**CHEST WALL INVASION.** Involvement of parietal pleura or chest wall muscle or rib constitutes T3 tumors (Table 31.2-10). The deeper the invasion, the worse is the prognosis. In all instances, it is recommended that the tumor be resected *en bloc* with the involved chest wall, with a minimum of 2 cm of normal chest wall removed in all directions beyond the tumor. When necessary, plastic reconstruction can be used to reconstitute the chest wall. Prognosis is related to the completeness of resection and depth of chest wall invasion, with no patients surviving 5 years after incomplete resection. Whether simple removal of the parietal pleura in tumors only invading this structure is adequate remains a contentious issue. A recent report suggested that with sufficient care and experience, pleurectomy is adequate in selected T3 tumors.<sup>319</sup>

Series of 200 patients in whom tumor was completely resected (n = 10).

**TABLE 31.2-10.** Results after Surgical Treatment for Non–Small Cell Lung Cancer with Chest Wall Invasion (T3)

**SUPERIOR SULCUS TUMORS.** Pancoast described a tumor in the apex of the lung invading the first rib, with associated involvement of the brachial plexus and stellate ganglion, creating Pancoast's syndrome (rib erosion, shoulder pain radiating down the arm, Horner's syndrome). Shaw and Paulson were the first to describe a curative resection in this disease. Since that initial report, most surgeons continue to treat a documented superior sulcus tumor with preoperative radiotherapy of 3000 to 4500 cGy, followed by *en bloc* resection of the involved lung, chest wall and, frequently, the T1 nerve root. Residual disease at the time of resection is treated with PORT or intraoperative brachytherapy,<sup>320</sup> but the results of these R1 or R2 resections are disappointing despite the adjuvant therapy.

The overall survival rate for patients with completely resected tumors is approximately 40% (Table 31.2-11). Adverse prognostic factors include involved mediastinal lymph nodes (stage IIIA) and bony erosion. In a report from MSKCC, lobectomy with *en bloc* chest wall resection proved far superior to smaller resections in treating this disease, and N2 disease severely affected prognosis.<sup>321</sup>

**TABLE 31.2-11.** Reported Results after Surgical Treatment for Non–Small Cell Lung Cancer with a Superior Sulcus Lesion (T3)

Usual contraindications to surgery for superior sulcus tumors include a T4 tumor (vertebral body invasion, subclavian artery, or vein invasion) or clinically evident N2 disease. On occasion, palliative resection of such lesions may be required for pain relief. More recently, aggressive curative approaches to remove and replace these adjacent structures have been reported, with some long-term survivors.<sup>322</sup>

**MEDIASTINAL INVASION.** Invasion of the mediastinal pleura, pericardium, or mediastinal fat also constitutes T3 disease. In many instances, *en bloc* resection of the involved mediastinal tissue can accomplish a complete resection. The results of such surgery for this type of invasion are not well-known. At MSKCC, a review

suggested that only approximately 10% of such patients with completely resected disease survive 5 years.<sup>323</sup> From this review of 225 patients with mediastinal invasion, it was apparent that once mediastinal invasion occurs, frequently major structures are involved (T4), or concomitant mediastinal lymph node disease is present (N2 or N3). In such patients, whenever possible, technical resectability should be determined preoperatively. MRI to detect mediastinal invasion value, then CT scanning to detect mediastinal invasion and mediastinoscopy, are indicated before resection of any of these tumors. Of 225 patients analyzed in this series, only 22% had tumors that could be completely resected, 44% had totally unresectable disease and, in 34%, tumors were incompletely resected. In this sole report of the results of mediastinal invasion, brachytherapy was used in incomplete resections, with a surprising 22% survival rate in this small subset of patients. A more recent reanalysis of this group of patients confirmed a 30% to 40% 5-year survival rate in patients with completely resected T3N0 disease.<sup>324</sup>

**DIAPHRAGMATIC INVASION.** Tumors invading the diaphragm frequently spread along the diaphragmatic pleura, and most patients present with a malignant pleural effusion (T4) that usually is unresectable. In the occasional patient, focal diaphragmatic invasion can be completely resected by lobectomy and *en bloc* resection of the diaphragm, replacing this structure with a synthetic mesh or fabric. In a recent analysis of our material at MSKCC, only seven patients were found with diaphragmatic invasion, and in only two was disease localized enough to be resected.<sup>326</sup> There are no reports of results of such surgery in a series large enough to analyze results, but one would anticipate a result similar to that for T3 tumors elsewhere.

**Stage IIIA Disease**

**t3n1 disease**

Stage IIIA disease includes T3N1 tumors. As with any other T status, once lymph nodes are involved, the prognosis is much worse, thus categorizing these patients as IIIA rather than IIB. Even with completely resected tumors, of 32 patients with lymphatic metastases in T3 lesions, only 20% survived 5 years, and few if any survive 5 years when mediastinal nodes are involved.<sup>319</sup>

**T1–3N2 DISEASE.** The existence of N2 disease remains the most controversial area for primary surgical management of lung cancer. Although potentially resectable, once ipsilateral mediastinal or subcarinal lymph nodes (or both) are involved by tumor, the ultimate prognosis is much worse. When disease is diagnosed preoperatively either by noninvasive or invasive staging techniques, fewer than 10% of all patients treated with primary surgery survive 5 years, no matter the adjuvant therapy.

Selectivity is important before considering surgery for patients with preoperatively identified N2 disease. Adverse prognostic factors include multiple levels of N2 disease, multiple lymph nodes at one level involved with tumor, adenocarcinoma, and extranodal spread of disease. More than 75% of patients with N2 disease present with disease extending beyond one lymph node station.

*“Minimal” N2 Disease.* Single-station lymph node involvement with microscopic foci of disease not clinically apparent on clinical staging constitutes most of the subset of patients with minimal N2 disease. This early-stage disease is usually discovered at the time of thoracotomy or at pretreatment mediastinoscopy. Five-year survival rates after surgical resection are 10% to 20% and are higher when a complete resection is performed ( [Table 31.2-12](#)). Incomplete (R1, R2) resection results in a noncurative treatment, with few if any patients surviving beyond 3 years. Patients found to have multiple lymph node stations involved at final pathologic staging also fare poorly.

Wang et al (			

no treatment or PORT.<sup>339</sup> Doses of PORT varied from 30 to 60 Gy, and most of the trials used cobalt 60. Patients with stage I disease were included in many of the trials. A significantly increased hazard ratio of mortality in stage I patients receiving PORT was reported.

**Stage II and Stage III Disease** The role of adjuvant radiotherapy for stage II (N1) NSCLC is controversial but has been recommended in the past because the incidence of local failure with surgery alone is high. A locoregional intrathoracic failure rate of 31% was observed by the Ludwig Lung Cancer Group for patients with completely resected stage II disease.<sup>340</sup> The Medical Research Council metaanalysis reported a trend toward decreased survival in patients receiving PORT with stage II disease.

The LCSG investigated the efficacy of postoperative mediastinal irradiation in completely resected stage II and III squamous cell carcinoma of the lung. This trial randomly assigned 210 patients to receive 50 Gy in 25 fractions after surgery versus observation alone. The locoregional failure rate (as first site of failure) was reduced from 41% to 3% with radiotherapy for all node-positive patients. Despite this improvement, the increase in locoregional control with radiotherapy did not translate into a survival benefit for stage II patients because more than two-thirds of first failures were distant.<sup>332</sup> The LCSG failed to separate patients with N1 and N2 disease but rather combined and analyzed them as a single group.<sup>332</sup> A trend toward improved survival was observed in N2 patients receiving radiotherapy.

The Medical Research Council of the United Kingdom also completed a randomized adjuvant trial in which 308 patients with stage II and III disease were treated with either 40 Gy or no further therapy, although a trend toward improved survival was seen in the T2N2 subgroup. Again, no overall survival benefit was observed.<sup>341</sup> The metaanalysis performed by the Medical Research Council confirmed these results. The Council reported higher local recurrences in 276 patients in the surgery-only arms of the trials. There were fewer local recurrences in patients receiving PORT. In addition, there was a trend toward improved survival in stage III and N2 patients in this arm, although it did not reach significance.<sup>339</sup> PORT has also been advocated for resected NSCLC invading pleura or chest wall without nodal metastases (T3N0). This issue has never been properly examined in prospective fashion, although the LCSG attempted to address this question in a study that was closed owing to poor patient accrual.<sup>323,342</sup> The survival rate approaches 50% for patients with chest wall tumors undergoing *en bloc* complete resection (R0), and there would appear to be little gained with additional local treatment.<sup>343</sup> Therefore, the role of PORT remains controversial. It has not been shown to produce a benefit in early-stage disease. It has been shown to improve local control in patients with mediastinal nodal disease but has no proven survival benefit. There is likely a subgroup of patients, such as those with micrometastatic disease, who will have an improved survival from PORT; however, this patient population has yet to be identified.

**Positive Margins (R1, R2 Resections)** The presence of microscopic disease after curative surgery for early-stage disease at the bronchial resection margin, chest wall, or vascular margin may adversely affect the prognosis of patients. Yet, despite data that suggest that adjuvant radiotherapy reduces local recurrence, the retrospective literature regarding the efficacy of radiotherapy to improve local control is conflicting.<sup>344,345 and 346</sup>

**BRACHYTHERAPY.** Intraoperative brachytherapy was used as an adjuvant treatment in 23 patients undergoing video-assisted thoracoscopic limited resections (wedge resections) who were unable to tolerate conventional resections.<sup>125</sup> I seeds implanted into a Vicryl mesh were placed thoracoscopically over the tumor bed and resection staple line. A dose of 100 to 120 Gy was delivered. As yet, there have been no local failures in this treatment group.<sup>347</sup>

**ADJUVANT CHEMOTHERAPY WITH OR WITHOUT RADIOTHERAPY.** Given the large number of patients with resectable disease, few randomized studies of adjuvant chemotherapy in NSCLC have been published. Most of these studies used chemotherapy regimens with limited activity.<sup>348,349</sup>

The LCSG published two large randomized trials using the CAP regimen. The first trial included patients with completely resected stage II or III adenocarcinoma or large cell carcinoma.<sup>304</sup> Patients were randomly assigned to receive either CAP chemotherapy or immunotherapy with intrapleural BCG and levamisole administered for 18 months. In 141 randomly assigned patients, there was a trend for increased time to recurrence and for prolonged overall survival favoring chemotherapy. The survival of the control immunotherapy group was similar to that of earlier patients treated with surgery alone, and the authors attributed the improved survival in the chemotherapy arm to the effects of chemotherapy.

Another study involved patients with incompletely resected disease who were randomly assigned to PORT alone or radiotherapy and six cycles of CAP.<sup>350</sup> Incomplete resection was defined as postoperative residual microscopic or macroscopic disease or disease in the highest resected paratracheal lymph node. One hundred sixty-four patients were analyzed. The chemotherapy group had a significantly longer time to progression ( $P = .066$ ); median survival was only marginally improved with chemotherapy, and there was no 5-year survival benefit.

Studies in patients with less advanced disease have also been published. The LCSG compared four cycles of CAP to no further therapy in 269 patients with stage I disease. No benefit was identified for chemotherapy, but only 53% of assigned patients completed chemotherapy. A study testing a lower-dose, six-cycle CAP regimen in T1–3N0 disease showed a benefit in time to recurrence and survival; however, an imbalance in the randomization process resulted in the assignment of more patients with advanced disease to the observation arm.<sup>351</sup> A metaanalysis of all trials of adjuvant chemotherapy failed to demonstrate a decided advantage (<5%) to this approach.<sup>352</sup>

Since the CAP regimens are no longer considered the most active available regimens in NSCLC, the question of adjuvant chemotherapy in NSCLC remains open. A large intergroup study in the United States is testing the value of four cycles of cisplatin plus etoposide (the first two cycles given with concomitant radiotherapy) versus radiotherapy alone in patients with completely resected N1 or N2 disease. Additional international studies are in progress.

It is possible that recurrence rates in early-stage disease are too low to be effectively influenced by adjuvant chemotherapy. An alternative concept of influencing survival rates in these patients is focused on a reduction in the incidence of second primary malignancies. A large North American intergroup study randomly assigning patients with stage I disease to postoperative placebo versus *cis*-retinoic acid chemopreventive therapy has been completed, but the results have yet to be reported. An interesting Japanese study using 1 to 2 years of oral Tegafur in early-stage lung cancer has demonstrated a survival benefit and reduction of second primary tumors in the treated group.<sup>353</sup>

After complete resection of stage I or II lung cancer or microscopic N2 disease, the current standard must be considered surgery alone without adjuvant treatments. Because of the minimal effect of chemotherapy as assessed in the foregoing recent metaanalysis, larger trials of adjuvant chemotherapy are being carried out in North America and Europe. Patients with completely resected disease should be offered inclusion in these randomized trials whenever possible.

**INDUCTION RADIOTHERAPY.** After the initial studies were published on the use of preoperative irradiation as a component of treatment of NSCLC, many attempts with this induction approach were initiated in the hope of improving both local control and survival of patients with marginally resectable disease.<sup>354,355 and 356</sup> Preliminary acceptance of preoperative irradiation was based on observations of improved resectability as well as on a significant number of complete responses in a surgical specimen after the use of preoperative irradiation. Reports of survival in patients with tumors arising in the superior sulcus after combined preoperative radiotherapy (where no previous survivals occurred) also contributed to the initial enthusiasm of a preoperative radiotherapy-alone approach. Subsequently, a few randomized trials were initiated to answer this question with larger cohorts of patients. The first such major randomized trial was performed by the U.S. Veterans Administration. With a minimum follow-up of 4 years in surviving patients, no increase in survival was noted in the pretreatment group. The overall survival rate was 12.5% in the pretreatment arm, as compared with 21% in the surgery-alone arm, although this was not statistically significant.<sup>356</sup> In 1975, the National Cancer Institute published two separate but integrated multiinstitutional randomized trials addressing the use of preoperative radiotherapy followed by surgery in both operable and inoperable NSCLC without evidence of preoperative radiotherapy advantage.<sup>357</sup>

It is clear from both the nonrandomized and randomized data that preoperative irradiation alone does not improve long-term survival and has no role as a single-induction modality in the management of marginally resectable or unresectable stage IIIA or IIIB disease. The use of radiotherapy as a single preoperative modality is no longer studied consistently, owing to the advent of effective chemotherapeutic agents. Most current trials investigate the use of preoperative concomitant chemoradiotherapy.

**Induction Chemotherapy** Phase II studies using a variety of chemotherapeutic regimens have suggested that preoperative chemotherapy could be administered and may be beneficial in locally advanced (N2) disease.<sup>358,359</sup> Martini et al.<sup>360,361</sup> had demonstrated that otherwise resectable patients with ipsilateral mediastinal lymphadenopathy as their sole site of distant spread can have 3-year survival rates of 43% and 5-year survival rates of 24% if both the primary tumor and ipsilateral mediastinal nodes are completely resected and followed by mediastinal irradiation. However, the same studies revealed that patients with ipsilateral mediastinal lymphadenopathy large enough to be clinically apparent on a plain chest radiograph had only an 18% resectability rate and only an 8% 3-year survival rate. A

program was developed that used preoperative combination chemotherapy with high-dose cisplatin (120 mg/m<sup>2</sup>), vinca alkaloids, and mitomycin (i.e., MVP) in stage IIIA patients with clinically apparent ipsilateral mediastinal spread.<sup>362</sup> In a group of 73 patients, the objective major response rate to MVP chemotherapy was 77%, with a 10% complete response rate. Overall, 60% of patients underwent complete resections, and 12% had pathologic complete responses at surgery. The median survival was 19 months for all patients and 27 months for those with complete resections. The 3-year survival rate for the completely resected patients was 44%, a significant improvement over the prior surgery-only experience, in which the 3-year survival rate for clinically evident N2 disease was only 8% ( *P* = .001).<sup>361</sup> Two treatment-related deaths occurred. Using the same MVP chemotherapy program before surgery, Burkes et al.<sup>363</sup> reported a 69% chemotherapy response rate, a 49% complete resection rate, and a median survival of 19 months for all 35 patients studied. Three randomized trials have compared surgery alone to the combined-modality program of induction chemotherapy before surgery. Despite small numbers of patients in each arm, all reported significant differences in both 2-year survival and distant recurrence rates, favoring the induction chemotherapy arm. These survival advantages have been confirmed in 5-year survival update reports.<sup>276,277,364</sup> Larger trials have yet to be reported, but a recent abstract of a very large phase III clinical trial of all resectable stages except T1N0 has failed to confirm this survival advantage in the N2 disease subset.<sup>365</sup> More recent phase II trials of chemotherapy have been reported in T4 disease and earlier stage tumors.<sup>366</sup> Because of these successful outcomes in most phase III trials of induction chemotherapy in stage III disease, this approach is now being investigated in earlier-stage disease. At least three phase III trials in North America and Europe have been instituted, involving patients with clinically evident stage I and II disease, excluding T1N0 tumors.

**INDUCTION CHEMOTHERAPY WITH CONCOMITANT RADIOTHERAPY.** Cisplatin - based combination chemotherapy has been combined with concomitant radiotherapy in an effort to improve results. In the 1950s, Faber et al.<sup>367</sup> conducted two consecutive trials in clinical N2 NSCLC patients. The first combined 5-fluorouracil, cisplatin, and 40 Gy of chest radiotherapy; the second added etoposide to the regimen. The complete resection rate was 68% in the first trial and 76% in the second program. Median survivals were 21 months and 34 months, respectively. The difference in survival was not significant. Four treatment-related deaths occurred in the two trials. The LCSG combined 5-fluorouracil, cisplatin, and 30 Gy of chest radiotherapy.<sup>368</sup> Overall, 42% of patients underwent a complete surgical resection, and a median survival of 11 months was observed. These results were similar to an earlier trial by the LCSG employing the CAP regimen with 30 Gy of chest irradiation; a 33% resection rate and 11-month median survival were seen in stage III patients.<sup>369</sup> The Cancer and Leukemia Group B (CALGB) tested the combination of 5-fluorouracil, vinblastine, and cisplatin plus 30 Gy of irradiation in 32 stage IIIA patients.<sup>370</sup> The complete resection rate was 62%, and three treatment-related deaths occurred. The SWOG employed 45 Gy with etoposide and cisplatin and documented a 65% complete resection rate.<sup>371</sup>

More recently, a significant effort has been put forth in phase I and II trials to optimize the locoregional therapy in a select group of patients with marginally resectable stage IIIA and IIIB disease. The goals of induction therapy are to convert marginally or unresectable disease, improve locoregional control, and eliminate distant micrometastases.

### **Sequential Chemotherapy and Radiotherapy**

Two phase II trials reported results with induction chemotherapy followed by preoperative radiotherapy and surgery for stage III NSCLC. Skarin et al.<sup>372</sup> treated 41 patients with pathologically determined marginally resectable stage IIIA NSCLC. Included within this group were patients with T3N0 disease and patients with N2 mediastinal metastases. Forty-one patients received two cycles of CAP chemotherapy followed by 30 Gy of irradiation. A complete resection was accomplished in 36 of 41 patients (88%). The median survival was 32 months, and the 3-year survival rate was 30%. Systemic treatment failed in 18 of 36 patients (50%), and local treatment failed in 4 patients. Using a sequential chemotherapy regimen of vinblastine and cisplatin, Sherman et al.<sup>373</sup> treated 21 patients with this neoadjuvant regimen followed by 30 Gy of irradiation to the mediastinum. The observed radiographic response rate, resection rate, and median survival were similar to those reported by Skarin et al.<sup>372</sup>

### **Concurrent Chemotherapy and Radiotherapy**

Several phase II trials have tested the feasibility of combining a variety of induction chemotherapy regimens concurrently with radiotherapy before surgery to maximize induction results through a trimodal strategy. To determine whether surgical resection is a necessary component of a combined-modality approach in the treatment of stage IIIA and select stage IIIB NSCLC, using the SWOG VP-16-platinum regimen, a North American intergroup effort is completing a phase III trial (chemoradiotherapy vs. chemoradiotherapy plus surgery).

It is a challenge to define an optimal regimen from this large group of phase II trials because of the heterogeneity of both the patients entered and the treatments delivered.<sup>374</sup> Different chemotherapeutic regimens were used, with either low-dose cisplatin alone or other agents in a multidrug regimen. Significant variability among the different trials can be seen in the sequencing of the chemotherapy in relation to the radiation, radiation dose, dose per fraction, continuous-course versus split-course strategy, timing of surgery, inclusion by some studies of T3N0 versus clinical N2 disease, inclusion of stage IIIB disease, staging methods, performance criteria, and the toxicity of individual regimens. Although a number of phase II trials report promising results, wide variation also exists in terms of initial response rates (range, 50% to 90%); complete resection rates (range, 28% to 88%); pathologic complete response rates (range, 9% to 21%); median survival rates (range, 13 to 32 months); and 2-year survival rates (range, 20% to 40%).

Recent trials have attempted novel fractionation schemes (especially hyperfractionation) combined with concurrent chemotherapy using a variety of drugs and dosage schemes further to enhance the response rates and optimize resection rates and local control.<sup>375,376 and 377</sup> Overall, these trials appear to suggest that a bimodality or trimodality approach combining neoadjuvant chemotherapy with or without radiation and followed by surgery provides a potentially superior method of enhancing resectability and improving locoregional control and survival over radiotherapy alone followed by surgery. Some series also demonstrated a doubling of both local control and survival rates over those reported with primary radiotherapy with or without chemotherapy. The use of altered fractionation also appears to provide greater response rates and local control rates than standard fraction irradiation combined with chemotherapy with acceptable toxicity.

The role of induction therapies followed by surgery in resectable lung cancer remains to be defined. In N2 disease, it does appear to improve long-term survival, although the role of surgery vis-à-vis radiotherapy as the primary control mechanism will be defined only as a result of the aforementioned current phase III trial in North America. Whether induction therapies will have an impact on earlier-stage (non-T1N0) disease has yet to be defined but, once again, it is hoped that current phase III trials will resolve this question.

### **Primary Radiotherapy**

**EXTERNAL-BEAM RADIOTHERAPY.** *Selection Criteria* The selection of patients for definitive management with radiotherapy depends on several factors, the most important of which are extent of disease, performance status, and pulmonary function. Accurate staging is required to establish and exclude patients with distant metastasis from undergoing radical treatment. In addition to distant metastases, malignant pleural and pericardial effusions are an absolute contraindication for definitive radiotherapy. In some circumstances, however, a small pleural effusion not seen on chest radiography is discovered on staging CT scanning, rendering the decision to proceed with definitive management less clear. Patients with this finding, in the setting of no other significant clinical, laboratory, or radiographic findings that suggest distant spread, should be considered for curative treatment.<sup>378</sup>

No specific criteria exist to define the extent of tumor bulk as unsuitable for treatment with curative intent using conventional treatment planning. In general, however, intrathoracic tumors 8 cm or larger are considered relatively prohibitive for high-dose treatment (55 to 70 Gy) due to excessive pulmonary toxicity. Patients with such large tumors without evidence of extrathoracic spread should be considered for induction chemotherapy to attempt tumor shrinkage and reduction in the volume of lung that would otherwise be targeted. Large tumors or bulky nodal disease may potentially receive high-dose radiotherapy with 3D-CRT. This approach has the potential to maximize delivery of the prescribed high dose to the target volume and minimize the dose to surrounding normal tissues. Clinical research is addressing this issue in ongoing phase I dose escalation trials.<sup>216,217 and 218</sup>

Most patients considered for primary radiotherapy have preexisting compromised lung function from underlying emphysema or chronic obstructive pulmonary disease secondary to a long history of smoking. It remains a difficult challenge for the radiation oncologist to predict accurately which patients will retain the minimum adequate posttreatment functional lung volume to provide basic pulmonary function for normal activity.<sup>379</sup> Physiologic changes in pulmonary function after radiotherapy depend on several factors, including preexisting pulmonary function reserve before radiotherapy, the anatomic region of lung treated, total dose, dose per fraction, prior chemotherapy or the desire to incorporate chemotherapy concurrent with radiotherapy, and the presence of more than a 10% shift of the ventilation or perfusion to the contralateral lung from tumor or nodal disease causing central bronchial or major pulmonary vessel obstruction.<sup>380</sup> Some investigators have found that the decrease in pulmonary function as determined by pulmonary function tests and single-photon emission CT imaging studies correlates with the amount of lung

receiving 30 Gy.<sup>381</sup>

For patients with clinical stage I and II NSCLC that otherwise is technically resectable but in whom surgery is prohibitive secondary to severe medical contraindications, as well as for patients who refuse surgery or have clinical but minimal N2 disease, primary radiotherapy alone offers a reasonable alternative approach and potential for locoregional control and cure.<sup>382,383,384,385,386,387,388,389,390,391,392,393,394,395,396,397</sup> and <sup>398</sup> Although surgery has resulted in the highest reported survival rates in stage I and II disease, no modern randomized studies have compared surgery to radiation in a comparable group of patients. The observed differences in results between surgery and radiation are due in part to selection bias because, in many instances, patients referred for radiation have worse performance status, are less rigorously staged, and have poor pulmonary function combined with comorbid illnesses.<sup>393</sup> In addition, most surgical series report results after pathologic staging. Surgical series reveal that approximately 25% to 50% of clinical stage I patients are up-staged (see Fig. 31.2-8). The rate of occult N1 or N2 disease is as high as 56% if the patient has a positive preoperative bronchoscopy.<sup>399</sup> Therefore, it is important to evaluate cause-specific survival as an end point in these studies, since many patients die of intercurrent disease. In addition, many historical series reporting results with radiation alone used inferior equipment and treatment planning by today's standards and delivered inadequate doses.

More modern series have examined the issues of dose and dose escalation in relation to tumor size, local control, and survival for stage I and II disease. The evidence suggests that radical radiotherapy is an effective treatment primarily for tumors smaller than 3 cm (T1) when treated to doses of 65 Gy or higher. This treatment has a greater probability of complete response rates, local control, and disease-free survival almost comparable to some surgical series.<sup>383</sup> Complete response and local control of larger tumors, however, appear less likely with standard radiation fraction schedules and doses, despite availability of modern equipment and CT-based planning.

The need electively to treat the mediastinum in patients with no evidence of nodal spread has been challenged. The inclusion of large volumes of lung within a radiation port, especially for peripheral T1 and T2 tumors, to prevent regional failure must be balanced against the potential for increased toxicity. The rationale for treating the local tumor volume alone appears justified when the patient's outcome is not subjected to negative impact if the regional lymph nodes are not included. The evidence appears to support the use of smaller target volumes to deliver higher doses without compromise of the regional outcome.<sup>388</sup> The regional failure rate is typically less than 10% in reported series where elective nodal areas were not treated.<sup>388,394,400</sup> In one series,<sup>396</sup> most patients did receive elective nodal irradiation but still had a failure rate approaching 10%, which suggests that a typical elective dose of 40 Gy is not enough to control occult disease. Selection for this approach would be improved by pretreatment invasive mediastinal staging.

The issue of split-course versus continuous-course radiation has also been examined for stage I and II NSCLC with mixed results and has generally been discouraged when treating with curative intent.<sup>385,388</sup> Split-course radiotherapy is a reasonable alternative for elderly patients or patients living at great distances in whom a protracted course of treatment is impractical. It is also potentially more cost-effective.

## Results

One of the earliest studies demonstrating the curability of medically inoperable lung cancer with radiation alone was reported by Hilton and Smart in the early 1940s and 1950s. Thirty-eight patients with stage I or II NSCLC were treated with curative intent. Doses of 50 to 55 Gy were prescribed for squamous cell histology, delivered to the primary site only, and doses of 40 to 45 Gy were prescribed for undifferentiated cancers, delivered to the primary site and mediastinum. Despite inadequate doses, frequent treatment breaks to allow recovery for acute reactions, orthovoltage equipment, unsatisfactory staging, and a mix of histologies, the 2-year and 5-year survival rates were 47% and 17%, respectively.<sup>386,390</sup>

In 1963, Morrison et al.<sup>401</sup> reported the results of the only randomized trial comparing surgery with radiation for stage I and II NSCLC. Although the outcome for surgery was superior to that for radiotherapy alone, the trial was severely flawed. This study of patients randomly assigned to radiation alone suffered from small patient numbers, the patients received low radiation doses in the range of 45 Gy, and the study included small cell histology (approximately 30%). Additionally, almost 30% of patients undergoing surgery received adjuvant PORT.<sup>401</sup>

Historical series reporting results with primary radiotherapy alone are often the victims of selection bias. Many of the same medical contraindications that prohibit surgery, such as age, performance status, severe intercurrent medical illness, and poor pulmonary function, are known to be significant prognostic factors for survival.<sup>402,403</sup> Patients referred for radiotherapy are more likely to be elderly and to be at greater risk for death from intercurrent diseases. Patients receiving radiotherapy alone generally have also undergone less extensive staging (clinical versus pathologic) than those in surgical series reporting pathologic versus clinical outcome. Some patients discovered on mediastinoscopy to harbor N2 disease may be excluded or separated from outcome analyses in surgical series.<sup>402</sup> Sandler et al.<sup>393</sup> demonstrated the importance of rigorous clinical staging in selecting true stage I NSCLC for primary radiotherapy. In their series of 77 patients with clinical stage I NSCLC treated with primary radiotherapy, treatment in only 2 of 12 patients who underwent "excellent" staging evaluation failed locoregionally at 3 years, in contrast to that in 22 of 24 (87%) and in 30 of 41 (79%) with locoregional failure for "good" or "other" staging, respectively. With the advent of noninvasive assessment of nodal regions through CT and PET, some of this discrepancy might diminish.<sup>402,403</sup>

Tumor size is a prognostic factor in almost every retrospective series reported. For example, Krol et al.<sup>388</sup> found that tumors smaller than 4 cm had a 35% overall survival at 3 years and tumors larger than 4 cm had a 13% 3-year survival. There has also been some evidence that higher doses (>65 Gy) lead to improved survival.<sup>383,394</sup> Jeremic et al.<sup>400</sup> and Morita et al.<sup>397</sup> have reported treating patients with some of the highest doses seen in the literature, 69.6 Gy and 65 Gy, respectively, and report favorable overall survival. These two factors, tumor size and dose, are interrelated, since a very large tumor, technically T2, is often difficult to treat to high doses secondary to pulmonary toxicity. Squamous cell histology has been shown to be a positive prognostic factor, as has younger age.<sup>393,396</sup> The results from many modern series appear in Table 31.2-13. Therefore, patients with smaller tumors treated to higher doses appear to be the best candidates for primary radiotherapy. Treatment of elective nodal regions prophylactically is probably not needed. The best radiotherapy results are still inferior to most surgical series, although there are many confounding factors to account for a portion of this difference. It is hoped that with improved staging and dose delivery, the results with primary radiotherapy will improve.

TABLE 31.2-13. Results for Patients Treated with Radiation Therapy Alone for Early-Stage Non–Small Cell Lung Cancer

**PRIMARY BRACHYTHERAPY.** Hilaris and Martini<sup>404,405</sup> described the use of brachytherapy at MSKCC for medically inoperable NSCLC in the setting of a tumor that was determined to be unresectable intraoperatively. Permanent or temporary implantation was used as a local conformal boost or as primary treatment alone. These authors reported the results of 55 patients with medically unresectable stage I and II NSCLC. Most (44 of 55) patients underwent biopsy only. The remainder underwent subtotal resection. After surgery, 24 patients received additional external-beam irradiation (median dose, 40 Gy). An actuarial 5-year overall survival of 32% was observed, with a local control at 5 years of 65%. Broken down into stages, the local control rates for T1N0, T2N0, and T1–2N0–1 disease were 100%, 70%, and 70%, respectively. The addition of external-beam irradiation for patients with N1 involvement improved the local control (86%), as compared with the local control rate in patients with N1 disease who received no further therapy (57%). These intraoperative situations are less frequent with the advent of better preoperative

imaging.

Perol et al.<sup>406</sup> examined the use of high-dose-rate EBB for early-stage NSCLC limited to the endobronchus that was smaller than 1 cm and not visible on CT scan. Nineteen patients were treated with 7 Gy per fraction every week for 3 to 5 weeks. The 2-year overall survival and local control rates were 58% and 75%, respectively.

Tredaniel et al.<sup>407</sup> reported the results of 29 patients with endoluminal localized tumor treated definitively with <sup>192</sup>Ir after loading sources prescribed to a depth of 1 cm from the source center. Complete macroscopic regression was seen in 21 of 25 evaluable patients, with histologically complete responses in 18 of 25. At 23-month follow-up, the median survival had not been reached.

#### “UNRESECTABLE” STAGE IIIA AND IIIB NON–SMALL CELL LUNG CANCER

Whether stage IIIA or IIIB disease is considered unresectable depends, to a large degree, on the experience and attitudes of physicians treating the patient. What one surgeon considers unresectable, another with an aggressive surgical attitude may deem completely resectable. Despite this, when stage IIIA disease is extremely bulky and enlarged lymph nodes surround vital structures in the mediastinum, it is unlikely that any primary surgical approach will allow a complete resection or significant cure. In centers with more aggressive attitudes, these “unresectable” tumors have become eligible for combined-modality programs that include surgery. Despite this, the standard treatment for locoregional unresectable disease does not include surgery.

Patients with unresectable stage IIIA or IIIB NSCLC have traditionally been treated with radiotherapy alone. Since all known macroscopic disease is confined to the chest, therapy is in theory given with curative intent. However, only 5% to 10% of patients survived beyond 5 years. This was frequently owing to distant disease progression (outside the radiation field), which occurs in up to 70% of patients and reflects the presence of systemic micrometastases at the time of initial therapy.<sup>408</sup> Disease in a large proportion of patients also progresses within the irradiated volume, reflecting the inability of radiotherapy to eliminate all macroscopic disease. Efforts to increase cure rates have, therefore, attempted to increase both locoregional and systemic control. In practice, induction chemotherapy or concomitant chemoradiotherapy (or both) has been most frequently studied to achieve these goals.

#### Aggressive Surgery

When stage IIIA (N2) disease is bulky, involving mediastinal lymph node stations or extracapsular disease, and is proven by an invasive staging technique, such as mediastinoscopy, the role of the primary surgery has been proven to be of little value with regard to an intent to cure. It is these patients in whom the role of induction therapies combined with surgery or radiotherapy has been intensively investigated. In all these patients, imaging studies must be correlated with invasive staging. Whether PET scanning can replace mediastinoscopy as positive proof of involvement of mediastinal lymph nodes has yet to be defined. At present, even with a positive PET scan, invasive staging is mandatory: Too many inflammatory processes (e.g., sarcoid reactions with concurrent tumors) can produce “positive” PET scan results. All too frequently, disease in some patients is deemed unresectable by imaging studies alone and not considered for a surgical approach because of this. It has been well recognized that imaging studies are in error at least 30% of the time and that confirmation of N2, N3, or T4 disease by invasive staging is mandatory unless there is incontrovertible evidence present.

Stage IIIB disease encompasses patients with a T4 or an N3 lesion, both of which are usually considered unresectable disease. Radiotherapy, chemotherapy, or a combination of both remains the standard treatment for these patients. In general, they are not referred for surgical treatment. Nevertheless, in a large retrospective study, patients with surgically resected stage IIIB disease had an overall 5-year survival rate of 6%.<sup>409</sup> There is a danger of clinically overstaging a tumor as T4 and denying a patient with completely resectable T1–3 disease the opportunity of a curative resection. T4 disease in highly selected patients can be completely resected, and long-term survival can be achieved in some of these patients. In this group of patients as well, combined-modality therapy (including surgery) is being investigated<sup>410,411</sup> (discussed in [Induction Chemoradiotherapy](#)).

**T4 TUMORS.** T4 tumors include those invading mediastinal structures (the carina and trachea, the heart and great vessels, the esophagus or vertebral body) as well as the presence of a malignant pleural effusion. Naruke et al.<sup>409</sup> reported a 5-year survival of 8% in 104 selected patients after resection of such a T4 lesion.

*Carinal Invasion* Although primary lung cancer invading the carina is generally considered unresectable, pneumonectomy with tracheal sleeve resection and direct reanastomosis of the trachea to the contralateral main stem bronchus can be accomplished, with reported 5-year survival rates approaching 20%. In most series reported, patients were highly selected, with most long-term survivors having T4N0 tumors.

Anastomotic dehiscence with bronchial fistula formation and postoperative pulmonary insufficiency are major postoperative problems and are the main cause of the high operative mortality rate, which ranges from 11% to 27%. Only highly selected patients without N2 disease should be offered such a resection. For this reason, prior to resection of such a tumor, mediastinoscopy should be considered mandatory. In some patients, “extended” sleeve lobectomies (resecting the carina) can be used to preserve pulmonary function.

*Invasion of Superior Vena Cava* Involvement of the superior vena cava has been treated occasionally by *en bloc* resection and graft replacement. Long-term survivors reported in the literature are limited to case reports.<sup>412,413</sup> In a retrospective analysis of 18 patients with superior vena cava invasion at MSKCC, there were no 5-year survivors after resection.<sup>323</sup> Preoperative distinction of superior vena cava invasion by the tumor (T4) or by its involved mediastinal lymph nodes (N2) can be difficult. Reported series include only few cases, and the significance of this finding cannot be assessed. It appears likely, however, that only T4 and not N2 lesions can occasionally be cured with such a radical resection.

*Invasion of Myocardium, Aorta, Esophagus, and Vertebral Body* Surgical resection resulting in complete excision of a primary tumor with other mediastinal organ invasion is usually not possible. Palliative incomplete resections have not demonstrated survival or palliation benefit. In the series from MSKCC, although not all patients underwent resection of the primary tumor or part of the invaded organ, there were no 5-year survivors among 19 patients with aorta involvement and 3 patients with atrial invasion, but 1 patient of 7 (14%) with esophageal invasion lived beyond 5 years.<sup>323</sup> Despite these results, a tumor with limited invasion of the atrial wall can occasionally be completely resected with the hope of an occasional cure.

*En bloc* resection of the lung with part of the involved aorta, esophagus, or vertebral body, not uncommon in the treatment of superior sulcus tumors, may result in long-term survival for selected patients. PORT may be of benefit in these situations to augment local control. An analysis from Japanese investigators suggested that long-term survival is limited to patients with minimal atrial or aortic adventitial involvement in tumors invading great vessels.<sup>414</sup>

*Pleural Effusion* Approximately 5% to 10% of patients with lung cancer present with a nonmalignant pleural effusion, a result of atelectasis, obstructive pneumonitis, lymphatic or venous obstruction, or pulmonary embolus. Despite being nonmalignant, an effusion evident on prior chest radiography has a poor prognosis, with a 5-year survival. Investigators at the Mayo Clinic demonstrated that even cytologically negative pleural effusions evident on chest radiographs were predictive of surgical unresectability in 95% of these patients. However, they concluded that in patients with cytologically negative pleural effusions, unresectability must be documented surgically. On the other hand, Naruke et al.<sup>409</sup> reported a 40% 5-year survival rate in 112 patients with nonmalignant effusion, identical to the 5-year survival rate in 1298 patients without effusion.

Even with malignant pleural effusions, occasional 5-year survivals have been documented when all disease has been eradicated.<sup>409,415</sup> In general, however, malignant pleural effusions, cytologically proven, indicate incurable disease by a surgical approach and are usually treated initially with primary chemotherapy. However, one should never consider a pleural effusion malignant without cytologic or histologic proof. A “bloody” pleural effusion may be due to a traumatic thoracentesis or concomitant pulmonary infarction and not indicate T4 disease.

**N3 DISEASE.** The role of surgery in preoperatively identified N3 disease previously considered totally inoperable has now been reexamined in phase II trials. Hata et al.<sup>416</sup> have investigated the use of two-field lymphadenectomy, including total mediastinal exenteration and supraclavicular node dissection for this group of patients. The exact role of postoperative therapies combined with this has not been discussed. The results of such treatment still await long-term reporting. Also, the induction therapies, especially chemoradiation, have been investigated by the SWOG group and others.<sup>417,418</sup> It does appear that with very intensive induction therapies, some patients survive long term. It does not appear, however, that these survivals are improved by the addition of surgery. In fact, in many phase II trials, no attempt was made to remove the involved N3 lymph nodes. Surgery was directed toward removal of the primary tumor and N2 nodes.

## Adjuvant and Neoadjuvant Therapies

After complete resection in patients proven to have T4 or N3 disease, radiotherapy has been usually recommended as adjuvant treatment because of the high incidence of locoregional failure after aggressive surgery for this advanced tumor. Because of the paucity of patients reported to have undergone this treatment, the exact role of adjuvant radiotherapy cannot be assessed. It is in this subset of tumors that neoadjuvant therapies have been investigated in many phase II trials. It does appear that clinically staged T4 tumors (especially T4N0 disease) do reasonably well after this combined-modality approach. <sup>419,420 and 421</sup> In one such study, <sup>420</sup> patients with clinically evident T4 tumors, including superior vena caval syndrome, tracheal involvement, and posterior mediastinal invasion, were treated with MVP chemotherapy followed by surgery. Sixty-three percent of patients underwent a complete resection, and overall survival at 4 years was 19.5%. Despite these encouraging results, in most instances T4 and N3 tumors cannot be resected completely and are usually considered for combined-modality therapy, using radiotherapy as the primary control mechanism.

**RADIOTHERAPY.** The 2-year survival rate for patients with unresectable locally advanced NSCLC receiving supportive care alone is approximately 4%. <sup>422</sup> Historical series examining the ability of thoracic radiotherapy to have an impact on the natural history of locally advanced NSCLC demonstrated mixed results. Higgins and Shields <sup>423</sup> reported the results of a randomized trial by the Veterans Administration in which male patients with a variety of histologic subtypes of lung cancer, including small cell lung cancer, were prospectively randomly assigned to receive supportive care only or external-beam radiotherapy. Two hundred forty-six patients were treated with placebo, and 308 male patients were treated to doses of 40 to 50 Gy. The results of the trial were reported with 1-year minimum follow-up. Most patients had performance status of less than 70. In addition, the radiotherapy was inadequate by modern standards, both in terms of the dose delivered (40 to 50 Gy) and the equipment used (orthovoltage). Radiotherapy alone provided a modest but significant improvement in survival at 1 year, as compared with that in patients who received supportive care only (22% vs. 16%, respectively). <sup>423</sup> Other earlier trials of thoracic radiotherapy for unresectable NSCLC despite inadequate doses also showed a modest but significant improvement in 2-year survival rates in the range of 9% to 18%. <sup>424,425</sup>

Cox et al. <sup>426</sup> analyzed the patterns of failure in locally advanced unresectable NSCLC treated with radiotherapy alone and found that the median survival was increased from 6 to 12 months when the primary tumor was controlled. However, they found that 75% of patients with squamous cell cancer died of complications secondary to intrathoracic tumor progression, as compared with approximately 40% of patients with either large cell cancer or adenocarcinoma. In contrast, Berry et al. <sup>427</sup> using similar doses of radiotherapy, could find no improvement in survival with the use of thoracic irradiation as compared with chemotherapy alone. A retrospective study from British Columbia that controlled for tumor stage and other prognostic factors reported improved survival of 79 days in patients receiving high-dose palliative radiotherapy and survival of more than a year in patients receiving radical radiotherapy. <sup>428</sup>

In a multiinstitutional cooperative trial, Johnson et al. <sup>429</sup> reported the results of 319 patients with locally advanced unresectable NSCLC without evidence of distant metastases who were randomly assigned prospectively to one of three arms: chemotherapy alone with vindesine, 3 mg/m<sup>2</sup>/week; standard thoracic irradiation to a dose of 60 Gy in 6 weeks; or combined vindesine and thoracic radiotherapy. Although the overall response rate was superior in the radiotherapy arms (radiotherapy alone, 30%; radiotherapy plus vindesine, 34%; vindesine alone, 10%;  $F = .001$ ), the intrathoracic progression rates were similar in the vindesine arm (60%) and in the radiotherapy arm (65%); both median survival and overall survival were also comparable in all three arms. This study has been criticized, however, for the large number of patients in the vindesine-alone arm who received radiotherapy and for the number of patients involved, which was inadequate to detect a difference in survival. <sup>430,431</sup> A randomized trial of low-dose thoracic radiotherapy compared to cisplatin and etoposide alone reported a higher response in the radiotherapy arm but similar overall survival. <sup>432</sup>

Although it seems clear that thoracic radiotherapy does offer a survival advantage to patients with disease limited to the thorax, the poor results of these earlier studies led the RTOG to investigate methods of improving outcome with radiation alone by initially concentrating on dose intensification with conventional fractionation and, more recently, using altered fractionation. In addition, they have attempted to identify appropriate selection criteria and prognostic factors for the various approaches and apply the use of innovative treatment planning and technology.

**Standard External-Beam Radiotherapy** The earliest trial by the RTOG for unresectable NSCLC focused on dose intensification by attempting to establish the optimal schedule of standard fractionated radiation alone. Protocol 73-01 was limited to 379 patients with either medically inoperable stage I or II or unresectable stage III NSCLC of various histologies. Patients in this trial were randomly selected for one of four dose-escalating arms, including 40-Gy split-course, or 40-Gy, 50-Gy, or 60-Gy continuous-course thoracic radiation delivered in 4, 5, or 6 weeks with a daily fraction size of 2 Gy. Analysis of patterns of failure and survival showed a higher complete response rate (24%) and 3-year survival rate (15%) with 60-Gy continuous-course radiotherapy, in comparison with lower doses of continuous- and split-course irradiation (40 to 50 Gy). The failure rate within the irradiated volume was 53% to 58% for 40 Gy, 49% for 50 Gy, and 35% for 60 Gy. This improvement in local control was still appreciated nearly 5 years later. The median time to any failure increased from 8 to 19 months as dose was increased from 40 to 60 Gy. Overall, patients who achieved a complete tumor response also experienced increased survival, as compared with partial responders or patients with stable disease. The 3-year survival rate in complete responders was 23%, as compared with 10% in partial responders and 15% in patients with stable disease. <sup>424</sup>

By escalating the total dose from 40 to 60 Gy, this trial established a significant dose-response relation between local control and short-term survival. Despite the preliminary local control and survival advantages in patients experiencing a complete response and in patients receiving a dose of 60 Gy, the overall median survival for patients receiving 40 Gy was 9.6 months, as compared with 10.1 months for patients receiving 50 to 60 Gy. In addition, the 5-year survival rate for all patients in this trial was approximately 6%, with no significant differences among the four arms.

**Brachytherapy and External-Beam Radiotherapy** Huber et al. <sup>433</sup> randomly assigned 108 patients to either conventional radiotherapy (60 Gy) alone or an EBB boost of 4.8 Gy before and after conventional radiotherapy. There was a trend toward improved local control in patients receiving brachytherapy, although it failed to reach significance. There was no difference in overall survival. Criticisms of the trial include that the majority of patient treatment significantly deviated from the protocol. However, it does suggest that EBB might play a role in the treatment of primary disease.

A pilot study examined the use of Gelfoam radioactive plaques in addition to postoperative external-beam radiation in patients who have had an R1 or R2 resection of stage III NSCLC. In 12 patients, there was a local control rate of 82% and overall survival of 45%. Whether this is an improvement from standard PORT for these patients remains to be examined in further studies. <sup>434</sup>

**Three-Dimensional Conformal Radiotherapy** In a dose-escalation protocol using 3D-CRT at the University of Michigan, patients were treated with dose ranges from 69.3 to 102.9 Gy. The researchers have reported a single case of acute grade 3 pneumonitis and five cases of acute grade 2 pneumonitis. <sup>217</sup> Recently, patients with advanced disease have been receiving neoadjuvant chemotherapy in addition to radiotherapy. The median survival in patients with stage III or recurrent disease was 16 months, and 2-year overall survival was 36%.

Graham et al. <sup>216,435</sup> reported the results of 3D-CRT from Washington University. They have treated tumors to a dose of 60 to 74 Gy. Elective nodal irradiation was given to all except those patients with poor pulmonary function. These investigators report a 2-year survival rate of 53% with this technique. The University of Chicago reported a 2-year local control and a survival rate of 23% and 37%, respectively, in patients treated with doses ranging from 60 to 70 Gy. <sup>436</sup> The MSKCC reported a 2-year local control, disease-free survival, and overall survival rates of 36%, 11%, and 22%, respectively, in a group of patients with advanced-stage disease. <sup>218</sup>

**Elective Nodal Irradiation** Standard radiotherapy typically involves a dose of 40 Gy to the entire mediastinum, supraclavicular fossa, and ipsilateral hilum, even if there is no evidence of disease in these areas (e.g., T4N0 tumors). It has been shown that this elective treatment can significantly add to the morbidity of radiation. <sup>437,438</sup> Many centers have made the decision to eliminate elective nodal irradiation in an effort to increase the dose to the tumor. When RTOG trials were reviewed to estimate the clinical impact of omitting nodal irradiation, it was found that when the ipsilateral hilum and mediastinum were incorrectly treated, there was an increased risk of progression. <sup>439</sup> The MSKCC reported an elective nodal failure rate of 8% and a local failure rate of 65%, <sup>440</sup> which suggests that until regions of known disease can be better controlled, there is probably no need to treat the entire mediastinum and supraclavicular region electively when T4N0 tumors are being treated. Invasive staging or PET scanning may improve decision making.

**ALTERED FRACTIONATION RADIOTHERAPY.** Altered fractionation implies any deviation from standard fractionation of 1.8 to 2 Gy delivered once daily, 5 days weekly for 6 to 7 weeks. Several forms of altered fractionation, such as continuous hyperfractionation accelerated radiotherapy (CHART), or variations of these have been investigated. <sup>441</sup> The basic goal of altered fractionation strategies is to deliver higher total doses of radiation to improve the local outcome without increasing late normal tissue toxicity. Altered fractionation schemes exploit the significant differences in the capacity of late-responding and early-responding tissues to repair

radiation cellular damage.

**Hyperfractionation** Hyperfractionated radiotherapy employs more than 1 fraction per day, using fraction sizes that are smaller than those used with standard fractionation (1.1 to 1.5 Gy per fraction versus 1.8 to 2 Gy per fraction). Thus, hyperfractionation uses multiple small fractions per day to deliver a higher total daily dose and final total dose to improve tumor cell kill without increasing late toxicity and accepting increased but recoverable acute toxicity. <sup>441</sup>

The RTOG initiated a phase I and II trial to evaluate 1.2-Gy twice-daily fractionation for locally advanced unresectable disease. Eight hundred eighty-four patients were randomly picked to receive doses of 60.0, 64.8, and 69.6 Gy, using 1.2 Gy twice daily with a minimum of a 4-hour interfraction interval. After reasonable time had elapsed to evaluate both acute and late effects, which were considered tolerable, patients were further assigned to either 74.4 Gy or 79.2 Gy, with closure of the two lowest dose arms. In a favorable subgroup of patients, the 69.6-Gy dose results appeared significantly better ( $P = .002$ ) than results with standard fractionation in comparable patients from an earlier RTOG study and the other arms of the trial. <sup>382</sup> No increased toxicity was seen in the higher-dose arms to account for the decreased survival as compared to the 69.6-Gy arm.

Based on these results, the RTOG began a phase III trial comparing 69.6 Gy given via hyperfractionation and 60 Gy given via standard fractionation of thirty 2-Gy fractions. The third arm of the trial replicated the study arm of CALGB protocol 8433: induction chemotherapy with cisplatin and vinblastine followed by 60 Gy of irradiation. The 5-year survivals for standard radiotherapy, hyperfractionated radiotherapy, and induction chemotherapy plus radiation were 4%, 5%, and 8%, respectively. The survival in the chemotherapy-plus-radiotherapy arm was significantly higher. <sup>442</sup> As yet, there is no clear survival advantage that can be demonstrated for hyperfractionation as compared to standard radiotherapy. However, many trials continue to use this hyperfractionation regimen of 69.6 Gy. Further studies are needed to find the maximum tolerable dose of radiation with either hyperfractionation or standard fractionation and compare it to 60 Gy.

**Accelerated Radiotherapy** RTOG trial 84-07 examined the role of an accelerated concomitant boost of radiotherapy. Patients received 45 Gy over 5 weeks to the primary tumor and mediastinal lymph nodes. Two to three times a week, a concomitant boost of 1.8 Gy would be delivered only to the primary tumor and involved lymph nodes. A dose of 25.2 cGy via concomitant boost (70.2 Gy) was found to be tolerable. <sup>443</sup> Two-year survival was 21% for the higher-dose patients. Another RTOG phase II trial (83-12) demonstrated a 2-year survival rate of 25% and a 3-year survival rate of 18%. <sup>435</sup>

**Continuous Radiotherapy** CHART employs many radiobiologic principles in an effort to improve the therapeutic ratio. CHART delivers 54 Gy in three daily doses of 1.5 Gy over 12 continuous days, including weekends. With CHART, treatment is given every day to counteract rapidly proliferating cells. Hyperfractionation with many smaller doses of radiation may reduce long-term toxicity. Accelerating the treatment time from 6 weeks to 2 weeks also may counteract tumor repopulation.

CHART was first examined in a small prospective phase II trial. <sup>444</sup> Some degree of esophageal toxicity was present in all patients. Ten percent of patients developed acute radiation pneumonitis. Two-year survival was 34%.

