to 17% of patients. In Table 42.3-4, clinical outcomes for charged-particle beam treatments and plaque therapy are compared, with no apparent significant differences between any of the modalities.

	Cochran <sup>222</sup>	Fry <sup>223</sup>	Siegel <sup>224</sup>	Preved <sup>225</sup>	Belle <sup>226</sup>

**TABLE 42.3-4.** Clinical Outcomes from Three Different Radiation Therapy Techniques

Preservation of useful vision is one of the anticipated benefits of plaque therapy. However, the documentation and analysis of visual outcomes after eye-conserving therapies have been limited by a number of factors. Acuity may decrease with time after radiation therapy, and follow-up data may be incomplete for patients referred to distant tertiary eye care centers. Data from the various retrospective series are not always directly comparable. Visual acuity has been expressed as useful vision, reading vision, ambulatory vision, Snellen chart line decrement, and other measures. As noted with particle beam treatment, loss of acuity is a complex interaction of tumor size, location, and treatment effects. In the recently updated report by Gunduz et al.,<sup>222</sup> final visual acuity was better than 20/200 for 44% of patients, but visual

decrement of 3 or more Snellen lines was seen in 82% of patients at 10 years.<sup>224</sup> The initial report of patients treated with <sup>103</sup>Pd shows more favorable visual preservation with 77% of patients at 20/200 or better, but follow-up has been only 3 years.<sup>218</sup> For tumors with favorable size and location, the rate of useful vision preservation is encouraging.

**PRENUCLEATION ORBITAL RADIATION THERAPY.** For the treatment of larger melanomas, where enucleation is the accepted standard treatment, COMS has reported initial results of a randomized comparison of preoperative orbital radiation therapy (20 Gy in 5 fractions) followed immediately by enucleation versus enucleation alone. The hypothesis tested was that preoperative orbital radiation might reduce the risk of seeding of viable tumor cells during surgery and thereby improve survival through the reduction in the incidence of distant metastasis.

With the sponsorship of the National Eye Institute of the National Institutes of Health, the COMS Group enrolled 1003 patients from 1986 through closure in December 1994. Five-year outcome data on the first 800 patients have been published.<sup>209,226</sup>

As shown in [Table 42.3-5](#), no advantage in overall survival or prevention of melanoma metastasis was seen with the use of preenucleation orbital radiation therapy at the dose and fractionation studied. The trial had the statistical power of 90% to detect a 20% relative difference in survival between the two arms. Acute complications (occurring 1 to 6 weeks after enucleation) were slightly more common in irradiated patients, but all complications were minor. For late complications (>6 months after enucleation), no increase in cosmetic or functional complications was seen after radiation therapy. In fact, severe ptosis was observed less frequently in patients receiving radiation therapy (5% vs. 10%).

	Enucleation	Preenucleation Radiation Therapy	Probability Ratio
No. of patients randomly assigned	386	407	-
Acute complications	45	35	P<.01
Severe pain	105	35	P<.001
Orbital recurrence (no. of patients)	5	0	P<.01
Overall Survival	57% (312/481)	62% (375/485)	-
Death from metastatic melanoma (n/5-y)	205	205	-

CI = 95% confidence interval.

**TABLE 42.3-5.** Collaborative Ocular Melanoma Study Randomized Trial of Preenucleation Radiation Therapy for Large Choroidal Melanomas

Preoperative radiation did appear to lower the risk of orbital recurrence, although this was a rarely noted event (<1% of the total study population developed local relapse). No recurrences were noted in the preenucleation radiation therapy arm, and five biopsy-proven recurrences were documented in the enucleation-only arm. The five patients with orbital recurrence had metastatic melanoma diagnosed prior to diagnosis of the orbital recurrence and died less than 1 year after presentation of the local recurrence.

With no survival benefit noted from the COMS trial, routine preoperative orbital radiation therapy, as administered in this trial, would not be considered standard therapy. The COMS patients will continue to have follow-up assessments, but any late difference in survival is unlikely, as 46% of patients on study have died at time of this analysis. Preoperative or postoperative orbital radiation therapy may still be considered for selected patients who are at high risk for incomplete tumor excision or perioperative tumor seeding.

#### INVESTIGATIONAL RADIOTHERAPEUTIC TECHNIQUES.

**Radiosurgery and Fractionated Stereotactic Radiation Therapy.** High-dose, highly focused radiation therapy for small target lesions (<2 cm) can be accomplished by either gamma knife radiosurgery (multiple fixed, precisely aimed cobalt teletherapy beams) or stereotactic radiation therapy (multiple rotational arcs of photon beams from a linear accelerator). Both techniques are similar in their use of standard energy proton beams for treatment and rely on meticulous patient immobilization to deliver treatment to a precisely localized target within a coordinate mapping system. These techniques have been widely used and well described for the treatment of intracranial neoplasms (meningiomas, acoustic neuromas, and metastatic tumors) and for the ablation of arteriovenous malformations. Several recent retrospective series have examined the application of these techniques for the treatment of ocular melanomas.

The use of high-dose single-fraction Leksell gamma knife radiosurgery has been reported in a few small retrospective series.<sup>227,228</sup> This technique has been marked by significant adverse radiation reactions, including retinopathy, optic neuropathy, and glaucoma after treatment with 50 to 70 Gy in a single fraction. Optimal dose and technique have not yet been defined for this approach.

Linear accelerator (photon) fractionated stereotactic radiosurgery has been studied to use the radiobiologic advantage of multiple- rather than single-fraction treatment.<sup>229,230</sup> Reproducible immobilization of the head and eye is required, and active optical fixation systems, similar to proton beam techniques, have been described.<sup>231</sup> In these studies, 35 to 70 Gy has been delivered in 2 to 8 fractions. Outcome data and toxicity reports will require additional follow-up time, and further refinement of treatment technique will be necessary.<sup>232</sup> The preliminary data indicate a risk of significant adverse treatment effects with the techniques and radiation doses reported to date. The use of these techniques outside of the investigational setting is not recommended, except for patients who cannot be treated with proton beam or plaque therapy.

**Hyperthermia and Episcleral Plaque Radiation Therapy.** Hyperthermia has been investigated in conjunction with radiation therapy to treat a variety of tumors. Preclinical experiments have demonstrated that neoplastic cell lethality is proportional to temperature increase in the target tissue and that the combination of hyperthermia and radiation produces enhanced antitumor effects.<sup>233,234</sup> Ocular tumor heating has been achieved by a variety of techniques, including microwave applicators,<sup>235</sup> ultrasonic applicators, or ferromagnetic seeds.<sup>236</sup>

One of the primary objectives for combining hyperthermia and radiation is to reduce the radiation dose, which is expected to result in fewer visual complications with a comparable rate of tumor control. An initial report of combined hyperthermia and episcleral plaque therapy employed a 30% reduction in radiation dose (72 Gy, as compared to the prior standard dose of 100 Gy).<sup>237</sup> In this phase I study of 25 patients, 22 showed decrease in tumor height, and ambulatory vision (>5/200) was maintained in 20 patients. Two patients had severe complications (hemorrhagic retinal detachment and vitreous hemorrhage). Evaluation of long-term efficacy and late effects will require additional follow-up.

**Boron Neutron Capture Radiation Therapy.** BNCT is a specialized form of radiation therapy in which a neutron beam is targeted against a tumor that has been pretreated with a boron-containing compound. The boron nucleus is 10,000 times more likely than a hydrogen atom to capture a thermal neutron; therefore, preferential localization of boron in the tumor would result in precise and focal radiation delivery. The capture of the slow neutron by the boron nucleus leads to an energetic fission reaction with the formation of a lithium ion and an alpha particle (helium ion), accompanied by 2.4 MV of energy. The lithium and helium ions travel a distance of only 10 mm, limiting the lethal effect of the radiation to a radius approximately the diameter of one cell.<sup>238</sup>

The administration of boron-containing compounds and neutron radiation therapy has shown efficacy in the Greene melanoma-rabbit model.<sup>239</sup> Boronated compounds have been administered experimentally to human subjects with ocular melanoma prior to enucleation. Increased uptake of boron within the melanoma cells, compared to vitreous body, retina, and sclera was observed.<sup>240</sup> The use of BNCT in humans with melanoma, for the treatment of skin nodules, has been reported.<sup>241,242</sup> This approach for the treatment of ocular melanoma is at an early experimental stage, and further technical refinement will be required before clinical trials can be considered.

#### FUTURE DIRECTIONS FOR RESEARCH

Uveal melanoma, like retinitis pigmentosa, may not constitute a single disease; it may instead consist of an assortment of maladies with multiple genetic origins that simply culminate in a limited phenotype. In the case of retinitis pigmentosa, varying proportions of rod and cone photoreceptor cells degenerate owing to a variety of genetic mutations within the same or different genes.<sup>243</sup> In contrast to a phenotype associated with cell death, uveal melanoma is characterized by uncontrolled proliferation. Fundamentally different mechanisms can lead to unwarranted cell growth, supported in the case of uveal melanoma by cytogenetic<sup>15,25,244,245,246,247,248,249</sup> and biochemical<sup>33,234,251</sup> findings that disparate genetic events likely initiate the transformation of normal uveal melanocytes.

Cancer, as a multistage process, has an impact on a large number of genes and their related cellular pathways. Recent advances in both biochemical and molecular methods render it possible to study the cellular pathways that comprise this multistage process, endowing tumor cells with properties related to their malignant and metastatic capabilities. Such studies can provide significant information about the course of the disease and about effective treatments, independent of knowing the genetic mutations that cause the disease. It may, in fact, be more prudent to study the common cellular pathways that define the properties of these cells and to develop treatments based on these findings rather than attempting to “fix” a diverse array of genetic mutations.

Many features of ocular melanoma can be studied initially using established cell lines derived from biopsies of human tissues.<sup>53,100,252</sup> Normal uveal melanocytes also can be passaged in culture.<sup>253</sup> They are nonmalignant, neither growing in soft agar or athymic nude mice and, therefore, differ from uveal melanomas that can grow in either circumstance as well as alter the structure of the uvea and metastasize to other sites. Comparisons between *uveal melanocytes* and *uveal melanomas* can reveal the biochemical pathways that promote malignancy and metastatic disease. It is important to note, however, that the results obtained from *in vitro* studies need to be confirmed using primary tumor tissue.

In addition, although several properties associated with transformation can be studied *in vitro*, animal models are essential, since the most general and accepted definition of malignancy requires demonstrating the formation of invasive or metastasizing tumors *in vivo*. Cells derived from human uveal melanomas, for example, have been shown to grow in athymic nude mice after intraocular or subcutaneous inoculation; migration to the liver ensues, resulting in metastatic lesions and death.<sup>254,255</sup> An animal model, therefore, can be used to grade the malignant and metastatic properties of different cell lines; these cell lines then can be modified to alter the expression of a gene suspected of being involved in tumor progression, and the consequences for growth and dissemination of the tumor then can be measured in the animal.

As a first step, how can *in vitro* comparisons be made between uveal melanocytes and uveal melanomas? Genes and their products (proteins) that are uniquely expressed in one cell type can be identified by one of several new approaches, including differential display,<sup>256,257</sup> suppression subtractive hybridization,<sup>258</sup> two-dimensional gel electrophoresis–mass spectrometry<sup>259,260</sup> and, most recently, by using cDNA chip arrays.<sup>261</sup> As an example, subtractive cDNA hybridization recently was used to identify differences in mRNA species obtained from normal uveal melanocytes and an epithelioid melanoma cell line. Tissue Factor was among the genes identified and suspected of elevated expression in the melanoma cell line. Tissue Factor has angiogenic properties, contributing to the formation of new vessels associated with solid tumors,<sup>257,258,262,263</sup> and perhaps including uveal melanoma. The expression of angiogenic factors is an example of one of the cellular events contributing to the cancer phenotype but which has little to do with the initial genetic mutation underlying transformation. Also, treatments based on antiangiogenic strategies are a prime example of how studying cellular pathways can be beneficial.<sup>265</sup>

The differential expression of Tissue Factor was confirmed by Western blot analysis (detecting levels of protein) and by RNase protection assay (measuring levels of mRNA), as illustrated in [Figure 42.3-4A](#) and [Figure 42.3-4B](#). Thus, multiple techniques support *in vitro* findings that Tissue Factor is expressed at elevated levels in a uveal melanoma cell line compared to normal uveal melanocytes.

**FIGURE 42.3-4.** **A:** Tissue Factor (*open arrowhead*) was compared by Western blot analysis using protein from cultured uveal melanocytes (UM) and a uveal melanoma cell line (Mel). GAPDH immunostaining (*filled arrowhead*) served as a control for loading artifact. **B:** Tissue Factor mRNA was detected by RNase protection assay (symbols are the same as in **A**). **C:** Reverse transcriptase-polymerase chain reaction detection of Tissue Factor using specific primers and RNA isolated from a paraffin-embedded section of human uveal melanoma.

To avoid *in vitro* artifacts stemming from culture conditions, however, differential expression must be confirmed in primary ocular tissues. Biopsies from primary uveal melanomas and normal tissues derived from human donor eyes can be compared by Western blot analysis and by immunohistochemistry using specific antibodies. The expression of the corresponding genes also can be compared by Northern blot hybridization using the same ocular tissues. In addition, archival specimens can be used for case-corroborative purposes by employing such techniques as *in situ* hybridization, immunohistochemistry, and reverse transcriptase-polymerase chain reaction. As illustrated in [Figure 42.3-4c](#), RNA isolated from a 6-mm paraffin section of an enucleated eye with a uveal melanoma was used for reverse transcriptase-polymerase chain reaction with primers specific for Tissue Factor. Tissue Factor was detected in the primary tumor tissue, thus corroborating *in vitro* studies. In the near future, it will be especially informative to compare these sorts of detailed molecular findings with outcome data for patients made available through the collection of archival specimens.

Further correlations can be established between specific biochemical events and the malignant properties of an ocular tumor by genetic manipulation using established cell lines. Transfection experiments can be conducted to alter the level of expression of interesting genes (e.g., Tissue Factor); the consequences of altered expression on division, growth, and progression of the transfected cells then can be determined both *in vitro* and *in vivo*. In some cases, the biochemical function of the protein can be ascertained, and this provides further clues about additional portions of a cellular pathway that might be useful for targeted intervention. The promoters for melanocyte-specific genes also may be useful for targeting oncogenic expression in a transgenic animal, thereby creating an important model of uveal melanoma.

Oncogenes, such as the SV40 transgene producing the large T and small t antigens, can be used to generate pigmented tumors of the eye. To obtain models more representative of uveal melanoma, however, the transgene apparently needs to be driven by a promoter specific for uveal melanocytes rather than one common to multiple cell types.<sup>266,267</sup> Again, this can be accomplished by comparing normal uveal melanocytes with related ocular tissues and skin. Once the identification has been successful and an appropriate model of uveal melanoma available, the efficacy of different treatments can be evaluated more fully.

However, there is a general misconception that ocular melanoma and cutaneous melanoma are essentially the same disease and that research of the more prevalent skin disorder will satisfy needs within the ophthalmology community. This is not the case. The two diseases differ in their systemic symptoms, metastatic patterns, and susceptibility to treatments.<sup>268</sup> Clearly, the study of ocular melanoma remains within the purview of the vision scientist. Further, the advent of new molecular and biochemical techniques coupled with the availability of tissue specimens and established cell lines now renders it possible to advance our understanding and treatment of ocular tumors. Additionally, as has often been the case, studies of ocular tissues have enhanced our understanding of other tissue types and associated pathologies; delineating the cellular pathways contributing to cancer phenotypes in the eye should be no exception.

#### INTRODUCTION

Neoplastic transformation appears to be a multistep process in which the normal controls of cell proliferation and cell-cell interaction are lost, thus transforming a normal cell into a tumor cell. This tumorigenic process involves an interplay between different classes of genes, including oncogenes, tumor suppressor genes, DNA repair genes, and cell death genes. Alterations of these types of genes in turn underlie human brain tumor formation. In addition, such molecular genetic information has begun to have clinical significance, in both the classification and management of brain tumors. The following chapter reviews the molecular basis of brain tumorigenesis, covering primary tumors of the brain as well as other primary intracranial neoplasms that commonly affect the central nervous system.

#### DIFFUSE, FIBRILLARY ASTROCYTOMAS

##### FORMATION OF LOW-GRADE ASTROCYTOMA

Diffuse, fibrillary astrocytomas are the most common type of primary brain tumor in adults. These tumors are divided histopathologically into three grades of malignancy: World Health Organization (WHO) grade II astrocytoma, WHO grade III anaplastic astrocytoma, and WHO grade IV glioblastoma multiforme (GBM). WHO grade II astrocytomas are the most indolent of the diffuse astrocytoma spectrum. Nonetheless, these low-grade tumors are infiltrative and have a marked potential for malignant progression, and any biologic model for astrocytomas must account for these cardinal features of malignant progression and invasion. <sup>1</sup>

p53, a tumor suppressor encoded by the TP53 gene on chromosome 17p, has an integral role in a number of cellular processes, including cell-cycle arrest, response to DNA damage, apoptosis, angiogenesis, and differentiation. The TP53 gene is involved in the early stages of astrocytoma tumorigenesis. <sup>2</sup> TP53 mutations and allelic loss of chromosome 17p are observed in at least one-third of all three grades of adult astrocytomas, suggesting that inactivation of p53 is important in the formation of the grade II tumors. Moreover, high-grade astrocytomas with homogeneous TP53 mutations evolve clonally from subpopulations of similarly mutated cells present in initially low-grade tumors. <sup>3</sup> Such mutation studies are complemented by functional studies that have recapitulated the role of the p53 inactivation in the early stages of astrocytoma formation. For instance, cortical astrocytes from mice without functional p53 appear immortalized when grown *in vitro* and rapidly acquire a transformed phenotype. Cortical astrocytes from mice with one functional copy of TP53 behave more like wild-type astrocytes and only show signs of immortalization and transformation after they have lost the one functional TP53 copy. <sup>4,5</sup> Interestingly, those cells without functional p53 become markedly aneuploid, <sup>4</sup> confirming prior work showing that p53 loss results in genomic instability and that astrocytomas with mutant TP53 are often aneuploid. <sup>6</sup> Thus, the abrogation of astrocytic p53 function appears to facilitate some events integral to neoplastic transformation, setting the stage for further malignant progression.