A phase III randomized study was performed in 13 centers in the United Kingdom. Patients were assigned to either standard radiation of 60 Gy in 30 daily doses of 2 Gy over 6 weeks or CHART. Approximately one-half the patients had stage III disease; the remainder had early-stage disease or unknown staging. No other therapeutic modality was used. Two-year survival significantly increased from 20% to 29% in the CHART arm. In addition, local control significantly improved from 15% to 23%. <sup>445</sup> Severe esophageal toxicity also increased from 3% to 19%, and acute radiation pneumonitis was 19% in the conventional group and 10% in the CHART arm. However, late pulmonary toxicity and fibrosis requiring treatment at 2 years was present in 16% of living patients who received CHART as compared to 4% receiving conventional radiotherapy. The physical and psychological symptoms caused by this aggressive regimen have been shown to be tolerable as well. <sup>446</sup>

The use of CHART has been limited by the need to reorganize radiation departments to accommodate the demanding radiation treatment schedule. In addition, patients are hospitalized during their entire course of radiation, which may significantly increase the cost of treatment. Therefore, trials have been conducted using CHART without treatment on weekends. <sup>447</sup>

An ECOG trial examined the feasibility of hyperfractionated accelerated radiotherapy. <sup>448</sup> Twenty-eight patients received 57.6 Gy over 15 days (12 treatment days) in 1.6-Gy fractions three times daily, 4 hours apart. The need to wait 6 hours was avoided by not treating consecutively those fields containing spinal cord. The investigators found that this regimen was tolerable, with the main toxicity being esophagitis and moist desquamation of the skin. Median survival of 13 months was similar to combined-modality approaches.

A North Central Cancer Treatment Group Trial evaluated standard radiotherapy (60 Gy in 30 daily fractions of 2 Gy over 6 weeks) to an accelerated hyperfractionated approach (60 Gy in 40 fractions of 1.5 Gy twice daily over 4 weeks). A third arm included the accelerated hyperfractionated approach with concomitant cisplatin and etoposide. The two radiation-alone arms were not significantly different, although there was a trend toward improved local control and overall survival when the two hyperfractionated arms were combined. <sup>449</sup>

**Hypofractionated Radiotherapy** The reality for most physicians treating unresectable NSCLC is that in many patients, favorable patient parameters are not present. In these patients with unresectable stage III tumors, the results with either radiotherapy alone or combined-modality treatment are poor, and the chance for cure is rare. Studies have examined the use of hypofractionated radiotherapy for unresectable stage III disease and compared the results to those for standard fractionation to 60 Gy in RTOG trials. Depending on one's philosophy, the use of hypofractionated radiotherapy may simply be a palliative approach, or it may be a curative approach with low expectation, based on known results with radiotherapy alone. A study revealed that patients with stage III disease treated with 40-Gy split-course irradiation had longer survival times and lower local relapse rates but higher distant failure rates than those receiving 24 to 32 Gy. Survival rates for patients with stage IIIA disease treated with 40 Gy at 1, 2, and 5 years were 47%, 22%, and 7%, respectively. For stage IIIB disease, the radiation scheme did not correlate with survival and relapse rates. Survival rates at 1, 2, and 5 years were 30%, 9%, and 2%, respectively. The hypofractionated regimen schemes were extremely well tolerated, and no severe complications were observed. <sup>450</sup> Although the data for both schedules of treatment appear comparable, split-course irradiation cannot be routinely recommended based on the available literature for locally advanced NSCLC.

**Radiosensitizers** Schaake-Koning et al. <sup>451</sup> demonstrated a survival advantage when weekly or daily cisplatin was added to thoracic radiotherapy. Three-year overall survival improved from 2% to 16% with the addition of daily cisplatin. The benefit was due to increased local control with cisplatin. It is not clear whether cisplatin actually enhances the effect of radiation or whether it is independently cytotoxic, with its effectiveness more dependent on dosing and dose level. Other studies have shown no benefit from the addition of concomitant chemotherapy with thoracic radiation. <sup>452,453 and 454</sup>

A CALGB-ECOG study examined induction chemotherapy with cisplatin and vinblastine followed by 60 Gy radiotherapy with or without radiosensitization with carboplatin, 100 mg/m<sup>2</sup>. <sup>455</sup> This study differs from those referenced heretofore because it used cytotoxic chemotherapy for induction in both arms and, therefore, was solely testing the value of radiosensitization. There was no difference in overall survival, failure-free survival, or response between the two arms. There was a higher local control in the carboplatin arms, but this did not have an impact on survival.

**Radiation Protectors** The radioprotectant amifostine is a sulfhydryl compound the metabolites of which scavenge free radicals that are generated in tissues exposed to radiation. <sup>456</sup> A phase II clinical trial using amifostine with sequential chemotherapy and standard radiation (60 Gy) demonstrated no episodes of grade 3 or worse esophagitis or pneumonitis. <sup>457</sup> There was no evidence of tumor protection, either. Amifostine might allow for the use of higher doses of chemotherapy and radiation with acceptable toxicity. RTOG protocol 98-01 is addressing this issue.

### **Prophylactic Cranial Irradiation for Locally Advanced Non-Small Cell Lung Cancer**

The hypothesis that prophylactic cranial irradiation (PCI) can improve survival is based on the assumption that isolated brain failures occur commonly and lead to death and that these can be effectively prevented by tolerable doses of radiation. PCI has recently been shown on metaanalysis to improve survival in patients with small cell lung cancer. <sup>458</sup> However, isolated brain failures in NSCLC are not common, and it is not possible to predict the patients at risk. Consequently, it is unlikely that survival would be improved to a detectable degree if effective prophylaxis were delivered to the entire population of patients with resected disease. Of 1532 patients treated surgically in prospective trials of the LCSG, only 6.8% (104 of 1532) had first recurrences in the brain. However, 71% of the patients in this series had T1–2N0 tumors. Patients with locally advanced disease treated with thoracic irradiation on the RTOG protocols had an initial brain failure rate of 7% for squamous histology, 19% for adenocarcinoma, and 13% for large cell carcinoma. Even for adenocarcinoma, brain is a less common site of initial failure than are bone (24%) and opposite lung (21%). <sup>286,389</sup>

single-modality efficacy.

Several single-drug chemoradiotherapeutic trials have been published (see [Table 31.2-15](#)).<sup>451,452,453,454</sup> and <sup>455,475</sup> In particular, cisplatin as a single agent has been tested in several randomized clinical trials. A study of weekly cisplatin (15 mg/m<sup>2</sup>/week) plus radiotherapy to 50.4 Gy found no survival benefit.<sup>452</sup> Similarly, studies of radiotherapy with low daily doses of cisplatin<sup>453</sup> or cisplatin given every 3 weeks<sup>454</sup> showed no survival benefit. Only one study showed improved local control and survival for daily cisplatin added to radiotherapy; however, the patients on the control arm received protracted radiotherapy.<sup>451</sup> Thus, concomitant chemoradiotherapy using single-agent cisplatin or other drugs has largely failed to improve the survival rates of patients with locoregionally advanced NSCLC, although it may provide a locoregional sensitization effect. This appears to be due to the lack of systemic activity of low-dose single-agent therapy; thus, the predominant site of failure in these patients (distant disease) is inadequately addressed.

Several studies testing combination chemotherapy with concomitant radiotherapy or using hyperfractionated radiotherapy have also been published.<sup>266,475,476,477,478,479,480</sup> and <sup>481</sup> These studies largely have been performed in the phase I and II settings. Results uniformly indicate increased toxicity. Some studies, however, have also suggested therapeutic benefit and encouraging survival data.

The SWOG has published two phase II trials using cisplatin and etoposide with concurrent radiotherapy.<sup>274,482</sup> In the first such trial, concomitant chemoradiotherapy to 45 Gy was administered in the preoperative setting. The response rate to this regimen prior to surgery was 59%, and 71% of patients were able to undergo surgical resection. This study forms the basis for the large current intergroup trial evaluating concomitant chemoradiotherapy plus chemoradiotherapy boost versus surgical resection in patients with marginally resectable stage IIIA NSCLC. The 3-year survival rate was 26%. In a second study, the SWOG evaluated this chemoradiotherapy regimen in patients with unresectable disease. Here patients received two cycles of cisplatin-etoposide with concurrent radiotherapy to 61 Gy followed by an additional two cycles of chemotherapy in the “adjuvant” setting. For 50 patients, the median survival time was 13 months, and 2- and 3-year survival rates were 33% and 26%, respectively. The SWOG has evaluated a similar regimen of carboplatin, etoposide, and concurrent radiotherapy in patients with poor prognostic features.<sup>483</sup> Pilot data in this group of patients indicated similar median and 2-year survival times, indicating the feasibility of chemoradiotherapy for a suboptimal patient population.

Definitive testing of combination chemotherapy with concurrent radiotherapy in the phase III setting has been limited. A three-arm study investigated the combination of carboplatin and etoposide at two dose levels added to hyperfractionated radiotherapy (1.2 Gy twice daily; total dose, 64.8 Gy).<sup>478</sup> Carboplatin, 100 mg/m<sup>2</sup> on days 1 and 2, and etoposide, 100 mg/m<sup>2</sup> on days 1 to 3, of each week of radiotherapy resulted in a significant increase in median survival as compared with hyperfractionated radiotherapy alone (median survival, 8 vs. 18 months). A similar comparison of twice-daily radiotherapy to 69.6 Gy with or without daily intravenous carboplatin (50 mg) and etoposide (50 mg) showed a significant increase in median survival time (22 vs. 14 months) and 4-year survival rates (23% vs. 9%).<sup>479</sup> These studies support the addition of chemotherapy to radiotherapy but do not clarify whether twice-daily radiotherapy is superior to single daily fractions. Intensified radiotherapy schedules are mainly supported by the British CHART study.<sup>445</sup>

Since both induction chemotherapy and concomitant chemoradiotherapy prolong survival, it can be asked which of the two approaches is superior. Induction chemotherapy has, indeed, been directly compared with concomitant chemoradiotherapy using the cisplatin-plus-vinblastine regimen in a randomized study by the RTOG. Based on previous pilot studies, patients with stage III NSCLC were randomly chosen to receive induction chemotherapy with cisplatin plus vinblastine (standard), or the same drugs given concomitantly during radiotherapy, or cisplatin with orally administered etoposide and concomitant hyperfractionated radiotherapy.<sup>484,485</sup> Results from this trial are expected in the near future.

A similar study has been reported by Japanese investigators. Furuse et al.<sup>275,486</sup> compared the administration of the MVP regimen as induction chemotherapy to its administration with concurrent radiotherapy. Median survival times were 16 versus 13 months, favoring the concurrent administration of chemoradiotherapy. A pattern-of-failure analysis indicated a higher relapse in the brain for patients treated with concurrent chemoradiotherapy, with the possibility of higher intrathoracic control ([Table 31.2-16](#)).

Treatment Arm	No. of Patients	Response Rate (%)	Median (mo)	Survival		P Value
				3Y (%)	5Y (%)	
Concurrent	18	33	16.5	37	37	.03
Sequential	18	33.3	13.5	22.2	22.2	

MVP = irinotecan, vinorelbine, cisplatin (intravenous).  
(Adapted from Furuse T, Nakada H, Sakai Y, et al. Phase III study of concurrent or sequential chemoradiotherapy (CRT) in combination with irinotecan (I), vinorelbine (V), and cisplatin (C) in unresectable stage III non-small cell lung cancer: the Japan Lung Cancer Group JLCG0101 study. *Clin Oncol* 2009;21:688-694.)

**TABLE 31.2-16.** A Randomized Phase III Study of Concurrent versus Sequential Radiotherapy with MVP in Stage III Non–Small Cell Lung Cancer

**INDUCTION AND CONCOMITANT CHEMORADIATION.** An alternative strategy to a direct comparison of induction versus concomitant combined-modality therapy is the administration of both. This strategy is supported by the suggestion that induction chemotherapy and concomitant chemoradiotherapy may exert their favorable influence on survival by different mechanisms. In particular, induction chemotherapy appears to improve systemic disease control, while concomitant chemoradiotherapy leads to higher locoregional control. This hypothesis has been evaluated in several studies. The CALGB compared administration of cisplatin and vinblastine followed by radiotherapy with administration of the same induction chemotherapeutic regimen followed by radiotherapy with weekly doses of concomitant carboplatin.<sup>455</sup> This study showed a median survival time of 13 months on both arms but suggested increased locoregional control for patients receiving carboplatin. This study adds to the evidence that single-agent radiation sensitization with a platinating agent is of clinical benefit.

More recently, similar investigations have focused on the integration of novel chemotherapeutic single agents into the setting. Preclinical and early clinical data support a role as radiation enhancers for the taxanes, gemcitabine, vinorelbine, and topoisomerase I inhibitors.<sup>487,488,489,490,491,492,493,494,495,496,497,498,499,500</sup> and <sup>501</sup> Additional trials have evaluated the administration of paclitaxel with or without carboplatin on a weekly schedule with concurrent chest radiotherapy. Phase II trials indicate high response and promising 1- and 2-year survival rates with this approach. Pilot studies using paclitaxel are summarized in [Table 31.2-17](#). A three-arm study by the CALGB evaluating three novel agents (gemcitabine, paclitaxel, or vinorelbine in combination with cisplatin) in the induction and concomitant setting is under way. The radiation dose in this trial is 66 Gy.<sup>499</sup>

Arms	No. of Patients	Concurrent Chemotherapy	Radiotherapy	Median OS (%)	Survival	
					1Y (%)	2Y (%)
Doc <sup>a</sup>	35	Paclitaxel	60 Gy <sup>b</sup>	16	73	34

**TABLE 31.2-17.** Selected Phase II Trials of Weekly Paclitaxel-Based Chemotherapy with Concurrent Radiotherapy in Patients with Stage III Unresectable Non–Small Cell Lung Cancer

demonstrated with single-agent chemotherapy in a population of patients exceeding the age of 70 years. <sup>515</sup>

Given the substantial experience with chemotherapy-based clinical trials in stage IV disease, large analyses for prognostic factors have been performed. The SWOG analyzed their database of 2531 patients with advanced NSCLC using Cox modeling, recursive partitioning, and amalgamation to identify prognostic factors in these patients. <sup>144</sup> Good performance status, female gender, age of 70 years or older, low tumor burden, normal lactate dehydrogenase and serum calcium levels, and a hemoglobin level of more than 11 g/dL were favorable factors. The use of cisplatin was an additional significant favorable predictor of survival. A European group conducted a similar analysis in 1052 patients and identified similar favorable prognostic factors of lower tumor burden, good performance status, higher age, and female gender. <sup>526</sup>

### Newer Chemotherapeutic Drugs

Randomized phase III trials investigating a new drug in stage IV NSCLC are aimed at demonstrating improved survival when compared with previous standard therapy. The randomized studies of the 1980s established the value of chemotherapy as compared with best supportive care. The combination of cisplatin with etoposide or vinblastine emerged as a standard in the United States, while in Europe, the combination of cisplatin and vindesine was frequently administered. Randomized studies testing a new agent or combination in the 1990s could, therefore, be designed with several possible control arms, including the two combinations noted previously or cisplatin as a single agent.

In the 1990s, reproducible single-agent activity was demonstrated for several new agents. Paclitaxel, docetaxel, vinorelbine, gemcitabine, and irinotecan have been extensively investigated (Table 31.2-20). Their definitive evaluation has frequently included a comparison of the new drug with cisplatin versus cisplatin alone (Table 31.2-21).

Agent	No. of Studies	No. of Patients	Total CR + PR	Median Survival (mo)	1/2 Survival (%)	No. of Deaths	% of Deaths
Docetaxel <sup>a</sup>	10	517	84 (16%)	37 (24-50)	6	42	7
Docetaxel <sup>b</sup>	4	300	77 (26%)	41 (27-46)	3	32	3
Vinorelbine <sup>c</sup>	4	401	136 (34%)	33 (24-41)	4	24	3
Gemcitabine <sup>d</sup>	4	372	122 (33%)	41 (24-41)	3	30	2

TABLE 31.2-21. Cisplatin Alone Versus Cisplatin and New Drug Combination

Vinorelbine has undergone thorough testing in NSCLC and was the first of the recent drugs to receive approval by the U.S. Food and Drug Administration for use in NSCLC (see Tables 31.2-20 and 31.2-21). <sup>515,527,528,529,530</sup> and <sup>531</sup> A randomized study conducted in Europe compared a standard of cisplatin and vindesine with cisplatin and vinorelbine and with single-agent vinorelbine. <sup>530</sup> The median survival time was 30 weeks for patients treated with cisplatin and vindesine and for those treated with vinorelbine alone. Patients treated with cisplatin and vinorelbine had a significantly longer median survival time of 40 weeks. An economic evaluation of this study concluded that this chemotherapy had acceptable efficacy and cost-effectiveness as compared with other common medical interventions. <sup>521</sup>

A second study in the United States compared the combination of cisplatin and vinorelbine with single-agent cisplatin. Again, the combination of cisplatin and vinorelbine proved superior to the single agent. <sup>531</sup> Finally, single-agent vinorelbine resulted in superior survival times as compared with 5-fluorouracil plus leucovorin (30 vs. 22 weeks). <sup>532</sup> This study has been criticized for its use of 5-fluorouracil plus leucovorin in the control arm, which is not a commonly used regimen in NSCLC and resulted in a low 6% response rate. An intriguing European study compared vinorelbine with best supportive care in the elderly (70 years). Increased median survival times (6.5 vs. 4.9 months) and QOL were demonstrated. <sup>515</sup> This study not only supported previous conclusions regarding prolongation of life but specifically indicated that patient age, as an isolated factor, should not be a primary determinant of whether the use of chemotherapy is indicated.

Paclitaxel also showed encouraging single-agent activity (see Table 31.2-20). <sup>533,534</sup> and <sup>535</sup> The ECOG performed a three-arm randomized study comparing a regimen of cisplatin plus etoposide with cisplatin plus paclitaxel with a regimen of paclitaxel given either at a low or high dose with granulocyte colony-stimulating factor support. The paclitaxel-plus-cisplatin arms were superior to the etoposide-plus-cisplatin regimen, with no evidence of an increased response rate with a higher paclitaxel dose. <sup>536</sup> This study evaluated paclitaxel as a 24-hour infusion. Shorter infusion duration (3 hours) has been used in most other studies. A European trial showed cisplatin and paclitaxel to result in median survival (10 months) similar to that of cisplatin and etoposide while being better tolerated. <sup>537</sup> Of note, median survival times in both of these studies were better in both arms than historic controls. Other randomized trials confirm the activity of cisplatin or carboplatin-paclitaxel regimens and the favorable toxicity profile of the latter combination (Table 31.2-22). <sup>537,538,539,540</sup> and <sup>541</sup>

TABLE 31.2-22. Comparison of Various Combination Chemotherapy Regimens

Encouraging data also exist for docetaxel,<sup>542,543,544</sup> and <sup>545</sup> gemcitabine,<sup>546,547,548,549,550</sup> and <sup>551</sup> irinotecan.<sup>552,553,554</sup> and <sup>555</sup> All three have reproducible single-agent activity and have been investigated in combination with a platinating agent. Gemcitabine has been evaluated in randomized phase II and III trials.<sup>556,557,558</sup> and <sup>559</sup> Equivalence of single-agent gemcitabine with the (more toxic) combination of cisplatin and etoposide was suggested in two small studies. The combination of gemcitabine and cisplatin showed a significant improvement in median survival (7.6 vs. 9.1 months) versus single-agent cisplatin.<sup>556</sup> A smaller European trial compared cisplatin and gemcitabine with cisplatin and etoposide and suggested a favorable impact on median survival.<sup>557</sup> Tirapazamine, a bioreductive alkylating agent, has been shown to increase the cytotoxicity of cisplatin and prolong survival after therapy with that combination.<sup>560</sup>

Docetaxel has been shown to have activity as second-line therapy in patients with cisplatin-refractory disease.<sup>544,545</sup> This is encouraging because second-line activity has rarely been observed with other drugs. Second-line activity has also been described for gemcitabine.<sup>561</sup>

Currently, investigators are focused on comparing some of the recent regimens with one another.<sup>539</sup> A comparison of cisplatin and vinorelbine with carboplatin and paclitaxel has been presented. Identical median survival times of 8 months suggested equivalence of antitumor activity, while the toxicity spectrum of the regimens predictably differed (more nausea and vomiting and myelosuppression with cisplatin, more neurotoxicity with carboplatin). The ECOG is comparing carboplatin-paclitaxel with gemcitabine-cisplatin, docetaxel-cisplatin, and cisplatin-paclitaxel. This is an important study, since it will establish the relative activity and toxicity of several novel cisplatin-based regimens versus the combination of paclitaxel and carboplatin. The CALGB is comparing single-agent paclitaxel therapy with the combination of paclitaxel-carboplatin.<sup>463</sup> Evaluating response, survival, economic, and QOL end points, this study will establish whether a benefit exists for this "doublet" over single-agent paclitaxel. Similarly, three drug regimens using novel drugs are being evaluated. Additional trials are evaluating the weekly administration of paclitaxel,<sup>562</sup> "non-platinum"-containing two-drug regimens,<sup>563,564</sup> three-drug regimens,<sup>275,565</sup> and other new cytotoxic agents.<sup>566,567</sup> Of current interest in particular are "cytostatic" molecules inhibiting specific cellular or extracellular targets, including inhibitors of farnesyl transferase, matrix metalloproteinase, or antiangiogenic agents.<sup>568,569,570,571</sup> and <sup>572</sup>

In summary, chemotherapy for stage IV NSCLC has been shown to prolong survival as compared with best supportive care. The use of chemotherapy can be supported by cost and QOL analyses. Its administration to the elderly has been shown to be of benefit. Based on recent evidence, current standard regimens are the doublets of cisplatin in combination with either vinorelbine, paclitaxel, or gemcitabine or the combination of paclitaxel and carboplatin. In selected cases, administration of second-line chemotherapy should be considered.

### **Current Clinical Approaches to Stage IV Non-Small Cell Lung Cancer**

In the 1990s, most patients with newly diagnosed stage IV NSCLC should undergo treatment with at least one chemotherapeutic regimen. Based on available data from randomized trials, treatment should consist of the combination of cisplatin and vinorelbine, cisplatin and gemcitabine or, alternatively, cisplatin or carboplatin and paclitaxel. Generally, chemotherapy should be restricted to patients with a performance status of 0 to 2, because it is that group of patients in which most phase II and positive phase III studies have been conducted. Available evidence suggests that patients with a performance status of 2 will have, at best, a minor prolongation of survival time by chemotherapy but may experience significant relief of disease-related symptoms. Single-agent therapy in elderly patients should be considered. Patients should understand that the treatment goals are not cure but prolongation of life and palliation of symptoms; additional palliative measures, such as pain relief, radiotherapy, and surgery, should be applied as most beneficial for symptom relief.

In patients with stable or responding disease, the treatment duration has traditionally been six cycles of chemotherapy. Historically, this is largely based on the cumulative toxicity observed with cisplatin, which frequently limits to six or less the total number of cycles. The optimal duration of chemotherapy is undergoing evaluation in randomized trials. It is possible that newer regimens, particularly those not containing cisplatin, might be tolerated (and active) for more than six cycles. In patients with stable or responding disease, it might, therefore, make sense to continue therapy beyond six cycles. The optimal duration of chemotherapy is undergoing evaluation in randomized trials.

Patients who progress on or after first-line chemotherapy but continue to have a good performance status may be offered second-line chemotherapy. Few drugs have undergone formal testing in this setting. Docetaxel has been most extensively evaluated. In phase II studies, the use of docetaxel in patients not previously exposed to another taxane resulted in a response rate of approximately 10%.<sup>542</sup> Two randomized trials have been presented.<sup>544,545</sup> A Canadian trial compared second-line best supportive care with docetaxel (at 75 or 100 mg/m<sup>2</sup>).<sup>545</sup> Improvement in survival (7 vs. 5 months) and improved QOL supported the use of docetaxel at the lower dose. In a second study, docetaxel (at two dose levels of 75 or 100 mg/m<sup>2</sup>) was compared with vinorelbine or ifosfamide.<sup>544</sup> Median survival times were similar, while 1-year survival was highest at the lower-dose docetaxel arm. QOL analysis also favored docetaxel therapy. Gemcitabine has also had second-line antitumor activity in phase II trials.<sup>561</sup> There is little published information to support the use of other drugs as second-line therapy.

Because novel and more effective or less toxic therapies are still much needed in treating NSCLC, it should be recommended to offer investigational therapies of new drugs or novel combinations of drugs to such patients in prospective phase I and II studies whenever possible. Such an approach holds promise for the intermediate and long-term identification of more active therapies. The empiric use of sequential chemotherapy regimens as second-, third-, or fourth-line therapy cannot be supported using current data. Given the lack of drugs with established activity as second-line therapy, using investigational drugs will not compromise a patient's chance of obtaining benefit from therapy.

### **Solitary Metastases**

**METASTASIS (M1) TO LUNG.** To differentiate between a second primary lung cancer and a metastasis in synchronous lung lesions or among local recurrence, a new primary lung cancer, and a pulmonary metastasis from a previous resected lung cancer in metachronous lung lesions can be difficult. A second or recurrent lung lesion is considered a metastasis if the histology is identified to the primary tumor and occurs in the opposite lung or a noncontiguous area of the ipsilateral lung.

Deslauriers et al.<sup>572a</sup> found that the presence of satellite nodules discovered at surgery, clearly separated from the primary tumor but with identical histologic characteristics, is a poor prognostic factor. In patients with satellite nodules from all stages of lung cancer, 5-year survival was 21.6%, as compared with 44% if no nodules were present. The mechanism of tumor spread in the lung is not well known, but metastases may develop as a result of a blood-borne or airborne spread from a primary bronchogenic carcinoma. The new TNM staging system fails to classify these synchronous lung lesions specifically.

The same criteria used in selecting patients for surgical resection of a pulmonary metastasis from a primary lung cancer should be used in patients with metastatic carcinoma to the lung from other primary tumors.<sup>572b</sup> If a solitary synchronous lesion is discovered in a different lobe from the primary tumor, both lesions should be resected whenever possible.

**METASTASIS (M1) TO BRAIN.** Brain metastases constitute more than 25% of all observed recurrences in patients with resected NSCLC and are seen with greater frequency at autopsy.<sup>573</sup> In a review by the LCSG, the brain was the sole site of first recurrence in only 6.4% of patients with completely resected NSCLC but accounted for approximately 20% of all recurrences.<sup>574</sup> Nearly one-half of the patients seen with brain metastases have solitary lesions on CT scan. When these lesions are symptomatic, the median survival without therapy is limited to 1 month. Corticosteroids and whole brain irradiation can offer effective palliation of symptoms but only modestly increase survival up to 6 months.<sup>575</sup>

A synchronous or metachronous solitary brain metastasis can be treated, whenever possible, by surgical resection, with 5-year survival rates of 10% to 20% ( [Table 31.2-23](#)). Surgical excision of a brain metastasis, no matter the primary site (approximately 75% from NSCLC), followed by radiation has been shown to be superior to whole brain radiotherapy alone in prolonging median survival (9.2 vs. 3.4 months), in preventing local recurrence, and in providing a better QOL.<sup>576</sup>

Study	No. of Patients	Estimated 5Y Survival Rate (%)	Morbidity Rate (%)

**TABLE 31.2-23.** Reported Results after Combined Resection for Primary Non–Small Cell Lung Cancer with a Single Brain Metastasis (M1)

A resurgence of interest in the use of high-dose 3D-CRT or stereotactic radiosurgery in managing solitary brain metastases has followed early results suggesting equivalence to a surgical approach.<sup>577</sup>

**METASTASIS (M1) TO THE ADRENAL GLAND.** Adrenal metastases from bronchogenic carcinoma are found in approximately one-third of patients at autopsy. Routine preoperative upper abdominal CT scanning may reveal an adrenal mass in approximately 10% of patients.<sup>578</sup>

A few case reports of adrenalectomy for solitary adrenal metastasis are available, and long-term survival after combined excision of the primary lung tumor and its metastatic lesion has been reported.<sup>579,580</sup> and <sup>581</sup> The ultimate role of such an approach has yet to be defined.

**METASTASIS (M1) TO LIVER, BONE, OR SKIN.** No reports of long-term survival have been made after combined surgical excision of a primary lung cancer with a synchronous solitary liver, bone, or skin metastasis. It is rare that these lesions are truly solitary metastatic foci. However, patients with solitary metachronous sites fare reasonably well after complete surgical excision.

### Palliation

In view of the poor survival rate of patients with locally advanced NSCLC and patients with metastatic disease, effective palliation is an important objective. Carroll et al.<sup>582</sup> followed up 134 inoperable patients and reported that 64% needed immediate local palliation and that, of those with no thoracic symptoms at presentation, one-half required subsequent local treatment. Thus, a watch-and-wait policy is appropriate for only a minority of patients, and it is critical that they be followed up carefully to prevent the development of serious local complications of the disease that may be less easily palliated. It is important to intervene before superior vena cava obstruction, obstructive pneumonia, or lobar collapse develops. The latter two conditions produce a radiographic picture in which tumor and other processes are not easily distinguishable, and large radiation fields may be necessary for effective control.

### Radiotherapy

**LOCAL DISEASE. External-Beam Irradiation** Numerous trials have been conducted in which the palliative benefit of radiotherapy has been documented.<sup>582,583,584</sup> and <sup>585</sup> Various regimens produce a high rate of palliation that often is sustained for a significant proportion of a patient's survival. The randomized trials suggest that certain symptoms, such as hemoptysis and pain, are more effectively palliated, while dyspnea and poor performance status appear to be more refractory. Investigators in Italy used either 5.5 Gy or 8.8 Gy once a week for a total dose of 44 Gy and reported that 80% of 45 patients experienced an average improvement of 20 points on the Karnofsky performance score.<sup>421,586</sup>

The RTOG trial showed that even regimens with larger fraction sizes had a low (8%) incidence of severe complications. An early Medical Research Council trial showed no difference in survival or toxicity between 17 Gy given in two fractions 1 week apart and more conventional palliative fractionation (30 Gy in ten fractions or 27 Gy in six fractions).<sup>583</sup> A follow-up study, however, demonstrated an increase in median survival from 7 months to 9 months when 17 Gy in 2 fractions was compared to 36 to 39 Gy in 12 to 13 fractions.<sup>587</sup> Palliation was quicker and more durable in the hypofractionated arm, however.

A significant number of patients, however, suffer recurrence of symptoms. Few data report on the result of re-treatment with radiation. Jackson and Ball<sup>588</sup> re-treated 22 patients whose disease recurred after radical irradiation and delivered between 20 and 30 Gy in 2-Gy fractions. Symptomatic improvement occurred in 52%, and median survival was 5.4 months.

Superior vena cava syndrome is characterized by venous distention, facial edema, headache, tachypnea, cyanosis, and plethora.<sup>589</sup> It is caused by the obstruction of the superior vena cava by compression, invasion, or thrombosis. Approximately 80% of cases are caused by bronchiogenic cancer, most frequently small cell lung cancer, but non–small cell histologies are also very common. Although some have questioned whether emergent radiation treatment is necessary,<sup>589</sup> others report symptomatic relief with palliative radiotherapy in 80% of patients.<sup>590</sup> High dose per fraction (300 cGy or greater) appears to incite faster relief.<sup>590</sup>

**Intraluminal Brachytherapy** Intraluminal brachytherapy or EBB is an excellent palliative treatment for symptoms of hemoptysis, obstruction, and dyspnea. It has been shown to work best in tumors that are endoluminal or submucosal.<sup>591</sup> Direct permanent implantation of <sup>125</sup>I seeds into endobronchial tumors was developed at MSKCC in the 1960s. Relief of symptoms was achieved in approximately 60% of cases, but there was significant morbidity due to perforation of the airway, hemorrhage, and ventilatory arrest.<sup>592</sup> Subsequent workers avoided direct implantation into tissues and used temporary intraluminal placement of cobalt 60 or <sup>192</sup>Ir to deliver one or more large fractions over a few days.<sup>593,594</sup> High-dose-rate fractionated intraluminal therapy was developed to avoid such prolonged treatment times, which were uncomfortable for the patient and required hospitalization with attendant expense and radiation risk to personnel. In a sequential comparison of low- and high-dose rate endobronchial radiation, there was no difference in palliative effect or toxicity.<sup>595</sup> In a population of patients receiving prior radiation, this approach yielded symptomatic improvement in 75% of patients, and there were a few long-term survivors.<sup>425</sup> Similar data were reported by Macha et al.,<sup>596</sup> who obtained a response in 79% (44 of 56) of patients receiving 7.5 Gy 1 cm from the source in four treatments. Radiologic improvement occurred in 88% (22 of 25) of patients with collapse or atelectasis, and improvements in FEV<sub>1</sub> and vital capacity were well documented. Delclos et al.<sup>597</sup> reported an 84% response rate in 81 previously treated patients. The median response duration was 4.5 months. Burt et al.<sup>598</sup> gave 15 to 20 Gy at 1 cm in one fraction of high-dose-rate endoluminal brachytherapy and reported relief of hemoptysis in 86% (24 of 28), dyspnea in 64% (21 of 33), and cough in 50% (9 of 18). Unlike in other series, these authors did not use laser therapy before radiation. Laser treatment provides immediate relief of symptoms, facilitates catheter placement beyond the obstruction, and may increase response rates and duration. Seagren and Harrell<sup>599</sup> reported significantly improved response rates among a population of 36 patients who received laser treatment versus 14 who did not.

The optimum brachytherapy fractionation schedule has yet to be determined. Single large fractions have been associated with a large risk of massive hemoptysis.<sup>258</sup> Huber et al.<sup>600</sup> compared two fractionation schedules of high-dose-rate EBB: 3.8 Gy in four fractions and 7.2 Gy in two fractions. There was no difference in overall survival or complications between the two groups, although there was a trend toward improved survival with the large fraction size. Therefore, doses in the range of 5 to 7.5 Gy prescribed to 1 cm should be considered safe for high-dose-rate endobronchial radiation. EBB has also been given concurrently with chemotherapy safely.<sup>601</sup>

### Distant Metastases

NSCLC metastasizes to a variety of organs. For asymptomatic metastatic disease remote from critical locations, the usual approach is expectant management or chemotherapy. Isolated symptomatic lesions, such as bone metastases and spinal cord compression (even if asymptomatic), are managed with palliative courses of radiation (e.g., 30 Gy in ten fractions).

Brain metastases are particularly common in NSCLC and can be debilitating. The standard therapy for multiple brain metastases in NSCLC is whole brain irradiation.

This is accompanied by dexamethasone, 4 mg four times daily before and during radiation, and anticonvulsants only if seizures occur.

The RTOG studied a variety of dose and fractionation schemes for 1994 patients with brain metastases arising from several primary sites, including lung (approximately one-half of patients). The schedules used were 20 Gy in 1 week, 30 Gy in 2 weeks, 30 Gy in 3 weeks, 40 Gy in 3 weeks, and 40 Gy in 4 weeks. The shorter schedules tended to give more rapid relief of neurologic symptoms, but otherwise the schedules had comparable palliative effects (50% overall), duration of improvement (9 to 13 weeks), and median survival (15 to 18 weeks).<sup>601,602</sup>

Surgical resection combined with postoperative resection has been advocated for single metastases. At MSKCC, 104 patients with NSCLC were treated with surgery and radiation (n = 35) or radiation alone (n = 69). Median survival was 18 months for the combined-therapy arm versus 4 months for the radiation-alone arm. The patients on the combined-arm had fewer metastases to other organs and tended to have controlled or more aggressively managed primary tumors.<sup>603</sup> Mandell et al.<sup>603</sup> and Patchell et al.<sup>604</sup> randomly assigned 45 patients with resectable single brain metastases (82% NSCLC primary tumors) to receive radiation alone or combined resection and radiation to the entire brain. Median survival (40 weeks vs. 15 weeks) and duration of functional independence (38 weeks vs. 8 weeks) were significantly higher in the combined surgery-plus-radiation arm. The magnitude of the difference in survival documented in the trial has prompted an increasing acceptance of resection and postoperative irradiation for solitary brain metastases arising from NSCLC. A subsequent study from Patchell et al.<sup>605</sup> examined the role of whole brain radiotherapy in patients who underwent surgical resection. They found that whole brain radiotherapy decreased the rate of neurologic death but did not have an effect on overall survival. Stereotactic radiosurgery for solitary brain metastases appears promising as a substitute for surgery.

**SURGERY.** Even when surgery cannot lead to cure, this approach may be used to afford best palliation of symptoms. Such surgical intervention may include bronchoscopic removal or ablation of tumor to relieve endobronchial obstruction or hemoptysis, pleurodesis to relieve symptomatic malignant pleural effusions, pericardial fenestration for malignant pericardial effusions, endobronchial or endoesophageal stents for relief of obstruction, and (occasionally) surgical resection of primary tumors and lung parenchyma for relief of septic complications or massive hemoptysis. On very rare occasions, *en bloc* resection, albeit incomplete, may be excellent palliation for painful invasion of bony structures, such as vertebrae or ribs.

**Relief of Endobronchial Obstruction** Bronchoscopic removal of endobronchial tumor is an efficient way of relieving endobronchial obstruction. Simple mechanical débridement with the use of the bronchoscope is often sufficient. Coagulative techniques, such as CO<sub>2</sub>, argon or neodymium-yttrium aluminum garnet laser, electrocautery, and cryotherapy have been used in conjunction with mechanical débridement. There has been an increase in interest in the use of photocoagulation employing hematoporphyrins and argon beam excitation as a method of relieving endobronchial obstructions.<sup>606</sup> All the techniques can be effective. Massive hemorrhage from the lesion is rare but can be avoided by the judicious use of coagulative techniques. In most instances, endobronchial débridement and coagulation are best carried out by rigid bronchoscopy. Frequently, endobronchial stents are employed for long-term palliation.

**Hemoptysis** Frequently, hemoptysis can plague the patient with stage IV lung cancer. As with bronchial obstruction, bronchoscopy is often the treatment of choice to control this annoying and sometimes devastating complication. All the coagulative methods discussed for bronchial obstruction can apply. In some patients, the bleeding can be controlled by the use of bronchial artery embolization to obstruct the hypertrophy in the bronchial arteries that have been eroded in the area of the tumor. On rare occasions, massive hemoptysis can be dealt with by a palliative resection.

**Pleurodesis of Malignant Pleural Effusions** Malignant pleural effusions associated with lung cancer can be difficult to treat. In most instances, a portion of the ipsilateral lung is atelectatic, making pleurodesis more refractory. Before pleurodesis, a chest tube should be inserted to drain the pleural effusion completely to ensure that the lung is expandable. Occasionally, endobronchial removal of tumor may allow such expansion. After confirmation that the visceral and parietal pleura can be opposed, pleurodesis can be effected using intrapleural tetracycline, bleomycin, or talc. The latter chemical appears to be most effective, especially since tetracycline has become unavailable in the United States.

**Pericardial Effusions** Symptomatic pericardial effusion secondary to metastatic disease from lung cancer can be treated by simple pericardial drainage, drainage followed by sclerosis of the pericardium, or the surgical creation of a pericardial window either by the subxiphoid laparotomy approach or anterior thoracotomy approach or using video-assisted thoracoscopic techniques. In all surgical approaches, a pericardial window is created, and a chest tube is inserted to complete the drainage of the pericardium.

**Bronchial and Esophageal Obstruction** Extrinsic compression of a major airway or the esophagus sometimes complicates lung cancer that involves mediastinal lymph nodes. When minimal endobronchial disease is present, bronchoscopy or esophagoscopy to relieve such obstruction yields temporary relief. In such instances, insertion of endobronchial or endoesophageal stents may relieve the problem. Because of the proximity of the major airways to the esophagus, these stents may cause compression of the other organ. This is especially true when endoesophageal stenting is used, with resultant major airway compression. Such treatment, however, frequently yields excellent palliation of symptoms.

**Palliative Resection** Palliative resection for uncontrolled symptoms rarely is indicated. Endobronchial obstruction with distal uncontrolled pneumonia or lung abscess can be treated by endoscopic removal of tumor or, in the case of lung abscess, percutaneous or transbronchoscopic drainage of the abscess. Massive hemoptysis may not respond to other therapeutic measures. It is rare that a palliative, incomplete surgical resection is required for patients presenting with these complications. In most instances, lesser procedures afford excellent palliation.

Invasion of tumors into vertebral bodies or the spinal canal may, on rare occasions, require surgical resection of all or part of the primary tumor plus the involved vertebral body to relieve uncontrollable pain or impending spinal cord damage. In most instances, such surgery provides palliation for only a short time.

## EPIDEMIOLOGY AND ETIOLOGY

Small cell lung cancer (SCLC) is the histologic diagnosis in approximately 18% of the more than 171,000 patients diagnosed with lung cancer annually in the United States.<sup>1,2</sup> Across the world, the proportion of lung cancers that are of the small cell histology tends to be between 10% and 20% in male subjects and 10% and 30% in women.<sup>3</sup> The predominant risk factor for lung cancer is tobacco exposure, which is the cause for up to 90% of cases diagnosed.<sup>4</sup> Among the major histologic subtypes of lung cancer, the association between the extent of tobacco exposure and risk is particularly strong for squamous cell and SCLC.<sup>5,6</sup> Thus, the incidence of SCLC has paralleled trends in cigarette smoking after a 20- to 50-year lag period. In the twentieth century, manufactured cigarettes first became popular among men, then among women, and successive generations began smoking at progressively earlier ages. Per capita consumption in the United States increased from approximately 54 cigarettes per adult in 1900, to a peak of 4345 cigarettes per adult in 1963.<sup>7</sup> Between 1965 and 1995, the number of adult men who were active smokers declined from 52% to 27%. For women, smoking prevalence declined from 28% to 23% in this time period. However, smoking prevalence for the adult population has changed little from 1993 to 1997, and during the 1990s there have been increasing trends in tobacco smoking among adolescents, particularly girls.<sup>7,8</sup> and<sup>9</sup> In 1997, the prevalence of current cigarette smoking was 36.4% among U.S. secondary school students.<sup>10</sup>

Exposure to other environmental respiratory carcinogens, such as asbestos, benzene, coal tar, and other industrial chemicals may interact with tobacco smoke to increase risk.<sup>11,12,13</sup> and<sup>14</sup> The presence of underlying lung disease and diet have also been implicated.<sup>12,15,16</sup> The risk associated with household exposure to radon gas remains controversial.<sup>12</sup> Pedigree studies and specific metabolic phenotypes have identified familial clusters and populations at increased risk for lung cancer, which is not surprising because several nonrandom genetic defects are associated with this disease.<sup>17,18,19</sup> and<sup>20</sup> Germline mutations of genes such as p53 are not likely to contribute to susceptibility to lung cancer. Rather, genetic polymorphisms in genes involved in the activation and metabolism of the procarcinogens in tobacco smoke probably contribute to risk.<sup>21,22</sup>

These trends in smoking prevalence have important implications for the current and future population demographics of SCLC. Over the next few decades, the incidence of lung cancer should continue to decline in the United States, and as the birth cohorts most heavily exposed to tobacco age, the median age at diagnosis for SCLC will also grow older. Among men, the incidence rates for lung cancer peaked in 1984 and have been declining at a rate of approximately 1.4% per year, with the largest declines noted in the incidence of small cell and squamous cell cancers.<sup>7</sup> Among women, the peak incidence appeared to be in 1994. However, if the increase in popularity of cigarette smoking among adolescents does not change, the declining incidence of lung cancer can be predicted to reverse. Furthermore, female subjects appear to be more susceptible to tobacco smoke carcinogens than male subjects, and racial differences in susceptibility may also exist.<sup>23,24</sup> and<sup>25</sup> These factors, along with the changing demographics of the smoking population, will define the patient population who develops SCLC in future generations.

## PATHOLOGY

A diagnosis of SCLC is based primarily on light microscopy. In 1981, the World Health Organization proposed a histologic classification that gained wide acceptance.<sup>26</sup> In this classification, SCLC was divided into three subtypes that consist of oat cell, intermediate cell type, and combined oat cell (SCLC combined with squamous or adenocarcinoma). It soon became clear that the morphologic features used to distinguish oat cell from the intermediate cell histology were imprecise, and that even when strict criteria were used, pure SCLC, whether it was classified as oat cell or intermediate cell, behaved identically. Consequently, the International Association for the Study of Lung Cancer proposed a revised classification in 1988 that recognized pure small cell cancer and two less common variants: mixed small cell and large cell carcinoma and combined small cell carcinoma.<sup>27</sup> This classification schema is what is typically used today.

SCLC is composed of neoplastic cells that are typically arranged in clusters, sheets, or trabeculae separated by a delicate fibrovascular stroma. The tumor typically arises in the central airways and initially infiltrates the submucosa, gradually obstructing the lumen by extrinsic or endobronchial spread. The cells are generally 1.5 to 2.5 times the diameter of a small resting lymphocyte.<sup>28</sup> They have scant cytoplasm and a finely granular nuclear chromatin. Nucleoli are absent or inconspicuous. Mitotic rates are high, and necrosis of individual tumor cells within cell clusters is common. Crush artifact, resulting in smearing of nuclear chromatin and hematoxyophilic encrustation of vessel walls is common.<sup>27,29</sup> More than 90% of untreated SCLC falls into this category.

In the mixed small cell and large cell variant, there is a subset of cells that resembles large cell carcinoma. These cells may be larger than, or equivalent in size to, the small cell component. These cells are distinguished by the presence of prominent, frequent nucleoli and a nuclear chromatin pattern that is more coarsely granular or open. There are variable amounts of cytoplasm present. The other subtype recognized in the International Association for the Study of Lung Cancer classification is combined SCLC. In this tumor, small cell carcinoma typically coexists with squamous carcinoma, although adenocarcinoma or one of the less common non-small cell histologies may be present.<sup>27</sup>

In most series, the frequency of the small cell and large cell variant is between 3% and 6%, and for combined SCLC it is 1% to 3%.<sup>27,30,31</sup> and<sup>32</sup> There is less concordance among pathologists on the diagnosis of the mixed cell variant than there is for pure SCLC.<sup>30,31</sup> Furthermore, the ability to identify a mixed population is influenced by the size of the biopsied material, with examination of a lymph node more likely to result in identification of a mixed cellular population than a typical

bronchial biopsy. It remains unclear whether the presence of a mixed cell or a combined histology confers a different prognosis or response to treatment than pure small cell carcinoma. For the mixed small cell subtype, there are series that have identified survival that is inferior to,<sup>33,34</sup> superior to,<sup>31</sup> or comparable with<sup>30,35</sup> pure SCLC. There is little information regarding the outcome of patients with combined SCLC. A review of 429 patients treated at Vanderbilt University for SCLC identified nine (2%) with combined small cell and non-small cell histologies.<sup>32</sup> Two of these patients were long-term survivors, and both underwent surgical resection in addition to chemotherapy. Thus, surgery may play a role in the management of combined SCLC, and the presence of non-small cell elements, although uncommon, must be considered in patients who might potentially benefit from resection of residual non-SCLC when the initial diagnosis is based on the limited material available by needle or bronchoscopic sampling.

Although the diagnosis of small cell carcinoma rests primarily on morphologic assessment, immunocytochemistry plays a role, and electron microscopy is of occasional value in difficult cases. Virtually all SCLCs are immunoreactive for keratin and epithelial membrane antigen, so that if a tumor does not stain for these markers, other diagnoses should be considered.<sup>36</sup> One or more markers of neuroendocrine differentiation, such as chromogranin, neuron-specific enolase, Leu-7, and synaptophysin, can be detected in approximately 75% of SCLC.<sup>29,36</sup> The presence of these markers, however, is not mandatory for the diagnosis and does not distinguish small cell from non-SCLC, as 10% to 20% of non-SCLC exhibit neuroendocrine differentiation. By electron microscopy, the cells are closely apposed, with a high nuclear to cytoplasmic ratio. Chromatin is finely clumped but uniformly dispersed within the nucleus. Few organelles and only occasional uniformly small dense core granules are located in the cytoplasm. The presence of large granules should raise the diagnosis of a carcinoid tumor.<sup>29</sup>

The major differential diagnostic considerations for a small cell carcinoma are non-SCLC, other small round cell tumors, reserve cell hyperplasia, and a lymphocytic proliferation. Small cell carcinoma composed of larger tumor cells may be difficult to differentiate from a poorly differentiated non-SCLC, particularly if neuroendocrine features are present. Reserve cells are progenitors for bronchial epithelial cells and proliferate in response to chronic irritation of the airways. Features that distinguish reserve cells from small cell carcinoma include retention of cell boundaries within a cell cluster, a lack of the extreme nuclear molding found in small cell carcinoma, and an absence of granularity of the chromatin.<sup>29</sup>

## CLINICAL PRESENTATION

In general, the clinical presentation of SCLC is similar to the other histologies of bronchogenic carcinoma. Few patients are asymptomatic at diagnosis. In screening studies, only 4% to 12% of the lung cancers detected as a solitary pulmonary nodule are small cell carcinoma.<sup>37,38</sup> The initial complaints usually reflect the local presence of a tumor. Cough is the most common symptom. Recent acceleration of cough or accompanying hemoptysis increases the likelihood that an underlying cancer is present. Dyspnea and chest pain are reported in 30% to 40% of patients at diagnosis.<sup>1</sup> Because SCLC typically develops in the central airways, hemoptysis, postobstructive pneumonitis, wheezing, or hoarseness due to vocal chord paralysis may be present. Superior vena caval obstruction is present at diagnosis in 10% of patients with SCLC.<sup>39</sup> Chest imaging typically shows hilar and mediastinal invasion and regional adenopathy. One-third of patients have some degree of atelectasis present.<sup>1</sup> A peripheral location or chest wall involvement by the tumor is uncommon. For example, no more than 2% of SCLC present as a superior sulcus tumor.<sup>40,41</sup>

Most patients with SCLC have clinically detectable metastases at diagnosis (Table 31.3-1). Bone involvement is usually characterized by osteolytic lesions, often in the absence of bone pain, or elevations in the serum calcium or alkaline phosphatase.<sup>42,43</sup> and<sup>44</sup> However, marked osteoblastic activity is present in a minority of patients. Hepatic and adrenal lesions are typically asymptomatic. Elevations of the serum lactate dehydrogenase (LDH), alkaline phosphatase, or hepatic transaminases are present in the majority of patients in whom liver metastases are identified.<sup>45</sup> In contrast, radiographically confirmed brain metastases are symptomatic in more than 90% of cases. Endovascular metastases (tumor emboli) or lymphangitic spread can be among the underlying causes of dyspnea. Constitutional symptoms, including weight loss, anorexia, and fatigue, are common and correlate with the presence of extensive-stage disease.

	At Presentation		At Autopsy
	All Patients (%)	As a Single Site (%)	(% of Patients)
Liver	21-27	6-7	69

**TABLE 31.3-1.** Sites of Involvement of Small Cell Lung Cancer at Diagnosis and Autopsy

The spectrum of paraneoplasia associated with SCLC differs to some degree from the syndromes observed with non-SCLC. Small cell carcinoma is the histology in only 5% of patients with lung cancer diagnosed with hypertrophic pulmonary osteoarthropathy. Humorally mediated hypercalcemia is rare.<sup>46</sup> On the other hand, the vast majority of lung cancer patients who develop the syndrome of inappropriate antidiuretic hormone, Cushing's syndrome, or neurologic paraneoplasia have SCLC. SCLC accounts for approximately 75% of the tumors associated with the syndrome of inappropriate antidiuretic hormone. Although serum concentrations of antidiuretic hormone are elevated in the majority of patients with SCLC, only approximately 10% of patients fulfill the criteria for syndrome of inappropriate antidiuretic hormone, and symptoms are present in no more than 5%. In some cases, ectopic production of atrial natriuretic factor contributes to the disorder in sodium homeostasis. Similarly, increased serum levels of adrenocorticotropic hormone can be detected in up to 50% of patients with lung cancer, but only 5% of patients with SCLC develop Cushing's syndrome. In approximately one-half of these cases, it is present at diagnosis. Some of the cutaneous manifestations of Cushing's syndrome may not be prominent, perhaps because of the rapid growth and clinical course of SCLC. A few studies have demonstrated that a low serum sodium level is an adverse prognostic factor,<sup>47,48</sup> and patients with Cushing's syndrome have a limited survival.<sup>49,50</sup>

Neurologic paraneoplastic syndromes include sensory, sensorimotor, and autoimmune neuropathies and encephalomyelitis. These syndromes are thought to occur through autoimmune mechanisms, and antinuclear antibodies that bind both to SCLC and neuronal tissues have been identified.<sup>51</sup> Symptoms may precede the diagnosis by many months and are often the presenting complaint.<sup>46</sup> They may also be the initial sign of relapse from remission. In contrast to the endocrine syndromes, for which successful treatment of the tumor effectively controls the symptoms, the severity of the neurologic symptoms is unrelated to tumor bulk and often does not improve despite successful antineoplastic therapy. Subacute peripheral neuropathy may be the most frequent neurologic syndrome. The Lambert-Eaton syndrome is characterized by proximal muscle weakness that improves with continued use and hyporeflexia and dysautonomia. Characteristic electromyographic findings confirm the diagnosis. The cause is related to autoantibody impairment of acetylcholine release from the cholinergic nerve terminals.<sup>52</sup> Rare neurologic entities include cerebellar ataxia,<sup>53</sup> retinal degeneration,<sup>51</sup> intestinal dysmotility,<sup>54</sup> limbic encephalomyelitis,<sup>55</sup> and necrotizing myelopathy.<sup>56</sup>

## STAGING EVALUATION AND PROGNOSTIC FACTORS

The goal of staging is to establish the prognosis, identify patients with disease confined to the chest who are appropriate for combined modality therapy, and assess whether an individual patient will be at increased risk of mortality if treated with an aggressive chemotherapy program. Surgery plays a minor role in the management of this disease, and less than 10% of patients might be considered candidates for thoracotomy. As a result, the revised TNM system for staging lung cancer is not widely employed.<sup>57</sup> Rather, a simpler system, introduced by the Veterans' Administration Lung Study Group (VALSG) is generally used.<sup>58</sup> In the VALSG system, limited stage is defined as disease confined to one hemithorax that can be encompassed in a tolerable radiation field. These patients are currently treated with a combined modality approach. In all other settings, patients are considered to have extensive-stage disease. At presentation, after appropriate staging procedures are performed, 60% to 70% of patients with SCLC have extensive disease and 30% to 40% have limited-stage disease.<sup>1</sup>

In the VALSG staging system, the appropriate classification of selected sites remains controversial. These sites include an ipsilateral pleural effusion, supraclavicular lymphadenopathy (ipsilateral or contralateral), or contralateral mediastinal lymphadenopathy. Several large series have failed to identify a difference in survival between patients with an isolated ipsilateral pleural effusion compared with other patients with limited SCLC,<sup>59,60,61</sup> and<sup>62</sup> and many groups have included patients with

ipsilateral pleural effusions within their definition of limited-stage disease.<sup>63,64,65</sup> and<sup>66</sup> However, only 2% to 7% of all patients with otherwise limited SCLC have an isolated pleural effusion,<sup>61,67</sup> so that small differences in outcome associated with this clinical factor might be missed. In an analysis of two large cooperative group databases, which included in toto more than 4000 patients, the survival of patients with an isolated effusion was similar to patients with one site of extensive disease.<sup>64,67</sup> In one of these analyses, an isolated effusion conferred a poorer survival compared with other patients classified as having limited disease, which was of borderline significance ( $F = .051$ ).<sup>64</sup> In clinical practice, small effusions, usually detected by computed tomography (CT) scan, are sometimes difficult to evaluate. It is assumed that these effusions are malignant, unless the fluid is a transudate, nonhemorrhagic, and cytologically negative on repeated examination results. Clinical judgment in individual cases should be applied for selection of these patients for combined modality therapy until this issue is addressed in a prospective trial.