Many growth factors and their receptors are overexpressed in astrocytomas, including platelet-derived growth factor (PDGF), fibroblast growth factors, and vascular endothelial growth factor (VEGF). PDGF ligands and receptors are expressed approximately equally in all grades of astrocytoma, suggesting that such overexpression is also important in the initial stages of astrocytoma formation. Tumors often overexpress cognate PDGF ligands and receptors in an autocrine stimulatory fashion. <sup>7</sup> The mechanisms for PDGF overexpression in most cases have not been elucidated, although rare astrocytomas display amplification of the PDGF- $\alpha$  receptor gene. Significantly, loss of chromosome 17p in the region of the TP53 gene is closely correlated with PDGF- $\alpha$  receptor overexpression, in that 17p loss is most often seen in those astrocytomas that have PDGF- $\alpha$  receptor overexpression. <sup>8</sup> These observations may imply that TP53 mutations have an oncogenic effect only in the presence of PDGF- $\alpha$  receptor overexpression. This interdependence is highlighted by observations that mouse astrocytes without functional p53 become transformed only in the presence of specific growth factors. <sup>5</sup>

Astrocytomas display a remarkable tendency to infiltrate the surrounding brain, confounding therapeutic attempts at local control. These invasive abilities are often apparent in low-grade as well as high-grade tumors, implying that the invasive phenotype is acquired early in tumorigenesis. Investigations into astrocytoma invasion have highlighted the complex nature of cell-cell and cell-extracellular matrix interactions. <sup>9,10</sup> A variety of cell surface and extracellular matrix molecules such as CD44 glycoproteins, gangliosides, and integrins are differentially expressed in astrocytomas. Many of the growth factors expressed in astrocytomas, such as fibroblast growth factor, epidermal growth factor (EGF), and VEGF, also stimulate migration. <sup>9</sup> Such growth factors, cell surface receptors, and extracellular molecules most likely reflect a dynamic interplay between cell-cell adhesion, remodeling of the extracellular matrix, and cell motility. <sup>10</sup>

Less common molecular changes also occur in grade II astrocytomas. Loss of chromosome 22q, for instance, suggests the presence of a chromosome 22q glioma tumor suppressor gene. <sup>11</sup> Comparative genomic hybridization studies have also demonstrated common gains of chromosome 7q in low-grade astrocytomas. <sup>12</sup> Finally, methylation of critical growth regulatory genes has been noted in some astrocytomas and may be another mechanism for gene alteration (W. Cavenee, unpublished data).

##### PROGRESSION TO ANAPLASTIC ASTROCYTOMA

The transition from WHO grade II astrocytoma to WHO grade III anaplastic astrocytoma is accompanied by a marked increase in malignant behavior. Although many patients with grade II astrocytomas survive for 5 or more years, patients with anaplastic astrocytomas often die within 2 or 3 years and frequently show transformation to GBM. Histologically, the major differences between grade II and grade III tumors are increased cellularity and the presence of mitotic activity, implying that higher proliferative activity is the hallmark of the progression to anaplastic astrocytoma.

A number of molecular abnormalities have been associated with anaplastic astrocytoma, and some studies have suggested that most of these abnormalities converge on one critical cell-cycle regulatory complex that includes the p16, cyclin-dependent kinase-4 (cdk4), cdk6, cyclin D1, and retinoblastoma (RB) proteins. The simplest schema suggests that p16 inhibits the cdk6/cyclin D1 or cdk4/cyclin D1 complex, preventing these complexes from phosphorylating pRB, and so ensuring that pRB maintains its brake on the cell cycle. Individual components in this pathway are altered in up to 50% of anaplastic astrocytomas and in the majority of GBM.

Chromosome 9p loss occurs in approximately 50% of anaplastic astrocytomas and GBMs, with 9p deletions primarily affecting the region of the CDKN2A gene, <sup>13</sup>

which encodes the p16 protein and the p14ARF protein. The CDKN2A gene is inactivated either by homozygous deletion or, less commonly, by point mutations or hypermethylation, thereby affecting p16 and p14ARF expression.<sup>14,15</sup> and <sup>16</sup> Moreover, replacement of CDKN2A/p16 into GBM cell lines lacking the gene results in growth suppression.<sup>17</sup>

Loss of chromosome 13q occurs in one-third to one-half of high-grade astrocytomas, with the RB gene preferentially targeted by losses and inactivating mutations.<sup>18</sup> Overall, analysis of chromosome 13q loss, RB gene mutations and RB protein expression suggests that the RB gene is inactivated in approximately 20% of anaplastic astrocytomas and 35% of GBM.<sup>14,18</sup> Interestingly, RB and CDKN2A/p16 alterations in primary gliomas are inversely correlated, rarely occurring together in the same tumor.<sup>13</sup>

Amplification of the CDK4 gene provides an alternative to subvert cell-cycle control and facilitate progression to GBM.<sup>19</sup> CDK4, located on chromosome 12q13-14, is amplified in 15% of malignant gliomas,<sup>20</sup> although this frequency may be higher among cases without CDKN2A/p16 loss, perhaps reaching 50% of GBMs without CDKN2A/p16 loss.<sup>19</sup> CDK4 amplification and CDKN2A/p16 deletions do not occur together in GBM cell lines and some GBM cell lines overexpress cyclin D1.<sup>21</sup> On the other hand, in some GBMs and GBM cell lines, CDK4 amplification and cyclin D1 overexpression appear to represent alternative events to CDKN2A/p16 deletions, because these genetic changes only rarely occur in the same tumors.<sup>19,21</sup> CDK6 amplification also occurs, although not as commonly as CDK4 amplification.<sup>22</sup>

Allelic losses on 19q have been observed in up to 40% of anaplastic astrocytomas and GBMs, indicating a progression-associated glial tumor suppressor gene on chromosome 19q.<sup>23</sup> This tumor suppressor gene may be unique to glial tumors<sup>24</sup> and is involved in all three major types of diffuse cerebral gliomas (astrocytomas, oligodendrogliomas, and oligoastrocytomas). This gene maps to a region of chromosome 19q13.3, telomeric to the marker D19S412 and centromeric to the STD locus gene,<sup>25,26</sup> but is yet to be identified.

## PROGRESSION TO GLIOBLASTOMA MULTIFORME

GBM is the most malignant stage of astrocytoma, with survival times of less than 2 years for most patients. Histologically, these tumors are characterized by dense cellularity, high proliferation indices, microvascular proliferation, and focal necrosis. The highly proliferative nature of these lesions is no doubt the result of multiple mitogenic effects. As mentioned previously, at least one such effect is deregulation of the p16-cdk4-cyclin D1-pRB pathway of cell-cycle control. The vast majority, if not all, GBMs have alterations of this system, whether it be inactivation of p16 or pRB or overexpression of cdk4.<sup>13,19</sup>

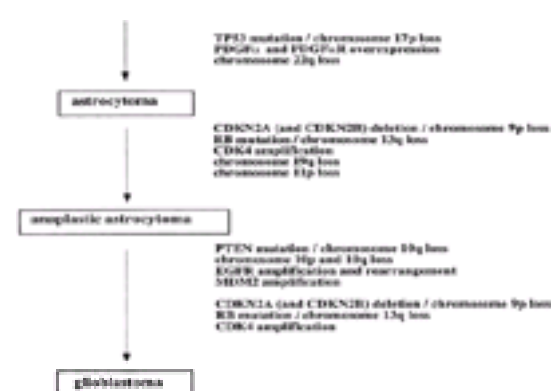

Chromosome 10 loss is a frequent finding in GBM, occurring in 60% to 95% of GBMs but far less commonly in anaplastic astrocytomas.<sup>27,28</sup> At least two tumor suppressor loci are present on the long arm of chromosome 10, and there may be a third locus on the short arm. The PTEN/MMAC1/TEP-1 gene at 10q23.3 has been implicated as one of these genes, with PTEN mutations identified in approximately 20% of GBM.<sup>29,30</sup> and <sup>31</sup> PTEN functions as a protein tyrosine phosphatase and has 3' phosphoinositol phosphatase activity; in addition, PTEN has an amino-terminal domain with homologies to tensin and auxilin.<sup>10</sup> Thus, PTEN may regulate cell migration via affecting focal adhesion kinase and may regulate cell proliferation via control of the AKT serine/threonine kinase. Indeed, introduction of wild-type PTEN into glioma cells with mutant PTEN leads to growth suppression.<sup>32</sup> Nonetheless, given the remarkably high frequency of chromosome 10 loss in GBM, it is likely that other glioma tumor suppressors reside on this chromosome; one candidate is the DBMT1 gene.<sup>33</sup>

EGFR is a transmembrane receptor tyrosine kinase, whose ligands include EGF and transforming growth factor- $\alpha$ . The EGFR gene is the most frequently amplified oncogene in astrocytic tumors,<sup>34</sup> being amplified in approximately 40% of all GBM<sup>27</sup> but in few anaplastic astrocytomas.<sup>35</sup> Those GBMs that exhibit EGFR gene amplification have almost always lost genetic material on chromosome 10<sup>27</sup> and often have CDKN2A deletions.<sup>36</sup> GBMs with EGFR gene amplification display overexpression of EGFR at both the mRNA and protein levels, suggesting that activation of this growth signal pathway is integral to malignant progression to GBM.<sup>35,37</sup> Approximately one-third of those GBM with EGFR gene amplification also have specific EGFR gene rearrangements, which produce truncated molecules similar to the v-erbB oncogene.<sup>10</sup> These truncated receptors are capable of conferring dramatically enhanced tumorigenicity to GBM cells.<sup>38</sup> The downstream targets of EGFR activation in GBMs include the Shc-Grb2-ras pathway, involving EGFR in a cascade that facilitates mitogenesis and decreases apoptosis in tumor cells.<sup>39</sup> Less commonly amplified oncogenes include *N-myc*, *gli*, PDGF- $\alpha$  receptor, *c-myc*, *myb*, *K-ras*, CDK4, and MDM2.

As mentioned previously, one of the hallmarks of GBM is microvascular proliferation. A host of angiogenic growth factors and their receptors are found in GBMs.<sup>10</sup> For example, VEGF and PDGF are expressed by tumor cells while their tyrosine kinase receptors, VEGF receptors 1 and 2 for VEGF and the PDGF- $\beta$  receptor for PDGF, are expressed on endothelial cells. VEGF and its receptors, in particular, appear to play a major role in GBM angiogenesis.<sup>40,41</sup> and <sup>42</sup> A paracrine mechanism has been suggested in which VEGF is secreted by tumor cells and bound by the VEGF receptors on endothelial cells. Interestingly, VEGF is preferentially up-regulated by tumor cells surrounding regions of necrosis, perhaps as a result of necrosis-induced hypoxia, since hypoxia can up-regulate VEGF. In addition, PDGF may up-regulate VEGF expression by endothelial cells, thereby providing an early stimulus for angiogenesis.<sup>43</sup> A link between p53 and tumor angiogenesis has been suggested by the observations that some mutant p53 molecules can enhance VEGF expression<sup>44</sup> and that wild-type p53 regulates the secretion of a glioma-derived angiogenesis inhibitory factor.<sup>44</sup> Related mechanisms may also be responsible for tumoral edema in GBM, because some of these angiogenic molecules, such as VEGF, may also cause vascular permeability and hence tumoral edema.

## SUBSETS OF GLIOBLASTOMA MULTIFORME

The assumption that all astrocytomas progress through distinct genetic stages in a linear fashion is most likely an oversimplification. Indeed, it appears as if there are biologic subsets of astrocytomas that may reflect the clinical heterogeneity observed in these tumors<sup>45</sup> (Fig. 43.1-1). For instance, approximately one-third of GBM have TP53/chromosome 17p alterations, one-third have EGFR gene amplification, and one-third have neither change<sup>46</sup> (i.e., TP53 mutations and EGFR amplification are mutually exclusive). Experimental data also support this distinction by showing that p53-deficient cells are not transformed when cultured in the presence of EGF, whereas they are transformed in the presence of other growth factors.<sup>5</sup> Primary GBMs with TP53 mutations may therefore not be expected to acquire EGFR gene amplification, if activation of the EGF-EGFR system does not produce a growth advantage in such cells.

**FIGURE 43.1-1.** Molecular alterations characteristic of different stages of astrocytoma progression. EGFR, epidermal growth factor receptor; PDGF $\alpha$ (R), platelet-derived growth factor- $\alpha$  (receptor).

The genetic pathway involving TP53 mutations often involves progression from a lower grade astrocytic lesion, so-called secondary GBM.<sup>46, 47</sup> and <sup>48</sup> On the other hand, those GBM with EGFR amplification may arise either *de novo* or rapidly from a preexisting tumor, without a clinically evident, preceding lower-grade astrocytoma.<sup>46,47</sup> Interestingly, younger age at initial diagnosis has been an important prognostic parameter among patients with GBM, with younger patients faring better than older patients. In turn, those GBMs with loss of chromosome 17p occur in patients younger than those characterized by EGFR gene amplification.<sup>49,50</sup> The predominance of tumors with 17p loss in a younger population of astrocytoma patients may therefore reflect the age-based difference in prognosis. The data suggest that genetic analysis may begin to explain the clinical observations concerning age differences in astrocytic tumors. However, convincing differences in prognosis have not been found in a variety of retrospective studies of either TP53 or EGFR alterations in GBM. Nonetheless, because effective therapies do not exist for GBM, possible clinical

differences may be obscured by the universally grim prognosis of these tumors (see [Oligodendrogliomas and Oligoastrocytomas](#), later in this chapter).

## OTHER GLIOMAS

### OTHER ASTROCYTOMAS

Pilocytic astrocytoma is the most common astrocytic tumor of childhood and differs clinically and histopathologically from the diffuse, fibrillary astrocytoma that affects adults. Pilocytic astrocytomas do not have the same genomic alterations as diffuse, fibrillary astrocytomas. Because pilocytic astrocytomas frequently affect patients with neurofibromatosis type 1 (NF1), it would not be surprising if the NF1 gene on chromosome 17q were altered in pilocytic astrocytomas; in fact, allelic loss occurs on chromosome 17q in one-fourth of cases.<sup>51</sup> Unfortunately, detailed mutational analysis of the NF1 gene in pilocytic tumors has not yet been performed, because of the large size of the gene.

Other pediatric astrocytic tumors are histologically similar to the astrocytomas, anaplastic astrocytomas, and GBMs that occur in adults. Some of these are associated with similar genetic alterations, such as TP53 mutations. For instance, brain stem gliomas have frequent TP53 gene and chromosome 17p alterations without EGFR gene amplification,<sup>52</sup> as do those diffuse cerebral astrocytic tumors that occur in children older than 4 years of age.<sup>53</sup> Desmoplastic cerebral astrocytoma of infancy and desmoplastic infantile ganglioglioma are large, superficial, usually cystic, benign astrocytomas that affect children in the first year or two of life. Allelic loss of chromosomes 10 or 17 have not been detected in these lesions.<sup>54</sup> In adult gangliogliomas, another benign form of astrocytic glioma, EGFR gene amplification or allelic loss on chromosomes 10, 13q, 17p, 19q, and 22q has not been detected (A. von Deimling and D. N. Louis, unpublished data).

Pleomorphic xanthoastrocytoma (PXA) is a superficial, low-grade astrocytic tumor that predominantly affects young adults. While these tumors have a bizarre histologic appearance, they are typically slow-growing tumors that may be amenable to surgical cure. Some PXAs, however, may recur as GBM. Nonetheless, the genetic events that underlie PXA formation and progression differ from those involved in diffuse astrocytoma tumorigenesis.<sup>55</sup> PXAs may have TP53 mutations, but the few documented mutations have been somewhat different from those usually found in diffuse, fibrillary astrocytomas.<sup>55</sup> EGFR gene amplification does not occur in PXAs, but GBMs that arise from PXAs may display EGFR gene amplification. On the other hand, allelic losses of chromosomes 9, 10, and 19q are not observed in PXA.

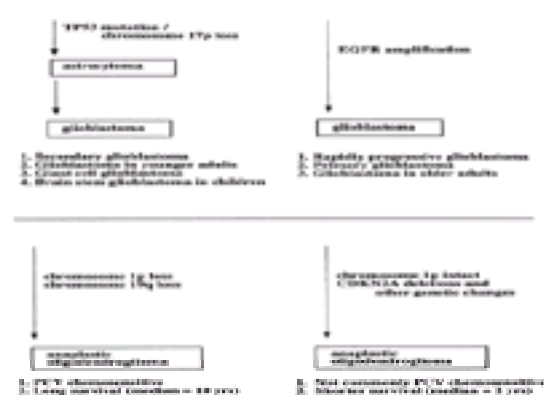

Subependymal giant cell astrocytomas (SEGA) are periventricular, low-grade astrocytic tumors that are usually associated with tuberous sclerosis (TS) and are histologically identical to the so-called candle-gutterings that line the ventricles of TS patients. Similar to the other tumorous lesions in TS, these are slowly growing and may be more akin to hamartomas than true neoplasms. The association of SEGA with TS leads to the prediction that the TS genes, TSC1 on chromosome 9q and TSC2 on chromosome 16p (see [Neurologic Tumor Syndromes](#), later in this chapter), are involved in SEGA formation. Loss of heterozygosity studies have shown allelic loss of chromosome 9q and 16p loci in some SEGAs, particularly of the TSC2 locus on 16p, suggesting that the TS genes act as tumor suppressors.<sup>56,57 and 58</sup>

### OLIGODENDROGLIOMAS AND OLIGOASTROCYTOMAS

Oligodendrogliomas and oligoastrocytomas (mixed gliomas) are diffuse, usually cerebral, tumors that are clinically and biologically most closely related to the diffuse, fibrillary astrocytomas. The tumors, however, are less common than astrocytomas and have generally better prognoses than the diffuse astrocytomas; patients with WHO grade II oligodendrogliomas, for instance, may have mean survival times of 10 years. In addition, oligodendroglial tumors appear to be differentially chemosensitive,<sup>59</sup> when compared with the diffuse astrocytomas.