Although most randomized trials evaluating the role of combined modality therapy in limited-stage SCLC have excluded patients with an ipsilateral pleural effusion, they have usually included patients with ipsilateral, and sometimes contralateral, supraclavicular lymph node metastases. The presence of supraclavicular lymphadenopathy is commonly associated with extensive disease, but when encountered in patients with otherwise limited disease (5% of cases), carries a trend toward poorer survival.<sup>67,68</sup> Contralateral mediastinal involvement is also usually classified as limited-stage disease. However, two randomized studies that evaluated the use of a more aggressive, twice daily, radiation regimen, excluded patients with contralateral hilar disease,<sup>69,70</sup> presumably to reduce the volume of irradiated field and the risk for toxicity. If this form of more intensive radiotherapy becomes a standard of care, the potential prognostic significance of the extent of mediastinal nodal involvement will need to be reexamined. Patients with limited-stage disease who present with superior vena cava syndrome have a similar prognosis to other patients with limited-stage disease<sup>62,71</sup> and have been included in randomized studies investigating the role of combined modality therapy.<sup>72,73</sup>

Several series have identified a more favorable outcome for patients with “very” limited disease, that is a tumor confined to the lung without evidence of spread to the mediastinum.<sup>66,74,75</sup> Retrospective analysis of the University of Toronto database demonstrated that patients without evidence of mediastinal metastases by CT scan or mediastinoscopy who were treated with chemotherapy and radiation had a median survival of almost 16 months and a projected survival at 5 years of 18%.<sup>66</sup> This was significantly better than other patients with limited disease who had more extensive tumor burden. Patients who undergo surgical resection and have an absence of mediastinal metastases have an especially favorable outcome. Survival in this select group is between 50% and 60%. Among the patients with extensive disease, a number of studies have shown that the number of metastatic sites is an important parameter.<sup>59,62,64,67</sup>

## OTHER PROGNOSTIC FACTORS

In addition to disease extent based on VALSG stage, multivariate analyses suggest that performance status and the serum LDH are the most reproducible prognostic factors. Performance status reflects both the underlying extent of the disease and partially dictates tolerance for the intensity of treatment. Although patients with a lower performance status are at a higher risk for treatment-related complications, they may still benefit from a combined modality approach.<sup>76</sup>

An elevated LDH is seen in 33% to 57% of all patients with SCLC,<sup>48,64,77</sup> and up to 85% of patients with extensive-stage disease.<sup>64</sup> Biochemical parameters, such as an elevation of the LDH and neuron-specific enolase, are strong predictors of poor outcome in SCLC.<sup>48,61,64,78,79</sup> Male gender is an adverse prognostic factor in some,<sup>80,81</sup> but not all series.<sup>67</sup> Older age has been an independent adverse prognostic factor in limited disease in some series,<sup>67,82,83</sup> but not in others.<sup>48,84</sup> Older age often results in a compromised dose intensity, usually due to treatment delays.<sup>84</sup>

Molecular studies have identified several specific lesions involved in the pathogenesis of SCLC, and the prognostic import of the gain or loss of function of these critical genes and gene products is now being evaluated clinically.<sup>22,85,86</sup> Drug sensitivity testing *in vitro* may be useful to guide selection of a chemotherapy regimen, but with current methodologies it is feasible in only a minority of patients and is labor intensive.<sup>87</sup>

## ASSESSMENT OF RISK

In many respects, treatment for SCLC is as demanding as a thoracotomy and pulmonary resection. In some large cooperative group trials, treatment-related mortality has exceeded 10%. Accordingly, a careful assessment of a patient's ability to undergo aggressive therapy, particularly if concurrent chemotherapy and radiation are planned, is warranted. Several retrospective analyses have attempted to identify patients at increased risk for a treatment-related mortality. An analysis of 382 patients treated in a single institution identified age older than 50 years, Karnofsky performance status less than or equal to 50, treatment with a regimen containing three drugs or more, and a prior septic episode during chemotherapy as risk factors for septic complications.<sup>88</sup> In this study, older patients with a poor performance status had a 22-fold greater risk of septic death than patients without those risk factors. In another study involving 610 patients, each one of the 71 fatalities that occurred during the first cycle of VP-16–based chemotherapy was matched to the next patient enrolled on the trial.<sup>89</sup> Patients dying early were more likely to have a poor performance status, clinical hepatomegaly, a low serum albumin, and elevations of the blood urea nitrogen and serum alkaline phosphatase. The Copenhagen Lung Cancer Group compared 937 patients treated in its two most recent studies with 819 patients treated in early clinical studies.<sup>90</sup> The mortality during the first cycle of chemotherapy in the recent studies was threefold higher (12.6% vs. 4.2%) compared with the earlier trials. An algorithm was developed to identify high-risk patients that included age, performance status, and serum LDH. Patients were defined as high risk if they had a poor performance status [Eastern Cooperative Oncology Group (ECOG) 3 or 4], or if they were 65 years old or older and had a serum LDH that was more than twice the upper normal level. Based on this algorithm, 21% of the 937 patients would be considered at high risk. In this high-risk group, the median survival time was 133 days, and the 2-year survival was 4.5%. Mortality during the first chemotherapy cycle was 33%, and among patients treated with etoposide and platinum the frequency was 41%. Of note, more than one-half of these early deaths occurred in older patients with an elevated LDH who had a preserved performance status. For these high-risk patients, therefore, less intensive chemotherapy would be appropriate, and careful monitoring and support during treatment is mandatory.

## STAGING PROCEDURES

Autopsy and clinical studies have shown that SCLC commonly disseminates to soft tissue and multiple viscera (see [Table 31.3-1](#)). Autopsy studies in patients with lung cancer who were staged without modern imaging methods and died within 1 month of a potentially curative surgical resection but of causes unrelated to the cancer, showed that 12 of 19 patients (63%) with SCLC had distant metastases, in comparison with 14% to 40% for the non-SCLC histologies.<sup>91</sup> Outside of the context of a clinical trial, it is reasonable to discontinue the staging survey once disease outside the chest has been identified. Exceptions would include the presence of additional symptomatic areas that may require prompt therapy, such as symptoms and signs suggestive of metastases to a weight-bearing bone or the neuraxis. In an era of cost containment, algorithms have been proposed that use each diagnostic modality in a stepwise fashion to reduce the costs of the staging workup.<sup>65,92</sup>

History, clinical examination, including neurologic examination, a complete blood cell count, and a biochemical panel, including electrolytes, liver function tests, and LDH determination, and a chest radiographic film make up the first line of pretreatment evaluation in SCLC. Selected biochemical parameters, in particular the serum LDH, have been shown to be predictive of the extent of disease.<sup>48,61,64,77,93,94</sup> Symptoms and abnormalities detected in these tests often direct subsequent testing. CT scanning of the chest is superior to chest radiography in delineating the extension of the primary tumor and detecting mediastinal lymphadenopathy and may up-stage T or N designations in up to 82% of cases.<sup>95</sup> A pericardial effusion is infrequently seen at presentation, but thickening of the pericardium detected on CT scan of the chest is a common finding of unknown significance.<sup>96</sup> A CT is necessary for purposes of planning the radiation portal field and for evaluation of the minority of patients who are candidates for surgical resection. In the pre-CT era, bronchoscopy was found to be helpful as an adjunct to chest radiography findings in assessing a complete response.<sup>97</sup> CT scan is now widely available and is commonly used for pretreatment evaluation and response assessment. However, its capability to assess tumor response is limited in areas of atelectasis and radiation-induced fibrosis where the presence of active tumor cannot be ascertained. The role of positron emission tomography (PET) scanning or somatostatin receptor imaging in distinguishing residual tumor versus benign radiographic abnormalities should be further investigated.

CT scanning detects intraabdominal lesions in approximately 35% of patients with SCLC at presentation.<sup>98,99</sup> By the use of chest and abdominal CT, locally advanced or distant disease is diagnosed in 94% to 96% of patients.<sup>95,98</sup> CT has an accuracy of 85% in detecting liver metastases in SCLC overall,<sup>95,100</sup> and that increases in patients with abnormalities in liver function test results.<sup>100</sup> Involvement of the adrenal glands by metastatic tumor is almost always clinically silent. Clinical studies have implicated the adrenals as the only metastatic site in SCLC in 8% to 11% of patients at presentation; however, the majority of these cases were not biopsy proven. In autopsy series, adrenal metastases are seen in 35% to 65% of patients with SCLC. The accuracy of noninvasive imaging in differentiating between adenomas and adrenal metastases in patients with lung cancer has been suboptimal,<sup>101</sup> although newer magnetic resonance imaging (MRI) techniques, such as chemical shift imaging, may improve the accuracy of MRI in differentiating adenomas from metastatic deposits.<sup>102</sup>

Brain metastases are found in 10% of SCLC patients at the time of diagnosis.<sup>103,104</sup> The cumulative risk for brain metastases increases with survival. Multiple lesions

are usually found in autopsy in patients with CNS involvement. <sup>103,105</sup> Leptomeningeal involvement is extremely rare at presentation, but may develop antemortem in 2% to 13% of patients. <sup>103,105,106</sup> The majority of these patients have simultaneous brain metastases. <sup>103,106</sup> The usefulness of a pretreatment brain scan in asymptomatic patients is controversial. Although the yield of brain CT in patients with neurologic abnormalities is high (42% to 88%), <sup>107,108</sup> it is only 3% to 8% in asymptomatic patients with SCLC. <sup>107,108</sup> and <sup>109</sup> In a patient in whom metastatic disease has been demonstrated by another test or who is not a potential candidate for thoracic irradiation for other reasons, imaging the brain is probably not a mandatory component of the initial staging evaluation. If asymptomatic brain metastases are present, chemotherapy may be adequate treatment, <sup>110</sup> and the early detection and treatment of asymptomatic brain metastases with radiation therapy has not been shown to significantly improve patient outcome, <sup>107,109</sup> partly due to the effect of systemic failure on survival. If brain metastases are the single site of distant disease, the prognosis may not be significantly altered because the median survival compared with patients with limited disease has been comparable in some series, <sup>111,112</sup> although not in others. <sup>106,107</sup> A CT of the brain is needed in patients considered for prophylactic cranial irradiation, as the presence of clinically occult metastases would affect treatment planning.

Up to 40% of patients with SCLC have a positive radionuclide bone scan at diagnosis; in fewer than 10% of cases this is the only site of metastatic disease. <sup>42,113</sup> Bone involvement shown by bone scan is frequently detected in asymptomatic patients with SCLC and correlates with an elevated alkaline phosphatase level and bone marrow positivity. Further diagnostic evaluation with a plain radiograph and in some cases with a bone CT scan or MRI may be required to investigate areas of equivocal findings that could be due to osteoarthritis or trauma. In assessing response, repeat bone scanning is helpful but not sufficiently reliable. <sup>113</sup> In some cases, patients demonstrate a more intense uptake of metastatic lesions on bone scan, which reflects bone regeneration and is a sign of response to therapy.

The bone marrow is involved in 15% to 30% of patients with SCLC at presentation, but is uncommonly the only site of metastatic disease. <sup>42,61,114,115</sup> and <sup>116</sup> As a result, routine bone marrow examinations rarely modify staging. The yield of bone marrow biopsy can be increased by *in vitro* semisolid cultures of bone marrow aspirates or immunostaining with anti-SCLC monoclonal antibodies, which are positive in 10% and 15% to 66% of histologically negative bone marrow, respectively. <sup>117,118,119,120</sup> and <sup>121</sup> However, the clinical significance of bone marrow involvement demonstrated by these methods has not yet been determined. A leukoerythroblastic picture on the peripheral blood, which is present in 8% to 19% of all cases at presentation, is highly specific for extensive bone marrow infiltration by SCLC. <sup>44,115,116</sup> Severe thrombocytopenia, with a platelet count of less than  $50 \times 10^9/L$ , and an elevated LDH are also suggestive of bone marrow metastases. <sup>44,94,115</sup> Bone marrow involvement usually coincides with bone and liver metastases, but not with CNS involvement. <sup>115</sup> At least one-half of the patients with a positive bone marrow result have bone metastases detected by bone scan. <sup>42,122,123</sup> In patients with a normal bone scan, normal LDH, and no evidence of thrombocytopenia or peripheral blood leukoerythroblastosis, the yield of bone marrow biopsy is extremely low, <sup>123</sup> and it can be omitted.

MRI allows for the noninvasive evaluation of large volumes of bone marrow and is a sensitive method for detecting bone marrow involvement by SCLC. Bone marrow positivity by MRI has been reported in 30% to 60% of patients with SCLC and identifies marrow involvement missed in the initial biopsy in 3% to 19% of patients. <sup>117,124,125,126</sup> and <sup>127</sup> Circulating malignant cells detected by reverse transcriptase polymerase chain reaction for cytokeratin can be found in the peripheral blood of 27% of SCLC patients. <sup>128</sup> The significance of this finding should be investigated.

PET scan has emerged as a promising imaging modality in lung cancer. Most commonly, a radiolabeled glucose analogue, [<sup>18</sup>F]fluoro-2-deoxy-D-glucose, has been used to demonstrate differences in the metabolism of normal and neoplastic cells. The potential role of PET scan in assessing a solitary lung nodule and mediastinal involvement by tumor has been demonstrated in multiple studies <sup>129,130</sup> and <sup>131</sup> and has also proven valuable in the detection of unexpected extrathoracic disease. <sup>132</sup> Thus, as PET continues to technically improve and become more widely available, it may assume an important role in the staging of SCLC.

Technetium-labeled monoclonal antibody imaging has been evaluated as a staging method in SCLC. <sup>133</sup> The accuracy of this imaging modality in staging patients with SCLC is approximately 90%. However, it has limited value in detecting liver metastases or lesions smaller than 2 cm. <sup>133</sup> The presence of somatostatin receptors in SCLC, a neuroendocrine neoplasm, has made possible the use of radiolabeled somatostatin analogues for the imaging of patients with SCLC. Somatostatin receptor imaging is accurate in detecting the primary lesion and mediastinal lymphadenopathy in SCLC, but has not shown sufficient sensitivity (50% or less) in detecting sites of metastatic disease. <sup>134,135</sup> and <sup>136</sup>

## TREATMENT

Early efforts at the management of SCLC with surgery were characterized by incomplete staging both before and during thoracotomy. Nevertheless, in the 1960s some studies reported 5-year or longer survival in more than 10% of the patients. <sup>137,138</sup> These results, however, were overshadowed by two studies in the 1970s that provided philosophical justification for not using a surgical approach in this disease. The British Medical Research Council published a 144-patient trial ( [Table 31.3-2](#)) that demonstrated the modest superiority of radiotherapy as primary treatment for "operable" SCLC. <sup>139</sup> Shortly thereafter, an American study <sup>140</sup> compared the survival of 146 operable but nonresected patients with 41 resected patients and found no differences.

Group	Patients	Mean Survival (mo)	Survival Rate		
			1Y	2Y	5Y
Surgery	71	6.5	21	4	1*
Radiotherapy	73	10†	22	10	4

\*One patient unable to receive surgery; given irradiation.  
†Significant survival difference ( $P = .04$ ) in favor of radiotherapy.  
(Modified from ref. 139.)

**TABLE 31.3-2.** Survival in Patients with Operable Small Cell Lung Cancer Randomized to Surgery or Radiotherapy

The inadequate results with surgery or radiation alone, even in carefully selected patients, highlighted the need for systemic treatment in SCLC, and the primary role of chemotherapy in the management of this disease is now well established. In a study conducted in the late 1960s testing various alkylating agents, cyclophosphamide was shown to double survival compared with supportive care in patients with extensive disease, and shortly thereafter a combination of cyclophosphamide with radiation was shown to improve survival compared with radiation alone in patients with limited disease. <sup>141,142</sup> An extensive evaluation of the drugs then available demonstrated that anthracyclines and vinca alkaloids, along with certain alkylating drugs, produced single-agent response rates of up to 50%. The antimetabolites appeared to be less active, with response rates reported of 20% to 30%. In the 1980s the epipodophyllotoxins (VP-16 and VM-26) and the platinum analogues were introduced, and their activity ranged from 40% to 60% in previously untreated patients. <sup>143</sup> During the 1990s, two new classes of chemotherapeutic agents, the taxanes and the camptothecins, entered clinical practice and are establishing a role in the management of this disease.

## DEFINITIONS OF ACTIVE CHEMOTHERAPY AND STRATEGIES FOR EVALUATING NEW AGENTS

As agents such as cyclophosphamide and doxorubicin became established in the management of this disease, it became clear in the evaluation of new drugs that exposure to prior chemotherapy and response to this therapy were at least as important as other known prognostic factors in predicting response to the new agent. For example, the epipodophyllotoxins produce response rates of 40% to 90% in untreated patients, <sup>144,145</sup> and <sup>146</sup> but in relapsed patients the response rate to VP-16 and VM-26 were 5% to 12% and 20%, respectively. <sup>147,148</sup> and <sup>149</sup> Based on retrospective analysis of the activity of effective chemotherapy drugs in different populations, response rates greater than or equal to 10% in patients with refractory disease, greater than or equal to 20% in patients in sensitive relapse (typically defined as response to initial therapy and a treatment-free interval of longer than 3 months before disease progression), and greater than or equal to 30% in patients with previously untreated extensive disease have been proposed as the appropriate targets to declare a new chemotherapy drug active. <sup>143,150,151</sup> Because of the biologic aggressiveness of SCLC, the patient population that should be selected to test new drugs remains controversial. Clinical trials that enroll patients with refractory disease, for example, pose the least risk that outcome might be compromised if the new agent turns out to be inactive. However, substantially more patients would

need to be evaluated to establish a response rate of greater than or equal to 10% than would be necessary to establish a response rate of greater than or equal to 30% in previously untreated patients. This means that a much larger number of patients would be exposed to the toxicity of a new drug before it was rejected. Thus, the initial testing of new drugs in patients with sensitive relapse has been proposed as a reasonable compromise,<sup>152</sup> although evaluation in previously untreated patients may be reasonable for new drugs of particular promise.<sup>151</sup>

### STANDARD CHEMOTHERAPY AGENTS AND ANALOGUES OF STANDARD AGENTS

A number of chemotherapy drugs fulfill the criteria for activity outlined in the previous section. Several of these drugs, such as nitrogen mustard, methotrexate, altretamine, and carmustine, are seldom used today. In the 1990s, five drugs, or analogues of these five drugs, have been used in the management of SCLC ( [Table 31.3-3](#)). Current treatment recommendations are based on the experience with these agents.

Drug	Dose (mg/m <sup>2</sup> )	No Prior Chemotherapy		Prior Chemotherapy	
		Response (%)	Median Response	Response (%)	Median Response
Cyclophosphamide	100	10	10	14	14
Carboplatin	360-450	40	40	14	14
Irinotecan	35-75	30	30	14	14
Epirubicin	35-45	30	30	14	14
Cisplatin	200-450	10	10	14	14
Docetaxel	10-100	—	—	10	10
Vincristine	1.5	—	—	10	10
Vinorelbine	2.5	—	—	10	10
Topotecan	1.25	47	47	10	10
Paclitaxel	175	30	30	10	10
Docetaxel	100-150	30	30	10	10
Topotecan	1.25	30	30	10	10
Epirubicin	35	30	30	10	10
Irinotecan	35	30	30	10	10
Docetaxel	100-150	30	30	10	10
Topotecan	1.25	30	30	10	10
Epirubicin	35	30	30	10	10

**TABLE 31.3-3.** Active Agents in Small Cell Lung Cancer

The activity of VP-16 is dependent on the schedule of administration. In randomized trials, bolus administration for 3 or 5 consecutive days repeated every 3 to 4 weeks is superior to one dose by bolus or 24-hour infusion every 3 weeks.<sup>145,153,154</sup> The 5-day bolus schedule is as effective as an 8-day bolus schedule.<sup>146</sup> Two studies that included a pharmacokinetic analysis suggested that the duration of exposure to a threshold concentration of VP-16 was an important determinant of efficacy and toxicity.<sup>145,146</sup> The availability of an oral formulation has led to the development of more prolonged schedules. As a single agent, prolonged oral regimens of VP-16 were tested in previously treated patients and appeared to have activity comparable with the standard 3- to 5-day bolus schedules.<sup>155,156</sup> When included in multidrug regimens, the schedule dependence of activity has not been demonstrated. In a randomized trial comparing cisplatin plus VP-16 given as an intravenous bolus for 3 consecutive days to cisplatin plus VP-16 given as a 21-day oral regimen, there was greater hematologic toxicity with no improvement in response or survival in patients receiving the prolonged oral regimen.<sup>157</sup> Continuous infusion of VP-16 for 72 hours was not superior to a 3-day bolus in combination with cisplatin.<sup>158</sup>

Cisplatin has been evaluated as a single agent, particularly in patients who have had previous treatment, and response rates from these studies approximate 15%. Carboplatin produces a comparable response rate in previously treated patients, and in newly diagnosed patients a 60% response rate has been observed.<sup>159</sup> Ifosfamide is an analogue of cyclophosphamide that appears to be at least as active as cyclophosphamide in the treatment of SCLC. In newly diagnosed patients, response rates of 50% to 65% have been reported. Teniposide is an analogue of VP-16 and, in a randomized trial in newly diagnosed patients with extensive disease, produced a response rate of 43%, compared with a response rate of 49% for ifosfamide and 56% for the standard cyclophosphamide, doxorubicin, and vincristine (CAV) regimen.<sup>160</sup> At the dose tested, hematologic toxicity and life-threatening complications were much more common in the patients treated with CAV. In other phase II studies, the response rate of teniposide has ranged from 38% to 90%, and in one, 5 of 30 patients experienced a toxic death, underlying the importance of patient selection in determining response and toxicity.<sup>161,162</sup> Epirubicin is an anthracycline that in preclinical models was as active as doxorubicin and less cardiotoxic. As a single agent, epirubicin has been shown to produce a response rate of approximately 50% in previously untreated patients with extensive disease.<sup>163</sup>

### NEWER CHEMOTHERAPY AGENTS

The taxanes bind microtubules and promote microtubular assembly. This interferes with tubulin depolymerization, resulting in a disruption of cell division. In an ECOG study, paclitaxel at a dose of 250 mg/m<sup>2</sup> infused over 24 hours produced a response rate of 34%.<sup>164</sup> The North Central Cancer Treatment Group used a similar schedule with the addition of granulocyte colony-stimulating factor (G-CSF) support and reported a response rate of 53% with a reduction in the grade IV leukopenia to 14%. Docetaxel at a dose of 100 mg/m<sup>2</sup> has been reported to produce a response rate of 25% in untreated patients and at a dose of 60 mg/m<sup>2</sup> a response rate of 13.5% in previously treated patients.<sup>165,166</sup>

Camptothecin is a plant alkaloid that has the unique mechanism of action of interacting with topoisomerase I, a nuclear enzyme that plays a key role in DNA metabolism. Schiller et al. treated 48 chemotherapy-naïve patients with extensive-stage SCLC with intravenous topotecan at 2 mg/m<sup>2</sup>/d for 5 days, repeated every 3 weeks. Most patients received G-CSF support. The regimen was active, with a response rate of 40%, 1-year survival of 39%, and median survival of 10 months.<sup>167</sup> In patients progressing or relapsing shortly after completing chemotherapy, the response rate was 6% to 11%.<sup>168,169</sup> Pooled data from three multicenter studies showed a response rate of 18% in 168 patients in sensitive relapse (>3-month interval from previous chemotherapy treatment); the median survival was 30 weeks, and the 1-year survival was 21%.<sup>170</sup> A randomized trial comparing topotecan with CAV in patients in sensitive relapse demonstrated comparable response rates and survival for the two regimens.<sup>171</sup> Topotecan is also available in an oral formulation, and this preparation appears to be at least as active as the intravenous drug.<sup>172</sup> Irinotecan also has activity in SCLC, but has not been as extensively evaluated. In patients previously treated with chemotherapy, response rates of 16% to 47% have been reported.<sup>173,174 and 175</sup>

Gemcitabine, a pyrimidine antimetabolite, produced responses in 7 of 26 (27%) previously untreated patients with extensive disease and 12 of 19 (63%) patients resistant to cisplatin and VP-16.<sup>176</sup> Preliminary results in another study enrolling patients with resistant disease identified three brief remissions in 12 evaluable patients, which together with the demonstrated activity of gemcitabine in previously treated non-SCLC suggests that the mechanism of drug resistance may differ between gemcitabine and other agents used to treat lung cancer.<sup>177</sup>

Vinorelbine (Navelbine) is a new vinca alkaloid that in previously treated patients has produced a response rate of 12% to 16%.<sup>178,179</sup> The activity in newly diagnosed patients with extensive disease was 26%.<sup>180</sup> Because vinorelbine is well tolerated in an elderly population, it may be a useful component of palliative combination regimens. In combination with carboplatin, for example, it produced a response rate of 74% (32 of 43 patients) and a median survival of 37 weeks in patients with extensive disease.<sup>180</sup>

### COMBINATION CHEMOTHERAPY

After the activity of cyclophosphamide was established in SCLC, multidrug combinations were developed and tested ( [Table 31.3-4](#)). Randomized trials of these early combinations demonstrated superior activity to single-agent cyclophosphamide. The combination of cyclophosphamide, doxorubicin, and dacarbazine produced a higher response rate and survival when compared with an equally toxic dose of single-agent cyclophosphamide.<sup>181</sup> Hansen et al. demonstrated that the addition of vincristine to the combination of cyclophosphamide, methotrexate, and CCNU improved survival compared with the three-drug combination, highlighting the usefulness of this relatively nonmyelotoxic agent in combination therapy.<sup>182</sup> Livingston et al. developed the CAV combination, and this became a standard.<sup>183</sup>

Regimen	Dose (mg/m <sup>2</sup> )	Schedule
CAVE		
Cyclophosphamide	1000	d <sub>1</sub>
Etoposide	80	d <sub>1</sub>
VP-16	1000	d <sub>1,2,3</sub>
CEV		
Cyclophosphamide	1000	d <sub>1</sub>
Etoposide	80	d <sub>1</sub>
Vincristine	1.4	d <sub>1</sub>
EP		
VP-16	1000	d <sub>1,2,3</sub>
Cisplatin	80	d <sub>1</sub>
EP		
VP-16	75	d <sub>1,2,3</sub>
Etoposide	80	d <sub>1,2,3</sub>
Cisplatin	80	d <sub>1,2,3</sub>
ICE		
Ifosfamide	1000	d <sub>1</sub>
Cyclophosphamide	1000	d <sub>1</sub>
VP-16	1000	d <sub>1,2,3</sub>
Etoposide	80	d <sub>1</sub>
VP-16	1000	d <sub>1,2,3</sub>
Paclitaxel	175	d <sub>1</sub>

**TABLE 31.3-4.** Commonly Used Chemotherapy Regimens

With the identification of VP-16 as an important new agent, several modifications of the CAV regimen that included VP-16 were tested. In extensive disease, a slight improvement in survival was noted when VP-16 replaced either doxorubicin or vincristine, although greater myelosuppression was evident in the cyclophosphamide, doxorubicin, VP-16 (CDE) arm in the latter trial.<sup>184,185</sup> Hong et al. compared intensive CV (with the dose of cyclophosphamide increased from 1000 to 2000 mg/m<sup>2</sup>) with CAV and cyclophosphamide, VP-16, and vincristine (CEV) and reported that patients treated with CV had a shorter survival and experienced more myelosuppression than patients treated on the other two arms.<sup>184</sup> Substitution of VP-16 for methotrexate in the lomustine, cyclophosphamide, vincristine, and methotrexate regimen also improved survival.<sup>186</sup> Administration of the VP-16 beginning on day 3 produced better survival but more myelosuppression than beginning the VP-16 on day 14 of the cycle, perhaps because this schedule provided greater dose density, or perhaps because it delivered the VP-16 at a point at which more tumor cells were in cell cycle and therefore more susceptible to the drug.<sup>187</sup>

Five randomized trials have evaluated the addition of VP-16 (CAVE) to the CAV regimen.<sup>188,189,190,191</sup> and <sup>192</sup> In three studies, the doses of CAV were equivalent in each arm.<sup>188,189</sup> and <sup>190</sup> Not surprisingly, in these studies the addition of VP-16 resulted in increased hematologic toxicity. Although a better response rate was evident in the arm containing VP-16 in at least some patient subsets in each of these studies, there was an improvement in response duration (of 3 months) and survival (of 6 weeks, *P* = .08) in only one study.<sup>189</sup> Jett et al. compared CAVE with CAV in 231 patients with limited disease.<sup>190</sup> Despite a reduction of the dose of cyclophosphamide by 33%, there was still greater myelosuppression in the CAVE arm. There was a small improvement in median and 2-year survival with CAVE, which was not statistically significant. Two randomized studies intensified components of this regimen: In one the cyclophosphamide was increased from 1000 to 1200 mg/m<sup>2</sup> and the dose of doxorubicin increased from 40 to 75 mg/m<sup>2</sup> in the CAV arm compared with the CAVE arm.<sup>192</sup> The regimens produced equivalent myelotoxicity, response rates, and survival. These results were comparable with the outcomes with less intensive CAV regimens in extensive disease.

The VP-16 and cisplatin (EP) regimen was tested in SCLC because this combination produced synergistic activity in preclinical systems and was established as an active regimen in other diseases. Evans et al. reported response rates of 55% in patients previously treated with CAV and 86% in newly diagnosed patients.<sup>193,194</sup> and <sup>195</sup> Einhorn et al. reported that two cycles of consolidation with EP added to the treatment of patients with limited disease who were responding to six cycles of CAV had a longer survival than patients randomized to CAV only.<sup>196</sup> Prospective studies comparing these two regimens showed comparable response and survival, with a significant reduction in toxicity with EP.<sup>197,198</sup> There was less myelosuppression with EP, and if given with radiation, patients experienced less esophagitis and interstitial pneumonitis. Consequently, EP became an alternative to CAV as the frontline regimen for SCLC.

Carboplatin can be substituted for cisplatin with no loss of activity and improved tolerance.<sup>199,200</sup> In combination with VP-16, Bishop et al. reported a response rate of 77% and 58% for limited and extensive disease, respectively.<sup>201</sup> Moreover, randomized trials of multiagent regimens in which the two platinum analogues were compared suggested that they were at least equivalent. The Hellenic Cooperative Oncology Group randomized 147 patients to receive VP-16, 100 mg/m<sup>2</sup>, days 1 to 3, and cisplatin, 100 mg/m<sup>2</sup>, or carboplatin, 300 mg/m<sup>2</sup>, along with concurrent radiation.<sup>199</sup> Response and survival were similar in the two arms, although the toxicity, particularly nausea, vomiting, nephrotoxicity, and neurotoxicity, were significantly lower in the patients who received carboplatin. Myelosuppression was also less in the carboplatin arm, but this was not statistically significant. In another large randomized trial, induction with teniposide, vincristine, and either carboplatin or cisplatin produced equivalent activity and toxicity.<sup>200</sup>

Ifosfamide produces less myelosuppression than cyclophosphamide and has significant single-agent activity. Ifosfamide has been substituted for cyclophosphamide in the CAV regimen.<sup>202</sup> Combinations of ifosfamide with cisplatin and with etoposide have also been tested. The three-drug regimen VP-16, ifosfamide, and cisplatin, initially tested in refractory germ cell tumors, has also been evaluated. In patients with SCLC, a population that is older and has more comorbid illness than patients with germ cell tumors, a 20% reduction in dose intensity was necessary to avoid excessive myelosuppression.<sup>203</sup> In a randomized trial comparing VP-16, ifosfamide, and cisplatin with EP, one study, which enrolled only patients with extensive disease, identified a significant, although small, difference in both median survival (9.0 vs. 7.3 months) and 2-year survival rates (13% vs. 5%).<sup>204</sup> Myelosuppression was more severe in the arm treated with ifosfamide. Carboplatin has been substituted for cisplatin in regimens that also include ifosfamide, carboplatin, and VP-16 (ICE), and in single-arm studies impressive response rates and cumulative myelosuppression have been reported.<sup>205,206</sup> Other three-drug regimens that incorporate these agents, such as ifosfamide, doxorubicin, and VP-16<sup>202</sup>; ifosfamide, carboplatin, and oral VP-16<sup>206</sup>; and paclitaxel, cisplatin, and VP-16,<sup>207</sup> have been tested but have not been demonstrated to be superior to either EP or CAV.

Several studies are in progress evaluating camptothecin (topotecan or irinotecan)-based regimens in SCLC. In combination with platinum agents, response rates are between 17% and 29% in previously treated patients and 75% and 84% in newly diagnosed patients.<sup>208,209</sup> and <sup>210</sup> Preliminary results of a multicenter randomized trial in Japan found that the combination of irinotecan and cisplatin produced superior survival than the standard VP-16 and cisplatin regimen in patients with extensive stage disease.<sup>211</sup> Combinations of camptothecins with other agents active in SCLC are also being evaluated, and many have shown significant activity, albeit with substantial associated myelosuppression.<sup>212,213</sup> and <sup>214</sup> Three-drug regimens, such as paclitaxel, cisplatin, and topotecan,<sup>215</sup> are also being developed.

**DURATION OF CHEMOTHERAPY**

Through the 1970s, sensitive tumors were often treated with chemotherapy for periods that might extend up to 2 years. This meant that most patients with SCLC received uninterrupted chemotherapy until disease progression or death. In 1984, Feld et al. reported that six cycles of CAV and thoracic irradiation produced survival comparable with the results of a previous treatment program that included 12 months of maintenance therapy.<sup>216</sup> Subsequently, a large number of randomized trials examined whether maintenance chemotherapy prolonged survival.<sup>217,218,219,220,221,222,223,224,225</sup> and <sup>226</sup>

A few studies have suggested that prolonged treatment programs improve survival, at least in certain patient subsets. The CALGB randomized 258 patients to one of four chemotherapy regimens, and 57 patients in complete remission underwent a second randomization to maintenance therapy or observation. Among the 46 patients with limited disease who proceeded to the second randomization, the median survival was improved with maintenance chemotherapy (16.8 vs. 6.8 months).<sup>217</sup> However, the induction regimens utilized in this study might be considered inferior to currently used treatments. The Medical Research Council randomized 265 patients who had responded to six cycles of induction chemotherapy to an additional six cycles of maintenance or observation.<sup>220</sup> Overall, there was no difference in survival between patients treated with six or 12 cycles of chemotherapy, though for patients in complete remission at the time of randomization a subset analysis suggested that maintenance may provide a survival benefit. In a second British study, patients treated with six cycles of CAV were randomized to six additional cycles of the same chemotherapy or observation.<sup>218</sup> Most of the patients treated in this study were in complete or near complete remission. For the patients with extensive disease, the median survival was improved by approximately 4 months with maintenance treatment. An additional trial, organized by the Eastern Cooperative Oncology Group (ECOG), randomized patients to CAV alternating with another three drug combination or CAV alone.<sup>221</sup> After six to eight cycles of induction, patients in complete remission underwent a second randomization to maintenance treatment or observation. Patients assigned to CAV and maintenance therapy had both a longer progression-free survival and overall survival ( *P* = .09) than patients who received only CAV with no maintenance. For the patients who received the six-drug regimen, those who were given no maintenance survived longer than the patients who received maintenance treatment.

In contrast, four other studies that randomized patients to five or six cycles of chemotherapy or a total of 12 cycles of chemotherapy found no difference in outcome.<sup>219,222,223,225</sup> Among these studies, only one trial evaluated maintenance therapy in complete responders,<sup>222</sup> one study included both complete and partial

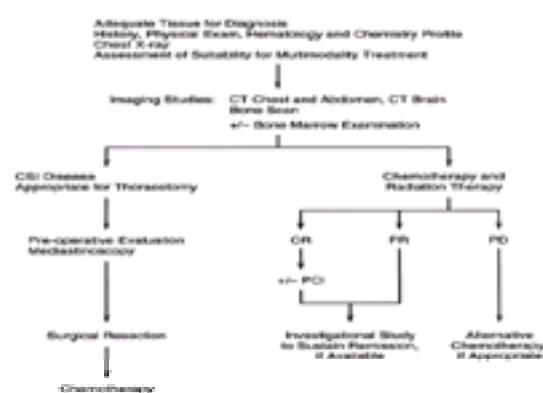

responders,<sup>225</sup> and two studies randomized all patients without evidence of disease progression following completion of induction chemotherapy.<sup>219,223</sup> In summary, these studies do not exclude the possibility that there is a subset of patients, perhaps those with particularly chemotherapy-sensitive disease treated with moderately intensive chemotherapy, who may derive a benefit from a maintenance program beyond five to eight cycles of standard chemotherapy. In unselected patients, however, treatment programs that extend beyond six cycles of chemotherapy have not demonstrated an advantage in survival and may be associated with inferior quality of life.

A number of additional studies have evaluated whether four cycles of chemotherapy are adequate.<sup>224,227,228</sup> Spiro et al. designed a study that included a double randomization at diagnosis.<sup>227</sup> Patients received four or eight cycles of CEV and on relapse received additional chemotherapy or supportive care. Of the four treatment arms, patients who received four cycles of chemotherapy and only supportive care at relapse had a significantly inferior median survival of 30 weeks. Thus, in this study four cycles of treatment were adequate if chemotherapy was offered to patients appropriate for additional therapy at relapse. Two additional studies also evaluated four cycles of induction with longer treatment programs.<sup>224,228</sup> Both studies found survival with the longer treatment program to be similar to the shorter program. The Medical Research Council randomized a total of 458 patients to treatment with VP-16, cyclophosphamide, methotrexate, and vincristine (ECMV) for three cycles, ECMV for six cycles, or VP-16 and ifosfamide for six cycles.<sup>229,230</sup> The median survival for patients treated for only three cycles was approximately 1 month shorter than for patients who received one of the regimens given for six cycles. Although this difference was not statistically significant, the study was not sufficiently powered to exclude a small advantage with longer treatment programs.<sup>230</sup> Among the more symptomatic patients, palliation of symptoms was slightly better for those treated with the ifosfamide and VP-16 combination, but the differences between the three arms were small.<sup>229</sup>

In summary, four to six cycles of induction chemotherapy appear to be optimal in the management of both limited and extensive SCLC. Maintenance chemotherapy beyond induction is of unproven value but may play a role in selected patients, depending on the sensitivity of their disease to chemotherapy and the induction regimen they received. Treatment at relapse should be considered if clinically appropriate.

## GENERAL APPROACH TO PATIENTS WITH LIMITED DISEASE

An overview of the management of patients with limited disease is shown in [Figure 31.3-1](#). An occasional patient has stage I disease by noninvasive staging; if this patient is a candidate for thoracotomy, a mediastinoscopy should be considered to ensure that mediastinal nodal metastases are not present before thoracotomy is attempted. Adjuvant chemotherapy is indicated in patients whose disease is resected. Other patients with limited disease should be carefully evaluated to determine their capacity to undergo combined modality therapy. Most patients who are not candidates for a clinical protocol should receive four to six cycles of chemotherapy and radiation to the chest. In limited disease, the CAV regimen produces an overall response rate of 80% to 90%, a complete remission rate of 50% to 60%, a median survival time of 12 to 16 months, and a 3-year disease-free survival of 10% to 15%. The VP-16 and cisplatin regimen appears to be at least as active as CAV and is associated with less toxicity if given with concurrent radiation.

**FIGURE 31.3-1.** Algorithm outlining management of patients with limited disease. CR, complete response; CSI, clinical stage I; CT, computed tomography; PCI, prophylactic cranial irradiation; PD, progressive disease; PR, partial response.

Intrathoracic SCLC appears optimally treated with 150 cGy twice a day to a total dose of 4500 cGy in 3 weeks.<sup>69</sup> At least 4 (and preferably 6) hours between treatments are allowed. Customized blocks are used to limit exposure to normal tissues throughout the entire 3-week period. Initial portals are delivered anteriorly and posteriorly each day, switching to a posterior oblique field to limit direct spinal cord dose to approximately 3600 Gy. Occasionally, a patient's pulmonary function is so marginal that a conscious decision is made not to shift to oblique fields because of fear of expanding total treatment volume and thereby increasing the risk of radiation pneumonitis in high-risk patients. In this setting, it becomes imperative to use a spinal cord block that is suboptimal from the standpoint of tumor control but essential from the standpoint of minimizing the risk of myelopathy. Conformal planning may help in this dilemma, but one must acknowledge that our quantitative knowledge of partial organ tolerance is presently negligible.

Some authors have advocated radiation doses up to 6000 cGy for SCLC.<sup>231</sup> In conjunction with multiagent chemotherapy, the routine need for such doses appears doubtful because of the impressive responsiveness of this neoplasm to both chemotherapy and radiation.

The sequencing of radiation and chemotherapy remains controversial and is more fully discussed later in this chapter (see [Sequencing of Radiation with Chemotherapy](#)). Concurrent rather than sequential administration of chemotherapy and radiation has produced superior survival in some but not all studies. Concurrent therapy can produce more toxicity than sequential chemotherapy and radiation, and because there is a broad range among individual patients in their capacity to tolerate aggressive therapy, a challenge in designing a treatment program is to satisfy the need to deliver optimal treatment without exposing patients to unacceptable toxicity. After induction therapy, most centers recommend prophylactic cranial irradiation to patients if they have achieved a complete or near complete remission. Some patients with significant adverse prognostic factors may be best served with treatment programs that attenuate the dose and duration of the standard regimens. At the time of disease progression, treatment with an alternative chemotherapy regimen (or even the initial induction regimen if there was an especially long initial remission) should be considered.

## ROLE OF RADIOTHERAPY IN LIMITED DISEASE

The systemic nature of SCLC, even when it appears to be localized after careful staging procedures, precludes complete reliance on any local form of treatment. Most patients with limited-stage disease who were treated with chest irradiation alone rapidly developed distant metastases, emphasizing the need for primary systemic treatment. After combination chemotherapy began to be used in the management of SCLC in the 1970s, the response rates and improved survival that resulted led to speculation that chest irradiation added toxicities while contributing little or no therapeutic advantage in patients treated with chemotherapy. However, this neoplasm is also the most responsive of all cell types of lung cancer to thoracic radiotherapy, with objective tumor regression occurring in more than 90% of patients,<sup>232</sup> and the primary tumor is the site of progression in up to 80% of relapsing limited-stage patients treated with chemotherapy alone.<sup>233,234</sup> Thus, it would seem to be logical to combine chemotherapy and chest irradiation in these patients.

Retrospective reviews of numerous nonrandomized studies using chemotherapy with or without chest irradiation for limited-stage disease revealed the following facts:<sup>235,236</sup> (1) A lower rate of chest relapse was seen with combined modality therapy, although the frequency of local recurrence still approached 33%; (2) hematologic, pulmonary, and esophageal complications were increased with combined modality treatment; and (3) although median survivals were similar, the 2-year disease-free survival appeared superior for combined modality therapy compared with that achieved with chemotherapy alone.

Retrospective data, however, suffer from many deficiencies. Because chemotherapy alone is less toxic than combined modality therapy, there may have been a consistent bias against giving combined modality therapy to poor-risk patients. If the administration of radiotherapy is delayed for several chemotherapy cycles, patients who develop early progression are generally excluded from receiving radiation. An analysis of local relapse may sometimes be misleading because the definition of what constitutes a relapse may be heterogeneous. Variations in dose and schedule of the radiation and specific chemotherapy programs used further complicate comparison of relapse rates from different series. Less effective chemotherapy combined with effective radiation reduces the site of first failure in the chest because distant metastases are more prone to develop, whereas more effective chemotherapy combined with less effective radiation yields the opposite result. All

these factors make it difficult to assess the value of adding chest irradiation to combination chemotherapy when reviewing uncontrolled data.

### **Sequencing of Radiation with Chemotherapy**

The problem of how to integrate chemotherapy and radiation therapy remains far from standardized. Concurrent therapy is defined as combined modality treatment in which chemotherapy and radiation therapy are administered throughout the same time period. In alternating therapy, radiation therapy is administered on days during which no chemotherapy is given, followed by a chemotherapy cycle, and the process is repeated for several iterations of interdigitation. Sequential therapy is defined as the administration of chemotherapy and radiotherapy separately in time, with one modality begun only after completion of the other, often associated with a delay for the second modality to allow the patient an adequate recovery from the initial treatment modality. Several randomized studies reported borderline or significantly improved survival using combined modality treatment. Two of these used concurrent radiotherapy<sup>72,237</sup>; one, alternating radiotherapy<sup>238</sup>; and two, sequential radiation.<sup>239,240</sup> The magnitude of survival benefit was modest, ranging from 1 to 4 months in improvement in median survival and increases in the 2-year survival from 7% to 17%. The two studies with the longest follow-up<sup>237,240</sup> demonstrated less advantage beyond 5 years for patients given radiotherapy, partially because of second primary lung cancers. Of the studies not demonstrating improved survival without chest irradiation, two used sequential radiation therapy and one a concurrent regimen in that only a single drug was given simultaneously with irradiation. The negative trial conducted exclusively in patients in complete remission from chemotherapy was initiated because of earlier uncontrolled data suggesting marked improvement in disease-free survival when radiation was given to complete responders at the completion of drug administration. The randomized trial showed a lack of survival benefit from consolidation treatment when irradiation was given after chemotherapy was completed. Combined modality therapy also increased the complete response rate in most of trials and also significantly reduced chest recurrence rates.

A 1992 metaanalysis evaluated randomized trials in which more than 2100 limited-stage small cell lung cancer patients were randomized to receive either chemotherapy alone or in combination with chest irradiation.<sup>76</sup> Patients given combined modality therapy had a 14% reduction in death rate, and an absolute 5.4% improvement in 3-year survival compared with those receiving chemotherapy alone. Both differences were highly significant in this metaanalysis. This study reinforces the results of individual studies that demonstrated modest but statistically significant improvement in survival after combined modality treatment. A second and independent metaanalysis reached similar conclusions.<sup>241</sup>

Whether the variations in the temporal relationships of the radiation therapy and chemotherapy components of combined modality treatment influence the antitumor effects is by no means resolved. Concurrent and alternating combined modality programs that do not incorporate planned delays in chemotherapy for radiotherapy administration may possess superior efficacy. Among the randomized trials, three of four concurrent or alternating programs yielded improved survival, whereas one of three sequential programs produced only marginally significant improvement favoring radiation. However, indirect comparisons from the metaanalysis do not document significant survival advantages for any of the three methods of combining chemotherapy with irradiation.<sup>76</sup>

The dose of thoracic irradiation needed to control local regional SCLC was initially thought to be reduced when chemotherapy was given with irradiation.<sup>242</sup> Because improved drug treatment yielded better control of distant metastases, however, a high frequency of local failures with lower dose schedules such as 3000 cGy in 2 weeks became apparent.<sup>243</sup> Retrospective data in patients given combined modality therapy suggested that doses higher than 5000 cGy were needed for optimal prevention of local regional failure,<sup>244</sup> and one randomized trial demonstrated superior local tumor control with 3750 cGy compared with 2500 cGy.<sup>245</sup> Many authorities recommend higher doses in the range of 4500 to 5000 cGy or more<sup>236,246,247</sup> for optimal local control. Furthermore, simply because a radiotherapy program reduces local recurrences does not mean that it is optimal.

Randomized trials have yielded conflicting results on whether concurrent irradiation is best given early or late in the chemotherapy program. One study by the Cancer and Acute Leukemia Group B found better results with delayed irradiation perhaps because a greater percentage of projected chemotherapy doses were actually administered.<sup>72</sup> The National Cancer Institute of Canada trial came to the opposite conclusion.<sup>73</sup> Indirect comparisons from the metaanalysis could not resolve this issue.<sup>76</sup>

Minimizing the toxicities of combined modality approach without compromising therapeutic efficacy is worthy of further research. The addition of chest irradiation has increased myelosuppressive, pulmonary, and esophageal complications of treatment, particularly with concurrent regimens. In the National Cancer Institute (U.S.) trial<sup>237,248</sup> 26% of combined modality patients developed severe pulmonary toxicity requiring hospitalization within a median of 2 months from the beginning of treatment compared with only 4% of patients given chemotherapy alone; moreover, five combined modality patients in complete remission died of this complication. In patients who responded completely, pulmonary function test results improved in patients given chemotherapy alone, but did not do so in patients receiving combined modality therapy.<sup>237</sup> The Finsen Institute from Denmark, which also used concurrent chemotherapy and irradiation, reported 7% death from pulmonary and pericardial complications in complete responders.<sup>249</sup> This frequency of cardiopulmonary complications among patients given combined modality treatment is clearly higher than what is seen in patients who are given chemotherapy alone.

One study analyzed the frequency of radiation pneumonitis in lung cancer patients treated with chemotherapy and chest irradiation.<sup>250</sup> Almost 80% of the patients in this series had SCLC. In a multivariate analysis, the only factors that significantly correlated with the increased frequency of radiation-related pulmonary injury were individual fraction sizes of more than 2.50 Gy/d, twice daily fractionation as opposed to once-a-day fractions, and the total cumulative dose. Somewhat surprisingly, there were no significant differences among concurrent, alternating, and sequential combined modality treatments. Several trials reported high rates of esophagitis (with occasional strictures) and weight loss in patients given combined modality therapy.<sup>237,249</sup>

Not all concurrent combined modality programs report excessive pulmonary toxicity,<sup>72</sup> suggesting that the selection of drugs combined with irradiation is influential in inducing some of these complications. Platinum and etoposide may be an especially suitable regimen for concurrent treatment in small cell carcinoma of the lung. Two successive trials of sequential combined modality treatment in limited-stage patients produced 4-year survival figures of approximately 10% in the Southwest Oncology Group; a subsequent trial in which a platinum-etoposide combination was given concurrently with chest irradiation beginning on the first day of therapy resulted in 30% 4-year survival, and severe pulmonary toxicity was seen only in one patient.<sup>251</sup>

Although used less often, alternating regimens interdigitating chemotherapy and irradiation appear to have reduced pulmonary toxicity while maintaining the therapeutic advantage of adding radiation therapy.<sup>238,252</sup> In one retrospective study,<sup>253</sup> irradiating only the postchemotherapy tumor volume after several chemotherapy cycles did not appear to increase marginal recurrences and was also associated with a low frequency of radiation injury.

### **Hyperfractionated Radiation**

Delivering chest irradiation in multiple daily fractions was theorized on experimental grounds to reduce long-term pulmonary toxicity while still maintaining antitumor efficacy. SCLC would appear to be an ideal neoplasm for twice-a-day treatment in that it has a high growth fraction, short cell-cycle time, and small to absent shoulder on the *in vitro* cell survival curve. Pilot studies in the late 1980s combining etoposide and platinum plus twice-a-day chest irradiation were promising, with median survivals greater than 2 years and in most series low rates of associated pneumonitis.<sup>254,255 and 256</sup> An intergroup study randomized 417 patients with limited-stage SCLC to a program that included cisplatin and etoposide for four cycles and radiation therapy beginning on day 1 of the first cycle.<sup>69</sup> The cumulative dose was 4500 rad in both arms, with one arm receiving the radiation in 180-cGy fractions daily and the other arm receiving 150-cGy fractions on a twice-a-day basis. The daily fractionation scheme required 5 weeks to reach the cumulative dose, whereas the twice-a-day schedule required only 3 weeks. The target volume included the primary tumor plus bilateral mediastinal nodes and the ipsilateral hilum and the supraclavicular nodes when involved. Margins of 1.0 to 1.5 cm were included and cone-downs were prohibited. Local failure was reduced from 52% with the daily schedule to 36% with the twice-a-day schedule ( $P = .06$ ). Patients who failed in both local and distant sites had a frequency of 23% with daily treatment, versus only 6% with the twice-a-day approach ( $P = .01$ ). More important, although statistically significant differences in survival were not seen at 24 months,<sup>255</sup> the curves deviated so that at 5 years the survival was only 16% with once-a-day treatment, as opposed to 26% with the twice-a-day schedule ( $P = .04$ ).<sup>69</sup> Overall morbidities were not significantly different between the two arms, although there was a higher frequency of grade III esophagitis with twice-a-day treatment.

It should be reemphasized that selecting patients for combined modality treatment requires an excellent performance status. Combined modality therapy is a complex undertaking requiring close coordination between both medical and radiation oncologists. Because not all combined modality programs have been shown to increase survival but usually do increase toxicities, chest irradiation need not be considered for all patients, especially those who have impaired pulmonary function or poor performance status. Investigational programs that do not include chest irradiation remain entirely appropriate for many patients because the greater antitumor efficacy of combined modality treatment appears to be at least partially offset by enhanced toxicity. If the results of chemotherapy improve so that most patients have

eradication of systemic but not of local disease, then chest radiation therapy could have a survival effect of even greater significance. At present, however, distant metastases remain the predominant cause of failure, and most patients with limited disease who are irradiated still die of their SCLC. Thus, improving systemic treatment currently has a much greater potential for achieving survival gains than does increasing the efficiency of local regional therapy.

### **Prophylactic Cranial Irradiation**

Brain metastases are detected in approximately 10% of SCLC patients at the time of presentation and are subsequently diagnosed during life in another 20% to 25%, with an increasing likelihood of development seen with lengthening survival.<sup>103,104</sup> In the absence of radiation therapy to the CNS, actuarial analysis reveals a probability of brain metastases ranging from 50% to 80% in terms of those patients who survive 2 years.<sup>104,257</sup> At postmortem examination, they are found in up to 65% of patients.<sup>105</sup> Because these metastases are sometimes the sole site of clinical relapse from complete remission and are frequently clinically disabling, prophylactic cranial irradiation has been recommended by many<sup>258</sup> but not all<sup>259</sup> since the mid-1980s to curtail their development. The rationale is essentially an extrapolation from original strategies used in acute lymphocytic leukemia of childhood.

A review of 667 patients entered on several prospective randomized trials assessed the benefit of prophylactic cranial irradiation given at or within a few months of diagnosis in patients who were initially free of CNS involvement.<sup>217,260,261,262,263,264,265,266,267,268</sup> and <sup>269</sup> When these trials were considered together, doses of prophylactic cranial irradiation ranging from 2000 to 4000 cGy reduced the frequency of clinically detectable brain metastases from 24% to 6%.<sup>270</sup> In most of these trials, a significant reduction of intracranial tumor spread was observed. However, no significant effect of prophylactic cranial irradiation on survival was observed in any of those studies. Retrospective analyses suggested that virtually all benefit in preventing intracranial metastases with prophylactic cranial irradiation was confined to patients who achieved a complete remission to their initial treatment.<sup>257,261</sup> In actuarial analysis, partial responders or nonresponders have similar risks of recurrence in the brain regardless of whether prophylactic cranial irradiation was administered.<sup>257</sup> This is not surprising because persisting systemic cancer could readily metastasize to the CNS after completion of prophylactic cranial irradiation.

More recently in a metaanalysis of almost 1000 patients in seven trials between 1977 and 1995, patients were evaluated with and without prophylactic cranial irradiation<sup>271</sup> after initially obtaining a complete response. The primary end point was overall survival, and the analysis was based on intent to treat. Prophylactic cranial irradiation doses ranged from 24 to 40 Gy in most patients, although the metaanalysis did include one series of 25 patients who received only 8 Gy in one fraction. The metaanalysis suggested that there was a significant gain in survival seen with prophylactic cranial irradiation in patients who achieved complete remission, with 3-year survival figures increasing from 15% to almost 21%. Prophylactic cranial irradiation did significantly decrease the probability of brain metastases and increased the likelihood of disease-free survival. Going to higher doses appeared to have no obvious effect on survival, although it did appear to have an increasing effect of eliminating brain metastases. There was also a trend toward a decreased risk of brain metastases when prophylactic cranial irradiation was administered earlier in time. The metaanalysis was not able to assess the effect of prophylactic cranial irradiation on cognitive function, because most of the studies included did not include a baseline assessment. Two studies<sup>272,273</sup> assessed baseline neuropsychological function before treatment and demonstrated that many patients appear to have abnormalities of cognitive function as initial manifestations of their cancer, even when brain metastases were not detected and before any treatment.

Some investigators have proposed forgoing the prophylactic cranial irradiation in favor of therapeutic brain irradiation when metastases are detected.<sup>274</sup> This policy assumes that cranial irradiation can effectively control symptoms from overt brain metastases for a substantial fraction of the patient's remaining life. Because the duration of survival is short in most patients who develop brain metastases during the course of therapy, this assumption is not unreasonable. However, other physicians have questioned the durability of palliation after radiotherapy for overt metastases as well as the difficulty of achieving long-term control in the unusual patient who does survive for a long time.<sup>275,276</sup> and <sup>277</sup>

Another factor that produces considerable controversy in recommending prophylactic cranial irradiation to patients who achieve a complete response is the significant risk of toxicity associated with it. Because the 5-year survival appears to have improved, it is evident that some patients have neurologic and intellectual impairment as well as abnormalities on CT scan that may be related to prophylactic cranial irradiation.<sup>277,278,279</sup> and <sup>280</sup> In one study, both CT scan and CNS abnormalities were significantly more frequent in patients who had received prophylactic cranial irradiation or therapeutic brain irradiation than in those who had not.<sup>280</sup> These findings were especially disturbing because complete responders are at greater risk for possible complications. Many deficits on neuropsychological testing have been unsuspected on casual examination, but a few patients have obvious major impairments. CT scan abnormalities continue to worsen for several years after treatment has ended, although the abnormalities may eventually stabilize.<sup>281</sup> Neurologic abnormalities were most prominent in one series of patients who were given prophylactic cranial irradiation concurrently with high-dose chemotherapy or individual radiation fractions of 400 cGy.<sup>278</sup> Some authorities suggest that prophylactic cranial irradiation should be administered only in standard fractions of 200 cGy after completion of chemotherapy.<sup>282</sup>

The neuropsychological and imaging abnormalities may or may not be due to prophylactic cranial irradiation. Chemotherapy, possible paraneoplastic syndromes, and the effects of chronic cigarette and alcohol abuse are some of the factors that may be important contributors. In one study that evaluated cognitive function in patients before and after chemoradiation but before any prophylactic cranial irradiation, deficits were discovered in verbal memory, frontal lobe function, and motor coordination within both groups of patients.<sup>273</sup> Administration of methotrexate, procarbazine, and lomustine has decreased since the 1980s; these particular agents have been incriminated in neuropsychological dysfunction.<sup>280,283</sup>

One of the studies in the metaanalysis included almost 300 patients who were randomized to receive prophylactic cranial irradiation after having achieved a complete remission to initial treatment.<sup>271</sup> Twenty percent of these patients had extensive-stage disease, virtually all of whom are ultimately expected to relapse and die. The mean time between the initiation of treatment and the randomization was 5 months. The actuarial likelihood of isolated brain metastasis as the first site of treatment failure was 19% in patients given prophylactic cranial irradiation and 45% in those who did not receive prophylactic cranial irradiation. Corresponding figures for total brain metastases were 40% and 67%, respectively; both differences were highly significant. However, in this one study, overall survival was not significantly improved. The important observation was that there were no obvious differences in the neuropsychological function between the two groups, but only 33 patients underwent a complete reassessment at 18 months. Inasmuch as neuropsychological abnormalities possibly due to prophylactic cranial irradiation progress over time, these data are insufficient to exclude radiation-associated cognitive damage, but they are nonetheless relevant.

It is important to understand that prophylactic cranial irradiation as opposed to therapeutic irradiation should not require a dose that approaches tissue tolerance. Higher doses may be more successful at eliminating brain metastases but there appears to be prophylactic benefit with relatively modest doses of 24 to 25 Gy. If prophylactic cranial irradiation is administered at a time when no chemotherapeutic agents are being administered, radiation-induced permeability alterations that allow more chemotherapeutic agent into brain parenchyma should be obviated. Our guidelines for prophylactic cranial irradiation, after thorough discussion with the patient of the potential risks and benefits, are (1) prophylactic cranial irradiation is typically not recommended until at least 2 weeks after completion of all chemotherapy and only to complete responders after induction therapy; and (2) radiotherapy fractions of 200 to 300 cGy are given over 2 to 3 weeks to a total dose of 2400 to 3000 cGy.

### **Large-Field Radiation Therapy**

Pilot studies have examined the role of hemibody and total body radiation in radioresponsive tumor. Hemibody irradiation is an active agent in SCLC and can induce some complete clinical responses in patients who achieved only partial response after combination chemotherapy.<sup>284</sup> The initial treatment is usually given to the upper hemibody where the bulk of tumor is located; in some studies treatment of the lower hemibody was administered after hematologic recovery occurred after the upper hemibody dose. A controlled German trial confirmed that chemotherapy produced markedly better survival than hemibody radiation in patients with extensive disease.<sup>285</sup> As an adjunct to combination chemotherapy in both limited and extensive disease, hemibody irradiation yielded substantial toxicity in several pilot studies without any obvious benefit in tumor response or survival.<sup>286,287</sup> There is also no evidence that low doses of total body irradiation are of benefit as an adjuvant to chest irradiation in limited-stage or chemotherapy in extensive-stage disease.<sup>288</sup> In a large randomized trial in patients with limited disease given chemotherapy and chest irradiation, additional hemibody radiation therapy to the upper abdominal sites of potential relapse produced no improvement in response duration or survival.<sup>260</sup> Currently, wide-field irradiation has no proven role in the management of this disease.

### **ROLE OF SURGERY IN LIMITED DISEASE**

Surgery is reserved for selected patients. In contrast to the majority of patients with limited disease, careful TNM staging is important in those patients being considered for surgical resection. The first hint that proper staging would lead to less bias in the interpretation of surgical results came from the subset of SCLC

patients described by Higgins et al.<sup>37</sup> in their report of the management of the solitary pulmonary nodule. In a 10-year follow-up of 15 small cell patients with solitary nodules (1% of total cases), 11 who would be presently classified as having stage I tumors<sup>289</sup> had a 5-year survival of 36%. Rejuvenation of interest in surgical resection for this cancer, however, received its greatest support from the recognition that newly available chemotherapeutic agents could possibly provide effective adjunctive therapy. Meyer<sup>290</sup> reported that of ten pathologically staged stage I and II patients resected and given chemotherapy for at least a year, 80% remained well at 30 months. Of greater significance, however, were the carefully designed trials conducted by the Veterans Administration Surgical Oncology Group.<sup>291</sup> Of 148 small cell carcinoma patients entered on four trials, 132 who survived a potentially curative resection were randomized to receive either preoperative adjuvant chemotherapy or surgery alone. A 23% overall 5-year survival was recorded, with survival patterns that were more favorable in less advanced stages: T1 to T2N0, 28% to 60%; T1 to T2N1, 9% to 31%; and T3 or N2, 3.6%. Although survival was marginally better with the addition of postoperative chemotherapy, it was clear that the small group of patients with localized disease after sophisticated surgical staging techniques could enjoy much better survival with surgical resection alone than was previously appreciated.

Several factors have strengthened the rationale for incorporating surgical therapy into the total package of treatment for selected SCLC patients. Despite the high response rate to present chemotherapy regimens, the rate of relapse in the thorax can approach 75% in the absence of properly administered radiotherapy. A gradual shift toward identification of more localized potentially resectable subgroups of limited disease patients with clinical staging occurred, encouraged both by the use of invasive procedures, including Wang needle biopsy, mediastinotomy, and mediastinoscopy, and the recognition that the new international staging system for lung cancer<sup>57</sup> can provide a common language for discussing these issues.

Theoretical justifications for combining surgery with other therapies for SCLC have been enumerated by Meyer.<sup>292</sup>

1. Since local relapse is a problem, could surgical removal offer a better chance for disease control?
2. Surgery used for local control, unlike radiotherapy, would not limit the intensity of chemotherapy that could be delivered.
3. By rendering the patient free of disease in the chest without affecting bone marrow reserves, surgery could possibly make the chemotherapy more effective.
4. Complete surgical staging could identify patients at higher risk of recurrence. Numerous uncontrolled reports, although not definitive, have provided considerable insight into whether these theoretical considerations are valid.

One of the chief theoretical justifications for adding surgery to the treatment regimen for SCLC is the possibility of influencing relapse in the tumor bed or mediastinum. In patients who have had surgery at diagnosis, local recurrences are infrequent,<sup>293,294</sup> possibly because patients with stage I or II disease are overrepresented in this group. Patients who have been pretreated with chemotherapy more often had clinical stage IIIA disease, and their local relapse rate is higher, in the range of 18% to 28%.<sup>295,296</sup> These local relapse rates still appear considerably less than in patients given chemotherapy with or without radiation therapy with no surgical intervention. Patients given initial chemotherapy who have a negative biopsy of the primary tumor site at the time of surgery and therefore do not have resection performed have a high frequency of local recurrence.<sup>297</sup> No cancer is present in the resected specimen in 10% to 20% of cases resected for CT,<sup>30,298,299</sup> and this particular patient subset enjoys a better prognosis.<sup>300</sup>

Only a modest quantity of data exists on how often surgical resection at the diagnosis of SCLC is possible. Prospective studies of the feasibility of initial thoracotomy by their nature cannot include cases discovered only at thoracotomy to have small cell carcinoma. A review of the literature<sup>301</sup> suggests that as many as 16% of patients with SCLC are operative candidates, but this is likely to be an unrealistically high estimate because those patients who are evaluated by a thoracic surgeon constitute a highly selected group.

There does not seem to be a marked increase in mortality in patients who have operative removal of small cell carcinoma. In the few studies that describe operative risks after chemotherapy and radiotherapy, the mortality varies between 0% and 10%,<sup>295,296</sup> and <sup>297,302,303</sup> and <sup>304</sup> with many studies reporting no operative mortality or increased morbidity compared with expected outcomes in patients undergoing pulmonary resection for other indications. The extent of resection, pneumonectomy or lobectomy, has generally been dictated by the intraoperative findings rather than the original extent of the tumor in patients given preoperative chemotherapy.

### **Surgery Followed by Chemotherapy**

The initial exceedingly poor long-term survival rates with surgery of SCLC were obtained in patients with clinical stages I through III, who for the most part underwent only minimal staging procedures by current standards. Only when results are categorized by tumor stages can the potential curative effects of surgery alone be demonstrated. One report, for example, documents 5-year survival of 35% in stage I and 23% in stage II patients.<sup>304</sup> The only randomized trials of surgery compared with surgery with postoperative chemotherapy were begun approximately 20 years ago and used inferior drug regimens by today's standards.<sup>305,306,307</sup> and <sup>308</sup> Nonetheless, they did in the aggregate reveal a survival advantage from chemotherapy ( [Table 31.3-5](#) ). Suffice it to say that in the 1990s thoracic oncologists never recommend surgery as sole treatment for SCLC.<sup>309</sup>

Adjuvant Therapy	Patients	2-Y Survival Rate (%)
Chemotherapy	92	25
Placebo	61	8

(Data from refs. 305 through 308.)

**TABLE 31.3-5.** Pooled Results from Randomized Surgical Adjuvant Studies in Small Cell Lung Cancer

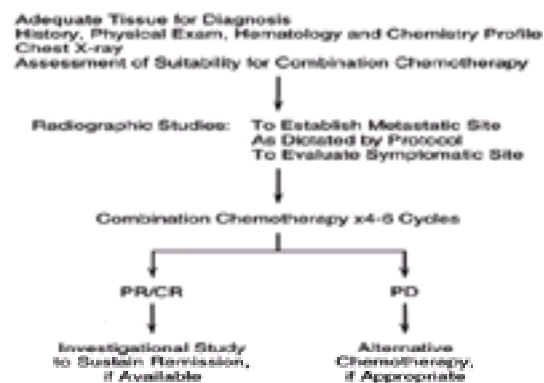

Statements regarding the efficacy of combined modality approaches for SCLC that include surgical resection can be evaluated only when stratified by the temporal relationships among the different modalities. There have been a number of programs of initial surgery followed by adjunctive chemotherapy after surgery; patients with multiple stages of tumor are included.<sup>75,292,293,303,310,311,312,313,314</sup> and <sup>315</sup> In general, modern combination chemotherapy programs, usually including cyclophosphamide, doxorubicin, vincristine, or etoposide, have been used. Survival experience is quite heterogeneous, ranging from 5-year survival of 9% in earlier studies to as high as 83% in more recent studies.

Both nodal status and primary tumor or T status have significant effects on the survival of patients whose SCLC is resected. These prognostic factors were addressed directly in a few studies. Angeletti et al.<sup>294</sup> and Shepherd et al.<sup>293</sup> reported increased survival of node-negative compared with N1 and N2 patients after surgical resection and postoperative chemotherapy, while Macchiarini et al.<sup>311</sup> found a decrease in 5-year survival with increasing T category in surgically resected patients without nodal metastases. Retrospective reviews published by Rea et al.<sup>314</sup> and Lucchi et al.<sup>315</sup> have reinforced the importance of surgical staging in evaluating the outcomes for surgery and SCLC. Rea et al. reported that of 51 stage I and II SCLC patients resected and given chemotherapy after resection had 5-year survival rates of 52.2% (stage I) and 30% (stage II). In the review by Lucchi et al.,<sup>315</sup> stage I or II resected SCLC patients having postoperative chemotherapy had 5-year survival rates of 47% and 14.8%, respectively. Stage III patients from this series having surgery followed by adjuvant therapy had a 5-year survival of 14.4%. In general, 5-year survival is rare in patients given postoperative chemotherapy after mediastinal node disease has been documented at initial surgical resection,<sup>303,304</sup> although this observation is not universal.<sup>293</sup>

The largest experience as a cooperative group trial examining the role of surgery followed by adjuvant therapy in SCLC was conducted by the International Society of Chemotherapy Lung Cancer Study Group.<sup>75</sup> Four-year survival rates for completely resected, pathologically staged SCLC patients with N0 (n = 69), N1 (n = 58), and N2 (n = 36) who received postoperative therapy were 60%, 36%, and 33%, respectively. Based on these studies, most authorities believe that any survival benefits of initial surgical resection will likely be confined to patients with pathologic stage I and II disease, and conventional wisdom currently holds that surgical resection at

**FIGURE 31.3-2.** Algorithm outlining management of patients with extensive disease. CR, complete response; PD, progressive disease; PR, partial response.

### ROLE OF CHEST IRRADIATION IN EXTENSIVE DISEASE

Retrospective reviews of the literature demonstrate that the addition of chest irradiation plus chemotherapy for patients who have extensive-stage SCLC may reduce the frequency of progressive disease in the thorax, but the overall response rates, median survival, and 2-year disease-free survival figures remain unchanged.<sup>236,327</sup> Because extensive disease patients generally achieve complete response rates of only 20% to 25% with current chemotherapy regimens and frequently relapse in distant metastatic sites, it is logical that an additional localized form of treatment would have minimal effect on survival. Successive large studies by the Southwest Oncology Group also confirm that although thoracic radiotherapy can substantially reduce the frequency of initial relapse at the primary tumor site, there is no apparent effect on survival.<sup>328,329</sup>

There have been several clinical trials that randomize patients with extensive disease to chemotherapy alone or in combination with irradiation to the chest disease as well as to some or all sites of overt distant metastases.<sup>243,329,330</sup> and <sup>331</sup> With one more recent exception,<sup>330</sup> no worthwhile advantages in survival have been seen with the addition of radiotherapy for patients with extensive disease. At present, except as part of a clinical trial, there is no indication for chest irradiation in extensive SCLC other than symptomatic palliation.

### ROLE OF CHEMOTHERAPY AND RADIATION THERAPY TO THE NEURAXIS

The therapeutic management of overt disease in the CNS with radiation therapy is discussed in detail in [Chapter 43.2](#). For overt metastatic lesions within the CNS, doses of 300 rad daily to doses of 3000 to 3600 Gy typically are used. Overt intracranial metastases appear to be more difficult to sterilize than intrathoracic disease.<sup>332</sup> If there are one or two clinically documented intracranial lesions only, a boost to 5000 cGy may be considered if the patient has an excellent performance status. Stereotactic treatment can also be used.

Chemotherapy is also a therapeutic option for brain metastases, perhaps because the blood–brain barrier is disrupted in the setting of macroscopic metastatic disease. Small series of patients in whom brain metastases were present at diagnosis have been treated with standard chemotherapy regimens without radiation, and the majority have demonstrated both clinical and radiographic improvement.<sup>110</sup> Chemotherapy has also been used at the time of relapse, and response rates of 33% to 43% have been reported.<sup>110,333,334</sup> In previously treated patients, the response to chemotherapy in the brain appears to be comparable with the response rates in other organs, and it is not dissimilar from the activity of irradiation, which in one series produced a partial response rate of 50%, and the median survival was 4.7 months in a series of 22 patients.<sup>335</sup> Thus, while brain irradiation remains the standard for patients who have not been previously irradiated, chemotherapy is a reasonable option for patients who develop recurrent disease after prior brain radiation, particularly if active systemic disease is also present.

### STRATEGIES TO OPTIMIZE CHEMOTHERAPY RESPONSE

A number of strategies have been investigated in an attempt to improve treatment outcome using the currently available drugs. These approaches include increasing the number of active agents used in the treatment program, often by the use of cyclic alternation between two combination regimens, increasing the dose intensity, often with the support of hematopoietic growth factors or blood progenitor cells, and weekly chemotherapy regimens, which increase the dose intensity by shortening the interval between treatment rather than increasing the dose.

#### ALTERNATING CYCLIC COMBINATION CHEMOTHERAPY

The recognition of clonal heterogeneity within a tumor and the inability to develop treatment regimens that included more than four drugs due to overlapping toxicity led to an interest in alternating chemotherapy combinations. The somatic mutation model developed by Goldie and Coldman provided a theoretical underpinning to this approach, as this model predicted that the best probability of cure was achieved by the earliest possible introduction and most rapid alternation of all active agents.<sup>336,337</sup> If two equally effective non–cross-resistant regimens were available, the model predicted that alternating between regimens every other cycle would be more effective than alternating after every three cycles or giving one regimen continuously for five cycles before switching to the second regimen.<sup>337</sup>

A large number of clinical trials have been conducted attempting to evaluate alternating multidrug combinations, particularly in extensive disease.<sup>197,221,328,338,339</sup> and <sup>340</sup> The EP regimen was initially tested in patients who had progressed after cyclophosphamide-based chemotherapy, suggesting that these drug combinations were non–cross-resistant.<sup>341</sup> The National Cancer Institute of Canada conducted a study in which 289 patients were randomized to CAV or CAV alternating with EP.<sup>338</sup> Chemotherapy was given for a total of six cycles. Both the response rate (65% vs. 47%), progression-free survival, and median survival time (9.6 vs. 8.0 months) favored the patients who had received alternating therapy. The results could be explained by the inclusion of a more active regimen (EP) within the alternating arm, an advantage due to greater drug diversity with five effective drugs rather than three, or as support of the Goldie and Coldman concept. Roth et al. subsequently evaluated 437 patients with extensive disease in a randomized trial comparing EP for four cycles, CAV for six cycles, or CAV alternating with EP for a total of six cycles.<sup>197</sup> Although there was a slight improvement in progression-free survival ( $P = .052$ ) there was no significant difference in response rate or overall survival between the treatment arms. Nonresponders to CAV crossed over to EP were twice as likely to respond to second-line therapy than nonresponders to EP who crossed over to CAV, although these differences were not statistically significant (28% vs. 14% for induction responders who relapsed, and 15% vs. 8% for patients with primary resistance, respectively). An assumption of the Goldie and Coldman hypothesis is that the alternating regimens are non–cross-resistant, which is not the case with the CAV and EP combinations as demonstrated by the modest activity when nonresponding patients are crossed over from one of these regimens to the other. The European Organization for Research and Treatment of Cancer developed a regimen consisting of vincristine, ifosfamide, mesna, and carboplatin (VIMP) that, in a randomized phase II study, appeared to be as active as CDE.<sup>342</sup> As important, patients who were progressing on, or were within 3 months of stopping either CDE or VIMP, had a greater than 50% likelihood of responding to the alternate combination, indicating that a significant degree of non–cross-resistance existed between these combinations. In a randomized trial, patients with extensive disease were treated with CDE or CDE alternating with VIMP.<sup>339</sup> The study was closed after 143 patients had been registered and demonstrated no significant differences in survival. Although it did not reach its planned accrual, it still had sufficient power to have detected a 2-month increase in median survival time with alternating therapy, had it existed. These studies, therefore, do not support the superiority of an alternating chemotherapy combination in patients with extensive disease.

Alternating non–cross-resistant chemotherapy has also been investigated in patients with limited disease.<sup>198,343,344,345</sup> and <sup>346</sup> The National Cancer Institute of Canada randomized 300 patients with limited disease to either CAV for three cycles followed by EP for three cycles, or CAV alternating with EP for a total of six cycles.<sup>344</sup> No differences were noted in response rates, time to treatment failure, or survival. A Japanese study compared CAV to EP with alternating CAV and EP.<sup>198</sup> Patients with limited disease received four cycles of chemotherapy followed by thoracic irradiation. Patients with extensive disease who responded to chemotherapy continued treatment for 1 year. A total of 288 patients were enrolled. No differences in survival based on treatment were noted in the patients with extensive disease. In patients with limited disease, there was improved survival, even after adjusting for other prognostic factors with the alternating regimen compared with CAV ( $P = .058$ ) or EP ( $P = .032$ ). In contrast, Urban et al. reported inferior survival with an alternating seven-drug regimen compared with a four-drug regimen, although the seven-drug combination was less intensive based on the magnitude of myelosuppression.<sup>346</sup> These results suggest that an equally intensive alternating regimen is a reasonable

alternative for patients with limited disease, although the survival advantage noted in the Japanese trial has not been confirmed by another study.

Additional studies have evaluated alternating chemotherapy introduced after achieving a response to an induction regimen. <sup>343,347,348</sup> For example, Wolf et al. randomized 321 patients, 135 of whom had limited disease, to treatment with ifosfamide and VP-16, to response plateau followed by CAV, or ifosfamide and VP-16 alternating with CAV. <sup>343</sup> A total of six cycles of chemotherapy were delivered in each arm. No difference in outcome was noted based on treatment arm in either limited or extensive disease. Other studies have compared alternating regimens that were designed based on the suggestion of *in vitro* synergy <sup>349</sup> or have compared an alternating multidrug combination with a different standard regimen. <sup>350</sup> For example, a German multicenter trial demonstrated that an alternating eight-drug regimen was slightly superior to CAV. <sup>350</sup> In sum, these studies may be viewed as suggesting a modest advantage for regimens that introduce a greater diversity of active drugs into treatment rather than a test of the Goldie-Coldman hypothesis.

## DOSE INTENSIFICATION

In experimental models, numerous chemotherapy drugs display log-linear or near linear dose-response curves. <sup>351,352</sup> Increasing the dose of chemotherapy delivered has been demonstrated to improve survival in a number of clinical settings. <sup>353,354 and 355</sup> In SCLC, several approaches to increase dose intensity have been evaluated. These include dose intensification without or with hematopoietic growth factor support, dose intensification with marrow or peripheral blood stem cell support, and compression of the time in which chemotherapy is delivered using a weekly schedule.

Hryniuk and Bush developed a methodology that expresses dose intensity as the drug dose administered per meter squared per week. <sup>356</sup> Limitations of this method include the assumption that all drugs and schedules of administration are therapeutically equivalent. Nevertheless, this method has been used to demonstrate a positive correlation between dose intensity and treatment outcome in advanced breast cancer and ovarian cancer. <sup>356,357</sup> In SCLC, a retrospective multivariate analysis of 131 patients suggested that modest increases in the dose intensity of cisplatin and cyclophosphamide in a four-drug regimen produced better survival. <sup>358</sup> In contrast, analysis of 60 clinical trials using this methodology found limited and conflicting correlations between dose intensity, response rates, and median survival. <sup>359</sup>

Several randomized trials have attempted to determine whether a modest increase in dose intensity improves survival in this disease. <sup>360,361,362,363,364 and 365</sup> In a small trial comparing different doses of a regimen consisting of cyclophosphamide (500 vs. 1000 mg/m<sup>2</sup>), lomustine (50 vs. 100 mg/m<sup>2</sup>), and methotrexate (50 vs. 100 mg/m<sup>2</sup>), survival was inferior in the lower dose arm. <sup>360</sup> Preliminary findings of a cooperative group study in which the dose of cyclophosphamide was increased from 700 to 1500 mg/m<sup>2</sup> in a regimen that also included lomustine and methotrexate also demonstrated improved survival in the patients treated with the more intensive regimen. <sup>361</sup> These early studies confirm that the use of lower than standard doses of drugs can compromise survival in chemotherapy-sensitive disease.

More recently, several investigators evaluated whether increasing the dose of drugs beyond the dose used in current regimens improves survival. Most of these studies were conducted in patients with extensive disease <sup>364,365,366,367 and 368</sup> (Table 31.3-7). A trial comparing dose-intensified with standard dose CAV <sup>364</sup> and a study comparing high-dose with standard-dose EP <sup>365</sup> identified increased toxicity without improvement in survival. Neither of these studies used a hematopoietic growth factor in the intensified arm. Standard doses of cyclophosphamide, 4'-epidoxorubicin, etoposide, and cisplatin given for six cycles have been compared with an intensified schedule in which three of the four drugs were given at a 50% higher dose for four cycles. <sup>368</sup> This study demonstrated a shorter response duration and survival in the dose-intensified arm. Although the planned cumulative doses of chemotherapy were equivalent for three of the drugs, the intensified arm actually received a lower total dose because of toxicity. The only study that has suggested that the administration of higher drug doses within a standard regimen was beneficial was conducted in patients with limited disease. This French study randomized 105 patients with limited disease to a higher dose of cisplatin (100 vs. 80 mg/m<sup>2</sup>) and cyclophosphamide (1200 vs. 1000 mg/m<sup>2</sup>) in a regimen that also included doxorubicin and VP-16. <sup>363</sup> The increased doses of chemotherapy were only given on the first cycle. At 2 years, both the progression-free (28% vs. 8%) and the overall survival (43% vs. 26%) were improved in the higher dose arm. These studies indicate that a modest intensification of the dose of the commonly used agents does not improve outcome for patients with extensive disease and may even compromise survival by producing excessive toxicity. Whether a modest increase in the dose of drugs improves the outcome of patients with limited disease should be confirmed, and this question should probably be addressed in randomized trials that include either growth factor or stem cell support to maximize the delivered dose.

Ref	Regimen	Patients (n)	Stage	Drug	Intensified Dose	Standard Dose	Toxicity (High vs. Standard)	2-Y Survival (High vs. Standard)
Jhones <sup>364</sup>	CAV	207	Extensive	Doc, C, A	1.17 mg/m <sup>2</sup> /d	1.17 mg/m <sup>2</sup> /d	Increased myelosuppression, increased nausea	NSD
Egervak <sup>365</sup>	EP	100	Extensive	Doc, C, P	1.17 mg/m <sup>2</sup> /d	1.17 mg/m <sup>2</sup> /d	Increased myelosuppression, increased nausea	NSD
Intensif <sup>366</sup>	EP	100	Extensive	Doc, C, P	1.17 mg/m <sup>2</sup> /d	1.17 mg/m <sup>2</sup> /d	Increased myelosuppression, increased weight loss	45% vs 35%
Intensif <sup>367</sup>	EP	100	Extensive	Doc, C, P	1.17 mg/m <sup>2</sup> /d	1.17 mg/m <sup>2</sup> /d	Increased myelosuppression, increased weight loss	NSD

Intensif <sup>370</sup>	CAV	403	Extensive	Cis, VP-16, Ifos, Carb	1.17 mg/m <sup>2</sup> /d	1.17 mg/m <sup>2</sup> /d	NSD	33% vs 18%
Intensif <sup>371</sup>	CAV	105	Limited	Cis, VP-16, Doxo, VP-16	1.17 mg/m <sup>2</sup> /d	1.17 mg/m <sup>2</sup> /d	Increased myelosuppression	43% vs 26%

Abbreviations: C, cyclophosphamide; Ca, carboplatin; Doc, doxorubicin; EP, etoposide; P, cisplatin; VP-16, vinorelbine; Ifos, ifosfamide; Carb, carboplatin; NSD, no significant difference; T, response; S, survival.

Note: The results listed in the high-dose arm, compared with standard care, are the number of cycles or total treatment.

Note: NSD, no significant difference.

Note: Significant difference in median survival time.

TABLE 31.3-7. Randomized Trials Evaluating Dose Intensity in Small Cell Lung Cancer

A number of other studies have evaluated whether shortening the interval between chemotherapy cycles improves survival. In patients with extensive disease, delivering CAV on days 1 and 8 of the first few courses of chemotherapy did not appear promising. <sup>366</sup> A multicenter study randomized 300 patients to six cycles of vincristine, ifosfamide, carboplatin, and VP-16 delivered every 4 weeks or every 3 weeks. <sup>369</sup> Most of the patients included in the study had limited disease. In the group receiving chemotherapy every 3 weeks, the delivered dose intensity was increased by 26% over the entire treatment program compared with the group treated every 4 weeks. Both the median survival (443 vs. 351 days) and the 2-year survival rate (33% vs. 18%) were better in the intensified arm ( *P* = .0014), even after adjustment in a multivariate analysis. Another multicenter study also explored the importance of the interval between treatment cycles by randomizing 403 patients, 77% of whom had limited disease, to cyclophosphamide, doxorubicin, and VP-16 delivered on an every-3-week schedule or on an every-2-week schedule. Patients treated every 2 weeks received G-CSF support. <sup>370</sup> The delivered dose intensity was 34% greater on the every-2-week schedule, and both the complete remission rate and the overall survival were better in this group. Improved survival was observed in both patients with limited and extensive-stage disease treated every 2 weeks. These studies suggest that for some standard regimens, compression of the treatment cycle, if this can be accomplished without a significant increase in toxicity, may be an effective means to improve survival.

## Hematopoietic Growth Factors

G-CSF and granulocyte-monocyte colony-stimulating factor (GM-CSF) are members of a group of glycoproteins that stimulate the production and maturation of hematopoietic progenitor cells and regulate the function of mature blood cells. <sup>371</sup> Two randomized, placebo-controlled trials demonstrated that the use of G-CSF as an adjuvant to CAE chemotherapy significantly reduced the duration of neutropenia, incidence of febrile neutropenia, and the use of hospital resources. <sup>372,373</sup> A decision analysis based on the results of one of these trials concluded that the routine use of G-CSF led to a net decrease in the total cost per treatment cycle based on billed charges, but was associated with an increased cost based on actual provider costs or payments by the U.S. Medicare system. <sup>374</sup> Moreover, this analysis was extrapolated from the rate of hospitalization due to febrile neutropenia during the first cycle of chemotherapy, which in this study was 55% in the placebo arm and 26% in the group treated with G-CSF. Another decision analysis suggested that from an economic perspective a rate of hospitalization greater than or equal to 40% was necessary to justify the routine inclusion of G-CSF into a chemotherapy regimen. <sup>375</sup> These conclusions are consistent with the 1996 guidelines of the American Society of Clinical Oncology, which recommended primary prophylaxis (G-CSF administration concomitant with the first chemotherapy cycle) only when the expected incidence of febrile neutropenia exceeded 40%. <sup>376</sup> A review by Nichols et al., however, concluded that the incidence of febrile neutropenia after conventional chemotherapy for SCLC was approximately 18%. <sup>377</sup> The differences in the reported rates of febrile neutropenia between studies was related both to the chemotherapy regimen used and also to the diligence with which fever was sought and with how febrile neutropenia was defined. Two analyses that compared the use of G-CSF as secondary prophylaxis (G-CSF administered with all subsequent courses of chemotherapy if febrile neutropenia occurred on the previous cycle) suggested that this approach was more costly than a strategy of reducing the dose of the chemotherapy by 25%. <sup>377,378</sup>

Maintaining the dose of chemotherapy with growth factor support, rather than reducing or delaying the dose because of hematologic toxicity, would be appropriate if this translated into improved treatment efficacy. The results of studies designed to determine whether hematopoietic growth factors can increase the delivered dose intensity have been mixed.<sup>368,369 and 370,379,380 and 381</sup> A study that randomized a total of 65 patients to vincristine, ifosfamide, carboplatin, and VP-16 demonstrated that the use of G-CSF as an adjunct significantly improved the delivered dose intensity, although there was no difference in the incidence of febrile neutropenia or the days of hospitalization.<sup>380</sup> In this study, there was no difference in median survival between the arms, although there was a suggestion that long-term survival may be improved with the intensified dose delivery. A subsequent larger trial randomized patients to treatment with this regimen at fixed treatment intervals of every 3 or 4 weeks.<sup>369</sup> In a second randomization, patients were given GM-CSF or placebo following each chemotherapy cycle. Survival was improved for patients treated every 3 weeks, but the addition of GM-CSF did not reduce the incidence or the duration of febrile neutropenia, nor was there any difference in survival between the patients who received GM-CSF or placebo. With the use of G-CSF, treatment with standard doses of doxorubicin, cyclophosphamide, and VP-16 are feasible every 2 weeks. A randomized trial comparing doxorubicin, cyclophosphamide, and VP-16 given every 2 weeks with G-CSF or every 3 weeks without the growth factor identified improved survival with the every-2-week schedule.<sup>370</sup> Treatment with intravenous antibiotics was similar in the two arms. Although the intensified group did require more transfusions of red cells and platelets, overall quality of life measured by a symptom scale was comparable between the groups.

Two studies evaluated G-CSF as an adjunct to weekly chemotherapy programs.<sup>379,381</sup> In one trial, G-CSF did not increase the delivered dose intensity,<sup>379</sup> whereas in the other study both dose intensity and survival were improved in the arm that included G-CSF support.<sup>381</sup> A subsequent trial, however, compared this latter regimen with G-CSF support to a standard chemotherapy regimen that was given every 3 weeks and found no survival advantage with the intensified program.<sup>382</sup> An attempt to use G-CSF to increase the dose of three myelotoxic drugs in a four-drug regimen by 50% was not feasible and resulted in increased marrow toxicity, a reduction in cumulative drug dose received, and inferior survival.<sup>368</sup> Inclusion of GM-CSF in a combined modality program that consisted of EP plus concurrent radiation in patients with limited disease demonstrated that although the neutrophil nadirs were increased in the arm receiving GM-CSF, these patients developed more episodes of febrile neutropenia requiring intravenous antibiotics and hospitalization.<sup>383</sup> Serious thrombocytopenia and blood transfusions were also increased in the group receiving GM-CSF.

These data suggest that the inclusion of a hematopoietic growth factor within a chemotherapy regimen may permit a modest escalation in the dose intensity of some regimens, but not others. Whether this dose intensification is clinically meaningful is a separate issue, and broad generalizations are difficult. For example, although it appears that administration of doxorubicin, cyclophosphamide, and VP-16 every 2 weeks rather than every 3 weeks improves survival for patients with favorable prognostic features,<sup>370</sup> a program delivering chemotherapy every week was not better than EP alternating with CAV every 3 weeks in patients with extensive disease.<sup>381</sup> In this latter example, multiple variables (drug doses, drug diversity, patient tolerance) differed between the treatment arms and may have contributed to the observed lack of benefit with the weekly dose-intensive treatment regimen. Another issue that has not been resolved is whether patients who are at higher risk of toxicity due to age or other adverse prognostic factors, and patients who have developed febrile neutropenia on a previous treatment cycle, are better managed by reducing the dose of standard chemotherapy regimens or by adding a myeloid growth factor so that standard regimens can be given at full dose. Thus, dose, treatment interval, drug diversity, and patient selection are all parameters that define clinical outcome. Meaningful improvements in disease control beyond that produced by the programs outlined in [Table 31.3-4](#) using the currently available cytotoxic chemotherapy drugs may still be possible, and this remains an appropriate area of study.

### **Marrow and Peripheral Blood Stem Cell Transplantation**

Dose intensification with high-dose chemotherapy, supported by stem cells collected from the peripheral blood or bone marrow, has provided a survival advantage to select groups of patients with hematologic malignancies.<sup>353,354 and 355</sup> In contrast, reviews of the efficacy of high-dose therapy in adult solid tumors have concluded that no role for this approach has been established, even in the diseases most sensitive to chemotherapy and radiation.<sup>384,385 and 386</sup> However, the efficacy of high-dose therapy in SCLC has been evaluated in a relatively limited number of patients when compared with other diseases, such as breast cancer. Many of the earliest studies in SCLC enrolled patients with relapsed or chemotherapy-resistant disease. Although response rates were higher than would be anticipated with additional standard doses of chemotherapy, response durations were brief (ranging from 2 to 8 months) and the median survival was often less than 4 months.<sup>387,388 and 389</sup>

Some subsequent studies evaluated high-dose therapy as an early component of treatment in newly diagnosed patients.<sup>390,391,392 and 393</sup> With this strategy, patients received little or no induction chemotherapy before the high-dose regimen. It was hoped that by avoiding exposure to multiple cycles of conventional chemotherapy the risk of developing drug resistance in the tumor could be reduced. Response durations and survival, however, were comparable with that achieved with standard chemotherapy.<sup>394</sup>

A more commonly applied approach has been to use high-dose therapy as late intensification after standard treatment.<sup>387,395,396,397,398,399,400 and 401</sup> Theoretic support for this strategy is provided by the mathematical model proposed by Norton and Simon, which predicts that as the tumor volume is reduced relative resistance to chemotherapy develops.<sup>402</sup> These studies differ in the number of cycles and type of regimen used for induction, the extent of tumor response required before high-dose consolidation, the composition of the high-dose regimen, and whether radiation, surgery, or both were included as part of the treatment program.

The only reported phase III trial administered five cycles of induction therapy and then randomized patients who achieved a good response to consolidation with cyclophosphamide, carmustine, and etoposide with bone marrow support, or one additional cycle of conventional doses of these same drugs.<sup>398</sup> A total of 101 patients were registered, and 45 patients were randomized, which included 13 patients who initially had extensive disease. Both the complete remission rate and the median relapse-free survival ( $P = .002$ ) were superior in the high-dose arm. Although the median survival time was improved (68 vs. 55 weeks), this was not statistically significant ( $P = .13$ ), and long-term survival was achieved in only 2 of the 23 patients treated with the high-dose regimen. A criticism of this study has been that thoracic irradiation was not included as part of the treatment plan, and in most patients the site of initial relapse was confined to the chest. Accordingly, many groups that have continued to investigate consolidative high-dose therapy have used a multimodality program. For example, the Southwest Oncology Group treated 58 patients with limited disease with induction chemotherapy and radiation followed by consolidation with high-dose cyclophosphamide and autologous marrow support.<sup>403</sup> Only 21 patients received the consolidation but nine achieved long-term disease-free remissions, and the median survival of the patients receiving consolidation was 27 months.

At the Dana Farber Cancer Institute, patients responding to conventional chemotherapy have been treated with high doses of carmustine, cyclophosphamide, and cisplatin along with stem cell or marrow support followed by thoracic and prophylactic cranial irradiation. The initial report described 19 patients, and this has been updated to include 36 patients.<sup>394,399</sup> With the period of observation after completion of the high-dose therapy ranging from 21 months to 9 years, 52% of these patients with limited disease have remained in remission. The majority of patients (81%) were in complete remission or near complete remission at the time they received high-dose consolidation, and, compared with patients transplanted in a partial remission, maximal cytoreduction with induction therapy appears to have been an important prognostic factor for long-term survival. Despite treatment with 50- to 60-Gy radiation to the chest, approximately one-half of the relapses occurred at the primary site.

Fetscher et al. have described a program whereby patients received two to four cycles of induction chemotherapy followed by dose-intensive VP-16, ifosfamide, carboplatin, and epirubicin along with peripheral blood stem cell support.<sup>401</sup> Additional locoregional therapy consisted of surgical resection or thoracic irradiation. Complete responders received prophylactic cranial irradiation. Over a 6-year period, 100 patients (67 with extensive disease and 32 with limited disease) were treated with this approach. Only 19 of the 33 patients with limited disease proceeded to high-dose therapy. Excluding the favorable subset of patients with early-stage disease in which complete surgical resection was performed, 5-year survival was 33%.<sup>401</sup> Leyvraz et al. have shown that multiple cycles of high-dose therapy can be given within a cooperative group.<sup>404</sup> In this study, treatment consisted of mobilization with epirubicin, collection of stem cells, and then three cycles of dose-intensified ICE given at 4-week intervals. Compared with standard doses of ICE, a two- to threefold escalation of each chemotherapy drug was feasible. The median duration of severe leukopenia was 4 days, and there was no evidence of cumulative toxicity with the multiple cycles of high-dose treatment. This program is now being compared with standard therapy in patients with a favorable prognosis in a randomized trial.

In sum, high-dose consolidative therapy has been evaluated in a selected population that is younger and healthier than the general population of patients with SCLC. Even in this more favorable subset, it is not clear whether survival is better than would have been expected with conventional treatment. Treatment-related complications have been reduced with the substitution of peripheral blood stems cells for bone marrow and with improvements in supportive care, but even the most recent series report treatment-related mortality that exceeds the 2% to 5% mortality currently expected with high-dose therapy. This may be the result of more comorbid illness, even in the best subset of patients with SCLC, or it may simply be due to the small numbers of patients included in the reported series. In addition, among the technical issues that need to be clarified is whether tumor cell contamination of the harvested stem cell product is a significant cause of treatment failure, as marrow involvement can be documented by immunocytochemistry in a substantial minority of patients with limited disease considered to be in a

chemotherapy-induced remission by routine histologic examination.<sup>405</sup> Several randomized studies are evaluating the role of high-dose consolidation in SCLC and should help define whether this approach, as currently practiced, is of value in this disease.

## WEEKLY DOSE-INTENSIVE CHEMOTHERAPY REGIMENS

Dose intensity is defined both by the dose and the time interval required to deliver the dose.<sup>356</sup> Therefore, shortening the time interval between chemotherapy cycles is an alternative to increasing the dose as a means of achieving greater dose intensity. Some groups have developed weekly regimens that use six or seven drugs.<sup>406,407</sup> and <sup>408</sup> For example, the Southwestern Oncology Group developed a six-drug program that included doxorubicin, cyclophosphamide, methotrexate and leucovorin, vincristine, VP-16, and cisplatin.<sup>406</sup> Among the 48 patients with extensive disease, the complete response rate was 38% and the median survival time was 11.4 months. A European group used a fairly comparable six-drug regimen in which the most significant differences were the inclusion of teniposide, a lower dose of methotrexate (30 mg/m<sup>2</sup> instead of 200 mg/m<sup>2</sup>), and a shorter treatment interval (12 weeks instead of 16 weeks).<sup>407</sup> In this study, the complete response rate for patients with extensive disease was 9.7%, and the median survival for this group was 7 months. These differences highlighted the importance of patient selection in the resultant outcome and the necessity for randomized trials to evaluate new treatment approaches in SCLC.

Three weekly programs have been tested in randomized multiinstitutional settings.<sup>382,408,409</sup> A multidrug combination developed by Sculier et al., which included seven drugs, was compared with standard treatment of CAV.<sup>408</sup> The planned duration of treatment was 18 weeks in both arms. A total of 215 patients were enrolled that included 120 patients with extensive disease and 95 patients with limited disease. Overall, there was no difference in median survival (49 vs. 43 weeks) or in 2-year survival rates (8.5% vs. 7.9%) between the treatment arms, and analysis by stage of disease failed to identify any difference in outcome based on treatment. A second randomized trial evaluated a regimen consisting of EP alternating on a weekly basis with ifosfamide plus doxorubicin. This was compared with a standard chemotherapy regimen consisting of alternating 3-week cycles of CAV and EP.<sup>409</sup> Patients who achieved at least a partial response to chemotherapy received thoracic irradiation, and some patients also received prophylactic cranial irradiation. Included in this study were 438 patients, the majority of whom had limited disease. No differences in either median or 2-year survival rates were evident. In both of these randomized studies, myelosuppression was a dominant side effect, and the actual dose intensity delivered was a lower percentage of the planned dose in the weekly treatment arms. However, treatment-related mortality was low, and no worse, with weekly treatment than with standard therapy.

A more intensive weekly program that included cisplatin, vincristine, doxorubicin, and VP-16 (CODE) delivered higher doses of chemotherapy by infusing myelosuppressive and relatively nonmyelosuppressive drugs on alternate weeks and by using an aggressive supportive regimen consisting of corticosteroids, gastroprotective agents, and prophylactic antibiotics. In the initial report, 19 of 48 (40%) patients with extensive disease attained a complete remission, and the 2-year survival rate was 30%.<sup>410</sup> In a small randomized trial, a Japanese group reported that G-CSF support improved both the delivered dose intensity and the median survival when CODE was used to treat patients with extensive disease.<sup>381</sup> They subsequently compared CODE plus G-CSF with a standard regimen consisting of alternate 3-week cycles of CAV and EP.<sup>382</sup> There were 220 patients with extensive disease enrolled in this study. Both the overall response rate and the complete remission rate (15%) were similar in the two treatment arms. The median survival time (11.6 vs. 10.9 months) and 2-year survival rates (11.7% vs. 8.5%) were also comparable. The incidence of neutropenic fever was significantly higher, and there were four toxic deaths in the weekly treatment arm. In North America, a randomized intergroup study compared CODE with alternating CAV and EP over 18 weeks.<sup>411</sup> A total of 219 patients with extensive disease with a good performance status were enrolled. Although the response rate was improved (87% vs. 70%) with the weekly program, the response duration and median survival were equivalent between the two treatment arms. Moreover, febrile neutropenia was more common in the patients treated with CODE, and there were more toxic deaths (8.2% vs. 1.0%) compared with the standard treatment arm. In aggregate, these studies demonstrate that weekly chemotherapy programs offer no advantage to standard treatment given every 3 weeks, and if given at the maximum tolerated dose, weekly chemotherapy is significantly more toxic than standard therapy.

## MANAGEMENT OF SMALL CELL LUNG CANCER IN THE ELDERLY AND INFIRM

At diagnosis, 25% to 40% of patients with SCLC are 70 years old or older.<sup>412,413,414</sup> and <sup>415</sup> Compared with younger patients, the elderly have a poorer performance status and more comorbidity.<sup>412,413</sup> They are at higher risk for complications from intensive treatment.<sup>88,90,416</sup> As a result, many physicians treat elderly patients less aggressively. For example, one retrospective review management for 20 of 123 (16%) elderly patients consisted only of radiation therapy, and another 23 patients (19%) received only supportive care.<sup>412</sup> Another review of the management of 312 patients diagnosed between 1985 and 1991 showed that in the management of the elderly population, 23% of the patients received only supportive care, and in the subset of patients with limited disease only 43% received both chemotherapy and radiation.<sup>413</sup> In contrast, in patients between the ages of 60 and 69 less than 10% of the patients received supportive care and 65% of the patients with limited disease received combined modality therapy.

When chemotherapy is given to elderly patients, it is usually given at attenuated doses and often for fewer cycles.<sup>84,412,413,415</sup> In one study, the median nadir white blood cell count was 2800/μL and the nadir platelet count was 198,000/μL.<sup>412</sup> Patients who are treated with chemotherapy derive a survival benefit despite attenuation of both the dose and duration of treatment, and in some series the response and survival for the elderly have been comparable with younger patients.<sup>84,412,413</sup>

Few elderly patients have been included in clinical trials, and those who have been enrolled are among a minority with less comorbidity and better functional status.<sup>413,415</sup> As a result, extrapolation of the published data for standard therapies to the general population of elderly patients may be inaccurate. Consequently, several chemotherapy programs have been developed for the elderly and for patients unfit for participation in standard therapy protocols that aim to optimize palliation with acceptable risks. One approach has been to use monotherapy with the epipodophyllotoxins.<sup>144,417,418</sup> VP-16 can be given orally, making it particularly attractive in the palliative setting.<sup>155</sup> In a study of 35 elderly patients, one-third of whom had poor performance status, a 5-day course of oral VP-16 every 4 weeks produced a response rate of 71% and survival comparable with the results with combination treatment in a younger population.<sup>417</sup> The Medical Research Council designed a trial comparing oral VP-16, 50 mg twice daily for 10 days, with standard combination chemotherapy consisting of either VP-16 and vincristine or CAV.<sup>325</sup> In each arm, chemotherapy was repeated every 3 weeks for a total of four cycles. The median age enrolled in this study was 67 years, and 38% of the patients had a performance status equal to 3 to 4. The study was prematurely stopped after an interim analysis that showed inferior survival in the patients treated with VP-16 monotherapy. Hematologic toxicity was also worse with oral VP-16, and there were 17 deaths during the first month of treatment in this arm compared with ten deaths on the control group. A second British trial comparing oral VP-16 given at 100 mg twice daily for 5 days with VP-16 and cisplatin alternating with CAV in poor-prognosis patients was also stopped early because of inferior progression-free and overall survival in the VP-16 monotherapy arm.<sup>326</sup> Moreover, palliation of symptoms and quality of life were better with combination chemotherapy. Based on the results of these two trials, monotherapy with oral VP-16 cannot be recommended as adequate treatment for patients with SCLC.

An alternative approach for providing palliative chemotherapy in Britain was the delivery of chemotherapy as needed to palliate symptoms, rather than at fixed 3- or 4-week treatment intervals. A total of 300 patients were randomized to receive CEV every 3 weeks for a total of eight cycles or to an as-needed treatment program.<sup>419</sup> In this arm, patients were evaluated at 3-week intervals after the first treatment cycle and were retreated only if they were symptomatic or had evidence of tumor growth while not receiving treatment. Patients randomized to receive chemotherapy as needed had a median interval between cycles of 42 days and received only 50% as much total chemotherapy as the patients treated on the fixed schedule. Although the median survival times were equivalent, better symptomatic control was achieved with the fixed interval treatment.