Allelic losses in oligodendrogliomas and oligoastrocytomas occur preferentially on chromosomes 1p and 19q, affecting 40% to 80% of these tumor types.<sup>23,60,61</sup> Because of the frequent loss of these loci in low-grade as well as anaplastic oligodendrogliomas and oligoastrocytomas, the 1p and 19q tumor suppressors are probably important early in oligodendroglial tumorigenesis. Mapping of the chromosome 19q locus has demonstrated that the gene resides in the same vicinity as the astrocytoma gene and is likely the same gene.<sup>25,62</sup> Similar mapping of chromosome 1p has implicated the telomeric region of 1p.<sup>61,62</sup> Interestingly, chromosome 1p and 19q losses are closely associated; oligodendroglial tumors with 1p loss typically also have loss of 19q, suggesting that these two putative tumor suppressor genes may be involved in biologically distinct pathways.<sup>60,61</sup> In fact, microdissection of the oligodendroglial and astrocytic components in oligoastrocytomas has shown that, despite the histologic differences, the molecular changes are identical in these two components.<sup>61</sup> Oligoastrocytomas may also suffer allelic losses of chromosome 17p,<sup>60</sup> although these losses are not often associated with TP53 mutations,<sup>60,63</sup> perhaps implying a second chromosome 17p glioma gene. Oncogene amplification has only rarely been noted in oligodendroglial tumors.<sup>34,60</sup>

Oligodendrogliomas and oligoastrocytomas may progress, either to WHO grade III anaplastic oligodendroglioma or anaplastic oligoastrocytoma, and sometimes to higher-grade tumors with histologic features similar to GBM ([Fig. 43.1-2](#)). Anaplastic oligodendrogliomas and oligoastrocytomas may display allelic losses of chromosomes 9p involving the CDKN2A gene and chromosome 10.<sup>60,64</sup> Thus, allelic loss of chromosome 10 may be a common finding in high-grade malignant gliomas, whether they are astrocytic or oligodendroglial in original lineage.<sup>28</sup>

**FIGURE 43.1-2.** Molecular genetic subsets of glioblastoma multiforme (see text for details). PCV, procarbazine, CCNU, and vincristine.

Anaplastic oligodendrogliomas have proven to be the first brain tumor for which molecular genetic analysis has had practical clinical ramifications: Anaplastic oligodendrogliomas that have allelic losses of chromosomes 1p and 19q follow different clinical courses from those tumors that do not have these genetic changes. Anaplastic oligodendrogliomas that have 1p and 19q loss are essentially always sensitive to procarbazine, lomustine, and vincristine chemotherapy, with nearly 50% of such tumors demonstrating complete neuroradiologic responses; correspondingly, patients whose tumors have 1p and 19q loss have median survivals of approximately 10 years.<sup>64</sup> On the other hand, anaplastic oligodendrogliomas that lack 1p and 19q loss are only chemosensitive approximately 25% of the time and only rarely have complete neuroradiologic responses; as a result, patients whose anaplastic oligodendrogliomas lack 1p and 19q loss have median survivals of approximately 2 years.<sup>64</sup> Thus, molecular genetic analysis of 1p/19q allelic status has already become a clinically useful test in neurooncology and is most likely an indication of the utility of molecular diagnostic approaches in neurooncology.

### EPENDYMOMAS AND CHOROID PLEXUS TUMORS

Ependymomas are a clinically diverse group of gliomas that vary from aggressive intraventricular tumors of children to benign spinal cord tumors in adults. Chromosome 22q loss is common in ependymomas.<sup>65,66</sup> A candidate glioma tumor suppressor gene on chromosome 22q is the NF2 gene, because NF2 patients have a higher incidence of gliomas, particularly spinal ependymomas, in addition to schwannomas and meningiomas. Analysis of the NF2 gene in spinal ependymomas has revealed mutations and deletions, confirming the role of the NF2 gene alterations in the genesis of spinal ependymomas.<sup>67,68</sup> For cerebral ependymomas, the paucity of NF2 mutations suggests that another, as yet unidentified, chromosome 22q gene will probably be a more integral ependymoma locus. The TP53 gene is not mutated in ependymomas<sup>69</sup> or in the malignant transformation of ependymomas to anaplastic ependymoma (S. Cortez and D. N. Louis, unpublished data).

Choroid plexus tumors are also a varied group of tumors that preferentially occur in the ventricular system, ranging from aggressive supratentorial intraventricular tumors of children to benign cerebellopontine angle tumors of adults. Choroid plexus tumors have been reported occasionally in patients with Li-Fraumeni syndrome and von Hippel-Lindau (VHL) disease (as well as in Aicardi's syndrome, which does not predispose to cancer), raising the possibility that the TP53 gene on chromosome 17p, responsible for Li-Fraumeni syndrome, or the VHL gene on chromosome 3p is involved in choroid plexus neoplasia. Studies of human choroid plexus tumors have not shown TP53 mutations, but choroid plexus neoplasms may be induced in transgenic mice by disrupting p53 and pRB function.<sup>69</sup> VHL mutations have also not been documented in choroid plexus tumors, but some reported choroid plexus tumors in VHL patients may instead reflect papillary tumors of the middle ear (endolymphatic sac tumors), which occur in higher frequency in VHL patients and which histologically resemble choroid plexus neoplasms.

Oncogenic viruses may cause human cancer, particularly those viruses whose products interfere with tumor suppressor gene functions, such as the human papillomaviruses implicated in cervical carcinoma. One study has identified sequences similar to SV40 virus, an oncogenic virus that has the ability to inactivate both the RB and p53 proteins in human ependymomas and choroid plexus papillomas.<sup>70</sup> This observation raised considerable excitement since SV40 has been implicated as an oncogenic factor in transgenic models of choroid plexus neoplasia.<sup>69</sup> However, SV40-like sequences have not been found in other choroid plexus papillomas or ependymomas and the role of oncogenic viruses in these tumors remains undefined.

## MEDULLOBLASTOMAS

Medulloblastomas are highly malignant, primitive tumors that arise in the posterior fossa, primarily in children. One-third to one-half of all medulloblastomas have an isochromosome 17q on cytogenetic analysis,<sup>71</sup> and corresponding allelic loss of chromosome 17p has been noted on molecular genetic analysis.<sup>72,73</sup> TP53 mutations, however, are rare in medulloblastomas.<sup>63,74</sup> Allelic losses occur preferentially at regions of chromosome 17p that are telomeric to the TP53 locus,<sup>73,75</sup> implying the presence of a second, more distal chromosome 17p tumor suppressor gene. Allelic losses of chromosome 6q, 11, and 16q have also been noted frequently in these tumors,<sup>72</sup> as have genomic losses on chromosomes 10q, 11, 16q, 17p, and 8p,<sup>76</sup> but deletions of the CDKN2A gene, which are common in many tumors, do not occur in medulloblastomas.<sup>77</sup> Oncogene amplification has not been found frequently in medulloblastomas; only c-myc is amplified in significant numbers of cases and this change appears more common in medulloblastoma cell lines than in primary tumors.<sup>71</sup> Comparative genomic hybridization studies have demonstrated amplification of chromosome bands 5p15.3 and 11q22.3 and gains of chromosomes 17q and 7.<sup>76</sup>

The discovery of genes underlying two hereditary tumor syndromes has directed attention to two pathways involved in medulloblastoma tumorigenesis. Gorlin syndrome, a condition characterized by multiple basal cell carcinomas (also termed *basal cell nevoid syndrome*), bone cysts, dysmorphic features, and medulloblastomas arises from defects in the PTCH gene on the long arm of chromosome 9, a homologue of the *Drosophila* patched gene. Medulloblastomas, particularly the nodular desmoplastic variants that are characteristic of Gorlin syndrome, can show allelic loss of chromosome 9q and PTCH mutations.<sup>78,79</sup> and <sup>80</sup> The protein encoded by PTCH functions in the pathway regulated by the Sonic hedgehog protein; other molecules in this pathway include smoothened, and rare smoothened mutations have been documented in sporadic medulloblastomas.<sup>81</sup> Turcot syndrome, a condition characterized by colonic tumors and brain tumors, is also linked to medulloblastoma; patients with the adenomatous polyposis phenotype may develop medulloblastomas, and these patients often have mutations of the APC gene on chromosome 5q.<sup>82</sup> Curiously, APC gene mutations and loss of chromosome 5q are rare in sporadic medulloblastomas.<sup>83</sup> The APC protein operates in a molecular pathway that includes the *b*-catenin protein, and rare mutations of *b*-catenin have now been noted in sporadic medulloblastomas.<sup>84</sup> It is likely that other components of these two pathways will also be implicated in medulloblastoma tumorigenesis.

The question of whether molecular analyses can provide ancillary information for the management of medulloblastoma patients remains open. Some papers have suggested that patients whose tumors have loss of chromosome 17p may follow a more aggressive course,<sup>85</sup> but this has not been a universal finding. Others have provided intriguing evidence that the level of expression of the trkC receptor may relate to prognosis, with those tumors showing high trkC expression following a more favorable course.<sup>86</sup>

## MENINGIOMAS

Meningiomas are common intracranial tumors that arise in the meninges and compress the underlying brain. Meningiomas are usually benign, but some atypical meningiomas may recur locally, and some meningiomas are frankly malignant. Monosomy 22 is common in meningiomas, with the NF2 gene on chromosome 22q frequently mutated in meningiomas, clearly implicating it in meningothelial tumorigenesis.<sup>87,88</sup> and <sup>89</sup> In sporadic meningiomas, both chromosome 22q allelic loss and NF2 gene mutations are more common in fibroblastic and transitional subtypes than in meningothelial forms.<sup>88</sup> As in schwannomas (see [Peripheral Nerve Tumors](#), later in this chapter), NF2 gene alterations result predominantly in immediate truncation, splicing abnormalities, or altered reading frames, producing grossly truncated proteins.

Approximately 40% of meningiomas have neither NF2 gene mutations nor allelic loss of chromosome 22q. For these tumors, it is likely that a second meningioma tumor suppressor gene is involved. This putative second gene is probably not on chromosome 22q, since NF2 gene mutations in meningiomas correlate fairly closely with chromosome 22q loss. Nonetheless, a few meningiomas have been described with loss of portions of chromosome 22q that do not include the NF2 gene, suggesting the possibility of a second meningioma locus on chromosome 22.<sup>90</sup> Furthermore, a family with multiple meningiomas but without vestibular schwannomas does not show linkage to the NF2 locus on chromosome 22q, suggesting yet another meningioma predisposition gene.<sup>91</sup> One study has suggested that alternative meningioma genes may reside on chromosomes 1p and 3p.<sup>92</sup> Allelic losses in meningiomas have been noted on a variety of other chromosomes, including 1p, 3p, 5p, 5q, 11, 13, and 17p.<sup>93,94</sup>

Atypical and malignant meningiomas are not as common as benign meningiomas. Atypical meningiomas often show allelic losses of chromosomal arms 1p, 6q, 9q, 10q, 14q, 17p, and 18q, suggesting that progression-associated genes may lie at these loci.<sup>94,95</sup> and <sup>96</sup> More frequent losses of chromosomes 6q, 9p, 10, and 14q also occur in anaplastic meningiomas.<sup>94</sup> Chromosomal gains have also been noted in higher-grade meningiomas, with gains of chromosomes 20q, 12q, 15q, 1q, 9q, and 17q most commonly observed.<sup>94</sup> Chromosome 10 loss, in particular, has been associated with those meningiomas with morphologic features of malignancy, rather than those meningiomas that are designated as malignant on the basis of brain invasion alone.<sup>96</sup> Interestingly, brain invasion used to be considered a histologic indicator of malignancy in meningiomas; molecular genetic inquiries have, however, shown that histologically benign meningiomas that invade the brain do not have the molecular hallmarks of higher-grade meningiomas.<sup>94,96</sup> These observations provide another example of how molecular genetic investigations have clarified grading issues in neurooncology.

## PERIPHERAL NERVE TUMORS

Schwannomas are benign tumors that arise on peripheral nerves. Schwannomas may arise on cranial nerves, particularly the vestibular portion of the eighth cranial nerve (vestibular schwannomas, acoustic neuromas) where they present as cerebellopontine angle masses. NF2 patients are defined by the presence of bilateral vestibular schwannomas,<sup>97</sup> although unilateral vestibular schwannomas are common in the general population as well. Therefore, like meningiomas, schwannomas occur frequently in NF2 patients, have frequent loss of chromosome 22q, and harbor NF2 gene mutations in at least 50% of cases, in vestibular tumors as well as schwannomas from other sites.<sup>97</sup> The majority of the somatic changes are small deletions or insertions that create either frameshifts and premature stop codons or altered splicing. Inactivating mutations are relatively evenly distributed across the first 15 exons with no outstanding hot spots. Furthermore, loss of the NF2 gene—encoded merlin protein occurs in all schwannomas, consistent with an integral and universal role for NF2 gene inactivation in schwannoma formation.<sup>98</sup> Thus, inactivation of NF2 is a common feature underlying both inherited and sporadic forms of schwannoma.

Neurofibromas are also benign tumors of peripheral nerve that most often arise on distal, superficial nerves. Multiple neurofibromas are associated with NF1, suggesting that the NF1 gene on chromosome 17q is involved in the genesis of these benign nerve sheath lesions. Unfortunately, the large size of the NF1 gene has precluded extensive mutation analysis in these lesions. Neurofibromas, particularly the plexiform variants associated with NF1, have the potential for malignant progression to malignant peripheral nerve sheath tumors, a transition that is associated with inactivation of the NF1, TP53, and CDKN2A genes.<sup>99, 100</sup> and <sup>101</sup>

## MISCELLANEOUS TUMORS

### HEMANGIOBLASTOMAS

Hemangioblastomas are tumors of uncertain origin that are composed of endothelial cells, pericytes, and so-called stromal cells. These benign tumors most frequently occur in the cerebellum and spinal cord of young adults. Multiple hemangioblastomas are characteristic of VHL, an inherited tumor syndrome in which patients have a tendency to develop tumors, particularly hemangioblastomas, retinal angiomas, renal cell carcinomas, and pheochromocytomas.<sup>102</sup> Allelic loss occurs in hemangioblastomas in the region of the VHL gene on chromosome 3p<sup>103</sup> and the VHL gene is mutated in sporadic hemangioblastomas.<sup>104</sup> These observations suggest that the VHL gene acts as a classical tumor suppressor and is involved in both sporadic hemangioblastomas and familial tumors. The mechanism of action of the VHL protein appears complex, with evidence suggesting that it may stabilize mRNA of angiogenic compounds such as VEGF,<sup>105</sup> as well as extracellular matrix components such as fibronectin.<sup>106</sup> These actions at least begin to explain the highly vascular nature of hemangioblastomas.

## HEMANGIOPERICYTOMAS

Hemangiopericytomas (HPCs) are dural tumors that may display locally aggressive behavior and may metastasize. The histogenesis of dural-based HPC has long been debated, with some authors classifying it as a distinct entity and others classifying it as a subtype of meningioma. Molecular genetic studies have greatly clarified this issue. Meningiomas contain frequent mutations of the NF2 gene, whereas HPCs do not, suggesting that HPC is genetically distinct from meningioma.<sup>107</sup> In addition, homozygous deletions of the CDKN2A gene are common in HPCs but not in meningiomas and suggest that alterations of the p16-mediated cell-cycle regulatory pathway may underlie the malignant potential of some HPCs.<sup>108</sup> Rearrangements of chromosome 12q13 are common in peripherally located, soft tissue HPCs and have been reported in meningeal HPCs, implying that an oncogene or tumor suppressor gene at this locus is important in HPC formation. A number of oncogenes reside in this region, including MDM2, CDK4, and CHOP/GADD153.

## NEUROLOGIC TUMOR SYNDROMES

Hereditary neurologic tumor syndromes, in which patients are at risk for developing multiple nervous system tumors, have provided important clues to the genetic basis of brain tumors. These tumor syndromes provide unique insights into tumor suppressor genes. For instance, the hereditary RB syndrome, which provided much of the impetus for current tumor suppressor gene research, results from a mutation in both RB tumor suppressor alleles.<sup>109</sup> In the case of familial RB, the patient inherits one mutant, inactive copy of the RB gene and thus carries a germline mutation in every cell,<sup>110</sup> which is unveiled when the second copy of the gene is inactivated, either by mutation or by loss of a portion of chromosome 13q. A patient with sporadic RBs does not carry the germline mutation and must acquire both inactivating hits in the same cell during his or her life. Therefore, a familial RB patient, in which every cell contains a mutation, is much more likely to develop a second RB than a sporadic RB patient. This same paradigm appears to hold true for most, but not all,<sup>111</sup> of the hereditary brain tumor syndromes.

Neurologic tumor syndromes include the so-called neurocutaneous syndromes, such as NF1, NF2, TS, and VHL, and other tumor conditions such as Li-Fraumeni, Turcot, Gorlin, and Cowden syndromes.<sup>97,102,111,112</sup> and <sup>113</sup> Each syndrome is accompanied by a characteristic panoply of tumors, both neurologic and nonneurologic. A catalogue of only the gliomas would feature optic nerve gliomas and other astrocytomas in NF1; ependymomas and astrocytomas in NF2; SEGAs in TS; and various malignant gliomas in Li-Fraumeni syndrome, Turcot syndrome, and the hereditary glioma pedigrees. Linkage studies have provided powerful means for tracking down the genes associated with these tumor syndromes and have assigned the NF1 gene to chromosome 17q; the NF2 gene to chromosome 22q; the TS genes to chromosome 9q and 16p; and Turcot syndrome genes to chromosome 5q (APC gene) and to the DNA mismatch repair genes on various chromosomes. The NF1 gene codes for a guanosine triphosphatase-activating protein termed *neurofibromin*. Neurofibromin interacts with the p21 product of the *ras* oncogene and is most likely important in growth factor-mediated signal transduction. The NF2 gene codes for a protein, termed *merlin*, which most likely functions by facilitating signal transduction from the cell surface via the cytoskeleton. One of the TS genes, TSC2 on chromosome 16p, TSC2 encodes a guanosine triphosphatase activating protein-related protein, tuberlin; whereas the TSC1 gene on 9q encodes a protein known as *hamartin* that has no known homology to other proteins. Nonetheless, tuberlin and hamartin appear to bind one another and function in a single cellular pathway, consistent with a similar phenotype for patients with either TSC1 or TSC2 gene mutations. For the Li-Fraumeni syndrome, mutational analyses have implicated the TP53 gene on 17p.

## SUMMARY

Human brain tumors have molecular alterations that are characteristic of each type of tumor and of most stages of progression. For instance, the formation of low-grade astrocytoma and the subsequent progression to anaplastic astrocytoma and GBM involve alterations of distinct tumor suppressor genes and oncogenes. Furthermore, molecular genetic analysis has been used to distinguish subsets of astrocytomas. For instance, one type of GBM, characterized by TP53 gene mutations, is more common in younger patients and may be associated with slower progression from lower-grade astrocytoma; another type of GBM, characterized by EGFR gene amplification, is more common in older patients and may be associated with more rapid progression or *de novo* growth. In the case of anaplastic oligodendrogliomas, molecular genetic subtyping has already provided practical information for the management of patients, since tumors with chromosome 1p and 19q loss are differentially chemosensitive and more indolent.

For the less common gliomas and for other primary tumors such as medulloblastomas, molecular genetic studies have defined sets of genetic alterations. For meningiomas and schwannomas, the NF2 gene has been clearly implicated, although other genetic alterations must underlie the formation of some meningiomas as well. For some tumors, such as HPC and brain-invasive meningiomas, molecular investigations have clarified classification and grading issues. For those tumors associated with hereditary tumor syndromes, such as the SEGAs in TS and the hemangioblastomas in VHL, the same genes appear responsible for the syndromes when mutated in the germline, and for sporadic tumors when mutated on a somatic basis. At present, however, these molecular data are incomplete. Once the molecular pathways are completely understood, such knowledge will no doubt contribute to the development of more effective therapies for many of these tumors.

## INCIDENCE AND CLASSIFICATION

Available registry data from Surveillance, Epidemiology, and End Results for 1973 to 1990 indicate that the combined incidence of all recorded primary intracranial and spinal axis tumors is between 2 and 19 in 100,000 per year, depending on age.<sup>1</sup> There is an early peak (3.1 in 100,000) between 0 and 4 years, a trough (1.8 in 100,000) between 15 and 24 years, and then a steady rise in incidence that reaches a plateau (17.9 to 18.7 in 100,000) between 65 and 79 years of age. In general, the incidence of primary brain tumors is more common in whites than blacks and the mortality is higher in male than female subjects.

The diversity in primary intracranial and spinal axis tumors partly results from the diversity of phenotypically distinct cells capable of transformation into tumors. [Table 43.2-1](#) shows the hypothetical 15 cell types that can give rise to these tumors. Because of changes in classification and reporting of these tumors, the tumor registry data are not completely accurate. The relative frequency of 15 families of intracranial tumors is given in [Table 43.2-2](#), and the distribution of spinal tumors is shown in [Table 43.2-3](#).<sup>2,3</sup> The most common tumors are those that are derived from glial precursors (astrocytes, ependymocytes, and oligodendrocytes). The existence of histologically mixed astrocytoma-oligodendroglioma and the extremely uncommon astrocytoma-ependymoma implies that astrocytomas, oligodendrogliomas, and ependymomas may arise from common stem or progenitor cells. The facts that these tumors arise in different locales within the cranium and the spinal axis and that various types predominate at different ages suggest that differing molecular and genetic mechanisms may underlie tumorigenesis at different times in the life span.

Normal Cell	Tumor
Astrocyte	Astrocytomas, glioblastoma multiforme
Ependymocyte	Ependymoma, ependymoblastoma
Oligodendrocyte	Oligodendroglioma
Arachnoid fibroblast	Meningioma
Nerve cell or neuroblast	Ganglioneuroma, neuroblastoma
External granular cell or neuroblast	Medulloblastoma
Schwann cell	Schwannoma (neurinoma)
Melanocyte	Melanotic carcinoma
Choroid epithelial cell	Choroid plexus papilloma or carcinoma
Pituitary	Adenoma
Endothelial cell or stromal cell	Hemangioblastoma
Primitive germ cells	Germinoma, pinealoma, teratomas, choriosteatomas
Pineal parenchymal cells	Pinealcytoma
Notochordal remnants	Chordoma

**TABLE 43.2-1.** Classification of Primary Intracranial Tumors by Cell of Origin

Histopathology	Primary Brain Tumors (%)	Gliomas (%)
Glioblastoma multiforme	21.7	47
Malignant astrocytomas	16.6	36
All oligodendrogliomas	5.1	6.7
All ependymomas	2.5	5.1
Low-grade astrocytoma	1.8	3.9
Meningiomas and other mesenchymal tumors	36.7	—
Pituitary	9.7	—
Nerve sheath (e.g., schwannoma)	7.3	—
CNS lymphoma	3.5	—
Medulloblastomas and other primitive neuroectodermal tumors	1.7	—
All neurons and neuroglial tumors	1.0	—
Cranio-pharyngioma	1.0	—
Germ cell	0.5	—
Choroid plexus	0.5	—
Other tumors	2.7	—

Astrocytoma	6.5	11.2
Other gliomas	—	1.9
Vascular tumors	6.2	—
Chordomas	4.0	—
Epidermoids	1.4	—
Other	2.7	5.6

<sup>2</sup>Lipoma and subarachnoid seeding from primary intracranial tumor.

**TABLE 43.2-3.** Distribution of Primary Spinal Tumors<sup>a</sup>

Central nervous system (CNS) tumors are the most prevalent solid neoplasms of childhood, the second leading cancer-related cause of death in children younger than 15 years of age, and the third leading cancer-related cause of death in adolescents and adults between the ages of 15 and 34 years. However, most intracranial tumors occur in people older than 45 years. Glioblastoma rarely occurs in people younger than 15 years, but dramatically increases after the age of 45. The incidence

of most glial tumors, other than glioblastoma multiforme, actually decreases with increasing age. There is some concern that the incidence of glioblastoma multiforme is increasing in the elderly population,<sup>4</sup> although incorrect ascertainment preceding the widespread availability of computed tomography (CT) scans in the late 1970s and magnetic resonance imaging (MRI) in the 1980s may account for some of the presumed increase in incidence.<sup>5,6</sup> A similar age-related increase in prevalence occurs with differentiated or *benign* meningiomas that increase from 0.2% of all primary intracranial tumors in patients younger than 24 years of age to 39% of tumors in patients older than 65 years.

The overall incidence of primary spinal cord tumors is approximately 15% of that of brain tumors. For gliomas, the age-adjusted incidence is 0.11% to 0.14%; for meningiomas, 0.08% to 0.28%, depending on sex (female higher than male subjects); and for nerve sheath tumors, 0.07% to 0.13%.<sup>3</sup> As shown in [Table 43.2-3](#), the frequency of specific spinal cord tumors is strikingly different from that of the brain tumors. Gliomas constitute 46% of primary intracranial tumors while only 23% of spinal tumors. Unlike brain gliomas, most spinal cord gliomas are ependymomas with a predilection for the cauda equina. Schwannomas and meningiomas account for approximately 60% of spinal tumors, with schwannomas being slightly more frequent; both types occur most often in adult life. Other less common spinal tumors are the lipomas, dermoids, and hemangioblastomas.

## GENETIC, MOLECULAR, ENVIRONMENTAL, VIRAL, AND OTHER FACTORS ASSOCIATED WITH CENTRAL NERVOUS SYSTEM NEOPLASIA

In [Chapter 43.1](#), the contribution of genetics and molecular biology to the understanding of CNS tumorigenesis is covered in detail. Less important associations of CNS neoplasia are those associated with viruses, chemicals, and physical forces.

The epidemiology of primary CNS tumors has provided hints but few definitive observations with respect to environmental or occupational causes. Although brain tumors can be experimentally induced in a high proportion of rodents by the use of certain chemicals, the association of chemical exposure and brain tumors is limited to a few occupations. A higher than expected increase in the incidence of brain tumors has been observed as a result of purported exposure to pesticides, herbicides, and fertilizers,<sup>7</sup> various petrochemical industries,<sup>8</sup> and health professions.<sup>9</sup> Whether these statistical observations are credible is difficult to determine. Aside from a known association between vinyl chloride and gliomas, there are no common chemical or environmental threads among these observations.<sup>8</sup> There has also been concern that electromagnetic fields could account for some glial tumors, although the majority of studies do not support such a conjecture.<sup>10,11 and 12</sup>

Viruses have been implicated directly in the development of gliomas only in rats, dogs, and monkeys. In all cases, direct CNS injection of the virus is required. In rats, the avian sarcoma virus produces glial tumors<sup>13</sup>; in dogs, Rous sarcoma virus leads to gliosarcomas<sup>14</sup>; in owl monkeys, a human polyoma virus (JC virus) produces glial neoplasms<sup>15</sup>; and in hamsters, JC virus produces medulloblastomas.<sup>16</sup> Although a direct association between virus exposure and CNS tumors has not been established in humans, patients with primary CNS lymphoma have been observed to have a high incidence of infection with Epstein-Barr virus and evidence of Epstein-Barr virus in their tumor tissue.<sup>17</sup> Common viral exposure could explain the occasional glioma cluster observed in schools and communities. However, it is extremely difficult to pinpoint mutations due to a virus to validate this hypothesis.

CNS neoplasia, like most cancers, appears to be unassociated with prior trauma. It has been suggested that the incidence of meningiomas is higher in patients with a prior history of head trauma, but this hypothesis was not supported by a prospective study.<sup>18</sup> Trauma could be a progression event; however, this theory would be difficult to prove.

The incidence of CNS tumors after treatment for a prior malignancy is small. The literature contains examples of astrocytomas occurring 3 to 7 years after craniospinal axis irradiation and chemotherapy for acute lymphocytic leukemia and craniopharyngioma<sup>19,20 and 21</sup> unfortunately, none of the reports contains sufficient information to determine risk assessment. In non-Hodgkin's lymphoma, 2% of 44 second malignancies were an astrocytoma.<sup>22</sup> As in the cases discussed previously, no measure of risk assessment is possible, although such infrequent reporting would suggest that these are uncommon or rare events. Meningiomas have been reported in association with scalp irradiation for tinea capitis, the risk for meningiomas being as high as 21% in one study.<sup>23,24</sup>

For unknown reasons, transplant recipients and patients with acquired immunodeficiency syndrome have substantially increased risks for primary CNS lymphoma but not gliomas.

## ANATOMIC AND CLINICAL CONSIDERATIONS

The clinical presentation of the various tumors is best appreciated by considering the relation of signs and symptoms to anatomy.<sup>25</sup>

### INTRACRANIAL TUMORS

Intracranial tumors produce symptoms primarily by two mechanisms: mass effect (and increased intracranial pressure), due entirely to the tumor or to the tumor and surrounding edema, or infiltration and destruction of normal tissue.

#### *General Signs and Symptoms*

Typical infiltrative intracerebral tumors, such as the various grades of astrocytoma and oligodendroglioma and some of the more primitive neuroectodermal tumors, can produce headache, gastrointestinal upset such as nausea and vomiting, personality changes, and slowing of psychomotor function. These may be the only clinical indications of tumor.

Because headache is a common presenting symptom in patients with intracranial tumor, clinical patterns and their localizing value must be appreciated. Brain parenchyma does not have pain-sensitive structures, and tumor pain (headache) has been attributed to local swelling and distortion of pain-sensitive nerve endings associated with blood vessels, primarily in the meninges. Tumors grow at different rates and, therefore, achieve variable size before signs and symptoms occur. But once a tumor has achieved a critical volume causing compression and displacement of brain, the onset and demise of headache seem to correlate with changes in intracranial pressure.

Headaches can vary in severity and quality; they often occur in the early morning hours or on first awakening. Patients sometimes complain of an uncomfortable feeling in the head rather than headache. Although there is not an exact relation between the location of tumor headache and the location of the tumor, some rules are worth remembering. More often than not, frontal and temporal tumors produce headache in frontal, retroorbital, or temporal regions, whereas infratentorial tumors tend to produce occipital and retroauricular headache. Occasionally, however, retroorbital headaches are observed with infratentorial tumors.

Gastrointestinal symptoms are common. Patients complain of loss of appetite, queasiness, nausea, and, occasionally, vomiting. Vomiting appears more commonly in children and in patients harboring infratentorial rather than supratentorial tumors. Although textbooks discuss projectile vomiting as an infrequent generalized symptom of brain tumors, in these authors' experience, it is common in children but rare in adults. From reports in the literature and discussions with experienced neurosurgeons, it seems as though there is a lower incidence of vomiting currently compared with past years; this may reflect the fact that patients are diagnosed earlier than in previous years and receive glucocorticoids that can modify dramatically many of the generalized signs and symptoms of brain tumors.

Sometimes the only presenting symptoms are changes in personality, mood, mental capacity, and concentration. Occasionally, merely a slowing of psychomotor activity is the antecedent symptom of intracranial tumor. Patients with brain tumors tend to sleep longer at night and nap during the day. These changes in function and activity often are apparent to the family and the examiner but not to the patient; in other instances, only the patient recognizes the changes in mental function. None of these symptoms are unique to brain tumors; they could easily be confused with depression, neurasthenia, or other psychological problems.

#### *Focal Cerebral Syndromes*

Although fewer than 10% of patients presenting with seizures have a brain tumor as the cause of the seizure, seizures are a presenting symptom in approximately 20% of patients with supratentorial brain tumors. With rapidly growing infiltrative malignant gliomas, they are likely to take the form of focal motor or sensory seizures, although generalized seizures are also common. In patients with slowly growing astrocytomas, oligodendrogliomas, or meningiomas, generalized seizures may antedate the clinical diagnosis by months to years. The value of the focal seizure as a means of tumor localization is high, sufficiently so that tumor should be

considered causative until proven otherwise.

The distribution of infiltrative parenchymal tumors in the brain is directly related to the mass of the lobe or region. Frontal tumors occur more commonly than parietal tumors, which, in turn, occur more often than temporal lobe tumors, and so forth. Anatomic or regional involvement by tumors, although not completely stereotypic as it is with CNS vascular disease, nonetheless has certain features that distinguish them and help the clinician localize the tumor or, at least, to consider the diagnosis.

The frontal lobe syndrome varies markedly from patient to patient. It can range from personality change to headache and mild slowing of contralateral hand movements and to contralateral spastic hemiplegia, marked elevation in mood, or loss of initiative and dysphasia (if it is the dominant lobe). Assuming the normal pattern of left hemisphere dominance, unilateral tumors affecting the right frontal lobe can cause left hemiplegia, slight elevation in mood, difficulty in adapting to new situations, loss of initiative, and even occasional primitive grasp and sucking reflexes. Left frontal lobe tumors can cause right hemiplegia and nonfluent dysphasia with or without some apraxia of lip, tongue, or hand movements.

Bifrontal disease, a condition usually associated with infiltrative gliomas and primary CNS lymphomas, can cause varying degrees of bilateral hemiplegia, spastic bulbar palsy, severe impairment of intellect, lability of mood, dementia, and prominent primitive grasp, suck, and snout reflexes.

Temporal lobe syndromes, like frontal lobe syndromes, can range from symptoms that are detectable only on careful testing of perception and spatial judgment to severe impairment of recent memory. Homonymous quadrantanopsia, auditory hallucinations, and even aggressive behavior can occur as a result of tumors of either temporal lobe. Involvement of the nondominant temporal lobe can also result in minor perceptual problems and spatial disorientation. Dominant temporal lobe involvement can lead to dysnomia, impaired perception of verbal commands, and even a full-blown, fluent Wernicke-like aphasia. Bilateral disease, involving both temporal lobes, is rare in comparison with the bilaterality of frontal lobe tumors that readily cross through the corpus callosum. This is fortunate, because bitemporal tumor involvement is devastating. It produces impairment of memory, especially recent memory, and can lead to dementia.

Parietal lobe syndromes affect sensory and perceptual functions more than motor modalities, although mild hemiparesis is sometimes seen with extensive parietal lobe tumors. Tumors impinging on either parietal lobe can produce a decrease in the perception of cortical sensory stimuli that may vary from mild sensory extinction, observable only by testing, to a more severe sensory loss with deep tumors that leads to hemianesthesia or other hemisensory abnormalities. Homonymous hemianopsia or visual inattention also may occur. In addition, involvement of the nondominant parietal lobe can lead to perceptual abnormalities and, in severe cases, to anosognosia and apraxia for self-dressing. Unilateral dominant parietal lobe tumors lead to alexia, dysgraphia, and certain types of apraxia.

Occipital lobe tumors can produce contralateral homonymous hemianopsia or visual aberrations that take the form of imperception of color, object size, or object location. Bilateral occipital disease can produce cortical blindness.

The classic disconnection syndromes associated with corpus callosum lesions are seen rarely in patients with brain tumors. Even though infiltrative gliomas often cross the corpus callosum in the region of the genu or the splenium, the involvement of additional structures complicates neurologic interpretation, obscuring classic disconnection syndromes. With respect to partial lesions, interruption of association fibers in the anterior part of the corpus callosum usually causes a failure of the left hand to carry out spoken commands. Lesions in the splenium of the corpus callosum interrupt visual fibers connecting the right occipital lobe and left angular gyrus, resulting in an inability of patients to read or name colors.

Symptoms related to thalamic tumors vary as a function of tumor size and whether the tumor produces secondary blockage of cerebrospinal fluid (CSF) flow and hydrocephalus. Occasionally, tumors in the thalamus and, less commonly, in the basal ganglia, can reach 3 to 4 cm in diameter before the patient has symptoms severe enough to seek medical attention. Patients typically present with headaches resulting from hydrocephalus and increased intracranial pressure secondary to trapping of the lateral horn of one of the ventricles. In addition or independently, patients can present with a mild sensory abnormality on the contralateral side, which is detected only by testing of sensory extinction or, rarely, severe neuropathic pain syndrome. Patients may complain of intermittent paresthesias on the contralateral side; because they are episodic and seizure-like, anticonvulsant drugs are used sometimes and actually may be beneficial. With more involvement of the basal ganglia, contralateral intention tremor and hemiballistic-like movement disorders can be observed. Thalamic tumors usually do not present in a manner typical of thalamic strokes, unless bleeding into the tumor has occurred.