Another investigation of less intensive therapy compared the ECMV regimen with EV.<sup>420</sup> Three cycles were planned for each arm because a prior study comparing three and six cycles of ECMV showed equivalent survival.<sup>230</sup> A total of 310 patients with extensive disease or limited disease and poor performance status were registered. The response rates and survival were comparable between the two arms.<sup>420</sup> There were twice as many early fatalities (death during the first treatment cycle) in patients receiving the four-drug ECMV regimen (37 vs. 18). Nevertheless, ECMV produced better palliation of symptoms than did EV. Another study compared a regimen of EP alternating with CAV every 3 weeks at standard doses with EP alternating with CAV every 10 to 11 days at 50% of the standard dose.<sup>421</sup> Response and survival were comparable with both schedules, and toxicity was not reduced with the more frequent administration of lower doses.

Several other less intensive regimens have been designed for high-risk and elderly patients that use lower doses of chemotherapy than are used in standard regimens and report reasonable response rates and survival with less toxicity.<sup>414,418,422,423,424,425,426</sup> and <sup>427</sup> In a study of 75 elderly patients with reasonably good performance status and limited disease, two cycles of carboplatin and prolonged oral VP-16 were given with concurrent hyperfractionated radiation, and a median survival of 15 months and a 5-year survival of 13% were observed.<sup>428</sup> In 55 patients with limited disease unfit for standard treatment, Murray et al. administered one cycle of CAV followed by one cycle of VP-16 and cisplatin along with 20 to 30 Gy of concurrent thoracic irradiation.<sup>414</sup> The complete remission rate was 51%, and 28% of the patients were alive and disease-free at 2 years. This same group of investigators have also reported a series of 66 patients older than 65 years and with a

performance status of 3 who were treated with a four-drug regimen consisting of attenuated doses of cisplatin, doxorubicin, vincristine, and VP-16 for a total of four cycles.<sup>427</sup> Concurrent thoracic irradiation was given to patients with limited disease and selected patients with extensive disease. The delivered total dose was 80% of the intended dose. Survival at 2 years was 38% and 18% for patients with limited and extensive disease, respectively. Hospitalization was necessary for 42% of patients receiving combined modality treatment and for 15% of the patients treated with chemotherapy alone. There was just one septic death. Comparison of these single-institution phase II trials with the outcomes observed in controlled cooperative group studies is difficult. Nevertheless, it highlights the importance of developing chemotherapy programs of sufficient intensity to achieve optimal palliation, with manageable toxicity, in elderly and high-risk patients.

## BIOLOGIC RESPONSE MODIFIERS AND OTHER TREATMENTS

Although cytotoxic therapy is effective in reducing the disease burden in SCLC, it is rarely curative. The immune response to SCLC appears to be modest, as evidenced by a lack of association with tumor-infiltrating lymphocytes in tumor biopsies. Efforts to augment the immune response have included treatment with nonspecific immunomodulators, therapy with interferons and interleukin-2, and active immunization with antiidiotypic antibodies. Studies that have evaluated bacille Calmette-Guérin, the methanol-extracted residue of bacille Calmette-Guérin, or thymosin fraction V, a soluble product of calf thymus thought to reconstitute immune function, have failed to demonstrate a beneficial effect on response rate, response duration, or survival.<sup>429,430,431,432 and 433</sup>

The expression of major histocompatibility complex antigens is reduced in SCLC, which may play a role in this tumor's ability to escape immune surveillance.<sup>434,435 and 436</sup> Interferon has been shown to increase the expression of major histocompatibility complex antigens on SCLC cells both *in vitro* and *in vivo*.<sup>437,438</sup> Small studies in newly diagnosed patients, however, treated with either interferon- $\alpha$  or interferon- $\gamma$  showed a total absence of activity.<sup>439,440 and 441</sup> Because immune augmentation may be most effective in patients with low-disease burden, larger studies have evaluated interferons as maintenance treatment in patients responding to chemotherapy. Mattson et al. conducted a study in which patients responding to induction chemotherapy were randomized to a maintenance chemotherapy, natural interferon- $\alpha$ , or observation.<sup>442</sup> Although there were no differences overall, a subset analysis showed improved survival for patients with limited disease who received interferon. Another study that administered interferon- $\alpha$  both along with the induction chemotherapy and as a maintenance reported a higher complete response rate and improved median survival.<sup>443</sup> Due to poor accrual, however, the study was stopped prematurely and only 77 patients were evaluable. Two other randomized trials, one in which interferon- $\alpha$  was included both as part of the induction and maintenance regimen, and a second, cooperative group trial in which interferon- $\alpha$  maintenance was evaluated in patients with limited disease who had responded to induction chemotherapy,<sup>444,445</sup> showed no survival advantage. Interferon- $\gamma$  maintenance therapy in patients with complete or near complete remissions has also been evaluated in two randomized trials.<sup>446,447</sup> Although the dose and schedule selected from one trial was confirmed to be biologically active as demonstrated by a significant increase in the expression of HLA-DR and Fc receptors on monocytes,<sup>448</sup> neither study produced an effect on survival. In addition to the typical influenza-like side effects and myelosuppression, a few of the studies in lung cancer have suggested that the interferons may enhance radiation-induced lung injury, and there was at least one case of fatal pneumonitis.<sup>447</sup>

High-dose interleukin-2 has also been evaluated in a group of patients with extensive disease who experienced less than a complete remission to induction chemotherapy.<sup>449</sup> The overall response rate was 21%, but the toxicity was severe, and treatment was discontinued in 11 of 24 patients because of life-threatening side effects. These studies indicate that at the present time treatment with cytokine therapy has not established a role in the management of this disease.

SCLC displays a variety of markers of neuroendocrine differentiation that could serve as targets for biologic agents. Neural cell adhesion molecule is one such target to which an immunotoxin, consisting of a murine monoclonal antibody linked to a modified ricin molecule, has been developed. In a dose-escalation trial, 1 of 21 patients had a partial response that lasted 3 months.<sup>450</sup> In an alternate strategy, a monoclonal antibody directed against gastrin-releasing peptide was developed with the intent of interrupting this autocrine growth loop. One of 12 evaluable patients had a complete remission that lasted 6 months.<sup>451</sup> The patients treated with these two biologic agents all had disease resistant to chemotherapy. The activity noted is encouraging for further clinical development.

The variable region of an antibody mirrors its antigen. Therefore, a second antibody raised against this variable region structurally mimics the original antigen. Infusion of this second antiidiotypic antibody often induces a more effective immune response than does infusion of the antigen of interest. Thus, a limitation of monoclonal antibody therapy, the development of a host immune response to the infused mouse protein [human antimouse antibody (HAMA) reaction] can be exploited by infusing a mouse antiidiotypic antibody to augment immunity to antigens preferentially expressed on tumor cells. An antiidiotypic antibody, BEC2, which resembles a ganglioside expressed on SCLC cells, has been tested in 15 patients who had responded to conventional chemotherapy.<sup>452</sup> Side effects of the vaccination were modest and consisted primarily of skin reactions to the bacille Calmette-Guérin adjuvant. The median progression-free survival was 11 months and longer than 47 months for patients with extensive and limited disease, respectively. Comparison with an historic matched control group suggested that both progression-free and overall survival were substantially improved. Antiidiotypic antibodies are being developed that resemble other poorly immunogenetic antigens expressed by SCLC cells. Because the expression of any one of these antigens is variable, a polypeptide vaccine containing multiple immunogenetic antigens will probably be needed to effectively target every SCLC cell.

A potential role of the coagulation system in the propagation of cancer has been recognized for many years. Thrombin is generated *in situ* and may function as a growth factor for the tumor.<sup>453</sup> Tumors produce urokinase-like enzymes that may participate in the degradation of the extracellular matrix.<sup>454</sup> Initial studies evaluating whether the addition of warfarin to the chemotherapy regimen improved survival yielded mixed results.<sup>455,456</sup> In a randomized trial involving a total of 50 patients, the addition of warfarin significantly improved both progression-free and overall survival.<sup>456</sup> In a larger cooperative group study, patients receiving coumadin with chemotherapy had a higher response rate ( $P = .012$ ) and a 6-week improvement in median progression-free and overall survival, although the difference for the latter two end points was not statistically significant.<sup>457</sup> The addition of 1 g/d of aspirin, a dose sufficient to inhibit platelet aggregation, failed to demonstrate a benefit.<sup>458</sup> A subsequent trial by the same group of investigators demonstrated that the subcutaneous administration of unfractionated heparin at therapeutic doses given during the first 5 weeks of chemotherapy resulted in a higher complete remission rate and improved survival.<sup>453</sup>

## TREATMENT AT RELAPSE

The majority of patients with SCLC relapse within a year of initial therapy, and many are candidates for second-line treatment<sup>193,197,198,342,459,460 and 461,467,468</sup> (Table 31.3-8). Factors that predict the likelihood of response to subsequent chemotherapy include the interval between completion of induction and relapse, the extent of tumor regression achieved with the induction regimen, and the composition of the induction program.<sup>462</sup> For example, the activity of teniposide in previously treated patients was 53% if the chemotherapy-free interval was greater than 2.6 months, compared with 12% if the treatment-free interval was shorter.<sup>463</sup> As a consequence, sensitive relapse is often, and somewhat arbitrarily, defined as a chemotherapy-free interval of greater than or equal to 3 months. In patients in sensitive relapse, response rates to second-line therapy often exceed 50%, and any chemotherapy regimen active in SCLC appears to be effective, including the drug regimen that was initially used for induction.<sup>152,464,465 and 466</sup>

TABLE 31.3-8. Activity of Combination Chemotherapy Regimens at Relapse

For patients who relapse early, both the regimen used for second-line and the induction regimen may be important in determining the likelihood of a secondary response.<sup>341</sup> For example, in patients treated with CAV as the induction regimen, second-line treatment EP produces a response rate of approximately 35%.<sup>193,459</sup> Only

approximately one-half as many patients (15%) who experience early relapse after EP induction respond to CAV as a second-line therapy.<sup>460</sup> In some of the randomized trials that have compared CAV with EP, patients not responding to initial therapy (primarily refractory) and crossed over to the alternative regimen were more likely to respond to EP than to CAV, although in this more resistant group of patients the response rates to second-line treatment overall were lower and were 15% to 23% for EP and approximately 8% for CAV.<sup>197,198</sup>

Drugs that have been reported to be active as second-line agents include carboplatin, ifosfamide, and paclitaxel (Taxol), although the reported response rates have been variable, reflecting the small, heterogeneous populations tested. For example, carboplatin in combination with ifosfamide or paclitaxel has been reported to be active in more than 50% of the patients relapsing early after induction with CDE.<sup>342,467</sup> In contrast, in another study zero of ten patients resistant to cisplatin, doxorubicin, and VP-16 responded to carboplatin, ifosfamide, and vincristine.<sup>461</sup> Furthermore, the survival from the start of second-line therapy is rarely more than 4 to 6 months. More dose-intensive therapy with a weekly regimen has been reported to produce a 30% 1-year survival rate in patients with good performance status in sensitive relapse.<sup>469</sup> These studies indicate that for patients with a reasonable performance status second-line therapy with a moderately intensive drug regimen is appropriate. The likelihood of a secondary response may be better in patients who have not previously been treated with a platinum agent.<sup>470</sup> Symptomatic sites of disease can frequently be managed with radiation.

### SURGICAL MANAGEMENT OF PERSISTENT OR RECURRENT LOCAL DISEASE

Histologically mixed disease is a not an uncommon occurrence when SCLC is resected after chemotherapy. Non-small cell lung and mixed small and non-small cell elements occur in 5% to 35% of specimens.<sup>296,302,319,471</sup> Whether these pathologic findings may be attributable to selection by chemotherapy of non-small cell elements present in the original tumor, histologic changes induced by chemotherapy, the presence of a second lung cancer, or incorrect initial diagnosis is not resolved. Nevertheless, surgery may prove therapeutically efficacious if the only residual cancer is non-small cell in type. Because of the frequency of mixed histologies at the time of resection after chemotherapy, the Toronto group reported a retrospective analysis of salvage surgery in limited SCLC.<sup>322</sup> Twenty-eight patients underwent thoracotomy after lack of response to induction chemotherapy or relapse after initial response. A resection rate of 82% was possible in this selected group, and ten patients (36%) had mixed elements histologically. Projected 5-year survival is 23%. We believe it is important to verify these findings in other patients who are prospectively identified by specific selection criteria before recommending such an approach.

### TREATMENT OUTCOME AND LONG-TERM SURVIVAL

Although current therapy has a significant effect on the natural history of this disease, the number of patients cured remains frustratingly small ( Table 31.3-9). Patients are at greatest risk of dying during the first 24 months after diagnosis; this risk declines between years 2 and 3 and is further reduced beyond the third year. In the Surveillance, Epidemiology, and End Results database, overall survival at 2, 3, and 5 years was 11.6%, 7.1%, and 4.6%, respectively.<sup>472</sup> In an analysis of 2196 patients treated on clinical trials in Britain, the hazard fell by a factor of 10 after 3 years but was still approximately seven times that of the general population.<sup>473</sup> Excessive mortality in long-term survivors is due both to late relapse with SCLC and to the development of second primary tumors. Late relapse occurs in approximately 10% of patients who are free of disease at 5 years.<sup>474</sup> Second primary tumors pose an even greater risk than relapse in long-term survivors. Overall, the relative risk of a second primary tumor in survivors beyond 2 years is increased by 3.5-fold.<sup>475</sup> Most of these second primary tumors are non-SCLC or other malignancies of the upper aerodigestive tract, indicating that field cancerization due to tobacco exposure has occurred.<sup>475,476</sup> The risk of a second primary tumor increases significantly over time, and continued smoking after the initial diagnosis of SCLC, radiation to the chest, and treatment with alkylating agents magnifies this risk.<sup>475</sup> For example, the risk of a second lung cancer in patients who continue to smoke was approximately fourfold more than those who stopped before the diagnosis of SCLC and twofold greater in patients who received chest irradiation compared with nonirradiated patients. The cumulative risk of a second lung cancer was 32% at 12 years and continued to increase beyond that time point. Consequently, patients successfully treated for SCLC constitute an extraordinarily high-risk group and deserve close medical follow-up. This population would be appropriate for studies evaluating new screening technologies, such as spiral CT scanning, and are candidates for chemoprevention trials.

Therapy	Median Survival (mo)		2 to 37 Survival Rate (%)	
	Limited Disease <sup>a</sup>	Extensive Disease	Limited Disease	Extensive Disease
Supportive care	5	13	--	--

**TABLE 31.3-9.** Effect of Treatment on Survival in Small Cell Lung Cancer According to Extent of Disease

Long-term survivors are also at increased risk for noncancer-related morbidity. In a French study of patients surviving beyond 30 months, treatment-related sequelae included neurologic impairment in 13% of the patients, pulmonary fibrosis in 18%, and cardiac disorders in 10%.<sup>477</sup> Return to work was possible in 40% of these patients and was not influenced by the presence of late treatment-related complications. In a Danish analysis of patients surviving 5 years or longer, there was a sixfold increase risk of death from nonneoplastic causes, particularly cardiovascular and pulmonary diseases.<sup>478</sup>

Few patients with extensive disease attain long-term survival. At 2 years after diagnosis no more than 5% of these patients remain alive, and the survival rate at 5 years is only 1%.<sup>472,479</sup> Although the effect of combination chemotherapy on survival is unambiguous, it is not clear whether any of the agents, treatment schedules, or supportive measures introduced since 1980 have improved survival compared with the therapies available in the 1970s. Analysis of 21 phase III trials conducted in North America between 1972 and 1990 showed an improvement in median survival time from 7 months to 8.9 months when studies initiated in the first decade were compared with studies initiated in the second.<sup>480</sup> In contrast, an analysis of 1111 consecutive patients treated in clinical trials in Scandinavia between 1973 and 1992 demonstrated no improvement in survival over those two decades.<sup>481</sup> In this series, severe myelosuppression and febrile neutropenia was significantly more common in patients treated between 1981 and 1992, suggesting that more intensive therapies in a relatively unselective population increase toxicity without improving survival. This study highlights one of the great challenges in the management of SCLC. There is significant heterogeneity among patients in their capacity to tolerate aggressive therapy, and optimal management requires therapy that is tailored to the tolerance of the individual patient.

### EXTRAPULMONARY SMALL CELL CARCINOMA

Extrapulmonary small cell anaplastic carcinoma is a clinicopathologic entity distinct from SCLC. It is estimated that approximately 1000 cases are diagnosed in the United States annually.<sup>482</sup> On routine histopathologic examination, pulmonary and extrapulmonary small cell carcinomas are indistinguishable. Mixed tumors, which include a variety of cell types, may occur more frequently, and deletions of chromosome 3p may be less common with extrapulmonary tumors.<sup>483</sup> Primary small cell carcinomas have been identified in virtually every organ site.<sup>484</sup> The most common sites include the esophagus and other gastrointestinal organs, the head and neck region, cervix, and bladder. There appears to be a sex predilection based on the primary site: Most of the small cell carcinomas of the head and neck region, esophagus, and bladder are found in male subjects. With the exception of primary tumors arising in the cervix in which a younger age group is affected, the majority of patients are middle-aged or older.

A history of tobacco use is common, particularly in tumors that occur in the head and neck region and the esophagus, but there is not as strong an association with smoking as there is with pulmonary small cell carcinoma. Paraneoplastic syndromes due to the ectopic production of adrenocorticotropic and antidiuretic hormones also occur with extrapulmonary small cell cancer, and there is at least one case report in which humorally mediated hypercalcemia was identified.<sup>485</sup>

By definition, patients with extrapulmonary small cell cancers must have a normal CT scan of the chest and preferably a normal bronchoscopic examination.

Merkel-cell carcinoma is a distinct entity that is primarily found in the skin and can be distinguished by certain immunocytochemical characteristics. Extrapulmonary small cell carcinomas can disseminate widely, and the recommended staging studies are similar for pulmonary small cell carcinoma.<sup>484</sup> A two-stage system is generally used. Limited disease is defined as tumor confined to the organ of origin and the local regional nodes that are encompassable within a radiation portal. Tumors that have spread beyond one radiation portal are defined as extensive. In contrast to SCLC, most patients in whom a primary site is identified have limited disease at the time of diagnosis. In a series of 71 patients from the Mayo Clinic, 76% of the tumors were localized at diagnosis.<sup>486</sup> In this series, the only sites that presented greater than or equal to 50% of the time with extensive disease were primary tumors of the gastrointestinal tract and tumors of unknown primary site.

In many respects, natural history and response to treatment for small cell carcinoma are similar for both pulmonary and extrapulmonary sites. Patients with extensive disease are candidates for treatment with combination chemotherapy. There are several reports in the literature in which a proportion of patients with limited disease managed, with local therapies alone, particularly surgical resection, to achieve a long-term progression-free survival.<sup>482,484,486</sup> Success of local therapy appears to vary depending on the primary site of the small cell carcinoma. For example, Koss et al. reported an approximate 30% 5-year survival in patients with small cell carcinoma of the minor salivary glands managed only with local therapy.<sup>487</sup> Surprisingly, small cell cancers of unknown primary site have been successfully managed by local therapy.<sup>486,488</sup> In contrast, small cell cancer rising in other head and neck sites, such as the larynx and hypopharynx, and primaries of the esophagus, prostate, and bladder recur rapidly despite complete surgical resection.<sup>482,489</sup> Patients with stage I small cell carcinoma of the cervix have been managed successfully by radical hysterectomy, but if the regional lymph nodes are involved local therapy alone is almost never curative.<sup>486,490,491</sup> Although some patients with small-volume disease confined to the organ of origin can be cured with surgery alone, the risk of relapse remains high even in this most favorable subset, and in most patients adjuvant chemotherapy should be strongly considered. For patients with locoregional disease, the combination of chemotherapy and radiation is a reasonable alternative to surgery. Overall, the prognosis for extrapulmonary small cell carcinoma is poor. In the Mayo Clinic series, 3- and 5-year survivals were 38% and 13%, respectively.<sup>486</sup>

## INTRODUCTION

Tumors involving the mediastinum may be primary or secondary in nature. Primary neoplasms can originate from any mediastinal organ or tissue but most commonly arise from thymic, neurogenic, lymphatic, germinal, and mesenchymal tissues. All primary mediastinal neoplasms, except those of thymic origin, also occur elsewhere in the body and are discussed in other chapters. Secondary (metastatic) mediastinal tumors are more common than primary neoplasms and most frequently represent lymphatic involvement from primary tumors of the lung or infradiaphragmatic organs, such as pancreatic, gastroesophageal, and testicular cancer. This chapter provides an overview of primary mediastinal neoplasms. Specific tumors are covered in detail, including thymic, primary mediastinal germ cell, mesenchymal, cardiac, and neurogenic tumors. Esophageal cancer and lymphomas are covered elsewhere, in [Chapter 33.2](#) (Cancer of the Esophagus) and [Chapter 45.1](#), [Chapter 45.2](#), [Chapter 45.3](#), [Chapter 45.4](#), [Chapter 45.5](#) and [Chapter 45.6](#) (Lymphomas).

## ANATOMY

The mediastinum occupies the central portion of the thoracic cavity. It is bounded by the pleural cavities laterally, by the thoracic inlet superiorly, by the diaphragm inferiorly, by the sternum anteriorly, and by the chest wall posteriorly. The mediastinum can be divided into three clinically relevant compartments: anterior, middle, and posterior ([Fig. 32-1A](#)).<sup>1</sup> The anterior mediastinum lies posterior to the sternum and anterior to the pericardium and great vessels, extending from the thoracic inlet to the diaphragm. The middle mediastinum is defined as the space occupied by the heart, pericardium, proximal great vessels, and central airways. The posterior mediastinum is bounded by the heart and great vessels anteriorly, the thoracic inlet superiorly, the diaphragm inferiorly, and the chest wall of the back posteriorly, and it includes the paravertebral gutters. [Table 32-1](#) lists the major anatomic structures within each of the compartments. A thorough understanding of each area's contents helps define the diagnostic possibilities. Other divisions have been proposed, dividing the mediastinum into three or four compartments ([Fig. 32-1B,C](#)). Heitzman even proposed seven anatomic regions.<sup>1</sup> Although the exact scheme that should be used is still debated, these other schemes have limited clinical utility.

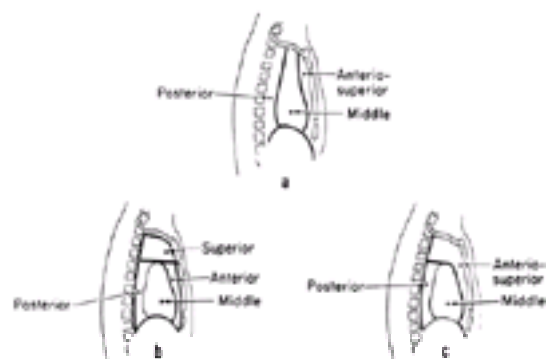

FIGURE 32-1. Mediastinal compartments.

**ANTERIOR MEDIASTINUM**  
Thyroid gland  
Esophageal mucosa, artery and vein  
Esophagus  
Parathyroid (one or two, if ectopic)  
Thymus (rarely, if ectopic)

**MIDDLE MEDIASTINUM**  
Heart and pericardium  
Ascending and aortic arch  
Superior and inferior vena cava  
Esophageal artery and vein  
Main and right pulmonary artery  
Pulmonary veins  
Trachea and mainstem bronchi  
Thoracic nerves  
Lymph nodes

**POSTERIOR MEDIASTINUM**  
Esophagus  
Descending aorta  
Sympathetic chain  
Vagus nerves  
Azygos and hemiazygos veins  
Thoracic duct  
Lymph nodes

**TABLE 32-1.** Anatomic Structures within the Mediastinum

**INCIDENCE AND PATHOLOGY**

Mediastinal neoplasms are uncommon tumors that can occur at any age but are most common in the third through the fifth decades of life.<sup>2,3</sup> and [Table 32-2](#) reviews the classification of mediastinal neoplasms. The incidence of primary mediastinal tumors was documented in a review of 1900 patients ([Table 32-3](#)).<sup>2</sup> Additionally, 439 patients (18% of all mediastinal masses) were found to have cystic lesions. The distribution of primary mediastinal neoplasms is shown in [Table 32-4](#). Thymic neoplasms predominate in the anterior mediastinum, followed in frequency by lymphomas, germ cell tumors, and carcinoma. Bronchial, enteric, and pericardial cysts are the most common masses in the middle mediastinum, followed by lymphomas, mesenchymal tumors, and carcinoma.<sup>5</sup> In the posterior mediastinum, neurogenic tumors and esophageal cancers are most common, followed by enteric cysts, mesenchymal tumors, and endocrine neoplasms.<sup>2,3</sup> and [Table 32-4](#)

Anterior Mediastinum	Middle Mediastinum	Posterior Mediastinum
Thymoma	Lymphoma	Neurogenic tumor
Teratoma	Germ cell tumor	Esophageal cancer
Carcinoma	Cyst	Enteric cyst
Mesenchymal tumor	Mesenchymal tumor	Mesenchymal tumor
Endocrine tumor	Endocrine tumor	Endocrine tumor
Other	Other	Other

**TABLE 32-2.** Classification of Mediastinal Tumors

Tumor	Incidence (%)
Neurogenic	25.3
Thymoma	23.5
Lymphoma	15.3
Germ cell neoplasm	12.2
Endocrine tumor	7.8
Mesenchymal tumor	7.5
Primary carcinoma	5.7
Other	2.9

(Adapted from ref. 2, with permission.)

**TABLE 32-3.** Relative Frequency of Primary Mediastinal Tumors

Anterosuperior Mediastinum	Middle Mediastinum	Posterior Mediastinum
Thymoma	Lymphoma	Neurogenic tumor
Teratoma	Germ cell tumor	Esophageal cancer
Carcinoma	Cyst	Enteric cyst
Mesenchymal tumor	Mesenchymal tumor	Mesenchymal tumor
Endocrine tumor	Endocrine tumor	Endocrine tumor
Other	Other	Other

**TABLE 32-4.** Distribution of Primary Mediastinal Masses by Anatomic Location

The incidence of mediastinal tumors in each anatomic compartment also varies with age. In adults, 54% of mediastinal neoplasms occur in the anterior, 20% in the middle, and 26% in the posterior mediastinum.<sup>2</sup> In pediatric populations, 43%, 18%, and 40% of neoplasms occur in the anterior, middle, and posterior mediastinum, respectively.<sup>4,6</sup> A higher incidence of thymic tumors and lymphomas in adults and neurogenic tumors in children account for these differences. Azarow<sup>4</sup> compared mediastinal masses in 195 adult and 62 pediatric patients ([Table 32-5](#)). Cysts were not included but accounted for 16% to 18% of adult and 24% of pediatric mediastinal masses.<sup>4</sup> Therefore, age as well as location establishes the probable diagnosis.<sup>2,3</sup> and [4,6,7,8](#) and [9](#)

Tumor	Incidence (%)	
	Adults	Children
Thymic	31	28
Neurogenic	15	47
Lymphoma	26	9
Germ cell	15	9
Vascular	1	6
Miscellaneous	13	2

(Adapted from ref. 4, with permission.)

**TABLE 32-5.** Relative Frequency of Primary Mediastinal Tumors in Adults and Children

**DIAGNOSTIC CONSIDERATIONS**

A meticulous history and physical examination, along with a variety of imaging, serologic, and invasive tests ([Table 32-6](#)), often can confirm the suspected diagnosis.

With improved imaging, biopsy, and pathologic techniques, the majority of patients no longer require open surgical biopsy before planning definitive therapy.

<b>HISTORY AND PHYSICAL EXAMINATION</b>
<b>RADIOGRAPHY</b>
Standard chest radiography
Computed tomographic scanning
Barium swallow
Radiotracer scanning
Angiography
Mycography
Ultrasonography
Magnetic resonance imaging
<b>ENDOSCOPY</b>
<b>SEROLOGY</b>
<b>NEEDLE BIOPSY PROCEDURES</b>
Computed tomography guided
Ultrasound guided
<b>SURGICAL PROCEDURES</b>
Mediastinoscopy
Thoracotomy

**TABLE 32-6.** Diagnostic Evaluation of Mediastinal Masses

**SYMPTOMS AND SIGNS**

Approximately 40% of mediastinal masses are asymptomatic and discovered incidentally on a routine chest radiograph.<sup>2,3</sup> The remaining 60% of cases have symptoms related to compression or direct invasion of surrounding mediastinal structures or to paraneoplastic syndromes. Asymptomatic patients are more likely to have benign lesions, whereas symptomatic patients more often harbor malignancies.<sup>2,3</sup> and <sup>4,7,8</sup> Davis found that 85% of patients with a malignancy were symptomatic, but only 46% of patients with benign neoplasms had identifiable complaints. Symptoms and signs of mediastinal neoplasms are shown in [Table 32-7](#). The most commonly described symptoms are chest pain, cough, and dyspnea.<sup>2,3,8</sup> Superior vena cava syndrome, Horner's syndrome, hoarseness, and neurologic deficits more commonly occur with malignancies.<sup>10</sup> Systemic syndromes associated with mediastinal neoplasms are shown in [Table 32-8](#) and [Table 32-9](#).

<b>SYMPTOM</b>
Chest pain
Dyspnea
Cough
Fatigue
Dysphagia
Night sweats
Hemoptysis
Hoarseness
<b>SIGN</b>
Weight loss
Fever
Adenopathy
Wheezing, stridor
Superior vena cava syndrome
Vocal cord paralysis
Neurofibromatosis
Neurologic abnormalities
Pericardial tamponade
Arrhythmias

**TABLE 32-7.** Symptoms and Signs of Mediastinal Masses

Tumor	Syndrome
Thymoma	Acute pericarditis, Addison's disease, agranulocytosis, alopecia areata, Cushing's syndrome, hemolytic anemia, hypogammaglobulinemia, limbic encephalopathy, myasthenia gravis, myocarditis, nephrotic syndrome, panhypopituitarism, pernicious anemia, polymyositis, pure red cell aplasia, rheumatoid arthritis, sarcoidosis, scleroderma, sensorimotor neuropathy, Still-person syndrome, thyroiditis, ulcerative colitis
Hodgkin's disease	Alcohol-induced pain, Pel-Ebstein fever
Neurofibroma	von Recklinghausen's disease, osteoarthritis
Thymic carcinoid	Multiple endocrine neoplasia
Neuroblastoma	Opsomyoclonus, erythrocyte abnormalities
Neurileioma	Peptic ulcer

**TABLE 32-8.** Systemic Syndromes Associated with Mediastinal Neoplasms

**RADIOGRAPHIC IMAGING STUDIES**

Radiographic imaging studies initially localize mediastinal neoplasms. The posteroanterior and lateral chest radiographs define the location, size, density, and calcification of a mass, limiting the diagnostic possibilities.<sup>11</sup> After these results, an intravenous contrast-enhanced computed tomography (CT) scan can further assess the nature (cystic vs. solid) of the lesion and detect fat and calcium.<sup>12,13,14,15,16</sup> and <sup>17</sup> The relationship to surrounding structures and blood vessels also can be determined.

Magnetic resonance imaging (MRI) is used less frequently than CT.<sup>18,19</sup> and <sup>20</sup> Its advantages include multiplanar imaging and absence of ionizing radiation.<sup>12</sup> MRI scans are superior to CT in defining vascular involvement and in distinguishing recurrent tumor from radiation fibrosis.<sup>20</sup> However, patient claustrophobia, time, and expense limit the use of MRI scanning. Other imaging modalities that may be useful include transthoracic sonography and transesophageal echocardiography.<sup>21,22</sup>

The utility of positron emission tomography in the evaluation of mediastinal masses is yet to be determined, but it may help clarify the nature of such masses and the presence of neoplasm in residual mediastinal tissue after therapy.<sup>23</sup>

**SEROLOGY AND CHEMISTRY**

Some mediastinal neoplasms release substances into the serum that can be measured by specific radioimmunoassays. These substances may be used to confirm a diagnosis, evaluate response to therapy, and monitor for tumor recurrence. a-Fetoprotein (AFP), human chorionic gonadotropin-b (b-HCG), and lactate dehydrogenase are elaborated by some germ cell tumors and should be obtained in male patients with anterior mediastinal masses.<sup>1</sup> Also, adrenocorticotropic hormone, thyroid hormone, and parathormone may help differentiate certain mediastinal tumors (see [Table 32-9](#)).

Symptoms	Hormone	Tumor
Hypertension	Catecholamines	Pheochromocytoma, chemodectoma, neuroblastoma, ganglioneuroma
Hypercalcemia	Parathyroid hormone	Parathyroid adenoma
Thyrotoxicosis	Thyroxine	Thyroid
Cushing's syndrome	ACTH	Carcinoid tumor
Gynecomastia	HCG	Germ cell tumor
Hypoglycemia	> Insulin	Mesenchymal tumors
Diarrhea	VIP	Ganglioneuroma, neuroblastoma, neurofibroma

ACTH, adrenocorticotropic hormone; HCG, human chorionic gonadotropin; VIP, vasoactive intestinal polypeptide.

**TABLE 32-9.** Systemic Manifestations of Hormone Production by Mediastinal Neoplasms

## INVASIVE DIAGNOSTIC TESTS

The determination of the histologic diagnosis of mediastinal masses often is essential for implementation of appropriate treatment. Previously, most patients underwent surgical procedures to establish the diagnosis of mediastinal neoplasms; however, improvements in less invasive diagnostic and immunohistochemical techniques and in electron microscopy have greatly improved the ability to differentiate the cell types in mediastinal neoplasms.<sup>24,25,26,27,28,29,30</sup> and <sup>31</sup> CT-guided percutaneous needle biopsy, using either fine-needle aspiration techniques and cytologic assessment or larger-core needle biopsy and histologic evaluation, now are standard in the initial evaluation of most mediastinal masses.<sup>32</sup> Although fine-needle specimens are usually adequate to distinguish carcinomatous lesions, core biopsies are recommended to distinguish most other mediastinal neoplasms, especially lymphoma and thymoma.<sup>26,27</sup> and <sup>28</sup> Most series report diagnostic yields for percutaneous needle biopsy of 72% to 100%, and, most recently, that figure is in excess of 90%.<sup>25,26</sup> and <sup>27,29</sup> Complications include simple pneumothorax (25%), pneumothorax requiring chest tube placement (5%), and hemoptysis (7% to 15%).<sup>29</sup>

Surgical procedures are still occasionally required in the diagnosis of mediastinal tumors.<sup>24,30</sup> Mediastinoscopy is a relatively simple procedure, accomplished under general anesthesia. It provides access to the middle and a limited portion of the upper posterior mediastinum and has a diagnostic accuracy of more than 90%.<sup>33,34</sup> Anterior parasternal mediastinotomy (Chamberlain procedure) yields a diagnosis in 95% of anterior mediastinal masses.<sup>33,34</sup> Thoracoscopy requires general anesthesia but is minimally invasive and provides a diagnostic accuracy of nearly 100% in most areas of the mediastinum.<sup>34</sup> Thoracoscopy should be reserved, however, for biopsies that cannot be obtained with mediastinoscopy or parasternal mediastinotomy. Thoracotomy is almost never necessary for diagnosis and should be reserved for rare circumstances.

## THYMIC NEOPLASMS

The thymus is an incompletely understood lymphatic organ functioning in T-lymphocyte maturation. It is composed of an epithelial stroma and lymphocytes. Although lymphomas, carcinoid tumors, and germ cell tumors all may arise within the thymus, only thymomas, thymic carcinomas, and thymolipomas arise from true thymic elements. Epithelial thymic neoplasms have been classified into three proposed categories: (1) thymomas, well-differentiated neoplasms; (2) atypical thymomas, moderately differentiated neoplasms; and (3) thymic carcinomas, poorly differentiated neoplasms. This classification is based on features of glandular differentiation; however, further validation of this system is needed.<sup>35,36</sup> and <sup>37</sup>

## THYMIC ANATOMY AND PHYSIOLOGY

The thymus develops from a paired epithelial anlage in the ventral portion of the third pharyngeal pouch. It is closely associated with the developing parathyroid glands.<sup>38</sup> The stroma of the thymus consists of epithelial cells, which are likely derived from both ectodermal and endodermal components.<sup>39</sup> During weeks 7 and 8 of development, the thymus elongates and descends caudally and ventromedially into the anterior mediastinum. By week 12, a separate cortex and medulla become evident, and mesenchymal septae develop perivascular spaces that contain blood vessels. Lymphoid cells arrive from the liver and bone marrow during week 9 and are separated from the perivascular space by a flat layer of epithelial cells that create the blood–thymus barrier. Maturation and differentiation occurs in this antigen-free environment. By the fourth fetal month, lymphocytes circulate to peripheral lymphoid tissue.<sup>39</sup>

Six subtypes of epithelial cells have been identified in mature thymus.<sup>39</sup> Four exist primarily in the cortical region and two in the medullary region. Type 6 cells form Hassall's corpuscles that are characteristic of thymus. These cells have an ectodermal origin and are displaced into the thymic medulla, where they hypertrophy and form tonofilaments, finally appearing as concentric cells without nuclei.<sup>38,39</sup>

At maturity, the thymus gland is an irregular, lobulated organ. It attains its greatest relative weight at birth, but its absolute weight increases to 30 to 40 g by puberty. During adulthood, it slowly involutes and is replaced by adipose tissue.<sup>39</sup> Ectopic thymic tissue has been found to be widely distributed throughout the mediastinum and neck, particularly the aortopulmonary window and retrocarinal area, and often is indistinguishable from mediastinal fat.<sup>40,41</sup> This ectopic tissue is the likely explanation for thymomas outside the anterior mediastinum and possibly for failure of thymectomy in some cases to improve myasthenia gravis.<sup>40,41</sup> and <sup>42</sup>

## THYMOMA

Thymic neoplasms, mostly thymomas, constitute 30% of anterior mediastinal masses in adults.<sup>2,3</sup> and <sup>4,8,43,44</sup> Thymomas are less common in children, accounting for only 15% of anterior mediastinal masses.<sup>8</sup> Thymomas exhibit no gender predilection and occur most often in the fifth and sixth decades of life.<sup>45</sup> Nearly one-half of these tumors are asymptomatic and are discovered only on routine radiographs. In symptomatic patients, 40% have myasthenia gravis<sup>35</sup> (diplopia, ptosis, dysphagia, fatigue, etc.), whereas others complain of chest pain and symptoms of hemorrhage or compression of mediastinal structures.<sup>45</sup>

### Pathology and Classification

Ninety percent of thymomas occur in the anterior mediastinum, and the remainder are located in the neck or other areas of the mediastinum. Grossly, they are lobulated, firm, tan-pink to gray tumors that may contain cystic spaces, calcification, or hemorrhage. They may be encapsulated, adherent to surrounding structures, or frankly invasive.<sup>46</sup> Microscopically, thymomas arise from thymic epithelial cells, although lymphocytes may predominate histologically.<sup>47</sup> True thymomas contain cytologically bland cells and should be distinguished from thymic carcinomas, which have malignant cytologic characteristics. Confusion exists because of previous “benign” or “malignant” designations. Currently, the terms *noninvasive* and *invasive* are used. Noninvasive thymomas have an intact capsule, are movable, and are easily resected, although they can be adherent to adjacent organs. In contrast, invasive thymomas involve surrounding structures and can be difficult to remove without *en bloc* resection of adjacent structures. Despite this difficulty, their cytologic appearance remains benign.<sup>46</sup> Metastatic disease does occur and is most commonly seen as pleural implants and pulmonary nodules. Metastases to extrathoracic sites are rare.<sup>46</sup>

In 1985, Marino and Muller-Hermelink<sup>48</sup> proposed a histologic classification system determined by the thymic site of origin—that is, tumors arising from epithelial cells of the cortex are termed *cortical thymomas*, those arising from the medullary areas are called *medullary thymomas*, and those with features of both are termed *mixed thymomas*. Spindle-shaped cells predominate in the medullary area and likely correspond to spindle cell thymomas of the traditional classification system. Likewise, the cortex contains predominantly round to oval epithelial cells; thus, cortical thymomas probably correspond to the traditional epithelial thymoma.<sup>49</sup> The Muller-Hermelink classification was later revised and further divided into medullary, mixed, predominantly cortical, and cortical thymomas. Well-differentiated and high-grade thymic carcinoma were also described.<sup>50</sup> Medullary and mixed thymomas were considered benign with no risk of recurrence, even with capsular invasion. Predominantly cortical and cortical thymomas exhibited intermediate invasiveness and a low but definite risk of late relapse, regardless of their invasiveness. Well-differentiated thymic carcinomas were always invasive, with a high risk of relapse and death.<sup>51</sup> Some support this revision, claiming that it better correlates pathology with prognosis.<sup>51,52</sup> and <sup>53</sup> Others believe that it has no distinct clinicopathologic advantage over the traditional system.<sup>49,50,54,55</sup> and <sup>56</sup> This issue has been re-examined,<sup>57,58</sup> and the World Health Organization Committee on the Classification of Thymic Tumors adopted a new classification system for thymic neoplasms

based on cytologic similarities between certain normal thymic epithelial cells and neoplastic cells, which is of prognostic significance ( [Table 32-10](#)).<sup>59</sup>

Tumor Type	Cell	Cytopathologic Classification	Staging Terminology
A	Lymphocytic	Large thymoma	Medullary
B	Lymphocytic	Capsular thymoma	Cortical, organoid
B1			Lymphocyte-rich, predominantly cortical
B2			Cortical
B3			NS-differentiated thymic carcinoma
B4	Large thymoma		Medullary
C	Capsular thymoma	Nonneoplastic thymic carcinoma, epithelial carcinoma of unknown primary, lymphoproliferative carcinoma, anaplastic carcinoma, clear cell carcinoma, hybrid carcinoma, neuroendocrine carcinoma, undifferentiated carcinoma	

**TABLE 32-10.** World Health Organization Staging System for Thymic Epithelial Tumors

In 1981, Masaoka et al.<sup>60</sup> developed a staging system based on the previous work of Bergh et al.<sup>61</sup> The four stages are shown in [Table 32-11](#). The Masaoka stage II classification assesses both microscopic invasion (occult in 28%) and gross tumor adherence as determined by surgical findings.<sup>49,54,62</sup> Staging was found to correlate with prognosis, with 5-year survival rates 96% for stage I, 86% for stage II, 69% for stage III, and 50% for stage IV.<sup>60</sup> The Groupe d'Etudes des Tumeurs Thymiques (GETT) staging system is surgery-based and demonstrates 90% concordance with the Masaoka system ([Table 32-12](#)).<sup>63,64</sup>

Stage	Description
I	Macroscopically completely encapsulated and microscopically no capsular invasion
II	Macroscopic invasion into surrounding fatty tissue or mediastinal pleura Microscopic invasion into capsule
III	Macroscopic invasion into neighboring organs (pericardium, great vessels, lung)
IVa	Pleural or pericardial dissemination
IVb	Lymphogenous or hematogenous metastasis

(From ref. 60, with permission.)

**TABLE 32-11.** Thymoma Staging System of Masaoka

Stage	Description
I	
Ia	Encapsulated tumor, totally resected
Ib	Macroscopically encapsulated tumor, totally resected, but the surgeon suspects mediastinal adhesions and potential capsular invasion
II	Invasive tumor, totally resected
III	
IIIa	Invasive tumor, subtotally resected
IIIb	Invasive tumor, biopsy
IV	
IVa	Supraclavicular metastasis or distant pleural implants
IVb	Distant metastases

(From ref. 63, with permission.)

**TABLE 32-12.** Thymoma Staging System of Groupe d'Etudes des Tumeurs Thymiques

### Associated Systemic Syndromes

A wide variety of systemic disorders are associated with 71% of thymomas.<sup>65</sup> The symptoms of these associated disorders often lead to the original discovery of the mediastinal tumor. Autoimmune diseases (systemic lupus erythematosus, polymyositis, myocarditis, Sjögren's syndrome, ulcerative colitis, Hashimoto's thyroiditis, rheumatoid arthritis, sarcoidosis, and scleroderma) and endocrine disorders (hyperthyroidism, hyperparathyroidism, Addison's disease, and panhypopituitarism) are most common.<sup>66</sup>

Blood disorders, such as red cell aplasia, hypogammaglobulinemia, T-cell deficiency syndrome, erythrocytosis, pancytopenia, megakaryocytopenia, T-cell lymphocytosis, and pernicious anemia, also have been noted.<sup>66</sup> Other than myasthenia, neuromuscular syndromes include myotonic dystrophy, myositis, and Eaton-Lambert syndrome.<sup>66</sup> Miscellaneous diseases include hypertrophic osteoarthropathy, nephrotic syndrome, minimal change nephropathy, pemphigus, and chronic mucocutaneous candidiasis.<sup>66</sup> Nearly 15% of patients with thymoma develop a second malignancy, such as Kaposi's sarcoma, chemodectoma, multiple myeloma, acute leukemia, and various carcinomas (e.g., lung, colon).<sup>66</sup>

**MYASTHENIA GRAVIS.** Myasthenia gravis is the most common autoimmune disorder, occurring in 30% to 50% of patients with thymomas. Younger women and older men usually are affected, with a female to male ratio of 2:1. Myasthenia is a disorder of neuromuscular transmission. Symptoms begin insidiously and result from the production of antibodies to the postsynaptic nicotinic acetylcholine receptor at the myoneural junction. Ocular symptoms are the most frequent initial complaint, eventually progressing to generalized weakness in 80%. The role of the thymus in myasthenia remains unclear, but autosensitization of T lymphocytes to acetylcholine receptor proteins or an unknown action of thymic hormones remain possibilities.<sup>52,67</sup>

Pathologic changes in the thymus are noted in approximately 70% of patients with myasthenia gravis. Lymphoid hyperplasia, characterized by the proliferation of germinal centers in the medullary and cortical areas, is most commonly seen. Thymomas are identified in only about 15% of patients with myasthenia.

The treatment of myasthenia gravis involves the use of anticholinesterase-mimetic agents [i.e., pyridostigmine bromide (Mestinon)]. In severe cases, plasmapheresis may be required to remove high antibody titers. Thymectomy has become an increasingly accepted procedure in the treatment of myasthenia, although the indications, timing, and surgical approach remain controversial.<sup>42</sup> Some improvement in myasthenic symptoms almost always occurs after thymectomy, but complete remission rates vary from 7% to 63%.<sup>42</sup> Patients with myasthenia gravis and thymomas do not respond as well to thymectomy as those without thymomas. Overall survival for myasthenia patients also is lower for patients with thymomas, but no differences were noted based on the extent of invasion present.<sup>68</sup>

**RED CELL APLASIA.** Pure red cell aplasia is considered an autoimmune disorder and is found in approximately 5% of patients with thymomas. Of patients with red cell aplasia, 30% to 50% have associated thymomas.<sup>69</sup> Ninety-six percent of the patients affected are older than 40 years of age. Examination of the bone marrow reveals an absence of erythroid precursors and, in 30%, an associated decrease in platelet and leukocyte numbers. Thymectomy has produced remission in 38% of

patients. Octreotide and prednisone were effective in one patient with recurrent disease.<sup>70</sup> The pathologic basis of these responses is poorly understood.<sup>69</sup>

**HYPOGAMMAGLOBULINEMIA.** Hypogammaglobulinemia is seen in 5% to 10% of patients with thymoma, and 10% of patients with hypogammaglobulinemia have been shown to have thymoma. Defects in both cellular and humoral immunity have been described, and many patients also have red cell hypoplasia. Thymectomy has not proven beneficial in this disorder.

### **Treatment**

Thymomas are slow-growing neoplasms that should be considered potentially malignant. Surgery, radiation, and chemotherapy all may play a role in their management.

**SURGERY.** Complete surgical resection is the mainstay of therapy for thymomas and is the most important predictor of long-term survival.<sup>71,72,73,74,75,76,77</sup> Although median sternotomy with a vertical or submammary incision is most commonly used, bilateral anterolateral thoracotomies with transverse sternotomy, or “clam-shell procedure,” is preferred with advanced or laterally displaced tumors.<sup>45,71,72,76</sup> Video-assisted thoracoscopy also has been reported, but long-term results remain unproven.<sup>78</sup> Because of concern about tumor seeding, biopsy procedures are not routinely performed.<sup>72</sup> During surgery, a careful assessment of areas of possible invasion and adherence should be made by the surgeon, who is the best judge of tumor invasiveness.<sup>62</sup> Extended total thymectomy, including all tissue anterior to the pericardium from the diaphragm to the neck and laterally from phrenic nerve to phrenic nerve, is recommended in all cases. Complete surgical resection is associated with an 82% overall 7-year survival rate, whereas survival with incomplete resection is 71% and with biopsy is only 26%.<sup>71</sup> Survival after complete tumor resection has been similar in patients with noninvasive and invasive thymomas in several studies.<sup>60,72,74,75,79</sup> Patients with myasthenia gravis and thymoma were studied by Crucitti et al.,<sup>84</sup> who reported a 78% 10-year survival rate and a 3% recurrence rate with 4.8% (1.7% since 1980) operative mortality after extended thymectomy. Aggressive resection, including lung, phrenic nerve, pericardium, pleural implants, and pulmonary metastases, is occasionally helpful.<sup>60,71,79</sup>

The role of debulking or subtotal resection in stage III and IV disease remains controversial. Several studies have documented 5-year survival rates from 60% to 75% after subtotal resection and 24% to 40% after biopsy alone.<sup>60,71,76,77,79</sup> More recent studies, however, suggest no survival advantage to debulking followed by radiation when compared to radiation alone.<sup>80,81</sup> The use of surgery in recurrent disease remains to be defined. Maggi et al.<sup>71</sup> reported a 71% 5-year survival rate in 12 surgery patients and a 41% survival rate in 11 patients treated with radiation and chemotherapy alone. Prolonged tumor-free survival also was reported by Kirschner<sup>82</sup> in 23 patients. Urgesi et al.,<sup>83</sup> however, noted a 74% 5-year survival rate in 11 patients undergoing surgery and radiation, compared with 65% in ten patients treated with radiation alone (not statistically different).<sup>83</sup>

**RADIATION THERAPY.** Thymomas are radiosensitive tumors and, consequently, radiation has been used to treat all tumor stages as well as recurrent disease.<sup>43,45,71,72,74,76,77,79,81,81</sup> In stage I thymomas, adjuvant radiotherapy has been administered but has not improved on the excellent results with surgery alone (more than 80% 10-year survival rate).<sup>71,72,74,77,79</sup> In stage II and III invasive disease, adjuvant radiation can decrease recurrence rates after complete surgical resection from 28% to 5%.<sup>43,76,86,87</sup> In addition, Pollack et al.<sup>76</sup> reported an increase in 5-year disease-free survival for stage II to IVa from 18% to 62% with the addition of adjuvant radiation. Others have documented similar results.<sup>72,79</sup> Stage II patients with cortical tumors<sup>88,89</sup> and microscopic invasion of pleura or pericardium are most likely to benefit from postoperative radiation.<sup>91,92</sup> Preoperative radiotherapy for extensive tumors has been reported in limited studies that suggest a decreased tumor burden and potential for tumor seeding at the time of surgery.<sup>71,77,86</sup>

Radiation therapy has proven beneficial in the treatment of extensive disease.<sup>76,77,80,81,85,86,93</sup> Radiotherapy after incomplete surgical resection produces local control rates of 35% to 74% and 5-year survival rates ranging from 50% to 70% for stage III and 20% to 50% for stage IVa tumors.<sup>72,77,80,83,85,86</sup> In addition, Ciernik et al.<sup>80</sup> and others<sup>81,83</sup> have reported similar survival rates (87% 5-year and 70% 7-year) in patients treated with radiation alone compared with partial surgical resection and adjuvant radiation in small numbers of stage III and IV patients and patients with intrathoracic recurrences. Large variations in the amount of tumor treated and radiation delivered, however, make interpretation of these results difficult.<sup>64,76,77,80,85,94</sup>

Radiation therapy is delivered in doses ranging from 30 to 60 Gy in 1.8 or 2.0 cGy fractions over 3 to 6 weeks.<sup>43,71,73,76,77,79,85,86,94</sup> and 96 No improvement in local control has been shown with doses exceeding 60 Gy<sup>80</sup>; however, completely resected and microscopic residual disease can be well controlled with only 40 to 45 Gy.<sup>77,80,85</sup> Treatment portals have included single anterior field, unequally weighted (2:1 or 3:2) opposed anterior-posterior fields, wedge-pair, and multifield arrangements.<sup>43,97</sup> The gross tumor volume is defined by visible tumor or surgical clips seen on a treatment-planning CT scan. Areas of possible microscopic disease and a small border to account for daily variability and respiratory motion are added to define the clinical and planning target volumes. Gating techniques to minimize respiratory variation and intensity-modulated radiation therapy are new techniques that can minimize the dose heterogeneity, increase total dose and fraction size, and minimize toxicity.<sup>98,99</sup> and 100 Prophylactic supraclavicular and hemithorax fields have been used but are not warranted because of increased risks of pulmonary fibrosis, pericarditis, and myelitis.<sup>43,77,80,81,101,102</sup>

**CHEMOTHERAPY.** Chemotherapy has been used with increasing frequency in the treatment of invasive thymomas. Both single-agent and combination therapy have demonstrated activity in the adjuvant and neoadjuvant settings. Doxorubicin, cisplatin, ifosfamide, corticosteroids, and cyclophosphamide all have been used as single-agent therapy.<sup>103,104</sup> The most active agents are cisplatin, ifosfamide, and corticosteroids; however, only cisplatin and ifosfamide have undergone phase II testing.<sup>43,104,105</sup> Cisplatin, at doses of 100 mg/m<sup>2</sup>, has produced complete responses lasting up to 30 months, but lower doses (50 mg/m<sup>2</sup>) have associated response rates of only 11%.<sup>103,104</sup> Ifosfamide (with mesna) at a single dose of 7.5 g/mn or as a continuous infusion of 1.5 g/m<sup>2</sup>/d for 5 days every 3 weeks has resulted in 50% complete and 57% overall response rates. Duration of complete remission ranged from 6 to 66 months.<sup>105</sup> Varying regimens of corticosteroids have shown effectiveness in the treatment of all histologic subtypes of thymoma (with and without myasthenia), with a 77% overall response rate in limited numbers of patients.<sup>103,106</sup> Corticosteroids also have been effective for patients unsuccessful with chemotherapy<sup>103</sup>; however, the actual impact may only be on the lymphocytic and not the malignant epithelial component of the tumor.