### Focal Infratentorial Syndromes

The brain stem, composed of the medulla oblongata and the pons, has both nuclear groups and traversing axons. Tumors invading or compressing the brain stem can produce dire consequences; even a small increase in size (e.g., 1 to 2 mm) may lead to death or devastating signs and symptoms. Tumors can be primarily intrinsic or intrinsic with exophytic components in the fourth ventricle, peripontine cisterns, or in both locations. Cranial nerve involvement, therefore, can be at the nuclear level or of the cranial nerve as it leaves the brain stem.

The most common tumor of the brain stem is an astrocytoma (glioma), the initial clinical manifestations of which are palsies involving cranial nerves VI and VII on one side in 90% of patients. These usually are followed by involvement of long tracts resulting in hemiplegia, unilateral limb ataxia, ataxia of gait, paraplegia, hemisensory syndromes, gaze disorders, and, occasionally, hiccups. Less commonly, long tract signs precede the cranial nerve abnormalities; this is more likely with confined intrinsic brain stem lesions.

The midbrain, juxtaposed between the pons and the cerebral hemispheres, encompasses the tectum, the cerebral peduncles, and the cerebral aqueduct. If the midbrain is involved, obstructive hydrocephalus can occur, producing vomiting, drowsiness, and cerebellar signs. Patients with medullary tumors have a more rapidly progressive course and are more likely to have deficits in cranial nerves VI (usually late), VII, IX, and X, and dysarthria, personality change, and head tilt. Unlike the expansive posterior fossa tumors, headache, vomiting, and papilledema occur late. Fourth ventricular tumors, because of their location, tend to produce obstructive hydrocephalus early in their development. This produces profound headache and vomiting and associated disturbances of gait and balance. With rapidly progressing lesions, cerebellar herniation may develop.

Tumors of the cerebellum have valuable localizing signs and symptoms. In slowly growing tumors, the initial symptoms may be headache and nausea, which are caused by increased intracranial pressure, and mild imbalance in gait or ataxia of a limb. In more rapidly growing cerebellar tumors, there may be prominent morning headache; vomiting; a stumbling gait with frequent falling, nystagmus, and dizziness; and visual symptoms caused by papilledema. Abnormal posturing of the head is seen often in children but not in adults. In children, the head is tilted back and away from the side of the tumor. Posturing of the head is curious in that it indicates unilateral cerebellum-foramen magnum herniation. Bilateral sixth cranial nerve palsies are uncommon. Midline lesions in and around the cerebellar vermis lead to truncal and gait ataxia, whereas lesions in a cerebellar hemisphere lead to unilateral appendicular ataxia, most readily observed in upper extremity movements.

Tumors of the base of the skull, although not particularly common, nevertheless are important because many are curable by surgery. [Table 43.2-4<sup>26</sup>](#) summarizes the salient clinical features of seven of the more common clinical syndromes.

Site of Lesion	Associated Tumor	Clinical Findings
Infratentorial	Carcinoma metastatic from breast and other sites; meningioma	Unilateral weakness, frontal lobe syndrome, ataxia
Superior orbital	Meningioma, carcinoma of nasopharynx	III, IV, VI, VII nerve lesions with ophthalmoplegia and pain and hyperreflexia in C1 distribution
Cerebellopontine	Chordoma, meningioma, ependyoma and paraneurial tumor	III, IV, VI, VII, and sometimes V nerve involvement with ophthalmoplegia
Apex of the pons	Chordoma, meningioma, astrocytoma, carcinoma metastatic	V and VI nerve involvement with ataxia and sensory findings and diplopia
Infratentorial and pons	Meningioma, chordoma, ependyoma, glioma, carcinoma metastatic	III, IV, VI, VII nerve lesions result in ophthalmoplegia; V may be associated with oligoparesis or sensory deficit
Infratentorial	Glioma (epidermoid, astrocytoma, chordoma, chondrosarcoma, meningioma, sarcoma, carcinoma metastatic)	III, IV, VI, VII nerve palsies producing difficulty with swallowing, speaking, and weakness of strap muscles of larynx
Cerebellopontine	Neurinoma, meningioma, chordoma, carcinoma metastatic	VII nerve lesion causing acute loss of hearing, vertigo, and ataxic gait; VIII and occasionally IX and X nerve lesions; brain stem symptoms and signs of increased intracranial pressure

(Adapted from ref. 26.)

**TABLE 43.2-4.** Differential Diagnosis of Tumors at the Base of the Skull

Neurologic Findings	Pathologic Cause
Pupillary dilation and ptosis	Compression of ipsilateral oculomotor nerve between tentorium and petrous part of temporal bone
Ipsilateral hemiplegia	Compression of contralateral cerebral peduncle against anterior horn of midbrain
Contralateral homonymous hemianopia	Compression of ipsilateral cerebral peduncle, when associated with compression of contralateral peduncle, lateral corticospinal tract signs will be present
Homonymous hemianopia	Compression of posterior cerebral artery space for tentorium can lead to occipital ischemia in inferior and contralateral homonymous hemianopia, occasionally lateral field cut over
Midline evidence: Cerebral peduncle depression, rigidity of neck, ipsilateral signs, decerebrate rigidity, dilated fixed pupils, parasympathetic signs, absent vestibular reflexes	Crushing of midbrain between tentorium and base of skull if tentorium associated with vascular occlusion and petrosal nerve damage
Coma, rising blood pressure, and bradycardia	These late signs occur from rising intracranial pressure and hydrocephalus as the upper brain stem and midbrain level are compressed

**TABLE 43.2-8.** Temporal Lobe-Tentorial (Uncal) Herniation

A rapid increase in the volume of the supratentorial compartment leading to herniation can be caused by many different factors. A rapidly growing glioblastoma can present in this manner, although it is more usual for it to occur as a terminal or near terminal event after ineffective therapy for the tumor. It can also occur when there is a dramatic increase in the amount of edema associated with metastasis to the brain or with hyponatremia and hypoosmolar syndromes. The injudicious use of parenteral hypoosmolar 5% dextrose in water often is sufficient to produce an abrupt increase in brain edema and temporal lobe herniation. The authors of this chapter also have seen temporal lobe herniation follow a group of shortly spaced seizures. Presumably, the seizures, which are associated with hypoventilation, produce local hypoxia around the tumor with a resultant increase in brain edema.

Mass lesions in the infratentorial compartment can displace brain tissue upward through the tentorium, but more commonly force brain tissue downward through the foramen magnum. In this situation, the cerebellar tonsils move caudally through the foramen magnum, and in doing so, wedge against the medulla, causing the findings summarized in [Table 43.2-9](#).<sup>29</sup>

Neurologic Findings	Pathologic Cause
Head tilt, stiff neck, posturing of neck, or paresthesias over the neck	Downward displacement of inferior hemispheres through the foramen magnum; may be unilateral or bilateral
Tonic extensor spasms of limbs and body (cerebellar fits) and later coma	Compressive effects of cerebellum or hydrocephalus on the upper brain stem
Respiratory arrest	Medullary compression

**TABLE 43.2-9.** Cerebellar Foramen Magnum Herniation

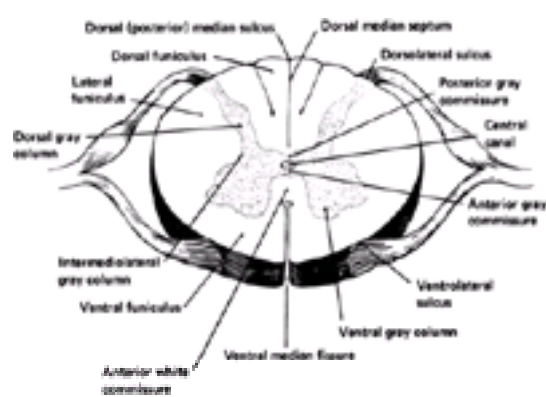

Cerebellar-foramen magnum herniation frequently results from, or is contributed to by, obstructive hydrocephalus. In such instances, emergency removal of fluid from the more cephalad ventricular system may relieve symptoms and be life saving. Surgical intervention is indicated only if the reason for the herniation is treatable. In the instance of cerebellar-foramen magnum herniation aggravated by acute obstructive hydrocephalus, ventriculo-peritoneal shunting is often necessary. Care must be taken, however, because too rapid a change in the CSF dynamics can lead to a rapid and damaging movement of the brain, which can lead to occlusion of posterior cerebral arteries and brain stem injury.

These two herniation syndromes lead to death, unless there is prompt intervention. The immediate intravenous administration of hyperosmotic agents, such as mannitol or urea, and large doses of synthetic glucocorticoids, such as dexamethasone or methylprednisolone, should be given promptly to reduce intracranial pressure and to avert impending death.

Hemorrhage into a tumor is not as common as might be expected, although the incidence of intratumor hemorrhage may increase because of iatrogenic thrombocytopenia associated with the current use of chemotherapy in the treatment of brain tumors. Primary tumors that most commonly bleed *de novo* are glioblastoma and oligodendrogliomas; of the metastatic tumors, those from the lung, melanoma, hypernephroma, and choriocarcinoma are most likely to be associated with intratumoral hemorrhage. Signs and symptoms of intratumoral hemorrhage may be temporized by the use of osmotic agents and glucocorticoids, but if extensive and life-threatening, operation and decompression are indicated. Under no circumstances should a lumbar puncture be performed in any of the acute herniation syndromes. In fact, lumbar puncture should never be done indiscriminately. The indications for lumbar puncture are discussed in another section of this chapter (see [Neurodiagnostic Tests](#), later in this chapter).

## SPINAL AXIS

To understand the clinical presentation of tumors of the spinal axis, the local anatomy ( [Fig. 43.2-1](#)) and how tumors might present with respect to anatomy must be appreciated. The cranial dura is firmly adherent to the skull (with the exception of dural duplications of the falx and tentorium), and no extradural space normally exists between dura and skull. An entirely different anatomic relation in the spinal canal accounts for a well-defined extradural space containing epidural fat and blood vessels. By way of the intervertebral foramina, this extradural space communicates with adjacent extraspinal compartments (e.g., the mediastinum and the retroperitoneal space). With rare exceptions, extradural tumors are metastatic, reaching the extradural space through intervertebral foramina.

**FIGURE 43.2-1.** Cross-section of thoracic spinal cord shows relation of spinal nerves to intraspinal tracts.

Tumors arising inside of the dural tube (intradural tumors) may originate within the spinal cord (intramedullary), or they may take origin outside the spinal cord (extramedullary). The two common extramedullary intradural tumors, neurilemmoma (schwannoma) and meningioma, are attached, respectively, to sensory nerve roots and to dura and involve the spinal cord by compression.

## Neurology of Spinal Cord Tumors

A spinal tumor produces two effects: local (focal) and distal (remote). Local effects indicate the tumor's location along the spinal axis, and distal effects reflect involvement of motor and sensory long tracts within the spinal cord. [Table 43.2-10](#) summarizes the clinical findings useful in localizing a spinal cord tumor.

Location	Findings
Foramen magnum	11th and 12th cranial nerve palsies; ipsilateral arm weakness early; cerebellar ataxia; and neck pain
Cervical	Ipsilateral arm weakness with leg and opposite arm in time; wasting and fibrillation of ipsilateral neck, shoulder girdle, and arm; decreased pain and temperature sensation in upper cervical regions early; and pain in cervical distribution
Thoracic	Weakness of abdominal muscles; sparing of arms; unilateral root pains; sensory level with ipsilateral changes early and bilateral with time
Lumbosacral	Root pain in groin region, sciatic distribution, or both; weakened proximal pelvic muscles; impotence; bladder paralysis; and decreased knee jerk and brisk ankle jerks
Cauda equina	Unilateral pain in back and leg becoming bilateral when the tumor is quite large; bladder and bowel paralysis

**TABLE 43.2-10.** Clinical Manifestations of Spinal Cord Tumors

Distal effects are common to all spinal tumors sooner or later, and symptoms and signs are confined to structures innervated below the spinal cord level of involvement. Although neurologic manifestations commonly begin unilaterally, a full-blown Brown-Séquard syndrome of cord hemisection can occur but is rare. More characteristic are motor changes: weakness and spasticity, if the tumor lies above the conus medullaris, or weakness and flaccidity, if at or below the conus. Typically, sensory impairment begins distally in the feet. Impairment of bladder function occurs later in tumors above the conus, but may be an early manifestation of tumors in or below the conus. The upper level of impaired long tract function usually is several segments below the actual site of tumor involvement.

Local manifestations may reflect involvement of bone, with pain constituting the cardinal symptom of metastatic tumors. Involvement of spinal roots produces pain, sensory impairment, and weakness with atrophy in the appropriate radicular distribution. Less often, involvement of spinal gray matter produced by extensive pressure from extramedullary tumors or direct damage by intramedullary tumors causes segmental sensory and motor changes.

Historically, tumors at or near the foramen magnum have been diagnosed incorrectly more often than have spinal tumors at any other site, because foramen magnum tumors can mimic such diverse conditions as multiple sclerosis, amyotrophic lateral sclerosis, and cervical disk disease. The frequency of delayed diagnoses of these tumors justifies the dictum that MRI is indicated as a diagnostic measure in any neurologic disease that can be accounted for by a lesion at or below the foramen magnum.

Occasionally, a cervical intramedullary tumor mimics syringomyelia, with dissociated sensory loss, weakness, and wasting in the arms and hands and variable long tract involvement. In most instances, the clinical presentation of a spinal tumor does not indicate if it is extradural or intradural.

The rate at which symptoms develop can be helpful in distinguishing extradural from intradural tumor, with a history of days to a few weeks characterizing metastatic extradural tumors, and a longer course, often many months, reflecting the slower growth of intradural tumors. A history of previously diagnosed cancer or other system involvement also is helpful.

## NEURODIAGNOSTIC TESTS

### NEUROIMAGING

The diagnosis of intracranial tumor requires radiographic confirmation. Fortunately, the great strides in radiology have yielded technologic advances best adapted for the brain and the spinal cord. Today MRI and CT are the major neuroimaging techniques used to demonstrate intracranial and spinal lesions. Both MRI and CT produce cross-sectional digital images. In both, the depicted anatomy and pathology are based on numeric computerized representations of certain physical properties of the tissue. The CT image is composed of pixels based on the attenuation of x-rays that are, in turn, dependent on the electron density of the tissue being studied. The MRI scan also produces an image based on pixels, but unlike CT scanning, MRI pixel intensity is based on proton density, T1 and T2 relaxation times, and flow (blood flow). The MRI scan, therefore, represents a complex interrelation of four parameters. Data acquisition also can be manipulated by the operator to a greater degree than can be done with CT scans. CT and MRI also differ in that MRI data can be acquired in any plane desired, including oblique planes, in a primary fashion such that there is no compromise of spatial or contrast detail. CT scans can be acquired only in the axial or half-axial planes. Computer-generated reformations are required to generate alternative views, such as orthogonal and off-axis images, all of which have degradation of both spatial and contrast detail. Because MRI scanning can generate images in any plane and offers high resolution and contrast without associated bone artifact, it has been shown to be superior to CT scan in detecting and localizing brain tumors and evaluating edema, hydrocephalus, or hemorrhage.

Intraaxial CNS tumors normally produce edema that is partially correlated with the rapidity of tumor growth. An exception is the benign cerebral meningioma, a slow-growing tumor that can produce profound edema. The so-called vasogenic edema associated with brain tumors is fluid that has leaked through an incompetent blood-brain barrier and is seen on the CT scan as relatively low attenuation compared with normal brain. On MRI, edema appears as an area of low-signal intensity on T1-weighted images and high-signal intensity on T2-weighted images.

Mass lesions in the brain can obstruct the ventricular system, resulting in hydrocephalus. MRI is superior to CT in evaluating hydrocephalus and its causes, because more planes of view are available to the radiologist. Dilatation of one or both of the lateral ventricles and not the rest of the ventricular system suggests obstruction at the foramen of Monro as is seen with colloid cysts or gliomas in this region. Dilatation of a temporal horn of the ventricular system suggests a tumor in the ventricular atrium *trapping* the temporal horn. Dilatation of only the lateral and third ventricles points to a lesion of the aqueduct; when all the ventricles are dilated, communicating hydrocephalus caused by tumor seeding to the meninges or by the reaction to previous therapy should be considered.

Brain tumors occasionally bleed, and this bleeding can be insignificant or can cause dramatic clinical consequences. Metastatic brain tumors that tend to bleed are melanoma, renal cell carcinoma, choriocarcinoma, and thyroid carcinoma. Of the primary CNS tumors, glioblastoma and oligodendrogliomas are more commonly associated with hemorrhage than are other primary tumors. Acute hemorrhage appears as high attenuation on CT, but subacute hemorrhage may be harder to detect by CT. On MRI, acute hemorrhage is of low-signal intensity on T1 and T2; the subacute hemorrhage poorly seen on CT produces a bright signal on both T1- and T2-weighted MRI scans.

Assessment of the disruption of tumor endothelia and the passage of contrast material compared with the intact blood-brain barrier is an important step in radiologic evaluation. The use of contrast agents in CT and MRI scanning provides, in some patients, improved tumor visualization and, in all patients, an improved ability to discern tumors from other pathologic entities, to discern one tumor type from another, and even to discern higher from lower grade malignancies. There are few situations when administration of contrast agents should not be included in the radiologic evaluation of the patient with a brain tumor.

Approximately 50% of patients with low-grade gliomas may present with tumors that do not exhibit contrast enhancement on CT scan. Some may not be detected on CT because they are isodense with brain. It is in these patients that the differential sensitivity of MRI can be seen clearly, even in the absence of a paramagnetic contrast agent. [Figure 43.2-2](#) shows an example of a CT scan in a patient with a seizure disorder that was interpreted prospectively and retrospectively as normal before and after contrast agent administration. The MRI scan is clearly abnormal. Stereotactic biopsy demonstrated a well-differentiated astrocytoma.