Combination chemotherapy regimens have shown higher response rates and have been used in both adjuvant and neoadjuvant settings in the treatment of advanced invasive, metastatic, and recurrent thymoma. Cisplatin-containing regimens appear to be the most active. Fornasiero et al.<sup>107</sup> reported a 43% complete and 91.8% overall response rate with a median survival of 15 months in 37 previously untreated patients with stage III or IV invasive thymoma treated with monthly (median, 5 months) cisplatin, 50 mg/m<sup>2</sup> on day 1; doxorubicin, 40 mg/m<sup>2</sup> on day 1; vincristine, 0.6 mg/m<sup>2</sup> on day 3; and cyclophosphamide, 700 mg/m<sup>2</sup> on day 4. Loehrer et al.<sup>108</sup> documented 10% complete and 50% overall response rates with a median survival of 37.7 months in 29 patients with metastatic or locally progressive recurrent thymoma treated with cisplatin, 50 mg/m<sup>2</sup>; doxorubicin, 50 mg/m<sup>2</sup>; and cyclophosphamide, 500 mg/mn, given every 3 weeks for a maximum of 8 cycles after radiotherapy. Park et al.<sup>109</sup> retrospectively described 35% complete and 64% overall response rates with a median survival of 67 months in responding and 17 months in nonresponding patients in 17 patients with invasive stage II and IV thymoma initially treated after relapse with cyclophosphamide, doxorubicin, and cisplatin, with or without prednisone. The European Organization for Research and Treatment of Cancer noted 31% complete and 56% overall response rates with a median survival of 4.3 years in a small study of 16 patients with advanced thymoma treated with cisplatin and etoposide.<sup>110</sup> The addition of ifosfamide to cisplatin and etoposide had a lower than anticipated response rate (approximately 32%) in patients with thymoma and thymic carcinoma.<sup>111</sup>

**COMBINED MODALITY APPROACHES.** The use of neoadjuvant chemotherapy as part of a multimodality approach to stage III and IV thymoma was reviewed by Tomiak and Evans.<sup>103</sup> Six combined reports document 31% complete and 89% overall response rates in 61 total patients treated with a variety of neoadjuvant chemotherapy regimens (80% cisplatin-based). Twenty-two patients (36%) underwent surgery, with 11 (18%) achieving a complete resection (all treated with cisplatin). Nineteen patients were treated with radiotherapy, but only five patients had disease-free survivals exceeding 5 years.<sup>103</sup> Rea et al.<sup>112</sup> reported 43% complete and 100% overall response rates with median and 3-year survival rates of 66 months and 70%, respectively, in 16 stage III and IVa patients treated initially with cisplatin, doxorubicin, vincristine, and cyclophosphamide, followed by surgery. At surgery, 69% were completely resected and the other 31% received postoperative radiation. Macchiarini et al.<sup>113</sup> reported similar findings. Twenty-five percent complete and 92% overall response rates with a remarkable 83% 7-year disease-free survival rate were reported in 12 patients at the M. D. Anderson Cancer Center who received cisplatin, doxorubicin, cyclophosphamide, and prednisone induction chemotherapy followed by surgical resection (80% complete) and adjuvant radiotherapy for locally advanced (unresectable) thymoma.<sup>114</sup> The degree of chemotherapy-induced tumor necrosis correlated with Ki-67 expression.

A multiinstitutional prospective trial demonstrated a 22% complete and 70% overall response rate with a median survival of 93 months and a Kaplan-Meier 5-year failure-free survival rate of 54.3% in 23 patients with stage III (22/23) unresectable thymoma (GETT stage IIIA/IIIB) stage IV (1/23) thymoma, and thymic carcinoma

(2/23) treated with 2 to 4 cycles of cisplatin, doxorubicin, and cyclophosphamide chemotherapy and sequential radiation therapy (54 Gy).<sup>115,116</sup> Just more than 25% had myasthenia gravis. Although these results compare favorably to those obtained with neoadjuvant therapy followed by surgical resection and radiation, further confirmation is needed.

### Results of Treatment

Five- and 10-year survival rates for stage I, III, and IV tumors are reported to be 89% to 95% and 78% to 90%,<sup>65,74,117</sup> 70% to 80% and 21% to 80%,<sup>65,74,117</sup> and 50% to 60% and 30% to 40%,<sup>60,65,74,117</sup> respectively. Disease-free survival rates of 74%, 71%, 50%, and 29% also have been reported for stage I, II, III, and IV disease, respectively.<sup>71</sup> Although Maggi et al.<sup>71</sup> reported a 10% overall recurrence rate in 241 patients, less than 5% of noninvasive thymomas and 20% of invasive thymomas were noted to recur.<sup>65</sup> Although myasthenia gravis was once considered an adverse prognostic factor, this is no longer the case because of improvements in perioperative care. Currently, myasthenia actually may lead to improved survival owing to earlier detection of thymomas.<sup>65,84,118,119</sup>

### THYMIC CARCINOMA

Thymic carcinoma is a rare aggressive thymic neoplasm that has a poor prognosis. Like thymoma, it is an epithelial tumor, but cytologically it exhibits malignant features. Extensive local invasion and distant metastases are common. Approximately 150 cases have been reported.<sup>120,121,122,123,124</sup> and <sup>125</sup> Suster and Rosai<sup>120</sup> reported the largest single series, which included 60 patients ranging in age from 10 to 76 years and with a slight male predominance. Nearly 70% of patients had symptoms of cough, chest pain, or superior vena cava syndrome. Myasthenia and other thymoma-associated syndromes are rare.<sup>120</sup>

The histologic classification of thymic carcinoma was proposed by Levine and Rosai<sup>126</sup> and revised by Suster and Rosai.<sup>120</sup> The tumors are classified broadly as low or high grade. Low-grade tumors include squamous cell carcinoma, mucoepidermoid carcinoma, and basaloid carcinoma. High-grade neoplasms include lymphoepithelioma-like carcinoma and small cell, undifferentiated, sarcomatoid, and clear cell carcinomas.<sup>120,122,123,127</sup> The classification of thymic carcinoma has prognostic significance, with low-grade tumors following a favorable clinical course (median survival rates of 25.4 months to more than 6.6 years) because of a low incidence of local recurrence and metastasis, and high-grade malignancies exhibiting an aggressive clinical course (median survival of only 11.3 to 15.0 months).<sup>120,121</sup> and <sup>122</sup> Although the Masaoka thymoma staging system<sup>120,122,124</sup> and a proposed tumor-node-metastasis classification system<sup>125</sup> have been used in staging thymic carcinoma, their utility is unproven. The histologic grade remains the best prognostic indicator.

The optimal treatment of thymic carcinoma remains undefined, but currently a multimodality approach, including surgical resection, postoperative radiation, and chemotherapy, is recommended. Initial surgical resection followed by radiation has been used in most studies.<sup>47,111,120,122</sup> and <sup>125</sup> Complete resection should be attempted, but usually is not possible.<sup>122</sup> One analysis noted a 9.5-month median survival after resection and postoperative electron beam radiation therapy,<sup>111</sup> with a trend toward improved survival in other studies.<sup>122,123</sup> Chemotherapy with cisplatin-based regimens similar to those used with thymomas have produced variable responses in small numbers of patients.<sup>120,122</sup> and <sup>124</sup> Combinations of doxorubicin, cyclophosphamide, and vincristine also have generated partial responses, as has the combination of 5-fluorouracil and leukovorin.<sup>124</sup> Use of neoadjuvant chemotherapy has been reported in a small number of patients.<sup>124</sup>

The prognosis of thymic carcinoma is poor because of early metastatic involvement of pleura; lung; mediastinal, cervical, and axillary lymph nodes; bone; and liver.<sup>120</sup> The overall survival rate at 5 years is approximately 35%.<sup>120,122</sup> Improved survival has been correlated with encapsulated tumors, lobular growth pattern, low mitotic activity, and low histologic grade.<sup>120</sup>

### THYMIC CARCINOID

Thymic carcinoid tumors are rare, with fewer than 125 reported cases.<sup>128,1,129,130</sup> and <sup>131</sup> They occur predominantly in males<sup>129</sup> and originate from normal thymic Kulchitsky's cells, which are part of the amine precursor uptake and decarboxylation (APUD) group. Most have the ability to manufacture peptides, amines, kinins, and prostaglandins. They are aggressive tumors that invade locally and commonly metastasize to regional lymph nodes. Metastases occur in 70% of patients within 8 years of initial diagnosis.<sup>131</sup>

The gross appearance of thymic carcinoids is similar to that of thymomas, but they are rarely encapsulated. Microscopically, the tumors exhibit a ribbon-like growth pattern with rosette formation in a fibrovascular stroma. The cells are small, round, or oval with eosinophilic cytoplasm and uniformly round nuclei.<sup>129</sup> Immunohistochemical studies reveal argyrophilic cells that stain with cytokeratin and neuronal-specific enolase. Electron microscopy reveals the presence of secretory granules.<sup>130</sup> Thymic carcinoids, like other foregut carcinoids, are associated with Cushing's syndrome, multiple endocrine neoplasia and, rarely, the carcinoid syndrome.<sup>129,130,131</sup> and <sup>132</sup>

The diagnosis of thymic carcinoid often requires open surgical biopsy. Complete surgical resection is recommended, although recurrence is common.<sup>129,130</sup> and <sup>131</sup> The effectiveness of adjuvant therapy is unproven, but most reports advocate adjuvant radiotherapy for incompletely resected tumors.<sup>129,130</sup> and <sup>131</sup> Chemotherapy rarely has been used in cases of metastatic or recurrent disease.<sup>129,130</sup> and <sup>131</sup>

Although a 5-year survival rate of 60% has been reported with complete surgical resection,<sup>130</sup> local recurrences are common and distant metastases occur in approximately 30% of patients.<sup>129</sup> The long-term prognosis is generally poor.

### THYMOLIPOMA

Thymolipomas are rare benign neoplasms composed of mature adipose and thymic tissue, and they account for 1% to 5% of thymic neoplasms.<sup>133</sup> These tumors are also known as *lipothymomas*, *mediastinal lipomas with thymic remnants*, and *thymolipomatous hamartomas*.<sup>133,134</sup> In a review of 27 patients, Rosado-de-Christenson et al.<sup>134</sup> noted an equal gender distribution and a mean age of 27 years. Approximately 50% of patients presented with symptoms of vague chest pain, dyspnea, and tachypnea. Others have reported, in adults only, an association with myasthenia gravis, red cell aplasia, hypogammaglobulinemia, lichen planus, and Graves' disease.<sup>133,135</sup>

Thymolipomas are soft, lobulated, encapsulated tumors that originate in the anterior mediastinum. They often attain a large size before becoming symptomatic. They frequently conform to the shape of the cardiac and mediastinal structures and are found in the anterior inferior mediastinum "draped along the diaphragm" and connected to the thymus by a small pedicle.<sup>134</sup> Microscopically, the tumors are composed of thymic tissue, often with calcified Hassall's corpuscles, and more than 50% adipose tissue.<sup>134</sup> Histologically, thymolipomas do not appear malignant, and malignant transformation does not occur.<sup>134</sup> Treatment involves complete resection. Long-term follow-up is not available, but recurrences have not been reported.

### GERM CELL TUMORS

The vast majority of germ cell tumors arise within gonadal tissue, but the mediastinum is the most common site for the development of extragonadal germ cell tumors. They are most commonly seen in the anterior mediastinum and account for 10% to 15% of all primary mediastinal tumors.<sup>2</sup> These tumors have generated considerable interest because of their uncertain histogenesis.

### ETIOLOGY

Extragonadal germ cell tumors are found along the body's midline from the cranium (pineal gland) to the presacral area. This line corresponds to the embryologic urogenital ridge. It is presumed that these tumors arise from malignant transformation of germ cells that have abnormally migrated during embryonic development.<sup>136,137</sup> Mediastinal germ cell neoplasms account for only 2% to 5% of all germinal tumors, but they constitute 50% to 70% of all extragonadal tumors.<sup>137,138</sup>

### CLASSIFICATION

Mediastinal germ cell tumors are broadly classified as benign or malignant. Benign tumors include mature teratomas and mature teratomas with an immature component of less than 50%. Malignant germ cell tumors are divided into seminomas (dysgerminomas) and nonseminomatous tumors. Nonseminomatous tumors include embryonal carcinomas, choriocarcinomas, yolk sac tumors, and immature teratomas.<sup>139</sup> Seminomas may exist in a pure form, but any elevation of AFP indicates the presence of an element of a nonseminomatous tumor. In addition, mediastinal germ cell tumors have a propensity to develop a component of non-germ cell malignancy (e.g., rhabdomyosarcoma, adenocarcinoma, permeative neuroectodermal tumor), which can become the predominant histology.

## INCIDENCE AND CLINICAL PRESENTATION

In adults, benign germ cell tumors have no gender predilection, but 90% of malignant germ cell tumors occur in men.<sup>136</sup> In the pediatric population, both benign and malignant extragonadal germ cell tumors occur with equal gender distribution. Mediastinal germ cell tumors are most commonly diagnosed in the third decade of life, but patients as old as 60 years of age have been reported. The incidence of these neoplasms is equal in all races. Many patients with benign tumors, including 50% of teratomas, are asymptomatic; however, 90% to 100% of patients with malignant tumors have symptoms of chest pain, dyspnea, cough, fever, or other findings related to compression or invasion of surrounding mediastinal structures.<sup>140,141</sup>

## DIAGNOSIS

Mediastinal germ cell tumors are most often detected on the basis of standard chest radiographs. More than 95% of the chest films are abnormal, with almost all masses noted in the anterior mediastinum. Three percent to 8% of tumors arise within the posterior mediastinum.<sup>136</sup> Chest CT scans demonstrate the extent of disease, relationship to surrounding structures, and presence of cystic areas and calcification within the tumor. Abdominal imaging should be performed to assess for possible liver metastases. Although careful examination of the testes, including a testicular ultrasound, should always be performed, an isolated tumor mass in the anterior mediastinum without retroperitoneal involvement is not consistent with a testicular primary tumor. It is not necessary to perform blind orchiectomy or testicular biopsy in patients with normal physical examinations and unremarkable ultrasound findings.<sup>137</sup>

Determination of serum tumor markers is important in the diagnosis and follow-up of mediastinal germ cell tumors. Immunoassays for b-HCG and AFP should be obtained in all patients possessing mediastinal masses suspicious for germ cell tumors. Elevations of b-HCG and AFP confirm a malignant component to the tumor. AFP or b-HCG, or both, are elevated in 80% to 85% of nonseminomatous germ cell tumors, with AFP being detected in 60% to 80% of these tumors and b-HCG in 30% to 50%.<sup>140</sup> Patients with benign teratomas have normal markers, and patients with pure seminoma may have low levels of b-HCG, but AFP is not detected.

## TERATOMAS

Benign teratomas are the most common mediastinal germ cell tumor, accounting for 70% of the mediastinal germ cell tumors in children and 60% of those in adults.<sup>136</sup> They can be seen in any age group but most commonly occur in adults from 20 to 40 years of age. There is no gender predilection.

Teratomas may be solid or cystic in appearance and are often referred to as *dermoid cysts* if unilocular. Teratomas contain elements from all three germ cell layers, with a predominance of the ectodermal component in most tumors, including skin, hair, sweat glands, sebaceous glands, and teeth. Mesoderm is represented by fat, smooth muscle, bone, and cartilage. Respiratory and intestinal epithelium are often seen as the endodermal component. The majority of mediastinal teratomas are composed of mature ectodermal, mesodermal, and endodermal elements and exhibit a benign course. Immature teratomas phenotypically may appear as a malignancy derived from these ectodermal, mesodermal, and endodermal elements. These latter tumors behave aggressively and generally are not responsive to systemic therapy.

Treatment of “benign” mediastinal teratoma includes complete surgical resection, which results in excellent long-term cure rates. Radiotherapy and chemotherapy play no role in the management of this tumor. The tumor may be adherent to surrounding structures, necessitating resection of pericardium, pleura, or lung. Complete resection of teratomas should be the goal of treatment. Resection of mature teratomas has been shown to result in prolonged survival with little chance of recurrence.<sup>139,142</sup> Immature teratomas are potentially malignant tumors; their prognosis is influenced by the anatomic site of the tumor, patient age, and the fraction of the tumor that is immature.<sup>139</sup> In patients younger than 15 years, immature teratomas behave similarly to their mature counterparts. In older patients, they may behave as highly malignant tumors. Currently, a trial of cisplatin-based combination chemotherapy (up to 4 cycles of cisplatin, etoposide, and bleomycin or vinblastine, ifosfamide, and cisplatin, if responding) is frequently administered before attempted surgical resection.<sup>139</sup>

## SEMINOMA

Primary pure mediastinal seminoma accounts for approximately 35% of malignant mediastinal germ cell tumors; it is principally seen in men aged 20 to 40 years.<sup>143</sup> Seminomas grow slowly and metastasize later than their nonseminomatous counterparts, and they may have reached a large size by the time of diagnosis. Symptoms are usually related to compression or even invasion of surrounding mediastinal structures. Twenty percent to 30% of mediastinal seminomas are asymptomatic when discovered,<sup>143</sup> but metastases are present in 60% to 70% of patients. Pulmonary and other intrathoracic metastases are most commonly seen. Extrathoracic metastases usually involve bone.<sup>143</sup>

The treatment of mediastinal seminoma has evolved since the early 1970s. Definitive conclusions regarding treatment are difficult, because several potentially curative treatment modalities exist. Seminomas are extremely radiosensitive tumors, and for many years, high-dose mediastinal radiation has been used as initial therapy, resulting in long-term survival rates of 60% to 80%.<sup>144</sup> A review of recommendations for radiation therapy treatment in extragonadal seminoma was reported by Hainsworth and Greco.<sup>143</sup> Thirty-five to 40 Gy are the most commonly used radiation doses. Doses as low as 20 Gy have been reported to be curative, but most reports note a significant local recurrence rate with doses of less than 45 Gy.<sup>143</sup> Radiation portals should include a shaped mediastinal field and both supraclavicular areas.<sup>143</sup>

Mediastinal seminoma often presents as bulky, extensive, and locally invasive disease, requiring large radiotherapy portals. These portals result in excessive irradiation of surrounding normal lung, heart, and other mediastinal structures. Additionally, for 20% to 40% of patients in whom local control is achieved, treatment can be expected to fail at distant sites.<sup>136,143</sup>

Chemotherapy was previously used only in advanced gonadal seminoma, but encouraging results and the above-mentioned problems with radiotherapy have led to broadened indications; chemotherapy is now being used as initial therapy in many patients with bulky tumors. Pure mediastinal seminoma falls into the intermediate-risk category of the new International Staging System for Germ Cell Tumors. Even patients with visceral metastases fall into this intermediate category and, as such, have a prognosis with cisplatin-based combination chemotherapy exceeding 75% for 5-year survival. Standard systemic therapy consists of cisplatin-based combination chemotherapy. Lemarie and coworkers<sup>140</sup> reported that 12 of 13 patients treated experienced complete remission, with two recurrences after treatment. Cisplatin-based combination therapy achieved a complete response in three of five patients treated by Giaccione.<sup>145</sup> A collective review of 52 patients was undertaken by Hainsworth and Greco.<sup>143</sup> Fourteen patients had received prior radiation therapy, but all underwent chemotherapy with cisplatin and various combinations of cyclophosphamide, vinblastine, bleomycin, or etoposide. Complete responses to treatment were noted in 85% of patients, and 83% were long-term disease-free survivors.<sup>143</sup> Although chemotherapy appears to be a superior modality in these small series, radiotherapy is less toxic, and the high salvage rate with chemotherapy after radiotherapy failure makes selection difficult. Therefore, the recommended treatment is either supradiaphragmatic radiation or 4 cycles of cisplatin-based combination chemotherapy.

The management of patients with residual radiographic abnormalities after chemotherapy is controversial. Studies have shown that the residual mass is a dense scirrhous reaction in 85% to 90% of patients, and the presence of viable seminoma is rare. Others have shown a 25% incidence of residual viable seminoma in these patients treated with chemotherapy followed by resection of residual masses larger than 3 cm.<sup>146</sup> Close observation without surgery is recommended for residual masses after chemotherapy unless the mass enlarges.<sup>147,148</sup> Empiric radiation therapy is not recommended.<sup>143</sup>

Most authors believe that surgery does not play a role in the definitive treatment of seminoma.<sup>144</sup> In addition, surgical debulking of large tumors has not been shown to be of benefit in improving local control or survival.<sup>143</sup>

All patients with mediastinal seminoma should be treated with curative intent. Isolated mediastinal seminoma without evidence of metastatic disease is most often

managed with radiotherapy alone, with an excellent prognosis and long-term survival. Locally advanced and bulky disease may be treated initially with cisplatin-based combination chemotherapy, usually 4 cycles of cisplatin and etoposide, with radiotherapy, and followed by salvage chemotherapy (vinblastine, ifosfamide, and cisplatin) in the event of recurrence.<sup>149</sup> Patients with distant metastases should undergo cisplatin-based combination chemotherapy as initial treatment.

## NONSEMINOMATOUS GERM CELL TUMORS

Nonseminomatous germ cell tumors include choriocarcinoma, embryonal carcinoma, teratoma, and endodermal sinus (yolk sac) tumors. They may occur in pure form, but in approximately one-third of cases, multiple cell types are present. Other malignant components, including adenocarcinomas, squamous cell carcinomas, and sarcomas, may be present or even represent the predominant tissue type, as usually occurs in immature teratomas.

Nearly 85% of nonseminomatous germ cell tumors occur in men, with a mean age of 29 years.<sup>136</sup> Karyotypic analyses have been performed on a number of these patients, and the 47,XXY pattern of Klinefelter's syndrome has been found in up to 20% of patients.<sup>136</sup> Mediastinal nonseminomatous germ cell tumors are most commonly found in the anterior mediastinum and appear grossly as lobulated masses with a thin capsule. They are frequently invasive at the time of diagnosis, with almost 90% of patients exhibiting symptoms. They appear on CT scans as large inhomogeneous masses containing areas of hemorrhage and necrosis. Elevated levels of <sup>b</sup>-HCG are seen in 30% to 50% of patients, and AFP is detected in 60% to 80%.

These tumors carry a poorer prognosis than either pure extragonadal seminoma or their gonadal nonseminomatous counterparts, and all patients with primary mediastinal nonseminomatous germ cell tumors fall into the poor risk category of the new International Germ Cell Consensus Classification.<sup>150</sup> Eighty-five percent to 95% of patients have obvious distant metastases at the time of diagnosis. Common metastatic sites include lung, pleura, lymph nodes, liver, and, less commonly, bone.<sup>143</sup>

A number of non-germ cell malignant processes have been found in association with nonseminomatous germ cell tumors. One of the most interesting is that found in association with acute megakaryocytic leukemia. Other hematologic malignancies, such as acute myeloid leukemia, acute nonlymphocytic leukemia, erythroleukemia, myelodysplastic syndrome, malignant histiocytosis, and thrombocytosis, have all been reported. These malignancies may antedate the discovery of the germ cell tumor or occur synchronously. Solid tumors, such as embryonal rhabdomyosarcoma, small cell undifferentiated carcinoma, neuroblastoma, and adenocarcinoma have been described and occur more frequently in primary mediastinal tumors compared to gonadal germ cell neoplasms.<sup>137</sup>

The diagnosis of nonseminomatous germ cell tumors can often be made without tissue biopsy.<sup>144</sup> In many centers, the presence of an anterior mediastinal mass in a young male with elevated serum tumor markers (AFP and b-HCG) is adequate to initiate treatment. If a tissue diagnosis is deemed necessary, fine-needle guided aspiration with cytologic staining for tumor markers may be used for confirmation. An anterior mediastinotomy provides the best exposure for open biopsy if necessary.<sup>144</sup>

Treatment of nonseminomatous germ cell tumors incorporates cisplatin-based chemotherapy, which has markedly improved the prognosis in these patients. In the past, long-term survival after treatment of nonseminomatous germ cell tumors was very rare; today, however, overall complete remission rates of 40% to 50% are obtained in most series.<sup>139,140,143,145</sup> Treatment is initiated with cisplatin-containing combination chemotherapy, which often includes etoposide and bleomycin. Treatment should be administered every 3 weeks for 4 courses; patients should then be restaged with serum tumor markers and CT scans of the chest and abdomen.<sup>143</sup> In a collective review of 158 patients undergoing a variety of combination chemotherapeutic regimens for the initial treatment of nonseminomatous germ cell tumors, complete responses were noted in 54% of patients, and 42% were long-term disease-free survivors.<sup>143</sup>

Patients with negative tumor markers and no radiographic evidence of residual disease after initial chemotherapy require no further treatment. Persistent elevation of serum tumor markers, particularly if they begin to rise again, usually requires salvage chemotherapy.<sup>143</sup> Patients with normal serum tumor markers but radiographic evidence of residual masses after induction chemotherapy should undergo surgical resection 4 to 6 weeks after completion of chemotherapy.<sup>143,144</sup> Complete resection should be attempted, because debulking procedures provide no benefit. Patients found to have residual viable germ cell tumor undergo 2 additional cycles of chemotherapy. Patients with immature teratoma or non-germ cell malignancies can simply be observed after complete resection. Nichols<sup>136</sup> reports complete remissions in 18 of 31 patients using this regimen, and other series report complete remission rates of 50% to 70%, with long-term survival rates approximating 50%.<sup>136</sup> Equivalent results are obtained in all histologic subtypes.

The treatment of recurrent disease is difficult, because patients with relapsing mediastinal nonseminomatous germ cell tumors do extraordinarily poorly with salvage therapy, such as vinblastine, ifosfamide, and cisplatin<sup>151</sup>; optimal therapy has not been determined. Standard salvage chemotherapy has not proven beneficial, and few patients achieve durable remissions. High-dose chemotherapy with stem cell rescue is effective in only a few selected patients.<sup>152,153</sup> Most patients are candidates for experimental phase I trials.

## MESENCHYMAL TUMORS

Mediastinal mesenchymal tumors, or soft tissue tumors, originate from the connective tissue elements of the mediastinum. Smooth and striated muscle, lymphatic tissue, fat, and vascular tissue all give rise to a variety of neoplasms, which may be benign or malignant. Most of these tumors also occur in other parts of the body and are discussed in detail elsewhere in the chapter on soft tissue sarcomas.

Mesenchymal tumors account for approximately 6% of primary mediastinal neoplasms.<sup>2</sup> They are less common in the mediastinum than in other locations. Approximately 55% are malignant, and there is no gender predilection.<sup>10,154</sup> In general, treatment of malignant mesenchymal tumors involves combination therapy, including surgical resection, radiation therapy, and chemotherapy. Benign tumors should be completely excised, after which little chance of recurrence remains.

Lipomas are the most common mesenchymal tumor of the mediastinum, representing 2% of all mediastinal neoplasms.<sup>8</sup> Benign lipomas are most often located in the anterior mediastinum. They may grow to large size without symptoms. Treatment is complete resection, and although local recurrence is possible, it is unusual. Malignant liposarcoma is more commonly found in the posterior mediastinum.

Fibromas are encapsulated asymptomatic tumors that may grow to a very large size. Fibrosarcomas often are symptomatic malignancies associated with hypoglycemia. Fibromas are cured with complete surgical excision, but fibrosarcomas are usually unresectable and respond poorly to radiation and chemotherapy.<sup>10</sup> Leiomyomas, leiomyosarcomas, rhabdomyomas, rhabdomyosarcomas, synovial cell sarcomas, mesotheliomas, and xanthogranulomas also occasionally occur in the mediastinum.<sup>8,154</sup>

Vascular tumors of the mediastinum include hemangiomas, hemangioendotheliomas, and benign and malignant hemangiopericytomas.<sup>8,154</sup> Ten percent to 30% of all vascular tumors are malignant.<sup>10</sup> Mediastinal hemangiomas represent 0.5% of all mediastinal neoplasms but are the most common vascular tumor.<sup>155</sup> They may be cavernous or capillary and are often associated with hemangiomas in other areas of the body.<sup>155,156</sup> Sixty percent occur in the anterior mediastinum, and 25% occur posteriorly.<sup>10</sup> Diagnosis is best accomplished by CT scan or MRI, in which phleboliths may be seen in 30% of these tumors. Angiography is important in identifying and embolizing major feeding vessels before surgery.<sup>156</sup> Total excision is considered the treatment of choice; however, large, incompletely resected hemangiomas usually do not recur.<sup>155</sup>

Lymphangiomas, also known as *cystic hygromas*, often extend into the anterior mediastinum from the cervical area. Seventeen percent are located exclusively in the mediastinum. They tend to enlarge as patients grow, particularly during puberty. Treatment involves surgical resection, but this is often difficult because of adherence to surrounding structures. Response to radiation is variable.<sup>10</sup> Other lymphatic soft tissue tumors include lymphangiosarcoma and lymphangiopericytoma.

## NEUROGENIC TUMORS

Thoracic neurogenic tumors occur most commonly in the posterior mediastinum but occasionally are found in the anterior mediastinum and elsewhere. They compose between 19% and 39% of all mediastinal tumors<sup>157,158</sup> and 75% of posterior mediastinal tumors.<sup>159</sup> They originate from peripheral nerves (nerves of the brachial plexus and intercostal nerves), autonomic sympathetic ganglia and, rarely, from the vagus nerve.<sup>160</sup> Neurogenic tumors in the anterior mediastinum originate in

chemoreceptor paragangliomas.

Whereas neurogenic tumors in infants and children are frequently malignant and often present with metastatic disease,<sup>161</sup> in adults the majority of these tumors are benign. They occur without gender predilection at any age but are more likely in young adults. Often asymptomatic, they are solitary (except in neurofibromatosis) and found on a routine chest x-ray. Benign tumors can attain a considerable size. They frequently arise in the paravertebral sulcus from the posterior roots of the spinal nerves at the zone of transition between the central and peripheral myelin.<sup>162</sup> They also may arise on the posterior portion of the spinal nerve root in the spinal canal and grow through the intervertebral foramen into the paravertebral area, giving rise to the appearance of a dumbbell- or hourglass-shaped tumor. These tumors must be recognized to plan an appropriate operation in conjunction with a neurosurgeon. Depending on their size and location, lesions may cause spinal cord compression, pain, paresthesias, Horner's syndrome, and muscle atrophy. Superior vena cava syndrome, dyspnea, cough, and bony erosions, which wrongly suggest a malignant process, also have been described.

### NEURILEMOMA (SCHWANNOMA)

Neurilemoma (schwannoma) is the most common tumor in the paravertebral sulcus. Arising from the intercostal nerve sheath, the tumor is encapsulated, white or yellowish pink in color, with calcifications and cystic degeneration. Histologically, it is composed of uniform slender biphasic fusiform cells with elongated, twisted nuclei that have a tendency to align in a regimented or palisaded appearance.<sup>163</sup> The tumor may contain large blood vessels and may be a source of considerable blood loss during surgical removal. Schwannoma may be further differentiated into melanotic, adenomatous, or psammomatous tumors ([Fig. 32-2](#)).<sup>163</sup>

**FIGURE 32-2.** Schwannoma in the paravertebral area in the apex of the left chest.

### NEUROFIBROMA

Neurofibromas are most often benign and asymptomatic. However, they can have an intradural as well as an extradural component and may cause symptoms of cord compression. They are not encapsulated and may have a plexiform appearance.<sup>164</sup> Microscopically, neurofibromas have a heterogeneous cell population, but Schwann cell differentiation is not always present.<sup>157</sup> Neurogenic tumors can be differentiated from leiomyomas, meningiomas, and fibrous histiocytomas by the immunohistochemical identification of S-100 protein. Solitary neurofibromas are cured by surgical excision.

Neurofibromas can occur as multiple lesions in von Recklinghausen's disease.<sup>165</sup> Neurofibromatosis is inherited as an autosomal dominant trait affecting both genders equally; however, approximately one-half of the cases are sporadic.<sup>166,167</sup> The clinical features vary and include hyperpigmented café au lait skin spots, skin and subcutaneous multiple neurofibromas (hamartomas), scoliosis, bowing of long bones, disorders of sexual development, and multiple neurogenic tumors and malignancies, such as malignant schwannomas.<sup>168,169</sup> Mediastinal neurofibromas may be multiple and appear as long plexiform masses. Histologically, they consist of large nerve fibers mixed with connective tissue stroma containing Schwann cells and fibroblasts. Surgical intervention is justified for lesions located in the spinal canal that cause spinal cord or nerve root compression. The prognosis generally is poor.<sup>170</sup>

### MALIGNANT SCHWANNOMA

Malignant schwannomas are the malignant counterparts of neurilemmomas and neurofibromas. Ultrastructural studies, however, cannot always document Schwann cells in these tumors derived from nerve sheaths, and therefore the terms *malignant nerve sheath tumor*, *neurogenic sarcoma*, and *neurofibrosarcoma* are sometimes used.<sup>170</sup> Malignant nerve sheath tumors commonly are large. They are painful and may cause superior vena cava obstruction; Horner's syndrome; dyspnea; dysphagia; hoarseness; and invasion of the lung, bones, and aorta, depending on their location and size.

The diagnostic criteria for malignant nerve sheath tumors are controversial.<sup>166</sup> Origin from a major nerve, presence of Schwann cells and S-100 protein, the diagnosis of neurofibromatosis, and nuclear palisading are important features. Histologic findings include hypercellularity, pleomorphic dense nuclei, multiple and abnormal mitoses, and invasion of the surrounding structures.<sup>160</sup> The malignant nerve sheath tumors are usually large (often larger than 5 cm in diameter), partially encapsulated, soft, and gray, with hemorrhage and necrosis. Histologically, they are composed of spindle cells with comma-shaped, irregular nuclei. Neural and perineural invasion, mature cartilage, bone, striated muscle, squamous differentiation, and mucin-secreting glands also may be seen.<sup>171,172</sup>

Clinically, these tumors are aggressive, locally invasive, and highly metastatic. They often recur after resection, leading to a 75% 5-year survival rate. Patients with neurofibromatosis and a malignant nerve sheath tumor have a 15% to 30% 5-year survival rate. Combination chemotherapy is recommended in stage III and IV disease ([Fig. 32-3](#)).

**FIGURE 32-3. A:** Malignant neurofibroma, initially considered to be nonresectable, in a 34-year-old man. **B:** The tumor was resected after a combination of chemotherapy and radiation therapy.

### TUMORS OF SYMPATHETIC GANGLIA

Mediastinal ganglioneuromas are found in the posterior mediastinum along the sympathetic chain in children older than 4 years and in adults in the third and fourth decades of life. Occasionally, a neuroblastoma may mature into a benign ganglioneuroma.<sup>173,174</sup> and <sup>175</sup> The tumor usually is asymptomatic, but sometimes presents with Horner's syndrome and, rarely, with diarrhea caused by production of vasoactive intestinal polypeptide. Ganglioneuromas have a smooth contour and contain areas of

stippled calcification. They may resemble other benign neurogenic tumors, causing rib erosions.<sup>176</sup> Microscopically, spindle cell proliferation is seen that appears identical to that in a neurofibroma, except that ganglioneuromas exhibit the presence of large ganglion cells.<sup>160</sup> Ganglioneuromas are benign tumors, although regional lymph nodes may contain islands of tumor cells attributed to matured neuroblasts.<sup>166</sup> They require complete excision.

## NEUROBLASTOMAS

Although neuroblastomas can be found in any location in which embryonic neuroblasts migrated from the neural crest, they usually originate in the adrenal glands and along nerve plexuses. In the chest, they occur along the sympathetic trunk in the paravertebral sulcus. This tumor is the most common malignancy of early childhood, occurring most commonly in the first 2 years of life. Patients with mediastinal neuroblastomas usually are symptomatic and frequently have metastatic disease.<sup>177,178</sup> Symptoms are related to local compression (Horner's syndrome and heterochromia of the iris) or to systemic release of vasoactive peptides, such as catecholamines, vanillylmandelic acid, homovanillic acid, and 3-methoxy-4-hydroxy phenylglycol. Encephalopathy, myasthenia, and Cushing's syndrome may be present.<sup>179</sup> Radiographically, a mass is seen in the posterior mediastinum with stippled calcifications, skeletal erosion, and occasional extension into the spinal canal.

Pathology reveals lobulated gray or red tumors with hemorrhagic areas. Microscopically, small cells with scant cytoplasm and polygonal nuclei exhibit various degrees of differentiation. Intracytoplasmic neurofilaments and neurosecretory granules and extracellular material seen on electron microscopy distinguish neuroblastoma from other childhood tumors, such as lymphoma, Ewing's sarcoma, and rhabdomyosarcoma.<sup>160</sup>

Neuroblastomas are highly aggressive tumors. Survival depends on the age of the patient, the stage of disease, the location of the tumor, and histologic differentiation. The prognosis is better in patients younger than 1 year of age and in patients with limited, well-differentiated tumors. Neuroblastomas may regress spontaneously or undergo maturation into ganglioneuromas. Ganglioneuroblastomas have a better prognosis than neuroblastomas.<sup>180</sup> The staging system for neuroblastoma shown in Table 32-13 was developed to help guide therapy. Treatment for stage I and II disease is simple surgical resection, although adjuvant postoperative radiotherapy is recommended for stage II tumors. For stage III and IV, a combination of chemotherapy and radiation is advised.

Stage	Description
I	Tumor is limited to site of origin.
II	Tumor extends beyond site of origin, or when limited to site of origin, has metastatic regional lymph nodes present on same side.
III	Tumor extends to contralateral side.
IV	Metastases are present beyond regional lymph nodes.

TABLE 32-13. Staging System for Neuroblastoma

## GRANULAR CELL TUMOR

Granular cell tumors (granular cell myoblastomas) are considered benign. They are found in the posterior mediastinum and are derived from Schwann cells. They are soft, gray, and poorly circumscribed tumors consisting of uniform polygonal cells either in nests or strands with eosinophilic granular cytoplasm and a stroma of fibrous connective tissue.<sup>181</sup> Resection is always curative.

## DIAGNOSIS

Although posterior mediastinal neoplasms are predominately neurogenic, other tumors also must be considered in the differential diagnosis. Goiters, esophageal leiomyomas, solitary fibrous tumors, and bronchial/esophageal duplication cysts all have been reported. Once identified, the nature of these lesions, their relationship to other structures, and the presence of distant metastases can be determined by CT scans. MRI scans can define vascular involvement and provide multiplanar views that are valuable in assessing tumor extension into paravertebral foramina. An iodine 131 nuclear scan may be helpful if a goiter is suspected.

Histologic diagnosis is not necessary before surgery. However, if surgical resection is not contemplated, a definitive diagnosis is required for further treatment planning. This diagnosis generally requires a generous biopsy obtained by an open surgical procedure or a CT-guided core-needle biopsy.

## MANAGEMENT

If no contraindication is present, resection of all neurogenic tumors is advised. Neurogenic tumors grow and can cause life-threatening symptoms, depending on their size and location. Therefore, observation of neurogenic tumors may be justified only with a stable, asymptomatic, benign tumor in an otherwise poor surgical candidate. The standard approach uses a posterolateral thoracotomy incision, removing the tumor with normal tissue margins. More recently, thoroscopic resection of small- to moderate-size tumors has been reported. In dumbbell tumors, the intraspinal component should be removed first. The mortality rate for surgical resection is less than 1%. Complications include Horner's syndrome and chylothorax. Surgery on tumors with spinal canal involvement may be complicated by direct spinal cord trauma, ischemia from spinal artery injury and, rarely, an epidural hematoma with spinal cord compression.

## PRIMARY CARDIAC MALIGNANCIES

The vast majority of tumors involving the heart and pericardium are metastatic.<sup>182,183</sup> In addition, most primary cardiac tumors are benign myxomas, 75% to 80% of which arise from the left atrium. Other benign primary cardiac neoplasms include rhabdomyoma, fibroma, lipoma, hemangioma, teratoma, and fibroelastoma. Primary malignant cardiac tumors make up one-fourth of all primary cardiac neoplasms and most commonly originate from the atria.<sup>184,185</sup> Most are some variant of sarcomas,<sup>186</sup> including angiosarcoma,<sup>187</sup> rhabdomyosarcoma,<sup>188</sup> fibrosarcoma,<sup>189</sup> lymphoma, malignant fibrous histiocytoma,<sup>190</sup> and mesothelioma of the pericardium.<sup>191</sup> Pheochromocytomas also occur as primary cardiac neoplasms.

A high index of suspicion is imperative in establishing a diagnosis, because the presenting symptoms often mimic other nonneoplastic cardiac pathology. Whole body gallium scans,<sup>192</sup> echocardiography, CT, and MRI all may serve to localize a primary cardiac neoplasm. Up to 80% of primary cardiac malignancies present with systemic metastases<sup>193</sup> and have clinical evidence of right heart failure, and many develop tamponade. Surgical resection is required for cure; however, negative margins usually are not possible.<sup>194</sup>

Chemotherapy and external-beam radiation can be administered after surgery, although a report of 15 cases treated at the Institut Gustave-Roussy does not support the routine use of adjuvant chemotherapy for primary cardiac sarcomas.<sup>190</sup> There has been a report of a patient receiving neoadjuvant (induction) chemotherapy, which resulted in a response and subsequent surgical resection.<sup>195</sup>

New surgical techniques, including orthotopic and autotransplantation, may be beneficial in carefully selected patients.<sup>196,197</sup> With the advent of "gating" technology and sophisticated treatment planning, more accurate targeting with electron beam radiation therapy may be possible, similar to stereotactic radiosurgery of the brain. At times, a pericardial window may be required to palliate symptoms of pericardial tamponade. Currently, long-term survival is rare.<sup>198,199</sup>

## INTRODUCTION

The specific etiologic factors and pathogenetic mechanisms underlying the development of cancers of the gastrointestinal tract appear to be complex and heterogeneous. Although likely etiologic factors include environmental and dietary exposures, defining specific agents that influence cancer risk remains a major challenge. Only limited progress has been made in treatment of patients with advanced gastrointestinal cancer. In light of the obstacles that hinder our ability to more effectively prevent and treat gastrointestinal cancers, it is important to recognize that increasingly significant advances have been made in the gastrointestinal cancer field. Arguably, some of the most encouraging advances have been successes in defining the specific genetic defects that underlie inherited forms of gastrointestinal cancer and in gaining new insights into the constellation of molecular alterations present in sporadic tumors. For most gastrointestinal tumor types, the prevalence and nature of mutations in several distinct oncogenes and tumor suppressor genes have been defined. The conversion of cellular protooncogenes into oncogenic variant alleles (gene copies) can result from specific point mutations or rearrangements that alter gene structure and function or from chromosomal rearrangements or gene amplifications that disrupt regulated expression of the protooncogene. Tumor suppressor gene inactivation can result from localized mutations, complete loss of the gene, or via epigenetic alterations that interfere with gene expression. At present, only somatic (arising in nongerm cells during the patient's lifetime) mutations in protooncogenes have been detected in gastrointestinal cancers. Similarly, the vast majority of tumor suppressor gene mutations are also somatic. Nevertheless, germline (constitutional) mutations in tumor suppressor genes do underlie cancer predisposition in several hereditary gastrointestinal cancer syndromes.

It is not possible to present in this chapter an exhaustive summary detailing the molecular alterations present in each gastrointestinal cancer type. Rather, the focus is on molecular defects in colorectal carcinoma. The basis for this focus is several-fold. Colorectal cancer is the most common gastrointestinal cancer type in the United States and several other regions of the world. Understanding of colorectal cancer molecular biology is generally more advanced than that of other gastrointestinal cancer types, although significant progress has been made on the molecular front in esophageal, gastric, pancreatic, and hepatocellular cancer. Some of the frequent genetic alterations in colorectal carcinomas are also common in other gastrointestinal cancers. Furthermore, study of the multiple genetic alterations that accumulate during the adenoma-carcinoma sequence in the colon has nicely illustrated the means by which multiple genetic alterations underlie tumor initiation and progression in other organ sites. Although the focus of this chapter is on colorectal cancer, selected advances in the molecular biology of pancreatic and esophageal cancer also are highlighted. The main objectives of this chapter are to review the following: (1) the genetic basis of two inherited forms of colorectal cancer; (2) some of the frequent molecular abnormalities in colorectal tumors; (3) common molecular abnormalities in pancreatic and esophageal cancer; and (4) the potential clinical utility of genetic alterations in early detection and clinical management of gastrointestinal cancer.

## COLORECTAL CANCER AS A MODEL SYSTEM

In 2000, approximately 140,000 U.S. residents will be diagnosed with colorectal cancer, and roughly 55,000 will die from the disease.<sup>1</sup> Males and females have a nearly equal likelihood of being diagnosed, and the cumulative lifetime risk of colorectal cancer in the United States is 6%, with an average age of 66 years at diagnosis. Individuals with a family history of colorectal cancer in a first-degree relative, but who otherwise lack clinical features or a family history consistent with a highly penetrant colorectal cancer syndrome [e.g., familial adenomatous polyposis (FAP) or hereditary nonpolyposis colorectal cancer (HNPCC)], are approximately twice as likely to develop colorectal cancer as those without a family history.<sup>2,3,4</sup> and <sup>5</sup> Other risk factors for colorectal cancer include older age, inflammatory bowel disease, a diet high in fat and animal proteins, and a sedentary lifestyle.<sup>2</sup> Many other exposures, including excess alcohol consumption, smoking, aspirin and nonsteroidal antiinflammatory agent use, and specific dietary components (e.g., micronutrients such as calcium and selenium), have been extensively studied for their effects on colorectal cancer risk.<sup>6,7,8,9,10,11,12,13,14,15,16,17,18,19,20</sup> and <sup>21</sup> However, these exposures remain uncertain risk factors. The reality is that the main dietary and environmental factors that contribute to most colorectal cancers are poorly defined, and perhaps 75% of all incident colorectal cancers arise in people with no well-defined risk factor. On the other hand, many colorectal cancers may be preventable, and improved adoption and implementation of current screening recommendations might save up to 30,000 lives per year.<sup>22</sup>

## THE ADENOMA-CARCINOMA SEQUENCE IN THE COLON

A variety of benign gastrointestinal tumors have been identified, but a generic term for a localized lesion projecting above the surrounding mucosa is *polyp*. Most colorectal polyps, particularly small polyps, are of hyperplastic type, and most data indicate hyperplastic polyps are not a precursor to cancer. The adenomatous polyp, or adenoma, is generally thought to be the important precursor lesion to cancer. Adenomas arise from glandular epithelium, and their common features are the dysplastic morphology and abnormal differentiation of the epithelial cells in the lesion. The prevalence of adenomas in the United States is approximately 25% by age 50 years and perhaps 50% by age 70.<sup>22</sup> The notion that most colorectal carcinomas arise from an adenomatous precursor is well supported. First, longitudinal studies have shown a high risk of colorectal cancer development in individuals whose adenomas are not removed,<sup>23,24</sup> and polypectomy decreases colorectal cancer risk.<sup>25</sup> Second, foci of carcinoma can often be detected in adenomatous polyps, and residual regions of adenomatous glands are often noted in carcinoma specimens.<sup>26,27</sup> and <sup>28</sup> Third, individuals affected by syndromes that strongly predispose to the development of adenomas, such as FAP (discussed later in [Familial Adenomatous Polyposis and the APC Gene](#)), invariably develop colorectal carcinomas by the third to fifth decades of life if their colons are not removed.<sup>29,30</sup> Nevertheless, only a fraction of adenomas progress to cancer, and progression probably occurs over a period measured in years to decades. Adenomas larger than 1 cm in size are estimated to have a 15% chance of progressing to carcinoma over a 10-year period.<sup>31</sup>

Besides adenomatous polyp development, another clinical situation associated with markedly increased colorectal carcinoma risk is ulcerative colitis (UC). Patients with longstanding and severe UC have a 20-fold or greater increase in colorectal cancer risk compared to the general population.<sup>32,33</sup> It is generally thought that carcinomas arise in UC patients as a result of chronic cycles of mucosal injury and subsequent regrowth, a situation that may bear some similarity to processes underlying the development of some esophageal, gastric, and pancreatic cancers. Possible cancer precursors in patients with UC include dysplasia and flat adenomatous plaques.<sup>28</sup> The relationship of these presumptive precursors to one another and to the villous regeneration seen in UC patients as well as the relative risks of progression of the lesion types are less well defined than the adenoma-carcinoma sequence.

## INHERITED COLORECTAL CANCER SYNDROMES

Highly penetrant, inherited predisposition syndromes are estimated to account for only approximately 5% of colorectal cancers.<sup>30</sup> Hereditary syndromes predisposing to colorectal cancer include FAP and HNPCC. Other rare syndromes also associated with an increased, but less clearly defined, risk of colorectal or other

gastrointestinal cancers include Peutz-Jeghers syndrome, Cowden disease, and juvenile polyposis syndrome. The genes responsible for these inherited syndromes have been identified (Table 33.1-1). Consistent with the Knudson two-hit model for tumor suppressor genes, in all cases, inactivating mutations in both alleles are present in the cancers that arise in affected individuals. However, these other cancer predisposition syndromes are rarer than FAP and HNPCC, and with the exception of the *DPC4* (deleted in pancreatic cancer locus 4) gene, defects in the other familial gastrointestinal cancer genes do not appear to contribute to sporadic cases of colorectal cancer. For these reasons, the discussion here focuses on FAP and HNPCC.

Syndrome	Features Commonly Seen in Affected Individuals	Gene Defect
Familial adenomatous polyposis	Multiple adenomas (polyps) of the colon and rectum; desmoid polyps and carcinoma; fundal gland polyps in the stomach; congenital hypertrophy of retinal pigment epithelium	<i>APC</i>
Gardner's syndrome	Same as familial adenomatous polyposis, also desmoid tumors and epidermoid cysts	<i>APC</i>
Turcot's syndrome	Polyps and colorectal cancer with brain tumors (medulloblastoma)	<i>APC</i>
Attenuated adenomatous polyposis coli	Colorectal cancer and brain tumors (glioblastoma)	<i>APC</i> , <i>PMS2</i>
Neurofibromatosis type 1	Brain tumor (NF1 polyp), although neural network in polyp may be due to NF1 polyp gene or to another common mutation in high levels	<i>APC</i> gene (sporadic cases), <i>NF1</i>
Neurofibromatosis type 2	Colorectal cancer without adenomatous polyposis; other cancers include endometrial, ovarian, and stomach cancer; neurofibromatosis, meningioma, and brain tumors	<i>PMS2</i> , <i>PMS1</i> , <i>PMS3</i> , <i>RECQL4</i> , <i>TGF-<math>\beta</math></i> type III, other genes
Hamman-Rich syndrome	Hamman-Rich syndrome (refers to the gastrointestinal tract); neurofibromatosis; neurofibromin 1; fibrous dysplasia of the skull and facial bones	<i>SMAD4</i> , <i>TGF-<math>\beta</math></i>
Cowden disease	Multiple hamman-Rich syndrome; thyroid, fibrous dysplasia of the skull and facial bones, and CNS; increased risk of breast and thyroid cancer; risk of CNS cancer is greatly reduced	<i>PDS</i>
Juvenile polyposis syndrome	Multiple hamman-Rich syndrome; polyps with proliferation in colonic and stomach; increased risk of colorectal and stomach cancer and a greatly reduced risk of CNS cancer	<i>DPC4</i> , <i>PDS</i> , other genes

TABLE 33.1-1. Genetics of Inherited Colorectal Tumor Syndromes

## FAMILIAL ADENOMATOUS POLYPOSIS AND THE ADENOMATOUS POLYPOSIS COLI GENE

FAP is an autosomal dominant syndrome affecting approximately 1 in 8000 individuals and accounting for approximately 0.5% of all colorectal cancers.<sup>29,30</sup> Hundreds to thousands of adenomas arise in the colon and rectum of affected individuals by the third to fourth decades of life, and the lifetime incidence of colorectal cancer in untreated FAP patients approaches 100%. Several variants of FAP have been described, including Gardner's syndrome, in which affected individuals may manifest extensive polyposis, epidermoid cysts, desmoid tumors, and osteomas; and Turcot's syndrome, in which polyposis and brain tumors can be seen. Families with attenuated forms of FAP (termed *attenuated adenomatous polyposis coli*) also have been described in which some affected individuals have only 10 to 20 adenomas by 50 years of age. The gene that, when mutant, underlies FAP, Gardner's syndrome, and other variants is the adenomatous polyposis coli (*APC*) tumor suppressor gene on chromosome 5q.<sup>34</sup>

*APC* is a large gene encoding a protein of 2843 amino acids, and its last exon is remarkable because it contains a 6579-base-pair open reading frame.<sup>34,35</sup> Although a fraction of germline mutations in FAP patients extinguish *APC* gene expression, more than 95% of the known mutations lead to premature truncation of APC protein synthesis. The mutations are located predominantly in the 5' half of the gene, and two "hot spots" at codons 1061 and 1309 account for approximately 35% of the germline mutations identified (Fig. 33.1-1).<sup>35</sup> Some phenotypic variation among those with FAP appears to be because of the specific mutant *APC* allele present.<sup>34</sup> In spite of the genotype-phenotype associations noted, however, patients with identical *APC* mutations can display distinct clinical features. For instance, some patients with germline mutations between *APC* codons 1403 and 1578 manifest Gardner's syndrome features, whereas others with the identical mutation do not. Similarly, despite the fact FAP patients have a greatly increased risk of medulloblastoma and an elevated risk of hepatoblastoma and thyroid cancers, only a subset of individuals within any one kindred manifests these tumors.

FIGURE 33.1-1. Schematic representation of adenomatous polyposis coli (*APC*) protein functional domains with respect to germline and somatic mutations. A putative domain involved in homo-oligomerization (?dimerization) of APC is located at the amino-terminus. Also noted are a series of repeats of unknown function with similarity to the *Drosophila* armadillo protein; sequences known to mediate binding to b-catenin and axin and regulate b-catenin's abundance and localization; a basic domain in the carboxy terminal third of the protein that appears to facilitate complexing with microtubules (MT), and sequences near the carboxy terminus of APC that interact with the EB1 protein and the human homologue of the *Drosophila* disc large (hDlg) protein. Germline mutations in the *APC* gene (predominantly chain-terminating) are dispersed throughout the 5' half of the sequence, with two apparent "hot spots" at codons 1061 and 1309. Somatic mutations in the *APC* gene in colorectal cancer appear to cluster in a region termed the *mutation cluster region*, and mutations at codons 1309 and 1450 are most common. (Modified from Fearon ER. Oncogenes and tumor suppressor genes. In: Abeloff MD, Armitage JO, Lichter AS, Niederhuber JE, eds. *Clinical oncology*, 2nd ed. New York: Churchill Livingstone, 2000:77, with permission.)

### Somatic Adenomatous Polyposis Coli Mutations in Sporadic Tumors

Notwithstanding the *APC* gene's critical role in FAP, the gene has an even more prominent role in sporadic colorectal tumors. Roughly 80% of sporadic colorectal adenomas and carcinomas have somatic mutations inactivating *APC*.<sup>34,35</sup> The nature and distribution of *APC* somatic mutations are similar to the germline mutations in FAP patients (see Fig. 33.1-1), with nearly all somatic mutations leading to premature truncation of the APC protein.<sup>35</sup> The data suggest somatic *APC* mutations are an early and likely rate-limiting event in adenoma development. First, *APC* mutations have essentially the same frequency in small adenomas as advanced adenomas and carcinomas,<sup>34,35</sup> in contrast to other somatically mutated genes in colorectal tumors, such as *K-ras* and *p53*. Second, somatic *APC* mutations are found in the earliest lesions analyzed, including microscopic adenomas composed of only a few dysplastic glands. As predicted by the Knudson model, both *APC* alleles appear to be inactivated in most colorectal adenomas and all colorectal carcinomas. *APC* somatic mutations are infrequent in tumor types other than colorectal carcinomas,<sup>34,35</sup> with the possible exception of ampullary carcinomas and desmoid tumors.<sup>36,37 and 38</sup>

### Adenomatous Polyposis Coli Protein Function

The APC protein has been suggested to regulate cell-cell adhesion, cell migration, or possibly apoptosis.<sup>34,35,36</sup> Presently, perhaps the best-characterized function of the APC protein is regulation of b-catenin. b-Catenin, an abundant cellular protein, was first identified because of its role in linking the cytoplasmic domain of the E-cadherin cell-cell adhesion molecule to the cortical actin cytoskeleton, via b-catenin's binding to a-catenin. The truncated (mutant) forms of the APC protein present in most colorectal carcinomas lack sequences crucial for binding b-catenin and other cellular proteins (see Fig. 33.1-1). A model has been developed to explain the significance of APC's interaction with b-catenin and these other proteins (Fig. 33.1-2). The model indicates that, in collaboration with the glycogen synthase kinase-3 (GSK3) and axin proteins, APC regulates b-catenin's abundance in the cytoplasm and nucleus. In 75% to 80% of colorectal cancers, APC is mutated and unable to regulate b-catenin (see Fig. 33.1-2B). As a result, b-catenin accumulates in the cytoplasm and nucleus, and complexes with transcription factors of the Tcf (T-cell factor family), such as Tcf-4. On binding to Tcf proteins, b-catenin functions as a transcription co-activator, activating expression of Tcf-regulated genes. The identities and functions of Tcf-regulated target genes are not yet well understood, although they may include powerful stimulators of cell growth and proliferation (e.g., the *c-MYC* and *cyclin D1* genes) and extracellular proteases [e.g., matrix metalloproteinase 7 (MMP-7)] that might facilitate invasion and metastasis.<sup>40,41,42 and 43</sup> Further

compelling support for the notion that gene activation by the Tcf/b-catenin complex is critical in colorectal tumorigenesis includes the fact that, in a subset of the 20% of colorectal cancers lacking *APC* mutations, somatic mutations in b-catenin have been found.<sup>44,45</sup> and<sup>46</sup> These mutations are present in the phosphorylation consensus sequences near b-catenin's amino-terminus, and they appear to render mutant b-catenin proteins resistant to regulation by the APC/GSK3/axin complex. Consequently, b-catenin accumulates and activates Tcf-regulated genes (see [Fig. 33.1-2C](#)).

**FIGURE 33.1-2.** A model indicating the function of the adenomatous polyposis coli (*APC*), axin, and glycogen synthase kinase 3b (*GSK3b*) proteins in the regulation of b-catenin (*b-cat*) in normal cells, and the consequence of *APC* or *b-cat* defects in cancer cells. *b-cat* is an abundant cellular protein, and much of it is often bound to the cytoplasmic domain of the E-cadherin (*E-cad*) cell-cell adhesion protein. **A:** In normal cells, the proteins *GSK3b*, *APC*, and axin function to promote degradation of free cytosolic *b-cat*, probably as a result of phosphorylation of the N-terminal sequences of *b-cat* by *GSK3b*. *GSK3b* activity and *b-cat* degradation are inhibited by activation of the wntless (*WNT*) pathway, as a result of the action of the Frizzled receptor and disheveled (*DSH*) signaling protein. **B:** Mutation of *APC* in colorectal and other cancer cells results in accumulation of *b-cat*, binding to Tcf-4, and transcriptional activation of Tcf-4 target genes, such as *c-MYC*, *cyclin D1*, *MMP-7*, and *PPAR $\alpha$*  (see text). **C:** Point mutations and small deletions in *b-cat* in cancer cells inhibit phosphorylation and degradation of *b-cat* by *GSK3b* and *APC*, with resultant activation of *c-MYC* and other Tcf-4 target genes. (Modified from Fearon ER. Human cancer syndromes: clues to the origin and nature of cancer. *Science* 1997;278:1043, with permission.)

### Variant Adenomatous Polyposis Coli Alleles and Familial Aggregations of Colorectal Cancer

In the majority of colorectal cancer patients, no definitive hereditary component can be identified. These cases are, therefore, labeled "sporadic." Nonetheless, some of these apparently sporadic cases may well have some hereditary component. The identification of genes that confer weak predisposition to colorectal cancer has been and will continue to be a difficult issue for the colorectal cancer field. One study has, however, provided fascinating insights into familial forms of colorectal cancer that do not manifest as highly penetrant cancer syndromes.<sup>47</sup> The study was initiated because of the identification of eight colorectal adenomas in a 39-year-old patient with a family history of colorectal cancer. The diagnosis of HNPCC was excluded by molecular analyses (the genetics of HNPCC is discussed in the section [Hereditary Nonpolyposis Colorectal Cancer](#)). Diagnosis of FAP was unlikely based on clinical findings. Nonetheless, detailed studies of the patient's *APC* alleles were carried out. No germline *APC* mutation of the type predicted to truncate the *APC* protein was identified. However, a sequence change at codon 1307 was found, resulting in a substitution of lysine (K) for isoleucine (I). Thus, the allele was referred to as the *APC* I1307K allele. The resultant amino acid change was not predicted to alter *APC* protein function. However, at the DNA sequence level, the variant allele had an extended mononucleotide tract in the coding region of (A)<sub>8</sub> instead of (AAATAAAA).

Further studies revealed that the I1307K allele was present only in individuals of Ashkenazi Jewish origin and that those who carried the I1307K allele had a twofold increase in their lifetime risk of colorectal cancer.<sup>47</sup> Moreover, the localized somatic *APC* mutations in colorectal cancers arising in individuals carrying the I1307K allele were nearly always small insertions or deletions in or adjacent to the (A)<sub>8</sub> mononucleotide repeat tract. The somatic mutations created frameshifts that lead to truncated *APC* proteins. Therefore, the I1307K allele appears to be a novel cancer predisposition allele that does not exert its effects by directly altering *APC* function. Rather, the I1307K allele contains a DNA sequence tract that is a more frequent target for somatic mutation in colonic epithelial cells than the normal *APC* sequence. Future studies may establish that subtle or unconventional mutations in *APC* or other genes also contribute to gastrointestinal cancer predisposition by similar mechanisms.

### HEREDITARY NONPOLYPOSIS COLORECTAL CANCER

HNPCC was first described by Warthin in 1913.<sup>48</sup> Roughly half a century later, Lynch and others described kindreds with autosomal dominant patterns of colorectal and other cancers that were not associated with extensive intestinal polyposis.<sup>49,50</sup> Before identification of the specific inherited mutations that underlie HNPCC, clinical criteria useful for ascertaining families most likely to be affected by HNPCC were outlined.<sup>51</sup> These criteria, termed the *Amsterdam [or International Collaborative Group (ICG)] criteria*, are as follows: (1) FAP must be excluded; (2) at least three affected relatives must have histologically verified colorectal cancer, and at least two of the affected must be first-degree relatives; (3) the affected individuals must be from at least two successive generations; and (4) at least one of the affected individuals must have developed colorectal cancer before age 50 years. Although the ICG criteria do not identify all individuals who are ultimately found to carry HNPCC gene defects, the criteria have proven useful for focusing attention on families most likely to have HNPCC. Based on the criteria, HNPCC cases are estimated to account for 2% to 4% of all colorectal cancer cases. Of note, other cancers often seen in families with HNPCC, including endometrial, ovarian, gastric, and hepatobiliary and urinary tract cancers, are not included in the ICG criteria.

### Mutations in DNA Mismatch Repair Genes in Hereditary Nonpolyposis Colorectal Cancer

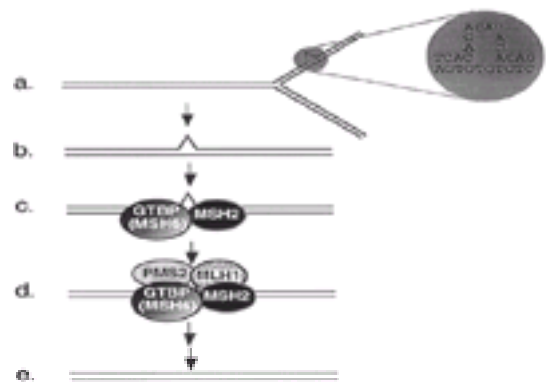

Unlike FAP, in which the intestinal polyposis phenotype usually permits diagnosis of patients by their late teenage years or early 20s, no distinct clinical features are seen in asymptomatic carriers of HNPCC defects.<sup>30,52</sup> As such, definitively ascertaining the phenotypic status of an individual in an HNPCC kindred who has not yet developed cancer is nearly impossible, thus rendering genetic linkage analyses for mapping predisposition genes very challenging. The initial genetic studies of HNPCC were successful in excluding a role for variant *APC* alleles in cancer predisposition in HNPCC, as well as in excluding a role for several of the genes known to be somatically mutated in sporadic colorectal cancers.<sup>53,54</sup> A subsequent search of the entire genome for linkage to HNPCC was undertaken using microsatellite sequence markers. Microsatellites are short, repetitive DNA sequence tracts, scattered throughout the genome, and many microsatellite tracts show polymorphic length variation among normal individuals. One such search for linkage in several HNPCC kindreds was successful in mapping a cancer predisposition gene to chromosome 2p.<sup>55</sup> In other HNPCC families, a predisposition gene was localized to chromosome 3p.<sup>56</sup> In yet other families with HNPCC, no evidence for linkage to either chromosome 2p or 3p was found. These findings clearly established that HNPCC was a genetically heterogeneous disease.<sup>55,56</sup>

In an attempt to establish the potential relevance of the Knudson two-hit model for HNPCC genes, investigators sought to demonstrate that loss of the wild-type HNPCC allele on chromosome 2p was present in cancers from individuals carrying a defect in that particular predisposition gene. However, not only was there no loss of heterozygosity (LOH) of chromosome 2p sequences in the cancers, but the microsatellite DNA sequences demonstrated marked variation in length in tumor tissue compared to the patient's normal tissue.<sup>57</sup> In fact, in any given cancer from an HNPCC patient, microsatellite sequence alterations were present at many loci scattered throughout the genome. This curious phenotype was termed the *microsatellite instability (MI)* or *replication error-positive (RER+)* phenotype. Independent studies revealed that the MI/RER+ phenotype was present in approximately 15% of apparently sporadic colorectal cancers.<sup>58,59</sup>

The demonstration that the MI/RER+ phenotype was present in all cancers from HNPCC patients and some sporadic cancers piqued the interest of researchers in the DNA mismatch repair field because similar instability phenotypes had previously been seen in yeast strains with defective DNA mismatch repair genes. The prediction that germline mutations in one allele of a DNA mismatch repair gene might underlie HNPCC was quickly borne out. A functional link between MI/RER+ and mutated mismatch repair genes was first provided by the demonstration that cancer cell lines derived from patients with HNPCC have at least a 100-fold increased rate of mutation in repetitive DNA sequence tracts (e.g., microsatellites).<sup>60</sup> Subsequently, a human homologue of the bacterial *mutS* mismatch repair gene, designated *MSH2*, was mapped to chromosome 2p,<sup>61</sup> and one allele was found to be mutated in the germline of some HNPCC patients.<sup>62</sup> As might have been predicted, based on the fact that mismatch repair is dependent on the function of a number of distinct proteins ([Fig. 33.1-3](#)), other DNA mismatch repair genes were found to be mutated in subsets of HNPCC patients, including the *MLH1* gene on chromosome 3p, the *PMS1* gene on 2q, the *PMS2* gene on 7q, and the *GTBP/MSH6* gene on chromosome

2p.63,64,65,66,67 and 68 Together, germline mutations in the *MSH2* and *MLH1* genes account for more than 60% of the known mutations present in HNPCC patients (Table 33.1-2).

**FIGURE 33.1-3.** Mismatch repair pathway in human cells. **A,B:** During DNA replication, DNA mismatches may arise, such as from strand slippage (shown) or misincorporation of bases (not shown). **C:** The mismatch is recognized by MutS homologues, perhaps most often *MSH2* and *GTBP/MSH6*, although another MutS homologue, *MSH3*, may substitute for *GTBP/MSH6* in some cases. **D,E:** MutL homologues, such as *MLH1* and *PMS2*, are recruited to the complex, and the mismatch is repaired through the action of a number of proteins, including an exonuclease, helicase, DNA polymerase, and ligase. (Modified from ref. 34, with permission.)

Gene	Chromosomal Location	Escherichia coli Homologue	Estimated Percentage of HNPCC Families with Mutation
<i>MSH2</i>	2p16-14	MutS	30
<i>MLH1</i>	3p21	MutL	35
<i>PMS1</i>	3p21	MutL	Rare (1 family)
<i>PMS2</i>	7p22	MutL	<5 (2 families)
<i>GTBP/MSH6</i>	2p16-14	MutS	Rare (1 or 2 families)
Other/unknown	?	?	25-30*

\*Estimate is based on the fact that colorectal carcinomas from approximately 95% of patients with a family history meeting the Amsterdam (International Collaborative Group) criteria displayed the microsatellite instability/replication error-positive phenotype. (Lin R, Parsons R, Papadopoulos N, et al. Analysis of mismatch repair genes in hereditary non-polyposis colorectal cancer patients. *Nat Med* 1996;2:98.)

**TABLE 33.1-2.** Germline Mismatch Repair Gene Mutations in Hereditary Nonpolyposis Colorectal Cancer (HNPCC)

The prevalence of germline mutations in the DNA mismatch repair genes in colorectal cancer patients not meeting the ICG criteria for HNPCC remains uncertain, although some preliminary findings have emerged. A study of 509 consecutive patients in a Finnish tumor registry found that the MI/RER+ phenotype was present in cancers from 12% of patients.<sup>69</sup> Ten of the 63 patients with MI/RER+ cancers (16%, or roughly 2% of total patients) had a detectable germline mutation in *MLH1* or *MSH2*. Patients with an identifiable germline mutation had either a first-degree relative with endometrial or colorectal cancer, were younger than 50 years, or had a previous colorectal or endometrial cancer. Another study of patients from the Netherlands and Norway found that 26% of the 184 families with clustering of colorectal cancer studied had germline mutations in the *MSH2* or *MLH1* genes.<sup>70</sup> Similar to the Finnish study, germline *MSH2* or *MLH1* mutations were more likely to be found in individuals from families meeting the ICG criteria, individuals whose cancers arose at a particularly young age, or individuals whose families manifested both colorectal and endometrial cancer.

### Mechanisms and Mutation Targets in Cancers with Defective Mismatch Repair

In normal cells of a patient with HNPCC, DNA repair is not usually impaired, because the cells have a wild-type copy of the gene. During tumorigenesis, however, and perhaps even at an early stage in that process, the wild-type allele of the gene that is mutant in all of the patient's constitutional cells is inactivated by a somatic mutation. Then, affected cells manifest a mutator phenotype and accumulate mutations in a much more rapid fashion. HNPCC appears, therefore, to be a disease with more rapid tumor progression from a benign, initiated clone to frank malignancy. In HNPCC patients, the transition from a small adenoma to carcinoma has been estimated to take only 3 to 5 years, instead of the 20 to 40 years believed required for development of most sporadic carcinomas.<sup>28,52</sup>

Germline mutations in the known mismatch repair genes have only been detected in 2% to 4% of colorectal cancer patients. However, approximately 15% of all colorectal cancers manifest the MI/RER+ phenotype, implying that germline or somatic mutations in mismatch repair pathway genes may be present in a substantial fraction of colorectal cancers, regardless of the patient's family history. Only a fraction of the 15% of apparently sporadic colorectal cancers with the MI/RER phenotype develop as the result of a germline mutation in a known mismatch repair gene, such as *MSH2* or *MLH1*. Similarly, somatic mutations in *MSH2*, *MLH1*, or other mismatch repair genes are present in only a small fraction of the apparently sporadic cancers with the MI/RER+ phenotype.<sup>52,71</sup> Although germline or somatic mutation of known mismatch repair genes are infrequent, inactivation of the *MLH1* gene via epigenetic changes, such as DNA hypermethylation of the *MLH1* promoter, appears to be a causal factor in the majority of "sporadic" colorectal cancer cases with the MI/RER+ phenotype.<sup>72,73</sup>

The vast majority of the mutations arising in cells with the MI/RER+ phenotype are likely to have either no effect on cell growth or detrimental effects. Such mutations do not promote the clonal outgrowth and evolution characteristic of colorectal tumor progression. A subset of mutations do, however, activate oncogenes, such as *K-ras*, or inactivate tumor suppressor genes, such as *APC* and *p53*.<sup>57,74,75</sup> Some genes may be more frequent targets for somatic mutations in cancers with MI/RER+. For instance, genes that contain repetitive DNA sequence tracts, such as microsatellites, would appear to be likely targets for mutation in MI/RER+ tumors. A gene containing a mononucleotide repeat tract in its coding sequence and that is frequently inactivated in colorectal cancers with the MI/RER+ phenotype is the transforming growth factor- $\beta$  (TGF- $\beta$ ) type II receptor (RII).<sup>76,77</sup> The *Rii* gene is a likely tumor suppressor gene, because both copies of the gene are inactivated by mutations in more than 90% of MI/RER+ colorectal cancers, and TGF- $\beta$  is known to be a strong inhibitor of cell proliferation in many normal epithelial tissues, including colonic epithelial cells. Approximately 15% of microsatellite stable colorectal carcinomas also show biallelic inactivation of *Rii*, although the mutations are located in regions other than the gene's mononucleotide tract.<sup>78</sup> Other suggested candidates for somatic inactivation in MI/RER colorectal cancers include *bax*, a p53-regulated gene in some cell types and whose protein product functions in promoting apoptosis,<sup>79</sup> and *E2F-4*, a gene encoding a transcription factor that may regulate cell-cycle progression.<sup>80</sup> Moreover, not all genes that appear to be more frequently mutated in MI/RER+ cancers than in microsatellite-stable cancers need themselves be mutated in microsatellite sequence tracts. The *b-catenin* gene appears to be more frequently activated by mutations in MI/RER+ colon cancers than in microsatellite-stable cancers, and the missense mutations seen are not associated with a microsatellite sequence tract.<sup>81,82</sup>

## ONCOGENE AND TUMOR SUPPRESSOR GENE MUTATIONS IN COLORECTAL TUMOR PROGRESSION

Somatic mutations in the *APC* gene appear to be an early and, perhaps, rate-limiting event in the development of upwards of 75% to 80% of colorectal adenomas and carcinomas. Presumably, mutations in other tumor suppressor genes and oncogenes play an important role in tumor progression. Some of the genes believed critical in colorectal tumor progression are discussed in this chapter and summarized in Table 33.1-3. Another important point already noted is that roughly 15% of colorectal carcinomas display the MI/RER+ phenotype. Although the MI/RER+ cancers have a very elevated rate of localized mutations (e.g., point mutations and small deletions and insertions), they are generally near diploid, with few chromosome losses or gains. In contrast to MI/RER+ cancers, upwards of 85% of colorectal carcinomas display frequent chromosome losses and gains.<sup>83</sup> Defects in genes that regulate formation of the mitotic spindle and proper alignment and segregation of chromosomes at mitosis may underlie the chromosome instability phenotype, although few of the specific defects likely to underlie the chromosome instability phenotype in cancer have been defined.

Gene	Estimated Frequency of Mutation	Comments
<i>K-RAS</i>	40-50%	Mutations involve the codons 12, codon 13, and codon 61; mutations in codon 12 are more common than 13.
<i>N-RAS</i>	<1%	Codon 12 and 13 mutations.
<i>H-RAS</i>	<1%	Codon 12 and 13 mutations.
<i>BRAF</i>	5-10%	Case 7 mutation involves a codon 600 deletion after transcriptional phosphorylation sites in the kinase domain; mutations occur in 50-90% of colorectal cancers with microsatellite instability.
<i>APC</i>	70-80%	Truncation and frameshift mutations in 1 half of genes leading to protein inactivation in 80% of cases; similar mutations in adenomas and carcinomas; mutations in 10% of adenomas and 40% of carcinomas; mutations in 10% of adenomas and 40% of carcinomas; mutations in 10% of adenomas and 40% of carcinomas; mutations in 10% of adenomas and 40% of carcinomas.
<i>p53</i>	60-70%	Mutations involve most frequently codons 175, 245, 248, 273, or 282; mutations in one allele are common in 10% of adenomas.
<i>TGF-<math>\beta</math>1</i>	30-40%	Approximately 50% of 90-95% cases have mutations in both alleles; most often in the 10-15% hyperplastic phase; approximately 10% of adenomas have mutations in both alleles, although not linked to the polypoid phase.
<i>DPC4/SMAD4</i>	30-40%	Truncation, frameshift, deletion, and deletion mutations; mutations in one allele rarely occur; mutations in 10% of adenomas and 40% of carcinomas.
<i>SMAD2</i>	<1%	Mutations involve most frequently codons 175, 245, 248, 273, or 282; mutations in one allele are common in 10% of adenomas.
<i>MSI</i>	>90%	Loss of heterozygosity; ML, microsatellite instability; MSI, microsatellite instability; SMAD2, SMAD2-related SMAD2 gene; SMAD4, SMAD4-related SMAD4 gene; TGF- $\beta$ 1, transforming growth factor- $\beta$ 1; APC, adenomatous polyposis coli; p53, p53 tumor suppressor gene.

**TABLE 33.1-3.** Summary of Selected Somatic Mutations in Colorectal Carcinomas

## K-RAS AND OTHER ONCOGENE DEFECTS

The *RAS* genes encode small guanosine triphosphatases with critical roles in signal transduction downstream of growth factor receptors, such as that for epidermal growth factor. *K-RAS* is the most frequently mutated of the three *RAS* genes, with *K-RAS* mutations found in approximately 50% of colorectal adenomas larger than 1 cm in size and a similar fraction of carcinomas.<sup>84,85</sup> and <sup>86</sup> The majority of *K-RAS* mutations are at codon 12, but codon 13 is mutated in 15% to 20% of cases, and codon 61 is infrequently affected. *N-RAS* mutations are infrequent, and no *H-RAS* mutations have been reported in colorectal tumors. In adenomatous polyps, *K-RAS* mutations have been associated with features predictive of subsequent progression to cancer—increased size and more severe dysplasia<sup>85,87,88</sup>—although *K-RAS* mutations also have been seen in some colonic lesions with very reduced or no malignant potential (e.g., hyperplastic polyps and aberrant crypt foci lacking dysplasia).<sup>89,90,91</sup> and <sup>92</sup> Notwithstanding these latter observations, inactivation of mutant *K-RAS* activity in advanced colorectal cancer cells abrogates the tumorigenic growth properties of colorectal carcinoma cells.<sup>93</sup> Hence, *RAS* gene mutations in colorectal tumors have a role not only in promoting growth of small adenomas to larger and more clinically significant lesions, but also in maintenance of the fully neoplastic phenotype in advanced carcinomas.

Somatic mutations in other protooncogenes, including amplifications of the *MYC*, *MYB*, *cyclin D1*, and *HER-2/NEU* genes, have been found in only a small percentage of colorectal cancers (see [Table 33.1-3](#)).<sup>94,95</sup> Gain of function mutations in the *b-catenin* gene are present in 2% to 8% of colorectal cancers and appear to render the mutant b-catenin protein resistant to regulation by the APC protein.<sup>45,81,82,96,97</sup> Like APC mutations, *b-catenin* mutations appear to be an early event in adenoma formation. Finally, some oncogene mutations may vary in their frequency in colorectal carcinomas, depending on whether the tumor has the MI/RER+ phenotype. For example, although *K-RAS* mutations have a roughly similar prevalence in MI/RER+ carcinomas compared with cases with chromosome instability, *b-catenin* mutations appear to be more common in MI/RER+ cases.<sup>82</sup>

## THE P53 GENE

Allelic loss or LOH is believed to be a common mechanism for tumor suppressor gene inactivation in the roughly 85% of colorectal carcinomas that manifest the chromosome instability phenotype. Although allelic loss of chromosome 17p is an infrequent event in adenomas, 17p allelic losses can be detected in nearly 70% to 75% of colorectal carcinomas.<sup>85,98</sup> Wild-type *p53* alleles are presumed to be targeted for inactivation by 17p LOH, because the remaining *p53* allele is mutated in the majority of colorectal tumors with 17p LOH, most often at codons 175, 245, 248, 273, or 282.<sup>99,100</sup> and <sup>101</sup> Only a small subset of carcinomas lacking 17p LOH have *p53* mutations, and most adenomas lack 17p LOH and *p53* mutation. Hence, mutation and LOH of *p53* appear to arise most frequently during the transition from adenoma to carcinoma. The biologic selection for *p53* inactivation at this point in tumor development is not well understood. However, based on our understanding of the functions of *p53* in cell-cycle checkpoints at the G<sub>1</sub>/S and G<sub>2</sub>/M boundaries and in apoptosis,<sup>102,103,104</sup> and <sup>105</sup> the selection for *p53* inactivation may reflect the fact that several distinct stresses on tumor cells activate apoptotic pathways in cells with wild-type *p53* function. Such stresses may include DNA strand breakage, hypoxia, and reduced access to glucose or other nutrients. Loss of *p53* function at the critical juncture between adenoma and carcinoma may facilitate continued growth and the acquisition of invasive properties in the face of stresses that might otherwise severely limit tumor cell growth in the colon and rectum.

## CHROMOSOME 18Q LOSS OF HETEROZYGOSITY

Chromosome 18q LOH is seen in approximately 60% to 70% of primary colorectal cancers and, rarely, in adenomas, with the exception of large villous adenomas that contain a focus of carcinoma.<sup>85,86</sup> The prevalence of 18q LOH rises to nearly 90% to 100% in liver metastases from colorectal primary tumors.<sup>106</sup> The findings suggest a role for inactivation of a chromosome 18q tumor suppressor gene(s) in the later stages of tumor progression and metastasis. Several studies have reported that patients whose primary colorectal cancers have 18q LOH have an increased likelihood of distant metastasis and death from their disease, independent of stage and perhaps other clinical and histopathologic features.<sup>107,108,109,110</sup> and <sup>111</sup> In colorectal carcinomas, a common region of LOH includes bands 18q12.3 to 18q21.3, and the *DCC* (deleted in colorectal cancer) gene at 18q21.2 has been suggested to be a candidate tumor suppressor gene.<sup>112,113</sup> In some studies, loss of *DCC* transcripts and protein has been noted in more than 50% of colorectal cancers, although the specific mechanisms accounting for *DCC* inactivation are not well understood.<sup>114</sup> Few specific mutations in the *DCC* gene have been identified, perhaps in part because the *DCC* gene spans more than 1.35 million base pairs.<sup>115</sup> *DCC* encodes a transmembrane protein that functions in transducing signals from netrin chemoattractant and cell guidance factors.<sup>114</sup> Some findings indicate that, in the absence of netrin, the *DCC* protein may induce apoptosis in epithelial cells,<sup>116</sup> perhaps reconciling why there might be selection for genetic or epigenetic inactivation of *DCC* in colorectal carcinomas.

Although *DCC* remains a candidate tumor suppressor gene in colorectal and other tumors, a well-established tumor suppressor gene, termed *DPC4/SMAD4* (also known as), is also present in the 18q21 region.<sup>117,118</sup> As is discussed later (see the section [Gene Defects in Pancreatic Carcinoma](#)), *DPC4* is mutated in 50% to 55% of pancreatic carcinomas. Furthermore, germline *DPC4* mutations have been seen in a subset of patients affected by juvenile polyposis syndrome.<sup>119</sup> Those with juvenile polyposis syndrome develop benign hamartomatous polyps in the intestinal tract, and they also have an increased risk of colorectal and gastric cancer. Nevertheless, *DPC4* is mutated in only approximately 10% to 15% of colorectal carcinomas and much less frequently in other gastrointestinal tumors, such as gastric and esophageal carcinomas.<sup>120,121,122,123,124,125,126</sup> and <sup>127</sup> The *DPC4*-related *SMAD2* gene is also located in the region of 18q commonly affected by LOH in colorectal carcinomas. A major role for *SMAD2* in colorectal cancer has been excluded, because *SMAD2* is inactivated in less than 5% of colon carcinomas and *SMAD2* alterations are rare or absent in other gastrointestinal carcinomas.<sup>127,128,129,130,131</sup> and <sup>132</sup> Based on the frequencies of mutations in *DPC4* and *MADR2*, neither gene appears to be the primary tumor suppressor gene targeted for inactivation by 18q LOH in colorectal cancer. Nonetheless, inactivation of either of the two genes likely to have an important role in the tumor process, because each gene encodes a protein that functions to transduce TGF- $\beta$  growth regulatory signals, and TGF- $\beta$  has significant growth inhibitory effects on colonic epithelial cells. Whether *DCC* inactivation is associated with 18q LOH in the majority of colorectal carcinomas or whether additional novel tumor suppressor genes are present in the 18q12.3-q21.3 region remains to be determined.

## GENE DEFECTS IN PANCREATIC CARCINOMA

Ductal epithelial cells in the pancreas comprise less than 5% of the total cell mass in the organ, yet they are the origin of the most common form of pancreatic carcinoma. The natural history of the progression from normal epithelium to carcinoma in the pancreas is less well understood than in the colon. However, it appears that a flat hyperplastic lesion in which the epithelium changes from its normal cuboidal pattern to columnar may be an early precursor.<sup>118,133</sup> Papillary hyperplasia, in which the mucosa becomes more crowded and folded, arguably represents the next recognizable stage. Papillary hyperplasia can be associated with varying degrees of cellular and nuclear atypia (i.e., dysplasia), and the most advanced premalignant stage is sometimes referred to as *carcinoma in situ*. Bona fide carcinoma is marked by invasion through the duct wall. A major difficulty hindering early molecular analyses of pancreatic carcinoma was the fact that pancreatic carcinoma cells engender a strong host desmoplastic and inflammatory response, and the neoplastic cells only constitute a fraction of the total cells in the cancer specimen. Generation and study of pancreatic carcinoma specimens explanted into the flank of immunocompromised mice (i.e., xenografts) have proven crucial in defining specific genetic alterations in oncogenes and tumor suppressor genes in pancreatic carcinoma, because all human DNA isolated from the xenografts is derived from neoplastic cells.<sup>118,134,135</sup>

As is the case for colorectal carcinomas, accumulation of multiple mutations in oncogenes and tumor suppressor genes is critical in tumor progression ( [Table 33.1-4](#)). Mutations in *K-RAS* have been found in more than 90% of pancreatic carcinomas, and the mutations appear to arise early in the natural history of the disease, with more than 50% of flat hyperplasias and the vast majority of papillary hyperplasias exhibiting *K-RAS* mutations.<sup>118</sup> Like colorectal carcinoma, other oncogene defects appear to be much less frequent, with the next most common oncogene changes—amplifications of the *AKT2* and *MYB* genes—present in only 10% to 20% and 10% of carcinomas, respectively.<sup>118</sup>

Gene	Gene Location	Frequency (%)	Mutation Origin
<b>ONCOGENES</b>			
<i>K-RAS</i>	12p12	95	Somatic
<i>AKT2</i>	10q15.1	10-20	Somatic
<i>MYB</i>	6q24	10	Somatic
<b>TUMOR SUPPRESSOR GENES</b>			
<i>p16<sup>INK4a</sup></i>	9q21	>80	Somatic; much more frequently than germline
<i>p53</i>	17p13	75	Somatic
<i>DPC4/SMAD4</i>	18q21	55	Somatic
<i>BRCA2</i>	13q13	5-10	Germline more frequently than somatic
<i>DCC</i>	18q21	6	Somatic
<i>RAR1/STRK1</i>	10p15	5	Somatic; much more frequently than germline
<i>MSK4</i>	17p13	4	Somatic
<i>TGF<math>\beta</math> type III</i>	3p22	3	Somatic
<i>AJAC3</i>	9q21	3	Somatic

(Modified from ref. 118, with permission.)

**TABLE 33.1-4.** Summary of Selected Mutations in Pancreatic Carcinoma

A number of distinct tumor suppressor gene defects are seen in pancreatic carcinomas, although three tumor suppressor genes stand out because of their frequent inactivation—namely, the *p16<sup>INK4a</sup>*, *p53*, and *DPC4* genes (see [Table 33.1-4](#)). Whereas mutations in the pRb/cyclin D1-cdk4/p16<sup>INK4a</sup> pathway are uncommon in colorectal carcinoma, mutations inactivating the *p16<sup>INK4a</sup>* gene are found in roughly 85% of pancreatic carcinomas.<sup>118</sup> A subset of pancreatic carcinomas may epigenetically inactivate *p16<sup>INK4a</sup>*, perhaps as a result of hypermethylation of *p16<sup>INK4a</sup>* promoter sequences.<sup>136</sup> In another small fraction of cases, rather than *p16<sup>INK4a</sup>* inactivation, the *RB1* tumor suppressor gene is inactivated,<sup>118</sup> presumably with similar net consequences to *p16<sup>INK4a</sup>* inactivation, because the pRb protein is functionally inactive when the p16<sup>INK4a</sup> protein is lacking in a cell (i.e., the cyclin D and cdk4 proteins constitutively phosphorylate pRb in this setting). Mutations in the *p53* gene are found in 50% to 75% of pancreatic carcinomas.<sup>118</sup> Similar to the situation in colorectal carcinomas, the vast majority of the *p53* mutations are missense mutations accompanied by loss of the wild-type *p53* allele. Some alterations inactivating the *p16<sup>INK4a</sup>* gene, particularly homozygous deletions, also lead to loss of the p14<sup>ARF</sup> protein, an alternative protein product synthesized in part from sequences shared with those encoding the p16<sup>INK4a</sup> protein. Because p14<sup>ARF</sup> inactivation appears to lead to functional inactivation of the p53 protein, the actual frequency of pancreatic carcinomas with p53 inactivation may be higher than the percentage of cases with demonstrable *p53* sequence alterations. As noted earlier in the section [Chromosome 18q Loss of Heterozygosity](#), *DPC4* mutations are found in approximately 50% to 55% of pancreatic carcinomas.<sup>117,118,137</sup> Among other potential effects, the mutations presumably render the cells resistant to the negative growth regulatory effects of TGF- $\beta$ . Finally, in addition to the frequent alterations of *p16<sup>INK4a</sup>*, *p53*, and *DPC4*, several other tumor suppressor gene defects are found in a fraction of pancreatic carcinomas, such as *BRCA2* inactivation<sup>118</sup> (see [Table 33.1-4](#)). Consistent with the view that *BRCA2* defects have an important role in a subset of pancreatic cancers, in addition to the very elevated risk of breast cancer in those carrying a germline *BRCA2* mutation, the lifetime risk of pancreatic carcinoma for *BRCA2* mutation carriers appears to be increased by three- to fivefold relative to the general population.<sup>138,139</sup>

## GENE DEFECTS IN ESOPHAGEAL ADENOCARCINOMA

Esophageal cancers are readily distinguished into squamous and adenocarcinoma types on the basis of their histopathologic appearance. Clear differences exist in the pathogenesis of the two types, as well as differences in their epidemiology and associated risk factors. Not unexpectedly, the genetic alterations detected in the two types appear to be largely distinct. The brief discussion here focuses on esophageal adenocarcinoma because its natural history and genetic alterations are better defined than squamous carcinoma. Moreover, the genetics of esophageal adenocarcinoma has interesting parallels with the genetics of colorectal and pancreatic carcinoma, as well as some interesting differences.

Efforts to define the natural history and likely precursor lesions for esophageal adenocarcinoma have focused on Barrett's esophagus (BE).<sup>140,141</sup> BE is a condition in which the normal squamous epithelium of the esophagus is replaced by a metaplastic columnar epithelium. BE is generally restricted to the lower esophagus, and it is thought to develop in response to the mucosal injury that arises in the setting of chronic gastroesophageal reflux, although only approximately 10% to 12% of patients with reflux develop BE. The important histologic feature that predicts increased adenocarcinoma risk in patients with BE is the development of dysplasia, and increasing grades of dysplasia are associated with increased aneuploidy.<sup>141</sup> Flow cytometry analyses indicate aneuploid cell populations are absent in normal esophageal mucosa from patients with gastroesophageal reflux and no BE. Aneuploidy is rare in metaplasia and low-grade dysplasia. However, aneuploidy is present in biopsy specimens from approximately two-thirds of patients with high-grade dysplasia and nearly 100% of cancers. The flow cytometry studies also have demonstrated clonal heterogeneity in DNA content among the neoplastic cell populations present in distinct dysplastic areas of a single patient with BE,<sup>141</sup> suggesting that a large area of BE is neoplastically transformed and multifocal progression ensues.

Various oncogene defects have been found in esophageal adenocarcinomas, most notably the amplification of several distinct protooncogenes, including the *HER-2/NEU/ErbB2* gene in 22% of cases, the *cathepsin E* and *GATA-4* genes in 14%, the epidermal growth factor receptor (*EGFR*) gene in 13%, and the *K-RAS* gene in 10%.<sup>142,143</sup> and <sup>144</sup> Among the tumor suppressor genes frequently inactivated by genetic and epigenetic alterations in esophageal carcinomas are the *p53* and *p16<sup>INK4a</sup>* genes.<sup>141,145,146,147,148</sup> and <sup>149</sup> Missense mutations in one p53 allele coupled with LOH of chromosome 17p and the remaining p53 allele are found in nearly 100% of esophageal adenocarcinomas. In contrast to the situation in the colon in which p53 mutation and 17p LOH are infrequent in premalignant lesions (i.e., adenomas) but frequent in carcinomas, p53 mutations and 17p LOH are frequently found in high-grade dysplastic regions of premalignant BE. Inactivation of *p16<sup>INK4a</sup>* by mutational and epigenetic (e.g., promoter hypermethylation) mechanisms is frequent not only in high-grade dysplasias, but also in low-grade and nondysplastic BE specimens. Hence, *p16<sup>INK4a</sup>* inactivation frequently precedes *p53* inactivation in esophageal tumor progression. Nevertheless, as indicated in [Figure 33.1-4](#), there appear to be multiple genetic routes to cancer in BE.<sup>148</sup> Of some note, although several of the chromosome regions frequently affected by LOH in colorectal and pancreatic carcinomas are also frequently affected by LOH in esophageal adenocarcinoma, including chromosomes 5q and 18q,<sup>148,150</sup> the *APC* and *DPC4* tumor suppressor genes appear to be infrequently, if ever, mutated in esophageal adenocarcinoma.<sup>125,126</sup> and <sup>127,151</sup> Further work will be needed to define the tumor suppressor genes on chromosomes 5q and 18q that are inactivated in esophageal adenocarcinoma.

**FIGURE 33.1-4.** Multiple genetic routes to esophageal adenocarcinoma in the setting of Barrett's esophagus (BE). The clonal progression of cell populations as they progress from the metaplasia (M) seen in BE is illustrated schematically. The figure is not intended to be comprehensive, as there are multiple pathways to cancer. Nevertheless, some general patterns appear to be consistent in studies of progression in many patients. Chromosome losses (i.e., loss of heterozygosity), such as those involving chromosomes 5q, 9p, 13q, 17p, and 18q appear to arise in a diploid, proliferating cell population (2N). Chromosome 17p and 9p losses are both early events and can precede detectable inactivation of the *p53* (*TP53*) or *p16<sup>INK4a</sup>* (*CDKN2A*) genes. In some cases, tetraploidy (4N) may precede aneuploidy (An).

Progression to cancer (Ca) is shown as an end point, although additional chromosome changes and mutations may contribute to further progression of the cancer. (Modified from ref. 148, with permission.)

## POTENTIAL CLINICAL APPLICATIONS OF MOLECULAR ADVANCES

Advances in the understanding of the inherited and somatic genetic alterations in gastrointestinal cancers have made possible several clinical applications that should improve the diagnosis and care of patients and families affected by these cancers. Although many future clinical applications can be envisioned, only a few potential applications in the colorectal cancer area are described here.

### RISK ASSESSMENT

Presymptomatic diagnosis of FAP or HNPCC may be of significant value to members of families with these syndromes. The ability to identify germline mutations in the *APC* gene in more than 80% of families with FAP and Gardner's syndrome provides the basis for genetic counseling of at-risk families. Individuals from polyposis kindreds who are not found to have inherited a disease-causing *APC* mutation would be spared frequent colonoscopic examinations in their adolescent and early adult years. In turn, individuals who have inherited a mutant allele can be closely monitored via colonoscopy and offered surgical intervention at an appropriate time. Perhaps in the not too distant future, effective chemopreventive regimens may delay the onset or perhaps even prevent entirely the development of adenomas and carcinomas. The nonsteroidal antiinflammatory agent sulindac can cause regression of polyps in FAP patients, <sup>152,153</sup> and <sup>154</sup> although sulindac's efficacy is limited in part by its side effects. Encouraging results with selective inhibitors of cyclooxygenase-2 (COX-2) in a mouse polyposis model imply that COX-2 inhibitors may be more useful in prevention than sulindac. <sup>155</sup> Furthermore, because sulindac inhibits colorectal tumor growth via both COX-2-dependent and COX-2-independent mechanisms and the COX-2-independent pathway involves the APC-regulated transcription factor PPAR $\alpha$ , <sup>156</sup> a strategy of using both COX-2-selective inhibitors and novel PPAR $\alpha$  antagonists may be most efficacious in preventing adenoma formation or progression.

Novel mutation detection strategies, such as "chip-based" approaches, will hopefully supersede present laborious methods for detecting mutations in patients with FAP and HNPCC. Nevertheless, although rapid and robust mutation detection strategies will be a significant advance, other problems must be conquered. For instance, although the vast majority of germline *APC* mutations in FAP patients and many of the germline *MSH2*, *MLH1*, *PMS1*, and *PMS2* mutations in HNPCC patients are clearly inactivating (e.g., nonsense, frameshift), a subset of the mutations are missense substitutions. Distinguishing cancer-predisposing missense mutations from benign polymorphic variants is a troublesome issue at present. The development of *in vitro* assays that accurately predict the functional activity of wild type and mutant alleles *in vivo* is critical, particularly if large-scale screening for HNPCC mutations in asymptomatic patients is envisioned. Some progress toward this important goal has been achieved. <sup>157</sup> After identification of novel variant alleles that contribute to modestly increased risk of colorectal cancer, akin to the effects of the I1307K *APC* allele in Ashkenazi Jews, <sup>47</sup> recombinant DNA-based approaches may be used in a more general fashion in the future to estimate an individual's risk of colorectal cancer. The technical and theoretical difficulties of identifying variant alleles that have only subtle effects on colorectal cancer risk are substantial. Moreover, because many uncertainties exist regarding the optimal clinical management of such lower risk patients, as well as legal and ethical issues surrounding presymptomatic genetic testing even in high-risk patients, <sup>158</sup> many challenges lie ahead.

### EARLY DETECTION

The results of clinical trials indicate that colonoscopic removal of larger adenomas and early colorectal carcinomas reduces colorectal cancer incidence and most likely decreases mortality. <sup>25,159</sup> Because of the reduced specificity and sensitivity of current noninvasive tests, such as fecal occult blood testing, the development of highly specific and sensitive tests for early detection of colorectal cancer is an important goal. If inexpensive and reliable molecular diagnostic tests of stool specimens could be developed, such tests might serve an adjunctive role along with more invasive and expensive methods for detection, such as colonoscopy. Perhaps someday the molecular tests might even supplant colonoscopy as a definitive screening methodology. The intent of the molecular stool tests would be to identify mutated oncogene or tumor suppressor gene DNA sequences, with such mutant DNA sequences presumably derived from adenoma or carcinoma cells shed into the stool. Preliminary findings from studies of DNA isolated from stool samples of patients known to have carcinomas or advanced adenomas indicate stool-based tests for mutant oncogenes and tumor suppressor genes may have utility. The early findings indicate that if a *K-RAS* gene mutation is present in the primary tumor and the tumor is of sufficient size, mutant *K-RAS* gene sequences can usually be detected in the DNA of cells shed into the stool. <sup>160,161,162</sup> and <sup>163</sup> The sensitivity and specificity of present methods for identifying *RAS* gene mutations in the stool of normal individuals and patients with various types of colorectal tumors have not been fully determined, nor have the preliminary results been confirmed in much larger cohorts. Nonetheless, the early results are encouraging, because approximately 50% of colorectal cancers and adenomas larger than 1 cm in size contain a mutant *K-RAS* allele. <sup>85</sup>

A possible concern with using *K-RAS* mutations for early detection of colorectal adenomas and carcinomas is that *RAS* mutations are not entirely specific to premalignant and malignant lesions of the colon and rectum. *K-RAS* mutations are frequent in nondysplastic aberrant crypt foci and hyperplastic polyps, <sup>88,90,91</sup> and <sup>92</sup> and neither lesion has a clear relationship to adenoma or carcinoma development. *K-RAS* mutations may also be found in stool samples from some patients with pancreatic cancer and pancreatic ductal hyperplasia, <sup>164,165</sup> presumably because the pancreatic duct drains cells from these lesions into the gastrointestinal tract and both lesions have frequent *K-RAS* mutations. Nonetheless, a *K-RAS* mutation test for early detection of colorectal tumors may prove useful because aberrant crypt foci, hyperplastic polyps, and nonneoplastic pancreatic lesions are small lesions that may often shed too few mutant *K-RAS* alleles into the stool to permit their efficient detection. Even if *K-RAS* mutations do not offer a robust stool-based test for colorectal adenomas and carcinomas, similar molecular approaches may be used to detect localized mutations in other oncogenes and tumor suppressor genes, particularly those mutations that are intimately linked to malignant potential in colonic epithelium (e.g., *APC* and *p53* mutations).

### PROGNOSTIC MARKERS AND PATIENT STRATIFICATION FOR THERAPY

In addition to presymptomatic diagnosis (risk assessment) and early detection of tumors, several studies indicate characterization of the specific genetic alterations present in a cancer may provide improved or increased prognostic information about the likelihood of local and distant tumor recurrence. Several studies have suggested that chromosome 18q LOH and loss of *DCC* expression in primary colorectal cancer specimens may predict poor outcome in both stage II (lymph node metastases absent) and stage III (lymph node metastases present) patients. <sup>107,108,109,110</sup> and <sup>111</sup> Molecular analyses of lymph node from patients who do not appear to have metastatic disease on the basis of histologic examination may also be very useful for detecting micrometastases and refining the staging of patients. For instance, carcinoembryonic antigen (CEA) is often highly expressed by colorectal carcinoma cells. Research has shown that *CEA* gene expression may be found in lymph nodes of roughly one-half of stage II patients and that the presence of *CEA* expression in the lymph node predicts poor survival, <sup>166</sup> presumably because *CEA* expression results from occult micrometastases. Molecular studies of lymph nodes for mutant oncogenes or tumor suppressor genes may also prove helpful in refining staging and prognosis. <sup>167,168</sup>

In the future, if differences are noted in the response rates between patients whose tumors have differing constellations of genetic alterations, it may be particularly useful to define the specific mutations in a patient's tumor, so that a patient might receive the particular chemotherapeutic regimen with greatest efficacy on tumors of that genotype. Similarly, analysis of gene expression patterns may also be of clear benefit in predicting response. Finally, some of the oncogene and tumor suppressor gene alterations in colorectal tumors may provide specific targets for novel chemotherapeutic agents. Some of these agents might antagonize or act selectively on the mutated oncogene products or the growth pathways in which they function. Other agents might act to counter loss of tumor suppressor function in affected cells.

#### EPIDEMIOLOGY

Esophageal cancer represents the third most common gastrointestinal malignancy and ranks among the ten most common cancers worldwide. The incidence of esophageal cancer varies considerably relative to geographic location; high incidence areas have been identified within the Caspian littoral region of northern Iran, Southern republics of the former Soviet Union, and northern China where the incidence exceeds 100 in 100,000 individuals. The incidence of esophageal cancer ranges from 10 to 50 in 100,000 in Sri Lanka, India, South Africa, France, and Switzerland. This disease is less common (average incidence less than 10 in 100,000) in most areas within Japan, Great Britain, Europe, and Canada.<sup>1,2</sup> Squamous cell carcinomas account for the vast majority of neoplasms observed in these regions.

In the United States, esophageal cancers are relatively uncommon (average incidence less than 5 in 100,000); however, U.S. mortality data from 1990 to 1994 have revealed a steady increase in age-adjusted mortality in male as well as female subjects due to this malignancy.<sup>2</sup> Within the United States, the incidence of esophageal cancer varies with location, with a high frequency of esophageal squamous cell carcinomas being noted in coastal regions in South Carolina and metropolitan areas including New York City, Detroit, Washington, DC, and Los Angeles, where the incidence approximates 30 in 100,000 individuals.<sup>1,3</sup> Squamous cell carcinomas predominate in these high incidence areas within the United States.