**FIGURE 43.2-2.** A young man presented with a single focal seizure that generalized into a major motor seizure. **A:** A postcontrast axial computed tomographic scan demonstrates a poorly defined area of low density involving the most anterior portion of the corona radiata extending anteriorly to the gray matter on the right. No contrast enhancement, sulcal effacement, or mass effect is present. **B:** After this computed tomographic scan, a T2-weighted (TR 2000, TE 20) axial magnetic resonance imaging scan was performed that shows an area of decreased signal intensity at the gray-white junction at the most anterior medial aspect of the right frontal lobe. **C:** On the second echo (TR 2000, TE 60), the lesion exhibits high signal intensity. On biopsy, the tumor was found to be a well-differentiated astrocytoma.

The possibility of obtaining high-quality coronal images without artifact associated with beam hardening through bone makes MRI particularly attractive for evaluating the base of the skull and the posterior fossa. [Figure 43.2-3](#) is an example of a high-quality MRI scan in a patient with pituitary adenoma. Although this lesion would be identified readily on CT, the relation to the optic chiasm and infundibulum would certainly not be identified as clearly.

**FIGURE 43.2-3.** A woman 30 years of age presented with hyperprolactinemia. Coronal T1-weighted (TR 600, TE 20) 3-mm-thick section scan of the pituitary gland demonstrates (*arrows*) a low-intensity lesion 9 mm in diameter involving the right side of the pituitary fossa displacing the gland and the stalk to the left. Findings are typical of a pituitary microadenoma.

In the posterior fossa, the lack of artifact and the availability of sagittal and coronal planes make MRI uniquely suited for detecting and characterizing neoplasms. Both intraaxial and extraaxial masses are distinguished easily, and their relation to the ventricular cisternal systems is assessed easily.

In the evaluation of intracranial tumors, cerebral angiography is used much less frequently than in the past. For many cases MR angiography suffices. Angiography may be used to confirm an impression gained by MRI or CT that the lesion in question is a vascular malformation or an aneurysm rather than a neoplasm. In certain situations (e.g., with large meningiomas) angiography may be useful before surgery to determine the blood supply so that it can be embolized during the angiographic procedure or obliterated during the surgical procedure, or both.

In the evaluation of intramedullary and extramedullary spinal cord lesions, high-quality MRI is the diagnostic study of choice. Indications for myelography currently are extremely limited, because multiplanar MRI can provide superb delineation of the spinal cord contour, and the addition of gadolinium-diethylenetriaminepenta-acetic acid provides enhancement and visualization of almost all intrinsic tumors (such as ependymomas, astrocytomas, meningiomas, and schwannomas) and facilitates the diagnosis of leptomeningeal disease. Tumor cysts are readily identified on MRI, and currently spinal cord tumors can be distinguished much more reliably from syringomyelia ([Fig. 43.2-4](#)).

**FIGURE 43.2-4.** A 39-year-old man with a known cerebral glioblastoma multiforme developed spinal cord symptoms. **A:** A T1-weighted (TR 600, TE 20) sagittal scan of the thoracolumbar spine shows mild heterogeneity of signal near the conus, but is otherwise normal. **B:** A T2-weighted (TR 2000, SE 35, 70) sagittal scan provides no additional information. **C:** A T1-weighted (TR 600, SE 20) image after gadolinium-diethylenetriaminepenta-acetic acid administration clearly shows high signal-enhancing tumor (*black arrows* show some of lesions) immediately caudad to the conus resulting in a high-grade partial block and multiple additional drop metastases. **D:** A water-soluble contrast myelogram demonstrates the drop metastases (*white arrows* show some of lesions) and incompletely delineates the mass adjacent to the conus. (Courtesy of Gordon Sze, Department of Radiology, Yale University School of Medicine, New Haven, CT.)

Another unique and particularly important application of MRI is the use of the sagittal image in radiation treatment planning. The MRI sagittal image can be superimposed on radiographic simulator films so that the tumor can be localized accurately for appropriate port design. The use of the MRI scan is now routine in treatment planning of brain and spinal cord tumors.

Newer MRI techniques such as MR spectroscopy, dynamic contrast-enhanced MRI, functional MRI, and diffusion-perfusion MRI can provide additional information. MR spectroscopy can evaluate the regional distribution of chemicals associated with energy metabolism in the tumor. Dynamic contrast-enhanced MRI, by quantitating the uptake of gadolinium contrast agents into the lesion, can distinguish the slow rate of uptake of radiation injury from the rapid rate of uptake commonly seen in highly malignant primary CNS tumors. Functional MRI reflects small localized changes in blood flow that occur in response to cortical localization of various neurologic functions. Thus, for instance, dominance of cerebral function or importance of a supplementary motor area can be quickly determined before surgery to enable the surgeon to better protect normal brain function during a surgical resection of a tumor. Diffusion-perfusion MRI can provide better information regarding free

and restricted water diffusion in the brain to help differentiate tumor malignancy and secondary effects of treatment on the tumor.

## TANGENT SCREEN, PERIMETRY, AUDIOMETRY, AND ELECTROENCEPHALOGRAPHY

Testing for abnormalities of the visual system is part of the neurologic examination. However, the results of confrontation visual field testing need quantitation to provide greater accuracy and to follow the effects of treatment. Formal visual field testing is done using tangent screens, and scotomas and field defects are diagnosed with perimetry. Schematic representation of the common visual field abnormalities and their anatomic localization can be readily found in any neurology text.

Quantitation of deafness is performed by formal audiometric testing. This can be helpful in the diagnosis of acoustic neurinomas.

Electroencephalography once had a place in the diagnosis and follow-up study of intracranial neoplasms. Its major value is in the diagnosis of seizure disorders and in following the rare patient whose neurologic deterioration may be related to subclinical seizures rather than tumor growth. Visual-evoked potentials measured over the visual cortex after visual stimuli are less valuable in the evaluation or follow-up study of patients with brain tumors, but can help distinguish multiple sclerosis from tumor.

## TUMOR AND CEREBROSPINAL FLUID MARKERS

For patients with intracranial and spinal tumors, examination of peripheral blood and CSF has been found to be helpful for diagnosis and for therapy monitoring. Pituitary tumors often produce endocrinologic abnormalities measurable by sensitive radioimmunoassays. Polycythemia associated with a tumor of the posterior fossa (cerebellum) may be useful as presumptive evidence for the diagnosis of hemangioblastoma. Some parasellar and pineal region embryonal tumors secrete unique hormones and proteins; human chorionic gonadotropin-b hormone (b-HCG) and a-fetoprotein (AFP) are examples of hormones associated with trophoblastic tissue and yolk sac, respectively.

## INDICATIONS FOR AND INTERPRETATION OF CEREBROSPINAL FLUID EXAMINATION

Lumbar puncture in a patient with headache, papilledema, and a presumed diagnosis of tumor is risky, because it increases the possibility of a fatal cerebellum-foramen magnum or temporal lobe-tentorial herniation. Lumbar puncture should follow rather than precede neuroimaging studies, such as MRI and CT scanning.

The examination of CSF is useful in following patients with intracranial tumors that have a propensity to seed the subarachnoid space and spread through the CSF pathways. Typically, medulloblastoma, ependymoma, choroid plexus carcinoma, and some embryonal pineal and suprasellar region tumors have a high enough likelihood of spread to justify CSF examinations. In these patients, it is important to obtain a lumbar puncture for CSF to examine for malignant cells (cytology), protein, and glucose, and specific markers such as b-HCG and AFP. These tests determine if malignant cells are in the CSF and if tumor deposits have reached sufficient size to begin to block CSF subarachnoid pathways. A high protein concentration with normal glucose levels and normal cytology is seen in tumors of the base of the skull, such as acoustic neurinoma, and in spinal cord tumors. The appearance of xanthochromic CSF, due to high protein content, with an absence of erythrocytes is characteristic of spinal cord tumors obstructing the subarachnoid space and producing stasis of the CSF in the caudal lumbar sac.

### *Evaluation of Patients with Intracranial Tumors during Therapy*

Critical to the evaluation of the efficacy of any therapy for brain tumors is the reliability of the measurement of tumor growth (deterioration) or tumor regression (response). Today, contrast-enhanced MRI and, to a lesser extent, CT are used as the primary measure of response to treatment. The extreme sensitivity of the MRI to changes in brain water content and small enhancing lesions can be confusing in the evaluation of tumor regrowth and progression, especially following radiotherapy. The use of MR spectroscopy, diffusion-perfusion algorithms, and dynamic contrast-enhanced MRI may improve the ability to assess tumor regrowth in the postirradiation period.

To interpret the results of therapy correctly and to improve patient care, understanding factors other than cell division is important.

## FACTORS THAT MAY PRODUCE CLINICAL DETERIORATION

The most common causes of neurologic deterioration in brain tumor patients undergoing radiation therapy or chemotherapy, or both, are growth of the tumor or increased peritumoral edema. Both cause increased pressure in the cranial cavity that is transmitted primarily to the adjacent brain; in turn, hydrostatic pressure on the brain can lead to impairment of cerebral blood flow. The clinical result can be progressive impairment of functioning brain with resultant neurologic deficits. These manifestations may include signs and symptoms of increased intracranial pressure and temporal lobe or cerebellar herniation (see [Table 43.2-9](#) and [Table 43.2-10](#)).

Neurologic deterioration, without neuroimaging evidence of tumor growth, can occur for any of the following reasons:

- Obstructive hydrocephalus can occur secondary to tumor in the ventricular system at the aqueduct of Sylvius, fourth ventricle, or foramen of Monro or communicating hydrocephalus due to infiltrative tumor (carcinomatosis, CNS leukemia, and arachnoiditis).
- Hemorrhage into a tumor may occur.
- Fluid imbalance, particularly hyponatremia caused by excessive administration of parenteral dextrose in water solutions, may develop.
- Hypertension can accentuate intratumoral and peritumoral edema.
- Reactive peritumoral edema (or demyelination) may develop early in the course of radiation therapy.
- An *early delayed* syndrome, observed in approximately 15% to 40% of patients completing a course of cranial irradiation, can be distinguished from tumor regrowth only by waiting and finding that the patient's condition improves without further treatment.<sup>41</sup> This encephalopathy responds to corticosteroids and resolves within several weeks without specific sequelae. This syndrome is not unique to patients with brain tumors and is observed in leukemic children after prophylactic cranial irradiation and in those with extracranial tumors who receive incidental radiation to the brain.
- Radiation necrosis can occur within 3 months to 13 years or longer after radiation therapy and can produce neurologic impairment that may be indistinguishable from tumor recurrence.
- Seizures may suggest that the tumor is growing and may result in an increase in the neurologic deficit apart from any direct effect of the tumor. Recovery from any increase in weakness and mental dullness may take several hours to a week in postictal patients who are already brain injured. Even subclinical seizures can cause deterioration, persisting for hours to days, which resolves with control of the seizures. Electroencephalography is usually diagnostic in these patients, and the treatment is better control of seizures. Patients receiving long-term chemotherapy often require higher doses of anticonvulsants or widely fluctuating dosages caused by drug-induced hepatic changes.
- Infection and fever often exacerbate neurologic signs and symptoms, regardless of the site of infection. The more common causes of infection include pneumonia secondary to aspiration or atelectasis and urinary tract infections; meningitis and cerebral abscess are less common.
- Metabolic disorders, anemia, fatigue, and emotional depression can cause clinical deterioration, including increase in focal deficit on testing, that is difficult to distinguish from tumor progression. Such conditions generally produce no alteration of neuroimages.

In these authors' experience, at least 10% of patients who eventually respond to therapy become significantly worse at the end of a first course of chemotherapy, and transient deterioration is observed occasionally even during the second year of continuous chemotherapy. Paradoxically, this clinical worsening early in therapy may result from an increase in tumor bulk resulting from *effective* therapy. Several factors contribute: cell mass may increase when doomed cells form giant cells or undergo one or more successful cell divisions before dying; the CNS also has an inefficient mechanism for disposing of dead cells produced by chemotherapy or irradiation; and edema, probably caused by irritative products of cell lysis, may be present within the tumor mass and in adjacent brain.

## GLUCOCORTICOID USE

Administration of glucocorticoids is usually begun before surgery for brain tumor. If an adequate surgical decompression is achieved, the corticosteroid dose can be tapered off rapidly and discontinued within the first week or two after the operation. Some patients require corticosteroid maintenance because a large volume of tumor remains, because tumor occupies the brain stem or spinal cord, or because of corticosteroid dependence resulting from long-term prior usage.

Patients who no longer require corticosteroids after surgery may need them during or after radiation therapy. Reactive edema may occur during irradiation, and there may be a transient period of drowsiness and increased deficit for 6 to 16 weeks after treatment. In both instances, signs and symptoms usually resolve within a few weeks; observation of the subsequent clinical course is often the only way to differentiate these reactions from tumor progression.

The lowest dosage of glucocorticoid that maintains patients at their maximum levels of comfort and function should be sought. Ordinarily, this is determined by decreasing the dosage until symptoms increase or become apparent, then increasing the dosage until they subside. If deterioration is secondary to tumor growth or treatment-induced effects, glucocorticoids may have to be increased to keep the patient comfortable. For example, 3 mg/d of dexamethasone may have the desired effect for a patient with stabilized disease; however, a deteriorating patient may require dexamethasone doses of 64 mg/d or more.

The efficacy of chemotherapy and radiation therapy can be affected by glucocorticoid dosage. A decrease in corticosteroid requirement suggests improvement, assuming that the previous dosage was actually required. An increase in dosage suggests deterioration. Because increased glucocorticoid dosage may improve neurologic status and reduce the image size on CT scan, an attempt should be made to document tumor recurrence before increasing glucocorticoid dosage. The ability of glucocorticoids to reduce the size of primary brain tumors as measured by MRI is well established.

## **SURGERY**

### **GENERAL CONSIDERATIONS**

No other modality can reduce tumor bulk as quickly as surgery, and advances in imaging, computerized navigation, pharmacologic agents for brain edema, neuroanesthesia, and surgical magnification, illumination, and instrumentation such as ultrasonic aspirators have made operative approaches to tumors in even the most remote corners of the CNS possible and reasonably safe. The goal of brain tumor surgery is to resect and cure the tumor completely. If surgical cure is not possible, such as in most gliomas, tumor bulk reduction and consequent decompression of the brain is the next goal and, when possible, should be the first therapeutic modality for the tumor.

An extremely important by-product of cytoreductive surgery is the acquisition of adequate tissue for histopathologic examination. Only rarely should brain tumors be treated with radiation or chemotherapy without a definitive tissue diagnosis. In patients with tumors that are believed to be inaccessible by open craniotomy or in patients for whom open craniotomy would not be helpful, a needle biopsy should be performed with guidance from CT, MRI, or ultrasound. CT-guided stereotaxy is the easiest method for obtaining tissue with a needle.

### **SURGICAL PLANNING**

The intrinsic characteristics of a tumor's appearance and its relative position in the brain as shown on a technically adequate MRI scan can most often narrow the diagnostic possibilities to one or two choices, and a view of the tumor in several planes simplifies surgical planning.

For tumors that appear to be located in critical motor or language areas, functional MRI is becoming an important preoperative screening test to determine the feasibility of the surgery. If the surgery is deemed possible, the functional MRI scans are used in conjunction with intraoperative electrophysiologic mapping (see [Craniotomy for Supratentorial Tumors](#), later in this chapter) to plan a safe approach to an intraaxial tumor.<sup>30</sup>

Cerebral angiography is sometimes useful in surgical planning for tumors that may encircle critical cerebral blood vessels, such as basal meningiomas, or for tumors that can be extremely vascular, such as hemangioblastomas, glomus tumors, and certain meningiomas. Angiography done in temporal proximity (24 to 96 hours) to the planned surgical procedure can be combined with embolization of the tumor's blood supply, in many instances making the surgical procedure technically easier.

The final selection of a surgical approach is made after adequate imaging, after developing a differential diagnosis, and after assessing the patient's general condition. In the era of modern neuroanesthesia, it is rare that a craniotomy must not be done because of poor general medical status. The design of an appropriate scalp incision and bone flap is the final preoperative decision.

### **PREOPERATIVE AND ANESTHETIC MANAGEMENT**

Patients undergoing surgery for supratentorial tumors should be placed on anticonvulsants except in the case of surgery for brain metastasis without prior history of seizures. Corticosteroids (commonly dexamethasone) should be administered for a few days preoperatively, when possible, to reduce cerebral edema and thereby facilitate cerebral retraction for perfect exposure. Blood levels of anticonvulsants should be monitored to ensure that the therapeutic range has been achieved. Anticonvulsants should also be continued for at least 1 year. Corticosteroids should be continued into the postoperative period and then tapered, when possible. The anesthetic agents are selected for their lack of effect on intracranial pressure. In general, the head is held rigidly with pin fixation to minimize movement as the surgeon is looking through the operating microscope, where the slightest movement is dramatically amplified. As the procedure is about to commence, mannitol (1 g/kg body weight) is administered and hyperventilation to a p CO<sub>2</sub> of 25 to 30 mm Hg is accomplished for definitive reduction of the intracranial pressure in preparation for brain retraction.

### **CRANIOTOMY FOR SUPRATENTORIAL TUMORS**

The bony opening is designed so that it is generous enough to facilitate surgery. The bone flap is centered over the tumor or positioned to provide access to the route of approach. In all instances, the scalp flap is designed to accommodate the bone flap fully, and the vascular supply to the scalp is given careful consideration in the design.

After the scalp incision is made and the scalp flap reflected, burr holes are drilled and connected with a power saw. The bone flap can be turned back, attached to the temporal muscle (osteoplastic flap) or its blood supply, or removed completely (free flap). The dura is opened only after the brain has been softened completely by mannitol diuresis and intraoperative hyperventilation. Sometimes a few minutes' wait is necessary to secure maximum decompression, and this brief pause can be critical to the success of the subsequent surgical approach.

The dura is reflected back, and the approach to the tumor is made. The surgeon can be confronted by a field of normal appearing and, in some areas, potentially critical functional cortical structures when seeking to resect a subcortical lesion. In this situation, mapping of cortical motor and speech function can be carried out intraoperatively using electrical stimulation of the cortex.<sup>31</sup> The preoperative functional MRI scan can serve as a guide. Motor mapping can be done in the anesthetized patient when muscle relaxants are not used during surgery, and an increasing number of glioma resections in the dominant hemisphere are being done under local anesthesia for the purpose of speech mapping.<sup>31</sup> Localization of subcortical tumors can be accomplished using intraoperative ultrasonography, but more recently, frameless image-guided interactive surgical systems have been developed.<sup>32</sup> With these systems, a preoperative MRI scan is done with markers on the patient's scalp, which at the time of surgery allow computer digitization of the images onto the patient's head. Placement of the system's probe at the time of surgery gives immediate feedback as to localization as visualized on the MRI. This sort of guidance is invaluable for the design of the craniotomy flap, the localization of the subcortical tumor, and even determination of the extent of tumor resection.

Tumor removal is usually done with grasping instruments, bipolar coagulation, and suction, but removal of firm, adherent, or calcified tumor tissue can be difficult and is simplified by use of the Cavitron ultrasonic aspirator (CUSA), which ultrasonically disrupts the tumor at its tip and sucks it away. Tumor in locations where access is limited (e.g., the third ventricle) and space to use graspers and other equipment is not available sometimes can be dealt with best by use of the CO<sub>2</sub> laser, which can vaporize tumor tissue with a hands-off technique. Tumor removal with a laser is slow, however, and is reserved for special circumstances.

In the rare situations in which brain swelling is worrisome at the time of closure, a catheter is left in the subdural space to measure the intracranial pressure. All patients are monitored in the intensive care unit for at least 1 night after surgery, and an MRI scan is done within 48 hours to evaluate the success of the tumor resection. Serum electrolyte levels and osmolality are measured frequently in the postoperative period to ensure that the patient is relatively dehydrated through the first several days and to detect the possible onset of inappropriate secretion of antidiuretic hormone or diabetes insipidus.

## CRANIOTOMY FOR POSTERIOR FOSSA TUMORS

The occiput and, commonly, the dorsal aspects of C-1 and C-2 are exposed. A generous craniotomy is done unilaterally or bilaterally to accommodate an approach through the vermis or through, over, or around the cerebellar hemisphere. A laminectomy of C-1 and sometimes C-2 is done in certain midline approaches to improve tumor exposure or extend the decompression. The cisterna magna is opened to drain CSF and decompress the cerebellum before initiating retraction.

## STEREOTACTIC TUMOR BIOPSY

For intrinsic tumors of the deep midline (e.g., pontine or corpus callosum gliomas), for deep tumors of the dominant hemisphere, or for diffuse nonfocal tumors, surgical resection is not practical. In these situations, needle biopsy for diagnosis is essential. There is no longer any reason to perform a full craniotomy for the purpose of biopsy only. Tissue can be obtained through a needle directed by hand through a burr hole under CT or MRI scan guidance or a needle directed by many devices that incorporate ultrasound images. However, in these authors' opinion, nothing is as simple or accurate as CT- or MRI-directed stereotactic biopsy.

A number of image-guided stereotactic systems are available.<sup>33,34</sup> Typically, the patient undergoes a CT or MRI scan with a rigid array of bars affixed tightly to the skull to minimize movement. In adults, local anesthesia usually is used; children usually require general anesthesia. The CT scan image demonstrates the lesion in which the biopsy will be performed and also the localizing rods, thereby relating the target to a volume encompassed by the rods. By digitizing the position of the target and the position of the rods, this relation is formalized, and the coordinates for a trajectory to the target are created in a way specific to the individual stereotactic system used.

The target is approached through a burr hole or a (smaller) twist drill hole. The biopsy instrument is guided to the target by use of an adjustable stereotactic arc that is placed on the head in fixed relation to the former position of the localizing rods used for the CT scan. A fragment of tissue is aspirated or grasped for removal, and a frozen section confirms the acquisition of diagnostic material and most often also suggests a working diagnosis. Experienced surgeons obtain diagnostic tissue in more than 95% of patients, and these patients stay only 1 night in the hospital.<sup>34</sup> The principal risk of the surgery, hemorrhage at the biopsy site, occurs in few patients. Occasionally, cerebral edema is exacerbated by the procedure.

## RADIATION THERAPY

### GENERAL CONSIDERATIONS

Most primary CNS neoplasms are unifocal; however, the more common brain tumors, such as the low-grade and malignant astrocytomas, are infiltrative into surrounding *normal* brain tissue for a distance of 1 to 3 cm or more. Radiotherapeutic approaches for these brain tumors generally consist of an initial dose to the enhancing disease (which contains solid tumor tissue) plus surrounding edema (which is comprised of normal brain infiltrated by microscopic tumor) plus a 2-cm margin of normal brain tissue followed by a boost dose to the enhancing tumor plus a 2-cm margin. Because of the penetrating nature of the high-energy radiation beams used in current practice, and the presence of a large amount of normal brain tissue in the edema and margin, substantial amounts of normal tissue are often irradiated in the typical patient receiving high-dose radiation with curative intent. The tolerance of the normal brain (and spinal cord in the case of cord tumors) may then be a limiting factor to achieving local control and cure of a CNS neoplasm.

### TOLERANCE OF THE BRAIN

Adverse reactions associated with cranial irradiation differ in their pathogenesis and can be temporally classified into (1) acute reactions that occur during or shortly after radiation therapy; (2) early delayed reactions that appear within a few weeks to 4 months after irradiation; and (3) late delayed injuries that develop several months to years after treatment.<sup>35</sup>

Acute reactions are thought to be caused by radiation-induced edema. Within a few hours after the first fraction of radiation, patients may develop headache, nausea, vomiting, somnolence, fever, and worsening neurologic symptoms. Symptoms occur most commonly after large dose fractions (3.0 to 6.0 Gy) are delivered to a large volume of the brain in patients with increased intracranial pressure from primary or metastatic brain tumors. Thus, if symptoms of increased intracranial pressure are present, patients undergoing cranial irradiation should be protected with corticosteroids, administered for at least 48 to 72 hours before beginning treatment.<sup>36</sup> When larger fractions (7.5 Gy or more) are used, this disorder may culminate in abrupt neurologic deterioration or death.<sup>35</sup> However, with conventional daily fractions of 1.8 to 2.0 Gy, the acute radiation reaction most commonly presents as mild headache and nausea, becoming progressively less severe with each succeeding fraction.<sup>36</sup> Treatment with hyperfractionated irradiation schedules of 0.9 to 1.2 Gy, two or three times daily and accelerated fractionation programs of 1.6 to 2.0 Gy given two or three times daily delivered to a portion of the brain are also well tolerated.<sup>35</sup>

The early delayed reaction is thought to result from temporary demyelination caused by the effects of radiation on oligodendroglial cells<sup>37</sup> or radiation-induced changes in capillary permeability.<sup>36</sup> It is characterized by transient neurologic deterioration, somnolence, and an exacerbation of tumor-associated signs and symptoms depending on the presence or absence of an underlying brain tumor, the volume of brain irradiation, and the dose delivered.<sup>35</sup> In patients with brain tumors, perilesional vascular abnormalities and tumor necrosis may induce clinical and radiographic changes that are indistinguishable from tumor progression. Although signs and symptoms are usually mild, corticosteroid therapy and intensive medical support may be required. The appearance of new findings during this early posttreatment interval does not always indicate that the tumor has recurred or that a change in therapy is needed; observation is often the only way to distinguish this situation from tumor progression.

Late delayed radiation injuries make up the most serious complications of therapeutic irradiation on the brain and vary in their appearance and severity from asymptomatic white matter changes to potentially fatal necrosis. Late radiation injury has been attributed to vascular endothelial injury or to a direct effect on oligodendroglial cells, and multiple mechanisms are probably involved.<sup>35</sup> The late delayed reaction presents as a focal or as a diffuse white matter injury that may occur together in the same patient. The clinical presentation depends on the site and volume of the brain exposed. Patients with focal radiation necrosis present with localizing neurologic signs, often accompanied by symptoms of increased intracranial pressure. Focal hypodensity or a contrast-enhancing mass with surrounding vasogenic edema may be seen on CT scan. MRI shows a contrast-enhancing mass with focal and confluent white matter alterations on T2-weighted images. Diffuse white matter injury typically occurs after large-volume or whole brain irradiation. Clinical features range from seizure disorders and varying degrees of neuropsychological impairment to incapacitating dementia. Diffuse white matter hypodensity is seen on CT scan, often accompanied by a focal enhancing mass, whereas T2-weighted MRI shows diffuse periventricular white matter hyperintensity. Cerebral cortical atrophy, probably a late finding related to diffuse white matter injury, is observed in 17% to 39% of patients who receive whole brain irradiation with chemotherapy for malignant gliomas. Enlarged cerebral sulci and ventricles are seen in neuroimaging studies.<sup>36</sup> The pathogenesis of this formal radiation damage is uncertain.<sup>36</sup> Rarely, therapeutic irradiation causes an intracranial vessel occlusive vasculopathy or secondary neoplasia.

The tolerance of the brain depends on the size of the dose per fraction, total dose administered, overall treatment time, volume of brain irradiated, host factors, and adjunctive therapies. The probability of injury increases with larger daily doses (2.2 Gy per fraction) and doses in excess of 60 Gy delivered in 30 fractions over approximately 6 weeks. [Table 43.2-11](#) defines the role of these factors in radiation tolerance and injury to the normal CNS tissues, as well as ways they might be modified to increase tolerance (i.e., reduce injury).<sup>35,38</sup> Sheline and associates suggested that the threshold doses for brain injury are approximately 35 Gy for 10 fractions, 60 Gy for 35 fractions, and 76 Gy for 60 fractions.<sup>39</sup> They further demonstrated that the isoeffective dose (termed *neurei*) formula should have an exponent of  $N = 0.41$  and an exponent of  $T = 0.03$  (where  $N$  is the number of fractions and  $T$  is the total time in days). This formula may not be applicable to extremely small or large numbers of fractions or to extremely short or long overall treatment times. Based on models such as these, the TD 5/5 (a 5% complication rate in 5 years) for the whole brain is between 40 and 60 Gy, for part of the brain is 50 to 10 Gy, and for a 10-cm segment of spinal cord is 45 to 50 Gy (see discussion of spinal cord tolerance in this section), as shown in [Table 43.2-12](#). Although the TD 50/5 (a 50% complication rate in 5 years) for spinal cord is reportedly lower than that of brain, there are not good data to support this difference. Rather, the sequelae of spinal cord radiation injury are perceived as greater than those of brain injury, therefore tolerance doses have been arbitrarily lowered. In clinical practice, TD 5/5's of 60 Gy for partial brain and 50 Gy for a limited segment of spinal cord are commonly used.

leukemia have long been attributed to cranial irradiation. However, a study comparing the long-term cognitive outcome of children treated with 18 or 24 Gy and intrathecal methotrexate or intrathecal and intravenous methotrexate without cranial irradiation failed to demonstrate an overall decline in verbal, performance, or full-scale IQ in any of the three groups, although 22% to 30% of children in each group showed at least a 15-point decline in IQ during the study period. The authors proposed that ecologic factors or continuation phase chemotherapy rather than radiation therapy might account for the IQ changes.<sup>50</sup>

Neuropsychological deterioration has been recognized in long-term surviving patients with small cell lung carcinoma who receive prophylactic cranial irradiation. These patients are treated with a variety of chemotherapeutic agents that may enhance the effects of radiation on the CNS. The risk and severity of impairment appear to be related to radiation dose and fraction size and to the type, sequence, and dose intensity of the chemotherapeutic agents used.

Children irradiated for brain tumors have IQ decrements and behavioral disturbances. Most require formal psychological intervention and special education programs. Young age at treatment, supratentorial tumor sites, the use of whole brain irradiation, poorly controlled seizure disorders, the presence of sensorimotor deficits, and the addition of chemotherapy have a negative influence on IQ.<sup>51</sup> The risk and severity of neuropsychological dysfunction are also affected by psychological stress, reduced school attendance, and the adequacy of rehabilitative efforts.<sup>52</sup>

Cranial irradiation also leads to intellectual impairment in adults. Unlike in children, however, only a limited amount of quantitative information is available, especially for patients treated with radiation therapy alone. Patients in whom a substantial portion of the brain is irradiated frequently develop recent memory loss and difficulty with attending to tasks that may prevent their return to gainful employment. Impairment is most pronounced in those patients who have had chemotherapy and whole brain irradiation.<sup>53</sup> We found that approximately 60% of long-term survivors irradiated for gliomas were able to be employed at occupations comparable with those they held before treatment.<sup>53</sup> As expected, patients irradiated with partial brain fields had superior memory function and better employment histories than those treated with whole brain fields. Decrements in tests of new learning ability, recent memory, abstraction, and problem solving have been observed in patients who fail to retain their premorbid social or occupational level of function.<sup>51</sup> Early return to work after treatment may lead to improvement or recovery of neuropsychological function.

Radiation therapy may cause hypothalamic-pituitary dysfunction, and the incidence and degree of hormone suppression appear to be dose related.<sup>41</sup> Growth hormone deficiency, the most frequent endocrine dysfunction observed after radiation therapy, can occur after doses as low as 18 Gy. Deficiencies of gonadotrophins, thyroid-stimulating hormone, and adrenocorticotrophins as well as hyperprolactinemia can be seen with doses in excess of 40 Gy.<sup>41</sup> Patients at risk for neuroendocrinologic sequelae should be evaluated for pituitary function before, and periodically after, irradiation. Early detection of a deficiency permits appropriate hormonal replacement therapy before irreversible damage has occurred.

### TOLERANCE OF THE SPINAL CORD

Radiation myelopathy may present as a transient early delayed or as a more ominous late delayed reaction. Transient radiation myelopathy is clinically manifested by momentary, electrical shock-like paresthesias or numbness radiating from the neck to the extremities, precipitated by neck flexion (Lhermitte's sign). The syndrome develops after an average latent period of 3 to 4 months and gradually resolves over the ensuing 3 to 6 months without the need for specific therapy. These findings have been attributed to transient demyelination caused by radiation-induced inhibition of myelin-producing oligodendroglial cells in the irradiated cord segment. An alternative hypothesis suggests that radiation induces a transient disruption of the blood-spinal cord barrier, resulting in vasogenic edema, which in turn leads to demyelination.<sup>5</sup>

Radiation myelopathy is one of the most feared complications in clinical radiotherapy. In addition to its obvious neurologic sequelae, nearly 50% of patients die from secondary complications.<sup>54</sup> The latent period between the completion of radiation therapy and the onset of symptoms is bimodal in distribution, with the first peak occurring at 12 to 14 months and the second occurring at 24 to 28 months. Demyelination and white matter necrosis due to a direct effect on oligodendroglial cells and intramedullary microvascular injury each play a role in the pathogenesis of radiation myelopathy. In addition, microglia, astrocytes, and the release of cytokines are also involved.<sup>38</sup> It is probable that multiple mechanisms exist and that the relative contribution of each depends on radiation dose and other factors. The signs and symptoms that accompany radiation myelopathy are irreversible. They may be partial in some patients, whereas in others there is progressive functional loss that becomes complete over several months. Less commonly, radiation myelopathy is manifested by the acute onset of paraplegia or quadriplegia that evolves over several hours or a few days, resulting from infarction of the cord. Myelopathy may also be heralded by lower motor neuron dysfunction due to selective injury to anterior horn cells.

The diagnosis of radiation myelopathy requires a history of radiation therapy in doses sufficient to result in injury. The portion of the cord irradiated must be slightly above the dermatome level of expression of the lesion, and the latent period from the completion of treatment to the onset of injury must be consistent with that observed in radiation myelopathy. There are no confirmatory laboratory tests or imaging studies that distinguish radiation myelopathy from other spinal cord lesions. MRI findings include swelling of the cord with decreased intensity in T1-weighted and hyperintensity in T2-weighted images.<sup>55</sup> The diagnosis is often one of exclusion.

The medical and legal consequences of radiation myelopathy are such that treatment with radiation therapy is often compromised to keep the spinal cord dose within a safe level.<sup>56</sup> A dose of 45 Gy in 22 fractions over 5 weeks usually is considered to be safe, the risk of myelopathy being less than 0.2%,<sup>38,56</sup> well below the steep portion of the dose-response curve.<sup>56</sup> It is estimated that with conventionally fractionated irradiation (1.8 to 2.0 Gy per fraction, five fractions per week), the incidence of myelopathy is 5% for doses in the range of 57 to 61 Gy and 50% for doses of 68 to 73 Gy.<sup>38</sup> There is no convincing evidence that the cervical and thoracic cord differ in their radiosensitivity. The belief that the cervical cord is more tolerant than the thoracic cord probably arose from differences in biologic dose resulting from the practice of treating with one field per day, which was common through the mid-1970s.<sup>57</sup> There appears to be little change in tolerance with variations in the length of cord irradiated.<sup>38</sup>

Various isoeffect formulas have been proposed for the spinal cord. Wara and coworkers, for example, derived a formula with an exponent of  $N = -0.377$  and an exponent of  $T = -0.058$ .<sup>58</sup> These formulas suggest that in addition to the total dose given, radiation myelopathy is related to the size of the individual daily dose and predict that spinal cord tolerance will continue to increase with decreasing fraction size. However, data indicate that reducing the fraction size to lower than 2 Gy does not alter the dose response significantly. Furthermore, because radiation damage is not completely repaired between multiple daily fractions, extrapolating from a conventionally fractionated cord dose to an equivalent hyperfractionated cord dose using any biomathematical formula should be approached with caution. A dose of 45 Gy in twice daily fractions of 1.2 Gy with an interfraction interval of 6 hours appears safe.<sup>38</sup> Interestingly, experimental animal studies suggest that the majority of occult lesions caused by a dose of 44 Gy in 20 fractions is revealed within 2 years. This may have implications on treatment recommendations for previously treated patients.<sup>38</sup>

### CENTRAL NERVOUS SYSTEM RADIOTHERAPY TOXICITY SCORING SYSTEMS

The most commonly used system for scoring radiation-associated acute and chronic CNS toxicity is that of the Radiation Therapy Oncology Group (RTOG) and its European counterpart, the European Organization for the Research and Treatment of Cancer (EORTC), and is shown in [Table 43.2-14](#).<sup>59</sup> Pavy et al. have proposed a more sophisticated system for scoring radiation toxicity, called Late Effects on Normal Tissues (LENT), in which they describe four components for each toxicity, including the subjective, objective, management, and analytical (SOMA) components.<sup>60</sup> The LENT/SOMA system is currently being validated by the RTOG and may eventually replace the RTOG/EORTC system.

ACUTE TOXICITY GRADE, BRAIN			
1. Fully functional state (ie, able to work) with minor neurologic findings; no medication needed	2. Neurologic findings sufficient to require home care; nursing assistance may be required; medications including corticosteroids and antiepileptics may be required	3. Neurologic findings requiring hospitalization for initial management	4. Severe neurologic impairment that includes psychosis, coma, or status epilepticus; requires medication and/or hospitalization
CHRONIC TOXICITY GRADE, BRAIN			
1. Mild headache; slight irritability	2. Moderate headache; great irritability	3. Severe headache; severe CNS dysfunction (partial loss of power or reflexes)	4. Severe or paralytic coma
CHRONIC TOXICITY GRADE, SPINAL CORD			
1. Mild Lhermitte's syndrome	2. Severe Lhermitte's syndrome	3. Objective neurologic findings at or below cord level assessed	4. Paralysis, paraplegia, or quadriplegia

Grade 1 events occur; grade 1, mild; grade 2, moderate; grade 3, severe; grade 4, life-threatening; grade 5, fatal. (From ref. 38, with permission.)

**TABLE 43.2-14.** Central Nervous System (CNS) Toxicity Levels of the Radiation Therapy Oncology Group and the European Organization for the Research and

## TUMOR TARGET VOLUME AND TREATMENT TECHNIQUES

The appropriate volume to encompass within the radiation treatment portal varies according to the specific histopathologic tumor type and, with certain histologies, is a topic of considerable controversy. Because their tendency to infiltrate beyond the lesional borders visualized by neuroimaging studies is limited, certain tumors, such as benign meningiomas, pituitary adenomas, craniopharyngiomas, and acoustic neurilemmomas, may be treated with narrow margins of surrounding normal tissue. In contrast, the astrocytic gliomas require larger margins for uncertainty because of their tendency to infiltrate beyond the identifiable tumor periphery. Improved imaging techniques and a better understanding of recurrence patterns have fostered the use of limited radiation portals rather than whole brain irradiation for malignant gliomas. Comparisons of CT and MRI studies with clinical and pathologic findings have shown that (1) malignant gliomas are localized, and microscopic invasion of the perilesional brain is limited at the time of initial diagnosis<sup>61</sup>; (2) only 1.1% of patients present with multiple lesions<sup>62</sup>; (3) after initial treatment, most of these lesions, when they recur, do so at their original location<sup>63</sup>; and (4) isolated tumor cell infiltration may extend to the periphery of T2-weighted MRI abnormalities.<sup>64</sup> Clinical studies have failed to demonstrate that irradiating the whole brain is superior to treating more limited fields,<sup>45</sup> and patients surviving for extended periods after whole brain irradiation, especially in combination with chemotherapy, may experience considerable treatment-related morbidity.<sup>52</sup> Until the primary tumor can be controlled with greater frequency, and the patterns of failure in such patients suggest that local fields are unjustified, there is little rationale for treating the whole brain.

The radiation beam energy and field arrangements are selected after consideration of the location of the tumor within the brain and the geometry of the target volume. The across target volume is defined as a three-dimensional reconstruction of the tumor contour based on operative findings and data from CT and MRI studies. The planning target volume consists of the volume of tissue that must be irradiated to encompass the tumor volume with a margin of surrounding tissue considered to be at risk for microscopic tumor spread and to account for patient movement and daily set-up uncertainties. Depending on tumor size and location, treatment portals may be coaxially opposed or designed in a more complex fashion, using multiple or rotational fields with wedge filters. Three-dimensional conformal radiation therapy and the advanced technique of intensity modulated radiation therapy (see [Chapter 29.4](#)) are new methods of treatment planning and delivery designed to enhance the conformation of the dose to the target volume, while maximally restricting the dose delivered to the normal tissue outside the treatment volume. In the future, these techniques may improve the outcome of patients with brain tumors by allowing higher than traditional radiation doses to be administered safely. Megavoltage equipment with energies ranging from cobalt 60 to 15 MV photons is used to administer radiation therapy. Treatment is generally given in daily fractions of 1.8 to 2.0 Gy/d five times per week. In this chapter, the total doses referred to assume that a *conventional* fractionation scheme is used unless otherwise specified.

Certain neoplasms, such as medulloblastomas and other primitive neuroectodermal tumors as well as some ependymomas and germ cell tumors, require treatment to the entire craniospinal axis. Patients are treated prone in an immobilization cast to ensure daily positional reproducibility. The intracranial contents, including the upper one or two segments of the cervical cord, are treated through parallel opposed lateral fields. The spine is treated through one or two posterior fields, depending on the size of the patient. The collimator for the lateral cranial fields is angled to match the divergence of the upper border of the adjacent spinal field, and the treatment couch is angulated so that the inferior border of the cranial field is perpendicular to the superior edge of the spinal field. Individualized focused blocks protect the normal extracranial head and neck tissues from the primary radiation beam. The cranial and posterior spine fields may be abutted, but a gap of 0.5 to 1.0 cm is often left between the fields. When two posterior spinal fields are used, as is usually the case, a gap is calculated so that the 50% isodose lines meet at the level of the spinal cord. All junction lines are moved 0.5 to 1.0 cm daily or at least every 10 Gy to avoid overdosing or underdosing segments of the cord. This is accomplished by expanding the lateral cranial fields and moving the posterior spine fields caudally without changing their dimensions. A fixed block is placed at the inferior margin of the caudal spinal field to keep the lower margin of the irradiated volume at the same location. Several modifications of this approach are used in clinical practice.

Radiosurgery is being used to treat a diverse group of intracranial lesions, including small arteriovenous malformations, pituitary adenomas, acoustic neurinomas, meningiomas, gliomas, and brain metastases. Radiosurgery is a method of highly focal, closed skull external irradiation that uses an imaging-compatible stereotactic device for precise target localization. The relationship between the stereotactic coordinate system and the radiation source(s) allows accurate delivery of radiation to the target volume. Radiosurgery can be administered by gamma knife units, made up of multiple cobalt beams, and by modified linear accelerators. This technique is designed to deliver a high radiation dose to an intracranial target in a single session without delivering significant radiation to adjacent normal tissues. The dose that can be safely administered in a single fraction is limited by the volume irradiated, and to maintain a steep dose gradient at the edge of the field, the application of radiosurgery is restricted to lesions measuring 4 cm or less in diameter.

Radiosurgery may be delivered in a fractionated dose schedule using stereotactic radiosurgery hardware and software and head frames that can be relocalized daily in a reproducible fashion. This approach is referred to as *stereotactic radiotherapy* or *fractionated radiosurgery*. Because fractionating the radiation dose improves the therapeutic ratio, larger tumors and those located within or adjacent to critical intracranial structures are suitable for this treatment technique. This approach is being applied to the treatment of malignant gliomas, craniopharyngiomas, pituitary adenomas, small optic tract tumors, and as a boost for medulloblastomas.

## CHEMOTHERAPY

### GENERAL PHARMACOLOGIC CONSIDERATIONS

The use of anticancer agents in the treatment of intracranial and spinal tumors is established for many primary tumors. For parenchymal CNS tumors, however, controversy surrounds the concept of limited antitumor efficacy for agents with restricted blood–brain barrier permeability,<sup>65</sup> supporting the concept is the fact that many infiltrative primary CNS tumors (e.g., gliomas) have cellular regions within the brain with apparently intact normal-appearing brain capillaries. In addition, the actual extent of capillary breakdown accounting for the leakage responsible for positive-contrast CT and MRI as well as radionuclide brain scans is small.<sup>66</sup> Although drug delivery to portions of any primary tumor would be expected to occur to the same extent as with non-CNS tumors, delivery (by diffusion) to infiltrative regions distant from leaky tumor capillaries would be expected to be compromised. Diffusion, being a slow process, cannot achieve significant drug concentrations, unless plasma drug levels are sustainable for prolonged periods, and the diffusing drug is relatively stable in the tumor tissue as it diffuses.

A secondary supporting argument is that most agents with antitumor activity against CNS tumors readily cross the blood–brain barrier.<sup>67</sup> For example, all of the non–sugar-containing chloroethylnitrosoureas such as bischloroethylnitrosourea (BCNU), lomustine (CCNU), [1-(2-chloroethyl)-3-(2,5-dioxo-3-piperidyl)-1-nitrosourea] (PCNU), and nimustine (ACNU) have shown efficacy as single agents, whereas sugar-containing chloroethylnitrosoureas are less effective.<sup>25</sup> Procarbazine and a new agent, temozolomide (Temodar), also cross the blood–brain barrier and are active. Agents such as bleomycin, doxorubicin, cisplatin, vincristine (VCR), and mithramycin do not readily cross the blood–brain barrier and have shown limited activity against gliomas and have limited activity against primitive childhood and embryonal tumors.

Whether ease of blood–brain barrier passage constitutes an absolute or relative advantage is somewhat academic, given the paucity of chemotypes with demonstrable antitumor activity. Even a small pharmacokinetic disadvantage takes on disproportionate importance when the selective cytotoxicity of a drug is small. This may well be the case with many of the drugs used, because they share narrow therapeutic indices because of dose-limiting systemic toxicity.

Finally, with respect to drugs for CNS tumors, many of the available anticancer drugs can be toxic to the CNS if given at extremely high doses or when given in a manner to circumvent the blood–brain barrier.<sup>68,69</sup> The blood–brain barrier exists to protect the brain from many potentially toxic compounds. If the blood–brain barrier did not exist, CNS toxicity rather than myelotoxicity or gastrointestinal toxicity would be dose limiting for most drugs.

Pharmacokinetic considerations for intracranial nonparenchymal tumors and extramedullary spinal tumors are less dependent on the ability to cross the blood–brain barrier readily, because many of these tumors gain blood supply from meningeal blood vessels that are significantly more permeable than those of the brain.

### REGIONAL DRUG DELIVERY CONSIDERATIONS

Under most circumstances regional drug delivery produces greater drug exposure than does systemic intravenous or oral administration. With respect to intracranial and spinal tumors, the regional delivery takes the form of intra-CSF therapy, intraarterial infusion, and intratumoral therapy.

Therapy by the CSF route (usually by ventricular reservoir) is a form of regional drug delivery that is used to treat meningeal neoplasia resulting from primary or secondary tumor invasion of the subarachnoid space and, less commonly, one of the ventricular cavities. It is often, but not always, associated with malignant cells floating in the CSF.

The advantages of intra-CSF therapy are high local drug levels; low systemic toxicity; and the ability to increase the frequency of treatments. However, delivery of drugs through the CSF can be dangerous and is associated with a high morbidity. The drugs commonly used are methotrexate, cytarabine, and thiotepa. All three drugs have been reported to produce CNS damage ranging from fever and chills to leukoencephalopathy and myelitis. Efficacy is limited when gross lesions exist (greater than or equal to 5 mm diameter) or when CSF pathways are blocked and CSF flows are diverted.

Of concern in the use of CSF therapy is that slow clearance of drug can lead to increased neurotoxicity. Normally, these authors find, after injection into a ventricular reservoir and pumping the reservoir five times, the CSF distribution and flow of radionuclide-labeled albumin in the ventricle is well distributed and the half-time from ventricle to cisterna magna is approximately 60 minutes. In many instances, obvious hydrocephalus is not apparent by neuroimaging, but a physiologic slowing of CSF flow (and presumably CSF absorption) is present. This slowing of CSF flow can lead to poor distribution in the subarachnoid CSF for drugs with high capillary clearance, such as cytarabine, and a greater likelihood of serious CNS toxicity for a drug such as methotrexate.

Another form of regional therapy is the intraarterial administration of anticancer drugs through carotid or vertebral arteries. The advantage of this approach is an increased uptake during the first passage of drug through tumor capillaries. Increased efficacy would be expected for patients whose tumors reside within the perfusion territory of the infused artery. Contrary to what may be thought, systemic toxicity is not reduced unless the total administered dose is reduced, because the actual amount of drug taken up into the tumor is a small fraction of the injected dose. On the other hand, focal brain and retinal morbidity are increased, as was demonstrated by the clinical trials with BCNU<sup>70</sup> and cisplatin.<sup>71</sup> Controversial results of clinical trials do not commend this form of treatment, except under controlled experimental conditions.

Intratumoral therapy is regional therapy that is applicable for cystic tumors or postsurgical cavities with a narrow rim of surrounding tumor. Pharmacokinetic considerations implicate problems with maintenance of tumor cavity drug levels if the goal is to maintain a concentration in the cavity as a drug source for diffusion into the surrounding tumor and brain. These problems relate to conservation of mass, diffusion distances from the cavity to the outer margin of tumor, nonspecific biodegradation and binding of drug or drug products, and the need for repeat treatments. Modern clinical trials evaluating this form of regional therapy have not been published.

Another intratumoral approach uses a biodegradable drug-containing polymer that allows zero order release of drug that can diffuse into the surrounding tumor and brain. This approach, using BCNU (the Gliadel wafer system) has received approval by the Food and Drug Administration for use in patients with glioblastoma multiforme at recurrence. Patient survival benefit is modest in published clinical trials.<sup>72</sup>

## CEREBRAL ASTROCYTOMAS

### PATHOLOGY CLASSIFICATION

This section deals primarily with the classification of astrocytomas of varying degrees of aggressiveness, ranging from juvenile pilocytic astrocytoma to glioblastoma multiforme. The slower growing or less aggressive lesions are often referred to as low grade or benign and the more rapidly progressive neoplasms are referred to as high grade or malignant. With the exception of juvenile pilocytic astrocytomas, subependymomas, and the limited number of astrocytomas that can be completely resected, even *benign* astrocytomas are highly lethal. For instance, median 5-year survival for low-grade infiltrating astrocytomas ranges between 21% and 55% following surgery and the 10-year survival between 10% and 43%. For patients with residual tumor after surgery, irradiation increases survival from an average 30% at 5 years to 49%.<sup>73</sup> Median survival for glioblastoma multiforme, on the other hand, ranges between 42 and 60 weeks ([Table 43.2-15](#) for later studies).

Radiation Therapy	Chemotherapy During Radiation	Postirradiation Chemotherapy	5% Survival (yr)	25% Survival (yr)	Reference
40 Gy WB	Hydrocortisone	BCNU	27	71	48
40 Gy WB	Hydrocortisone	PCV	15	36	48
40 Gy LT	—	PCV/BCNU/PC	38	na (8)*	49
40 Gy LT	Procarbazine	PCV	42	34	49
37 Gy WB	Carboplatin	PCV	15	31	49
37 Gy WB	Procarbazine	PCV	17	29	49
40 Gy LT	Hydrocortisone	PCV/BCNU	38	120	49
40 Gy LT	Hydrocortisone or none	PCV/BCNU	38	26	49
		PCV	48	81	49
Radiation therapy followed by brachytherapy	None	PCV	48	142	128

Abbreviations: WB, whole brain; LT, limited-field; BCNU, carboxymethylglutimidyl-L-glutamine; PCV, procarbazine, carmustine, and vincristine; na, not available; WB, whole brain; PCV, procarbazine, carmustine, and vincristine; LT, limited-field.

\*Only data on tumor progression available.

†Of the 100 patients, 46 require resection PCV following combined external beam and brachytherapy; tumor size and location relative to RT field from the other studies (na).

**TABLE 43.2-15.** Survival for Adult Glioblastoma Multiforme Patients with Karnofsky Performance Scores Greater Than or Equal to 60 Treated on Protocols Published Since 1990

Many classification systems for astrocytomas have been advanced that have advocated the presumed cell of origin, the degree of malignancy, or both. Most common classification schemas in use over the past two decades have been modifications of that developed by Ringertz.<sup>74</sup> A slightly different approach was proposed by Daumas-Duport and colleagues. Their grading system assigned a point system to nuclear atypia, mitoses, endothelial proliferation, and necrosis.<sup>75</sup> Grade I tumors had none of these features, grade II had one feature, grade III had two features, and grade IV had three or more features. While in their initial evaluation, this grouping led to distinct and separate median survival curves, a subsequent review of 251 cases at the Massachusetts General Hospital found no statistical difference in survival between grades II and III.<sup>76</sup> Necrosis was found to be a significant predictor of short survival, in agreement with previous studies.<sup>77</sup> The most recent grading system is that proposed by the World Health Organization.<sup>74</sup> For practical purposes, a three-tier system is generally satisfactory for infiltrative adult astrocytomas:

- Astrocytoma (includes fibrillary, protoplasmic, gemistocytic)
- Astic (malignant) astrocytoma
- Glioblastoma multiforme (includes gliosarcoma and giant cell glioblastoma)

### RATIONALE FOR SURGERY

Data from animal experiments suggest, and a large clinical experience with tumors at many sites would confirm, that maximal surgical resection improves the results of subsequent radiation therapy and chemotherapy. This principle is transferable to the treatment of astrocytomas. Gross total surgical resection was among the dominant factors favoring longer survival in patients with grade I or II astrocytomas treated at the Mayo Clinic<sup>78</sup> and in patients with the more malignant astrocytomas.<sup>79,80</sup> If one takes a different perspective and looks at the amount of tumor present on the postoperative CT scan and compares it with survival it can be shown that the two are inversely related even comparing for other variables.<sup>81,82 and 83</sup>

A number of factors might be responsible for the improved clinical outcome when astrocytomas are aggressively resected. An assiduous resection can remove 90% of a typical astrocytoma (1-log cell-kill) and thereby decompress the brain as well as substantially reducing the tumor cell burden. In addition, a large tumor mass left in the brain can serve as a nidus for cerebral edema after radiation therapy because of the indolent removal of dead cells from the brain.<sup>84,85</sup>

### SURGICAL PRINCIPLES FOR CEREBRAL ASTROCYTOMAS

The goal of every craniotomy for a cerebral astrocytoma is gross total resection, and adequate exposure should be accomplished for this purpose, although sometimes aggressive resection proves impossible at the time of the operation. Tumors are approached through an incision in the crest of an overlying gyrus or