In the recent past, the incidence of esophageal adenocarcinomas has risen dramatically, whereas the incidence of squamous cell carcinomas has remained relatively steady in the United States.<sup>2</sup> Before 1980, adenocarcinomas constituted approximately 15% of esophageal malignancies; however, by 1994, nearly 60% of all esophageal malignancies were adenocarcinomas.<sup>2</sup> Rates of adenocarcinoma are highest in white men. The incidence of esophageal carcinoma in women is much lower, although the incidence of adenocarcinomas is also increasing in women. Similar trends have been noted in western European countries.<sup>4,5 and 6</sup> The rising incidence of esophageal adenocarcinoma cannot be attributed solely to the increased incidence of carcinomas of the cardia, which now account for approximately one-half of gastric cancers in American men.<sup>4,7</sup> Although the precise etiology of these neoplasms has not been elucidated, considerable data indicate that esophageal adenocarcinomas result from chronic gastroesophageal reflux often in the context of hiatal hernia.<sup>8,9,10 and 11</sup>

Although cultural as well as dietary practices contribute to esophageal cancers in high incidence areas in Asia, South Africa, South America, and the Middle East, tobacco and ethanol exposure are believed to be the primary risk factors associated with esophageal squamous cell carcinomas in the United States and western Europe.<sup>1,2,12,13</sup> Tobacco and ethanol consumption have been identified as individual risk factors for this malignancy, and their effects are multiplicative.<sup>1,14</sup> A five- to tenfold increase in esophageal squamous cell cancers has been noted in smokers relative to nonsmokers, and the risk of esophageal carcinoma correlates with extent of tobacco exposure.<sup>1,15,16 and 17</sup> Tobacco abuse may also contribute to the pathogenesis of esophageal adenocarcinomas, although to a much lesser extent; a multicenter study by Gammon et al.<sup>18</sup> as well as additional clinical studies have indicated that the risk of esophageal adenocarcinoma is approximately twofold higher in smokers compared with nonsmokers.<sup>2,14</sup> Interestingly, whereas the risk of esophageal squamous cell cancer decreases significantly following cessation of tobacco abuse, little change is noted in esophageal adenocarcinoma risk following smoking cessation.<sup>18</sup> These data suggest that tobacco-related carcinogens may be influencing different stages of malignant transformation associated with squamous cell cancers relative to adenocarcinomas. Chemicals in tobacco are known to induce p53 mutations,<sup>19</sup> and these mutations appear to be extremely early events during multistep esophageal adenocarcinogenesis.<sup>20,21</sup> The timing of p53 mutations during squamous cell carcinogenesis has not been defined; however, these mutations appear to be relatively late events during pulmonary carcinogenesis.<sup>22,23</sup>

Alcohol abuse has been associated with increased risk of esophageal squamous cell cancers, and risk increases with amount of alcohol consumed.<sup>24,25</sup> Alcohol interacts in a multiplicative manner with tobacco, with nearly a 100-fold increase in the risk of esophageal malignancy observed in individuals with heavy tobacco and ethanol exposure.<sup>1,2</sup> Specific beverages have been implicated in the pathogenesis of squamous cell cancers in Europe, South Africa, South America, and the United States; however, in all likelihood, ethanol is the major component related to the pathogenesis of these cancers.<sup>14</sup> Ethanol consumption appears to have a less significant role in the pathogenesis of esophageal adenocarcinomas.<sup>18,26,27</sup>

Data indicate that obesity may be related to risk of esophageal cancer, particularly adenocarcinomas.<sup>28,29</sup> In general, the risk of esophageal squamous cell cancers decreases, whereas risk of adenocarcinoma increases with enlarging body mass. Esophageal squamous cell cancers have been associated with nutritional deficiencies; a low intake of fruits and vegetables may increase the esophageal cancer risk twofold.<sup>1,30,31</sup> Deficiencies in b-carotene, vitamin E, and selenium may also increase the risk of squamous cell cancer in underdeveloped areas. Dietary practices including drinking of extremely hot beverages or ingestion of fermented vegetables may contribute to increased cancer risk in Asia and South America<sup>32,33</sup>; however, the role of dietary practices in the pathogenesis of esophageal cancers in the United States is unclear. Although several environmental carcinogens, including asbestos, perchlorethylene, and combustion products, may contribute to the pathogenesis of esophageal squamous cell cancers,<sup>34,35 and 36</sup> no occupational risk factors have been associated with esophageal adenocarcinomas.

#### ANATOMY

The esophagus commences at the cricopharyngeus muscle at the level of the cricoid cartilage and extends 5 to 6 cm in the cervical region to enter the thoracic inlet (Fig. 33.2-1). The intrathoracic esophagus extends an additional 20 to 25 cm to the gastroesophageal junction. Typically, many radiologists and surgeons divide the

esophagus into thirds whereby the upper third extends from the cricopharyngeus to the superior portion of the aortic arch, the middle third extends from the aortic arch to the inferior pulmonary veins, and the distal third extends from the level of the inferior pulmonary veins to the gastroesophageal junction.

**FIGURE 33.2-1.** General anatomy of the esophagus with major landmarks identified. GE, gastroesophageal.

The blood supply to the esophagus is segmental, with vessels extending into the esophagus to form a submucosal vascular plexus ( [Fig. 33.2-2](#)). The cervical esophagus is supplied primarily by the superior and inferior thyroid arteries, whereas the thoracic esophagus is supplied by esophageal arteries arising directly from the aorta near the level of the carina; the distal esophagus and gastric cardia are supplied primarily by the left gastric artery. Venous drainage from the esophagus is into the azygous and hemiazygous veins as well as intercostal veins that ultimately drain into the azygous system ( [Fig. 33.2-3](#)).

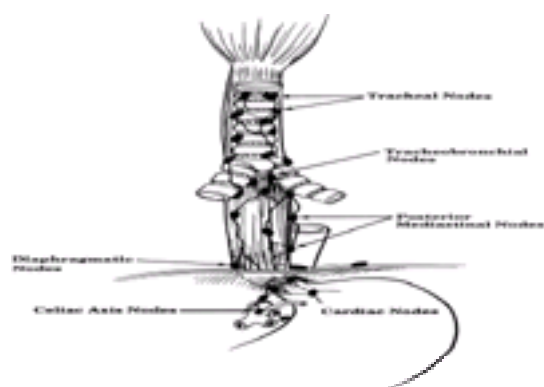

**FIGURE 33.2-2.** Blood supply of the esophagus.

**FIGURE 33.2-3.** Venous drainage of the esophagus.

The esophagus contains abundant mucosal and submucosal lymphatics that communicate with lymphatic channels in the muscular layers to drain either directly through the esophageal wall to adjacent lymph nodes or to the thoracic duct ( [Fig. 33.2-4](#)).<sup>37</sup> Lesions in the upper third of the esophagus tend to drain initially to internal jugular, cervical, and supraclavicular nodes; in contrast, middle third lesions drain initially to paratracheal, hilar, subcarinal, paraesophageal, and pericardial nodal regions. Distal third tumors tend to drain to nodes along the lesser curvature, left gastric artery, and celiac axis. However, because the pattern of lymphatic drainage is primarily longitudinal rather than segmental, extensive regional dissemination of cancer cells may occur irrespective of the location of the primary tumor. Celiac nodal metastases have been observed in 10% of patients with upper third carcinomas, and nearly 45% of individuals with middle third lesions; approximately 30% patients with middle or lower third carcinomas have metastatic disease in deep cervical lymph nodes at presentation.<sup>38,39</sup>

**FIGURE 33.2-4.** Major lymphatic drainage areas of the esophagus.

## HISTOLOGY

The overwhelming majority of esophageal malignancies may be classified as either squamous cell carcinomas or adenocarcinomas. Squamous cell carcinomas account for approximately 40% of esophageal malignancies diagnosed in the United States and the vast majority of cancers arising in high-incidence areas throughout the world.<sup>1,2</sup> Approximately 60% of these neoplasms are located in the middle third of the esophagus, whereas 30% and 10% arise in the distal third or proximal third of the intrathoracic esophagus, respectively.<sup>40,41</sup> Typically, these tumors are moderately well differentiated and often are associated with contiguous or

noncontiguous carcinoma *in situ*, as well as widespread submucosal lymphatic dissemination.<sup>42,43</sup>

Adenocarcinomas frequently arise in the context of Barrett's esophagus; as such, these tumors tend to be localized in the distal third of the esophagus and may be fungating or stenotic in appearance.<sup>44,45</sup> Many of these tumors are well-differentiated adenocarcinomas, and the vast majority are associated with intraepithelial neoplasia.<sup>46,47</sup> No significant survival differences have been noted in adenocarcinoma patients compared with similarly staged individuals with squamous cell cancers.<sup>36,48</sup>

Several rare cancers of the esophagus have been described, including squamous cell carcinoma with sarcomatous features, as well as adenoid cystic, and mucoepidermoid carcinomas.<sup>49,50,51,52</sup> and <sup>53</sup> These neoplasms are indistinguishable clinically and prognostically from the more common types of esophageal carcinomas.

Small cell carcinomas account for approximately 1% of esophageal malignancies and arise from argyrophilic cells in the basal layer of the squamous epithelium.<sup>54,55</sup> These neoplasms are usually located in the middle or lower third of the esophagus and may be associated with ectopic production of a variety of hormones including parathormone, secretin, granulocyte colony-stimulating factor, and gastrin-releasing peptide; individuals with these cancers often present with systemic disease.<sup>56,57</sup> Although small cell carcinomas frequently respond to radiation and chemotherapy, patients with these neoplasms typically succumb to widespread distant metastases.<sup>58,59</sup> and <sup>60</sup>

Leiomyosarcoma is the most common mesenchymal tumor affecting the esophagus, accounting for less than 1% of all esophageal malignancies.<sup>49,61</sup> These neoplasms usually arise as lower third tumors and typically present as bulky masses with significant hemorrhage and necrosis.<sup>62,63</sup> Malignant lymphoma and Hodgkin's disease rarely involve the esophagus; esophageal involvement typically is secondary to extension from other sites, although primary malignant lymphoma of the esophagus has occasionally been observed.<sup>64,65</sup> Patients with acquired immunodeficiency syndrome may exhibit Kaposi's sarcoma involving the esophagus.<sup>66,67</sup> Malignant melanoma involving the esophagus is exceedingly rare and presents as a bulky polypoid intraesophageal tumor of varying color depending on melanin production.<sup>49,68</sup> The prognosis is extremely poor for these patients despite aggressive therapy.

## PREDISPOSING CONDITIONS

### TYLOSIS

Tylosis (focal nonepidermolytic palmoplantar keratoderma) is a rare disease inherited in an autosomal dominant manner that is characterized by hyperkeratosis of the palms and soles and esophageal papillomas. Patients with this condition exhibit abnormal maturation of squamous cells and inflammation within the esophagus and have extremely high risk of developing esophageal cancer.<sup>69,70</sup> The tylosis esophageal cancer (TOC) gene has been mapped to 17q25 by linkage analysis of pedigrees associated with high risk of esophageal cancer development.<sup>71</sup> In addition to being mutated in tylosis, the TOC gene is frequently deleted in sporadic human esophageal cancers.<sup>72,73</sup> Iwaya et al.<sup>73</sup> used 20 microsatellite markers focusing on the TOC locus to investigate loss of heterozygosity in 58 sporadic esophageal squamous cell carcinomas. Loss of heterozygosity was observed in 37 of 52 (71%) informative cases, 80% (33 of 37) of which involved the TOC locus. Envoplakin, encoding a protein component of desmosomes that is expressed in esophageal keratinocytes, has been mapped to the TOC region<sup>74</sup>; however, no tylosis-specific mutations involving this gene have been observed.<sup>75</sup> Further studies are required to define the tumor suppressor gene(s) mapping to 17q25 that are inactivated in tylosis-associated as well as sporadic esophageal carcinomas.

### PLUMMER-VINSON/PATERSON-KELLY SYNDROME

Plummer-Vinson/Paterson-Kelly syndrome is characterized by iron-deficiency anemia, glossitis, kelosis, brittle fingernails, splenomegaly, and esophageal webs. Approximately 10% of individuals with Plummer-Vinson/Paterson-Kelly syndrome develop hypopharyngeal or esophageal epidermoid carcinomas.<sup>76</sup> The mechanisms by which these tumors arise have not been fully defined, although nutritional deficiencies as well as chronic mucosal irritation from retained food particles at the level of the webs may contribute to the pathogenesis of these neoplasms.<sup>77</sup>

### CAUSTIC INJURY

Squamous cell carcinomas may arise in lye strictures, often developing 40 to 50 years following caustic injury.<sup>78</sup> The majority of these cancers are located in the middle third of the esophagus. The pathogenesis of these neoplasms may be similar to that implicated in esophageal cancers arising in patients with Plummer-Vinson syndrome. These cancers are often diagnosed late due to the fact that chronic dysphagia and pain due to the lye strictures obscure symptoms of esophageal cancer.

### ACHALASIA

Achalasia is an idiopathic esophageal motility disorder characterized by increased basal pressure in the lower esophageal sphincter, incomplete relaxation of this sphincter following deglutition, and aperistalsis of the body of the esophagus. A 16- to 30-fold increase in esophageal cancer risk has been noted in achalasia patients.<sup>79,80</sup> In a retrospective analysis, Aggestrup et al.<sup>81</sup> observed the development of esophageal carcinomas in 10 of 147 patients undergoing esophagomyotomy for achalasia. These neoplasms typically are squamous cell carcinomas, believed to result from prolonged irritation from retained foods at the air-fluid interface in the midesophagus, and arise an average of 17 years following onset of achalasia symptoms. The insidious nature of carcinomas arising in the context of chronic dysphagia and pain attributable to megaesophagus contributes to their late diagnosis in achalasia patients.<sup>82</sup>

### HELICOBACTER PYLORI INFECTION

*Helicobacter* infection has been associated with gastritis and peptic ulcer disease. Several studies suggest that the extent of *Helicobacter* gastritis may correlate inversely with diminished gastroesophageal reflux and esophageal cancer.<sup>83,84</sup> Sharma et al.<sup>85</sup> observed no evidence of *Helicobacter pylori* in specialized intestinal metaplasia in 209 esophageal biopsies from 58 patients with columnar-lined epithelium. In another study, El-Serag et al.<sup>86</sup> evaluated the database of the Department of Veterans Affairs and noted that *Helicobacter pylori* infection and atrophic gastritis were associated with diminished acid output and increased risk of gastric carcinoma, but diminished risk of esophageal cancer. These data have been confirmed by Chow et al.,<sup>83</sup> who also noted an inverse relationship between *Helicobacter* infection and risk of gastroesophageal adenocarcinoma. Thus, available data indicate that *Helicobacter* has little, if any, role in the pathogenesis of esophageal cancer.

### HUMAN PAPILOMAVIRUS INFECTION

Several studies suggest that human papillomavirus (HPV) may contribute to the pathogenesis of esophageal squamous cell cancers in high-incidence areas in Asia and South Africa.<sup>87</sup> This oncogenic virus, which has been associated with cervical and oropharyngeal cancers,<sup>88,89</sup> encodes two proteins (E6 and E7) that sequester the Rb and p53 tumor suppressor gene products. Using polymerase chain reaction techniques, de Villiers et al.<sup>90</sup> detected HPV DNA sequences in 17% of esophageal squamous cell cancers from China. In an additional study using similar techniques, Lavergne and de Villiers et al.<sup>91</sup> identified a broad spectrum of HPV in approximately one-third of esophageal cancer specimens obtained from patients living in high-incidence areas in China and South Africa. Shibagaki et al.<sup>92</sup> detected HPV sequences in 15 of 72 (21%) esophageal cancer specimens obtained from Japanese patients. In contrast, HPV sequences have not been observed in cancers arising in low-incidence areas. Poljack et al.<sup>93</sup> observed no evidence of HPV in 121 formalin-fixed, paraffin-embedded esophageal cancer specimens obtained from patients in Slovenia. Similarly, Ruge et al.<sup>94</sup> detected no HPV in 18 carcinomas arising in Italian patients. Turner et al.<sup>95</sup> observed no evidence of HPV in 51 formalin-fixed, paraffin-embedded esophageal cancer specimens obtained from patients in North America. In a large population-based control study, Lagergren et al.<sup>96</sup> compared 121 esophageal squamous cell cancers and 173 adenocarcinoma patients with 302 population-based controls in Sweden. These authors observed no association between HPV infection and risk of esophageal cancer in this low-incidence area. Collectively, these data suggest that HPV may contribute to the pathogenesis of esophageal squamous cancers in high-incidence regions; however, this oncogenic virus appears to have little, if any, role in the pathogenesis of esophageal malignancies arising in low-incidence areas.

## PRIOR AERODIGESTIVE TRACT MALIGNANCY

Carcinomas of the aerodigestive tract arise as the consequence of multistep processes in cancerization fields. Patients with upper aerodigestive tract cancers develop second primary cancers at a rate of approximately 4% per year.<sup>97</sup> Nearly 10% of secondary neoplasms arising in patients with prior histories of oropharyngeal carcinoma arise in the esophagus.<sup>97</sup> Levi et al.<sup>98</sup> observed that approximately 10% of second primary cancers in patients with prior histories of lung carcinoma arose in the esophagus. The increased risk of second primary tobacco-related carcinomas<sup>99</sup> warrants close surveillance of patients with histories of aerodigestive tract malignancy.

## BARRETT'S ESOPHAGUS

Barrett's esophagus is characterized by the presence of columnar epithelium lining 3 or more cm of the distal tubular esophagus in the presence or absence of hiatal hernia. Short segment Barrett's esophagus is defined as intestinal metaplasia involving less than 3 cm of the distal esophagus at the region of the lower esophageal sphincter.<sup>100,101,102</sup> and <sup>103</sup> The prevalence of Barrett's esophagus ranges between 0.45% and 2.2% among all patients undergoing upper gastrointestinal endoscopy, increasing to 10% to 20% in patients undergoing endoscopy for symptomatic gastroesophageal reflux disease, and 30% to 50% in patients with peptic strictures.<sup>104,105,106,107</sup> and <sup>108</sup> Barrett's esophagus is twice as prevalent in men compared with women, and increases with age, reaching a plateau in the seventh to ninth decade of life; this disease is infrequently observed in nonwhites.<sup>100,105,109</sup> In all likelihood, the prevalence of Barrett's esophagus exceeds that which has been previously reported given the fact that most individuals with this disease are asymptomatic.<sup>100,110</sup>

Although a congenital etiology has been proposed, considerable data indicate that Barrett's esophagus is primarily an acquired condition resulting from gastroesophageal reflux.<sup>11,100,103</sup> The vast majority of patients diagnosed with Barrett's esophagus have significant gastroesophageal reflux, and Barrett's metaplasia has been observed following esophagogastrectomy or Heller's myotomy presumably as the result of gastroesophageal reflux in the absence of a competent lower esophageal sphincter.<sup>111,112</sup> Three types of columnar metaplasia have been identified in Barrett's esophagus. The fundic type mucosa is characterized by the presence of chief and parietal cells in addition to surface mucus-secreting cells containing neutral sialomucins; junctional type epithelium resembling that of gastric cardia is composed primarily of mucus-secreting cells. Specialized or intestinal type epithelia resemble that of the small bowel, appearing as a villiform surface comprised of mucus-secreting cells as well as goblet cells staining positively for acid nonsulfated mucins. Specialized epithelium is distinctive for Barrett's esophagus, being present in virtually all cases, and is the type most commonly associated with malignant degeneration.<sup>113</sup>

Barrett's esophagus has been associated with a 30- to 40-fold increase in the risk of adenocarcinoma, the incidence of which increased at a rate of 10% per year during the 1980s.<sup>1,7,100</sup> Currently, esophageal adenocarcinomas account for as much as 60% of all esophageal cancers diagnosed in the United States, and nearly 65% of esophageal adenocarcinomas had evidence of metaplastic columnar epithelia adjacent to them.<sup>4,47</sup> Presumably, many other esophageal adenocarcinomas have arisen in and replaced short segment Barrett's esophagus before clinical presentation.<sup>47,114</sup>

Although presumed to arise as the result of malignant transformation in specialized epithelia, the prevalence of adenocarcinoma in Barrett's esophagus has not been conclusively defined; however, estimates range between 0% and 64%.<sup>105</sup> Sharma et al.<sup>115</sup> identified 20 individuals with high-grade dysplasias (nearly one-half of whom would be expected to have invasive carcinomas<sup>10,116</sup>) out of 177 patients with short segment Barrett's esophagus. Hirota et al.<sup>109</sup> prospectively examined the prevalence of adenocarcinoma of the esophagus and gastroesophageal junction in patients with specialized intestinal metaplasia involving long segment Barrett's esophagus, short segment Barrett's esophagus, or esophagogastric junction. Of 833 patients studied by esophagogastroduodenoscopy, the overall prevalence of specialized intestinal metaplasia was 13.2% (1.6% long segment Barrett's esophagus, 6.0% short segment Barrett's esophagus, and 5.6% esophagogastric junction). Dysplasia or cancer was noted in 31% of long segment Barrett's esophagus, 10% of short segment Barrett's esophagus, and 6.4% of esophagogastric junction-specialized intestinal metaplasia patients. Although the prevalence of short segment Barrett's esophagus or esophagogastric junction-specialized intestinal metaplasia was approximately 3.5-fold higher than that of long segment Barrett's esophagus, the prevalence of dysplasia in long segment Barrett's esophagus was two to four times higher than that observed in the two other conditions.

Additional studies have been performed to ascertain the incidence of adenocarcinoma in Barrett's esophagus. Cameron et al.<sup>117</sup> followed 104 patients with Barrett's esophagus for an average of 8.5 years, only two of whom developed carcinoma, for an incidence of 1 in 141 patient-years. In an additional study, Spechler et al.<sup>118</sup> observed the development in carcinoma in 2 of 105 patients followed for an average of 3.3 years. In a prospective study, Robertson et al.<sup>119</sup> observed one case of cancer in Barrett's esophagus in 56 patient-years. In a retrospective study, Katz et al.<sup>120</sup> reported on 102 patients with Barrett's esophagus undergoing surveillance over a 24-year period; during 563 patient-years, three patients developed adenocarcinoma a minimum of 4 years after diagnosis; 23 additional patients progressed to low-grade dysplasia (19) or high-grade dysplasia (4) during the study period. In a large prospective analysis, O'Connor et al.<sup>121</sup> evaluated 136 patients enrolled in an endoscopic surveillance program at the Cleveland Clinic. The average duration of follow-up was 4.2 years, with a total of 570 patient-years. Thirty patients (22%) had short segment Barrett's esophagus. Two patients developed adenocarcinoma (incidence, 1 in 285 patient-years), and four patients progressed to high-grade dysplasia. Low-grade dysplasias developed in an additional 24 patients. In another prospective study, Weston et al.<sup>8</sup> reported that the incidence of high-grade dysplasia or adenocarcinoma in Barrett's esophagus was 1 per 72 patient-years.

Although esophageal adenocarcinomas are frequently preceded by histologically defined stages of metaplasia and progressively severe dysplasia in Barrett's esophagus,<sup>122</sup> the risk of progression to malignancy cannot be predicted by histologic parameters due to significant discordance between histologic, cytogenetic, and flow cytometric abnormalities in this condition. Fennerty et al.<sup>123</sup> analyzed 86 patients with Barrett's esophagus and noted that 23 of 73 patients without dysplasia, and 4 of 13 patients with dysplasia had aneuploidy or increased G<sub>2</sub>/tetraploid fractions evaluated by flow cytometry. Widespread cellular proliferation and aneuploidy occur relatively early in Barrett's esophagus, and progression to malignancy is associated with three well-defined cell-cycle events: (1) mobilization of G<sub>0</sub> cells into G<sub>1</sub>; (2) loss of G<sub>1</sub>/S regulation and increased S-phase fraction; and (3) accumulation of cells in G<sub>2</sub>/M, frequently with significant aneuploidy.<sup>20,124</sup> Evidence of genomic instability has been observed in metaplastic epithelia as well as histologically normal tissues adjacent to Barrett's esophagus, indicating that the histologic alterations underestimate the severity of genetic events during progression to malignancy in Barrett's epithelia.<sup>125,126</sup> and <sup>127</sup> Reid et al.<sup>128</sup> prospectively evaluated 62 patients with Barrett's esophagus and observed that 9 of 13 patients with abnormal flow cytometry, including two with Barrett's metaplasia, five with low-grade dysplasias, and two with high-grade dysplasias, progressed to either high-grade dysplasia or invasive carcinoma; none of 49 patients with normal flow cytometry progressed to malignancy during the 34-month study. Interestingly, five patients with low-grade dysplasia who had normal flow cytometry parameters reverted to Barrett's metaplasia during the study. Collectively, these data indicate that histologic changes do not accurately reflect the severity of genomic instability in Barrett's esophagus. Furthermore, 15% to 20% of patients with Barrett's esophagus have columnar-lined epithelia exhibiting aberrant cell-cycle regulation; 70% of these individuals progress to malignancy within a 3-year period. Although the incidence of adenocarcinoma in patients with Barrett's esophagus may be relatively low, use of flow cytometry techniques may help to identify those patients who are at high risk for the development of esophageal cancer.<sup>126,128</sup>

Flow cytometry techniques may enhance the efficiency and optimize expense of screening surveillance programs in patients with Barrett's esophagus, which already appear to identify cancers at earlier stages compared with those detected outside the context of screening programs.<sup>129,130,131,132,133</sup> and <sup>134</sup> However, surveillance protocols may have limited effect overall on the incidence of advanced esophageal carcinomas. Bytzer et al.<sup>6</sup> evaluated the incidence of esophageal adenocarcinoma in Denmark over a 20-year period and ascertained the proportion of patients with a prior diagnosis of Barrett's esophagus. A history or diagnosis of reflux was present in 21% of patients, and 23% of individuals had undergone previous endoscopy for reflux or dyspepsia. Interestingly, only 1.3% of 524 esophageal adenocarcinoma patients had a prior diagnosis of Barrett's esophagus. In essence, greater than 98% of patients would not have entered endoscopic surveillance programs. Collectively, those data indicate that endoscopic surveillance may be beneficial in patients with Barrett's esophagus, but the vast majority of esophageal cancer patients have no antecedent symptoms that might enable early detection. Clearly, additional factors other than gastroesophageal reflux contribute to malignant transformation in Barrett's esophagus.

## MOLECULAR BIOLOGY

Flow cytometric and molecular analyses of dysplastic squamous and Barrett's epithelia have revealed that esophageal cancers arise via widespread clonal outgrowth of cells exhibiting aberrant cell-cycle regulation.<sup>20,124,135,136</sup> In general, genomic instability precedes the appearance of histologic abnormalities in esophageal mucosa,<sup>125,135</sup> and the extent of cell-cycle derangements influences progression to malignancy in this setting.<sup>128,137,138</sup> Many of the oncogene and tumor suppressor gene mutations frequently observed in esophageal cancers and their precursor lesions perturb cell-cycle regulation by disrupting the G<sub>1</sub> restriction point ([Table](#)

Oncogenes	Tumor Suppressors
EGFr	3p (FHIT)
erbB2	Rb
Cyclin D	p53
	p16
	p14/ARF
	Telomerase

**TABLE 33.2-1.** Oncogene and Tumor Suppressor Gene Mutations in Esophageal Cancers and Their Precursor Lesions that Disrupt the G<sub>1</sub> Restriction Point

A reciprocal relationship between retinoblastoma (Rb), cyclin D, and p16 expression has been observed in esophageal cancers similar to what has been reported for other solid tumors.<sup>139,140</sup> In general, esophageal cancers that lack Rb expression tend to have normal cyclin D1 and p16 expression, whereas cancers that retain Rb expression typically exhibit overexpression of cyclin D1, p16 inactivation, or both. In the majority of esophageal cancers, restriction point control is circumvented via overexpression of cyclin D1, and inactivation of p16, often in the context of p53 mutations.

The epidermal growth factor receptor (EGFr) is a 170-kD tyrosine kinase receptor that is overexpressed in approximately 30% and 70% of esophageal adenocarcinomas and squamous cell cancers, respectively.<sup>141,142</sup> Approximately 40% of these tumors also express transforming growth factor- $\alpha$ , which binds to EGFr and stimulates proliferation via autocrine mechanisms. Several studies suggest that overexpression of EGFr may have prognostic significance in esophageal cancer patients. Itakura et al.<sup>142</sup> reported that EGFr immunoreactivity correlated significantly with diminished survival of patients undergoing esophagectomy for squamous cell cancer. Iihara et al.<sup>143</sup> noted that expression of transforming growth factor- $\alpha$ , EGFr, or both correlated with reduced survival in patients with node-positive esophageal squamous cell carcinomas. More recently in studies involving a total of 223 patients, Kitagawa et al.<sup>144</sup> and Shimada and coworkers<sup>145</sup> observed that EGFr overexpression significantly enhanced predilection for lymph node metastases, hematogenous recurrence, and diminished survival in patients undergoing potentially curative esophagectomies.

The erbB2 gene product is a 185-kD receptor molecule with intrinsic tyrosine kinase activity, which also regulates expression and function of a variety of other receptors including EGFr; in addition, p185 modulates expression of matrix metalloproteases and vascular endothelial growth factor by cancer cells.<sup>146,147,148 and 149</sup> Overexpression of erbB2 correlates with *in vitro* drug resistance, and abrogation of p185 expression enhances chemosensitivity in cancer cells.<sup>150,151</sup> The prognostic significance of erbB2 overexpression in esophageal cancers is unclear. Polkowski et al.<sup>129</sup> observed overexpression of erbB2 in approximately 25% of adenocarcinomas of the distal esophagus and gastroesophageal junction. Interestingly, 10 of 30 stage III to IV tumors overexpressed erbB2 in contrast to 0 of 11 stage I to II cancers; however, subsequent regression analysis revealed that erbB2 expression was not independent of clinical stage in determining patient survival. Furthermore, Wang and colleagues<sup>152</sup> observed no significant correlation between erbB2 expression and long-term survival in 117 patients undergoing potentially curative resections for esophageal squamous cell carcinoma. In contrast, Brien et al.<sup>153</sup> observed that erbB2 amplification independently correlated with diminished survival in patients with Barrett's adenocarcinomas.

Together with its kinase partners, cdk4 and cdk6, cyclin D1 directly regulates phosphorylation of the Rb protein at the restriction point, thereby facilitating G<sub>1</sub>/S transit; abrogation of cyclin D1 expression inhibits the proliferation and tumorigenicity of cancer cells.<sup>154,155</sup> Approximately 40% to 60% of esophageal carcinomas and 30% of premalignant esophageal lesions<sup>156,157,158 and 159</sup> exhibit overexpression of cyclin D1 resulting directly from amplification of the cyclin D1 protooncogene, or indirectly from mutations involving upstream growth factor receptors such as EGFr and p185. Several studies suggest that cyclin D1 overexpression may be prognostically relevant in esophageal cancers. Shimada et al.<sup>145</sup> observed that cyclin D1 overexpression correlated with hematogenous recurrence and diminished survival in esophagectomy patients. In an additional study, Roncalli et al.<sup>160</sup> detected amplification of cyclin D1 in 17 of 55 of esophageal carcinomas, noting that overexpression of cyclin D1 correlated significantly with lymph node metastases, advanced tumor stage, and reduced overall survival in esophageal cancer patients. Takeuchi and colleagues<sup>161</sup> have also observed a significant correlation between cyclin D1 overexpression, and distant metastases as well as diminished survival in esophagectomy patients.

Cytogenetic and molecular analyses have revealed nonrandom patterns of allelic loss in esophageal cancers and their precursor lesions indicative of selective pressure to specifically inactivate tumor suppressor genes in these regions during multistep esophageal carcinogenesis.<sup>136,137,162,163 and 164</sup> Deletions involving 3p have been detected in 60% to 100% of esophageal cancers as well as a significant percentage of specimens derived from Barrett's esophagus. Although the tumor suppressor genes that are silenced by 3p mutations have not been identified conclusively, one major target appears to be the fragile histidine triad (FHIT) gene, which modulates cell-cycle progression and apoptosis.<sup>165,166</sup> Point mutations as well as promoter hypermethylation contribute to aberrant expression of FHIT in 50% to 90% of esophageal cancers, and the majority of Barrett's metaplasia specimens examined to date.<sup>167,168,169 and 170</sup> Although FHIT mutations correlate with increased tobacco exposure and diminished survival in lung cancer patients,<sup>171,172</sup> the prognostic significance of these mutations in esophageal cancers has not been defined as yet.

The retinoblastoma (Rb) gene, located on 13q14, encodes a 105-kD nuclear phosphoprotein that governs the G<sub>1</sub> restriction point via complex interactions with a variety of cyclin-dependent kinases, transcription factors, and viral oncoproteins.<sup>173,174</sup> Rb is a critical mediator of cell-cycle arrest after DNA damage.<sup>175</sup> Mutations resulting in the loss of Rb protein expression have been observed in 20% to 60% of esophageal cancers and their precursor lesions.<sup>136,139,176</sup> Rb mutations tend to occur more frequently in tumors that also exhibit mutations involving p53<sup>176</sup> and appear to correlate with advanced disease, nodal metastases, and diminished survival in esophageal cancer patients.<sup>160,176,177</sup>

The p16 tumor suppressor gene product encoded on 9p21 inhibits the activity of cdk4 and cdk6, thereby preventing cyclin D–dependent phosphorylation of the Rb protein at the restriction point.<sup>178</sup> Restoration of p16 expression by gene therapy techniques results in profound cell-cycle arrest in esophageal cancer cells.<sup>140</sup> Allelic deletions or point mutations inactivate p16 in approximately 20% of esophageal cancers, and allelic loss involving 9p21 precedes the onset of aneuploidy in Barrett's esophagus.<sup>179,180</sup> Promoter hypermethylation silences p16 in an additional 30% to 50% of esophageal cancers and adenocarcinomas.<sup>179,181</sup> Although not extensively studied, loss of p16 expression appears to correlate with overexpression of cyclin D1 and diminished survival in esophageal cancer patients.<sup>161</sup>

The p14/ARF gene product is encoded by an alternate reading frame in the p16 locus and functions to stabilize p53 by preventing its interaction with MDM2.<sup>182</sup> ARF is critical for initiating p53-mediated apoptosis in response to activated protooncogenes, but appears dispensable for p53-mediated response to genotoxic stress.<sup>183</sup> Inactivation of ARF occurs by allelic deletion as well as methylation mechanisms that may simultaneously inactivate p16.<sup>184</sup> Xing et al.<sup>185</sup> performed a comprehensive analysis of the mechanisms responsible for silencing of p16 and p14/ARF in 40 esophageal cancers. Promoter hypermethylation involving ARF and p16 was observed in 15% and 40% of specimens, respectively. Nearly all of the methylations involving ARF also silenced p16; in contrast, most of the p16 methylations were exclusive. Homozygous deletions involving ARF or p16 were seen in 33% and 18% of specimens, respectively. These data suggest that p14/ARF is a primary target for homozygous deletion, whereas p16 appears to be silenced by hypermethylation in esophageal cancers. The prognostic significance of p14/ARF mutations in established esophageal cancers has not been defined.

The p53 gene product regulates cell-cycle progression, DNA repair, apoptosis, and neovascularization in normal and malignant tissues via highly complex DNA and protein interactions.<sup>186</sup> As previously mentioned, oncogene activation is mediated to p53 via p14/ARF; however, genotoxic stress resulting from DNA damage as well as telomeric shortening directly induces p53 expression.<sup>183,187</sup> In response to aberrant growth signals, p53 mediates either cell-cycle arrest in part via induction of p21 or apoptosis by a variety of transcription-dependent, as well as transcription-independent, mechanisms.<sup>186,188,189</sup> p53 may influence the metastatic potential of tumor cells by inhibiting expression of vascular endothelial growth factor.<sup>190</sup> Additional studies have shown that restoration of p53 expression by gene therapy techniques

results in cell-cycle arrest and apoptosis as well as enhanced sensitivity to chemotherapy and ionizing radiation in esophageal cancer cells. [191,192](#)

Fifty percent to 80% of esophageal cancers exhibit p53 mutations, most of which occur in evolutionarily conserved residues within the sequence-specific DNA binding domain. [164,193,194](#) p53 mutations precede the development of aneuploidy in Barrett's esophagus, [125](#) and the frequency of these mutations increases dramatically during histologic progression to malignancy in this condition. [20,195,196](#) Several studies suggest that p53 mutations correlate with Rb mutations in esophageal cancers, as well as disease-free and overall survival in patients with these neoplasms. [176,177,197](#)

Malignant transformation not only depends on the inactivation of growth constraints mediated by the Rb and p53 tumor suppressor pathways, but equally important requires activation of telomerase, a ribonucleoprotein that adds hexameric DNA repeats to chromosomal ends to prevent loss of telomere length during DNA replication. [187,198,199](#) Aberrant expression of telomerase has been observed in the vast majority of esophageal cancers examined to date [200](#); Koyanagi et al. [201](#) detected telomerase expression in 100% of 57 esophageal squamous cell cancers compared with less than 10% of normal tissue samples. In addition, Morales et al. [202](#) observed high-level telomerase expression in 100% of adenocarcinomas and high-grade Barrett's dysplasias; in contrast, only weak or moderate expression was seen in metaplasia or low-grade dysplasia samples. Similar findings have been noted by Lord et al., [203](#) who observed high-level telomerase expression in all stages of Barrett's esophagus, the level of which appeared to increase during histologic progression to cancer. Interestingly, telomerase reverse transcriptase expression in histologically normal esophageal squamous epithelia in cancer patients was significantly higher than that observed in esophageal biopsies obtained from noncancer patients. Although the clinical relevance of telomerase activity in esophageal cancers has not been defined, the fact that telomere length may correlate with chemosensitivity in esophageal cancer cells and that inhibition of telomerase activity induces death in cultured cancer cells [204](#) strongly suggest that telomerase expression may significantly influence the clinical course of esophageal carcinomas.

## CLINICAL PRESENTATION

Because it lacks a serosal coat, the esophagus is able to distend and accommodate considerable intraluminal tumor growth before deglutition is affected; as such, 50% of esophageal cancer patients have locally advanced unresectable disease or distant metastases at presentation. Dysphagia and weight loss are the initial symptoms in approximately 90% of patients presenting with esophageal cancer. Approximately 75% of the esophageal circumference must be involved with tumor before dysphagia is experienced; hence, although many patients relate a vague discomfort with swallowing for several months, dysphagia to solid foods may progress rapidly to total obstruction from circumferential tumor growth. Approximately 20% of patients experience odynophagia (painful swallowing). Although the vast majority of esophageal cancer patients present with weight loss, cachexia is seen in less than 10% of these individuals. Additional presenting symptoms may include dull retrosternal pain resulting from invasion of mediastinal structures, cough, or hoarseness due to paratracheal nodal or recurrent laryngeal nerve involvement. Infrequently, patients may present with pneumonia secondary to tracheoesophageal fistula or exsanguinating hemorrhage due to erosion of the esophageal neoplasm into the aorta.

## DIAGNOSIS

Esophageal cancer should be suspected in any patient complaining of dysphagia and weight loss. A thorough history should be ascertained, focusing on preexisting conditions, as well as tobacco and ethanol abuse, which are known to be associated with increased esophageal cancer risk. Aspiration cytology should be performed on palpable cervical lymph nodes to rule out extrathoracic metastases. Chest radiography and barium swallow should be performed; the barium swallow provides an inexpensive and important initial assessment of the extent of the disease within the esophagus and should include the entire esophagus as well as stomach and duodenum; double-contrast studies are preferable because they provide more precise evaluation of mucosal patterns and allow detection of small lesions that may be missed on single-contrast examination. Computed tomography (CT) of the chest and upper abdomen should be obtained to evaluate the extent of disease within the chest and rule out visceral metastases in the abdomen.

Patients who are suspected to have a primary esophageal carcinoma on the basis of history, physical examination, or radiographic studies should undergo esophagoscopy to establish tissue diagnosis and define the extent of the esophageal lesion. At the time of endoscopy, attention should focus on the identification of the neoplasm in relation to cricopharyngeus, the squamocolumnar junction, and the diaphragmatic hiatus; in addition the presence or absence of satellite lesions, Barrett's esophagus, and esophagitis should be noted. Biopsies and brushings should be obtained from suspicious lesions; the combined diagnostic accuracy of these two procedures exceeds 90%. [205](#) Vital stains including toluidine blue or Lugol's iodine may be useful to guide endoscopic biopsies in situations in which lesions are equivocal. Frequently, strictures are encountered that require dilation to allow passage of the endoscope and provide temporary relief of dysphagia. Occasionally, the esophagus is so strictured it cannot be safely dilated; in these situations, multiple biopsies in four quadrants should be obtained, and the patients treated as if they have esophageal carcinoma irrespective of biopsy results. Bronchoscopy should always be performed in patients with potentially resectable upper and middle third esophageal carcinomas to rule out recurrent laryngeal nerve involvement and to identify and biopsy suspicious areas within the membranous trachea to rule out impending esophagorespiratory fistula.

Once a tissue diagnosis of esophageal cancer has been established, additional studies should be obtained to accurately stage the disease according to American Joint Committee on Cancer criteria (outlined in [Table 33.2-2](#) and [Tables 33.2-3](#)) in order to ascertain prognosis and optimize treatment. Tumor length and the degree of obstruction appear to have less effect than the extent of wall penetration and lymph node metastases in determining survival of esophageal cancer patients. Current noninvasive imaging modalities are imperfect regarding evaluation of local regional disease and detection of distant metastases in these individuals. [206](#) Conventional CT scans detect the primary tumor in 75% to 80% of cases; however, sensitivity for local regional nodal disease is only 50% to 70%. [207,208](#) and [209](#) Furthermore, although CT scans may accurately predict resectability in as many as 75% of cases, they have not proven useful for assessing response to induction therapy in esophageal cancer patients. [207,209,210](#)

Primary tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor invades lamina propria or submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades adventitia
T4	Tumor invades adjacent structures
Lymph node	
NX	Regional nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
Distant metastasis	
M0	No distant metastasis
M1	Distant metastasis (including positive celiac nodes)

	T4	Any N	M0
Stage IV	Any T	Any N	M1

**TABLE 33.2-3.** Tumor Stages for Esophageal Cancer

Endoscopic ultrasonography (EUS) has been advocated as a means to enhance the accuracy of staging of esophageal cancers. <sup>211</sup> Several studies indicate that in experienced hands, EUS accurately assesses wall involvement in 50% to 90% of tumors and mediastinal lymph node status in 67% to 100% of patients with localized esophageal cancers. <sup>212,213</sup> Reid et al., <sup>214</sup> as well as Catalano and colleagues, <sup>215</sup> reported that EUS may be a valuable noninvasive means to detect celiac nodal metastases in esophageal cancer patients (sensitivity, 70% to 80%, and specificity, 88% to 98%). However, the accuracy of EUS is highly dependent on the expertise of the ultrasonographer <sup>216</sup>; an incomplete or erroneous assessment of lymph node metastases, invasion of adjacent organs, and poor staging of early carcinomas have been reported. <sup>217</sup> Furthermore, EUS has limited value in staging patients with high-grade obstruction or assessing response to induction therapy in esophageal cancer patients. <sup>218,219</sup>

[<sup>18</sup>F]fluorodeoxyglucose (FDG) positron emission tomography (PET) scans have been used for staging patients with locally advanced esophageal cancers. Kole et al. <sup>209</sup> prospectively compared FDG PET and CT scans in 26 esophageal cancer patients. The primary tumor was visualized in 80% of patients by CT scan and 96% by FDG PET; neither modality accurately assessed the extent of wall involvement. Nodal disease was imaged in 62% of patients by CT scan and 90% by PET scan. PET scans detected distant metastases not seen by CT scans in three patients. Although these data suggest that PET scans may improve the staging of esophageal cancer patients, McAteer et al. <sup>220</sup> reported that PET scans do not accurately assess regional lymph node involvement in these individuals. Luketich et al. <sup>208</sup> reported their experience with FDG PET scans in 91 consecutive esophageal cancer patients. Minimally invasive procedures were used to confirm or refute imaging results. FDG PET scans detected metastases in only 27 of 39 cases documented by minimally invasive techniques (sensitivity, 69%; specificity, 97%; accuracy, 84%); CT scans revealed metastases in only 18 of these cases (sensitivity, 46%; specificity, 74%; accuracy, 63%). Although FDG PET scans were more accurate than CT scans in detecting distant metastases, they were only 69% sensitive relative to minimally invasive surgery techniques. Krasna <sup>221</sup> observed greater than 93% diagnostic accuracy using thoracoscopy and laparoscopic techniques to stage esophageal cancers. Collectively, these data indicate that minimally invasive surgery techniques presently represent the most accurate means to stage locally advanced esophageal carcinomas; in addition to enabling pathologic assessment of lymph nodes, thoracoscopy can confirm the presence of unresectable (T4) lesions, which are not accurately assessed by current noninvasive techniques.

Kobori et al. <sup>222</sup> compared <sup>11</sup>C-methylcholine PET and <sup>18</sup>F-FDG PET in 50 patients with locally advanced esophageal cancer. Methylcholine PET scans were more effective than FDG PET or CT scans in detecting small metastases in the mediastinum, but could not detect metastases in the upper abdomen due to uptake of <sup>11</sup>C-choline in the liver. FDG PET scans were superior to CT scans for detection of metastases in the chest and abdomen. When combined, <sup>11</sup>C-choline and <sup>18</sup>F-FDG PET were 85% sensitive for detecting metastatic nodes in the mediastinum and abdomen. Thus, combination PET scans may enhance the sensitivity for imaging small metastatic deposits in the mediastinum and abdomen. Further refinement may enable the diagnostic accuracy of PET scans to equal that achieved by minimally invasive staging techniques. Furthermore, preliminary data suggest that PET scans may prove to be valuable for assessing response to induction therapy in esophageal cancer patients <sup>223</sup> in contrast to CT scans or EUS, which appear to be unreliable for evaluation of treatment response in these individuals. <sup>207,218,219</sup> Use of these imaging modalities may enhance the accuracy of staging in esophageal cancer patients, thereby improving stratification of individuals for multimodality treatment protocols.

## TREATMENT

The treatment of choice for patients with esophageal cancer is controversial. Esophagectomy remains the standard of care; however, its role has been challenged due to the generally poor outcomes following surgical resection alone in patients who typically have locally advanced disease. <sup>224,225</sup> A survey of community care practice patterns between 1988 and 1993 revealed an increase in the use of chemoradiotherapy relative to surgery as primary management of esophageal cancer. <sup>226</sup> Currently, in many institutions, primary resection is deferred in favor of combined modality therapy with or without adjuvant esophagectomy. The routine use of combined modality treatment outside the realms of controlled clinical trials is troublesome since most randomized trials have not shown a survival advantage of various induction regimens compared with esophagectomy alone. Furthermore, there is considerable controversy within the surgical literature as to what represents the appropriate operation for patients with esophageal cancer ( [Table 33.2-4](#)); the debate focuses primarily on the need for and the extent of lymph node dissection during esophagectomy for cancer. The following discussion summarizes the current status of surgery, chemotherapy, radiation therapy, and combined modality regimens in the treatment of esophageal cancer.

TRANSHIATAL ESOPHAGECTOMY
Esophagectomy and preservation of gastric conduit with limited upper abdominal and low neck dissection
Left neck esophagectomy and mobilization of cervical esophagus
Transhiatal resection
Posterior mediastinal placement of conduit
Cervical anastomosis
TRANSHIATAL ESOPHAGECTOMY WITH FIELD RESECTION
Esophagectomy and preservation of gastric or colonic conduit with upper abdominal lymph node dissection
High thoracotomy for esophageal mobilization and resection with limited mediastinal lymph node dissection
Resection to cervical anastomosis
MINI-OPEN ESOPHAGECTOMY (THREE-FIELD RESECTION)
Esophagectomy and preservation of gastric or colonic conduit with upper abdominal and retroperitoneal lymph node dissection
High thoracotomy and low neck resection with
Thoracic esophagectomy
Mediastinal lymph nodes
Anterior neck
Tracheal tube
Intra-abdominal or cervical anastomosis
MINI-OPEN ESOPHAGECTOMY (THREE-FIELD RESECTION)
Esophagectomy and preservation of gastric or colonic conduit with upper abdominal and retroperitoneal lymph node dissection
High thoracotomy and low neck resection with
Thoracic esophagectomy
Anterior neck
Tracheal tube
Mediastinal and low cervical lymph nodes
Cervical anastomosis

**TABLE 33.2-4.** Types of Esophageal Resection

## SURGICAL RESECTION

### Transhiatal Esophagectomy

Transhiatal esophagectomy entails extirpation of the intrathoracic esophagus through the esophageal hiatus of the diaphragm without the need for a thoracotomy incision. An upper abdominal incision and a low-neck incision are required to isolate the esophagus at either end. The organ is next carefully stripped from its mediastinal attachments and removed. The prepared esophageal substitute, usually a greater curvature gastric tube, is advanced across the esophageal bed in the posterior mediastinum, and gastrointestinal continuity is restored by an end-to-side esophagogastrostomy in the neck. No attempt is made to perform a systematic lymph node dissection apart from the few parahiatal nodes removed with the specimen. Occasionally, sampling of readily accessible celiac and periesophageal nodes is performed. <sup>227</sup>

Transhiatal esophagectomy is one of the more commonly used techniques for esophagectomy in North America and Europe. Orringer et al. <sup>227</sup> reported on 800 patients with cancer of the intrathoracic esophagus and cardia treated with transhiatal esophagectomy; adenocarcinoma was present in 69% of these individuals, whereas 28% had epidermoid cancer. Hospital mortality was 4.5% and morbidity was 27%. Major complications included anastomotic leaks (13%), recurrent laryngeal nerve injury (7%), wound infection (3%), pulmonary complications (2%), bleeding (1%), and chylothorax (1%). More than 90% of patients were discharged within 21 days of hospitalization. Overall survivals at 2, 3, and 5 years were 47%, 34%, and 23%, respectively. Five-year survival was 59% for stage I patients and 22% for patients with stage IIA. Patients with stage III disease had 2- and 5-year survival rates of 32% and 10%, respectively. There was an overall statistically significant survival advantage for patients with adenocarcinoma (24% vs. 17%). This study by the University of Michigan group represents the largest experience with transhiatal resections for carcinoma, and the survival rates are quite consistent with those reported by other surgeons who practice a similar approach ( [Table 33.2-5](#)). <sup>227,228,229,230,231,232,233</sup> and <sup>234</sup> Gelfand et al. <sup>228</sup> reported on 160 patients who underwent transhiatal esophagectomy for carcinoma of the lower esophagus and cardia. The majority of the tumors were adenocarcinomas, and most were in early stages; survival rates at 2 and 5 years were 40% and 21%, respectively. Gertsch and colleagues <sup>229</sup> described their experience with 100 esophageal cancer patients who were uniformly treated with transhiatal esophagectomy without adjuvant therapy over a 10-year period. Hospital mortality was 3% and morbidity was 68%. The median survival was 18 months and the overall 5-year survival was 23%. Survival was better for T1 and T2 tumors (63% 5-year survival). Vigneswaran et al. <sup>230</sup> reported on 131 patients who underwent transhiatal resection with a 2% operative mortality. Overall 5-year survival was 21%. Patients with stage I disease had a 47.5% 5-year survival compared with patients with stage III disease whose

5-year survival was 5.8%. Patients with adenocarcinoma had a 5-year survival of 27%, whereas none of those with squamous cell cancer were alive at 5 years.

Randomized trial comparing transhiatal and transsternal esophagectomy

**TABLE 33.2-5.** Transhiatal Esophagectomy for Esophageal Cancer

Only two studies have reported local recurrence rates following transhiatal esophagectomy. One of these studies <sup>235</sup> was published in abstract form only as an update of the results of a randomized trial comparing transhiatal esophagectomy alone with transhiatal esophagectomy following induction chemoradiotherapy. A significant reduction in the local recurrence rate without improvement in overall survival was noted in the combined modality arm. Local recurrence as a component of treatment failure was observed in 39% of patients in the surgery alone arm versus 19% of those receiving combined modality treatment. In a prospective study using serial CT scans, Barbier et al. <sup>236</sup> also detected local recurrence in 39% of 50 esophageal cancer patients following transhiatal resection.

In summary, transhiatal esophagectomy can usually be performed with an operative mortality of 5% or less in the hands of experienced esophageal surgeons. Five-year survival rates are generally in the 20% to 25% range. Survival for patients with stage I tumors is in the 60% to 70% range, whereas patients with stage III disease have a 5% to 10% 5-year survival. Finally, the procedure is associated with failure to control or eradicate local disease in nearly 40% of patients.

### Standard Transthoracic Esophagectomy

Transthoracic esophagectomy is probably the most widely performed operation for cancer of the esophagus worldwide. The procedure can be carried out through a right or left thoracotomy incision depending on the preference of the surgeon and the location of the tumor within the esophagus. Generally, a right thoracotomy is required for adequate exposure of tumors in the middle or upper third that are anatomically intimately related to the membranous trachea or the arch of the aorta. Tumors located at the gastroesophageal junction or in the lower third of the esophagus can be usually approached through a left thoracotomy incision. A left sixth interspace incision provides excellent exposure of the lower mediastinum, and a semicircular diaphragmatic incision performed 1 inch from the costal arch allows access to the upper abdomen. The esophagus is mobilized from its mediastinal bed along with adjoining periesophageal as well as lesser curvature lymph nodes; no radical mediastinal or upper abdominal lymphadenectomy is performed. Gastrointestinal reconstruction is subsequently achieved by preparation of the esophageal substitute (usually stomach) and advancing it to the neck for a cervical anastomosis. Patients operated on through a right thoracotomy require a laparotomy to prepare the gastric tube and pass it across the posterior mediastinum or retrosternal space for a cervical anastomosis. In patients operated on through a left thoracotomy, the esophagus is mobilized along its course in the supra aortic posterior mediastinum well into the neck. The prepared gastric tube is then passed underneath the aortic arch and attached to the esophageal stump. Following reattachment of the diaphragm and closure of the thoracotomy, a small left cervical incision is performed to retrieve the esophagus and the gastric tube. A cervical incision is then performed and the previously mobilized esophagus and gastric tube are easily delivered to the neck for a cervical anastomosis.

Ellis<sup>237</sup> reported his experience with more than 500 esophageal cancer patients who underwent standard transthoracic esophagectomy. One-third of the patients had squamous cell cancers, whereas the remaining two-thirds had adenocarcinomas of the esophagus or gastroesophageal junction. Hospital mortality was 3.3%. Complications occurred in 34% of patients and resulted in a prolonged hospital stay in 21% of individuals. Overall 5-year survival including operative mortality and noncancer-related deaths was 24.7%. Patients who had a complete (R0) resection had a 5-year survival of 29%, whereas no patients with either residual microscopic (R1) or macroscopic disease (R2) survived 5 years. There was no significant effect of cell type on survival. Five-year survival was 79% for patients with stage I disease, 38% for those with stage IIA, and 27% for those with stage IIB. Patients with stage III disease had 3- and 5-year survival rates of 20% and 13.7%, respectively.

Some of the more pertinent surgical series pertaining to standard transthoracic esophagectomy that have been reported within the last decade from North America and Europe are listed in [Table 33.2-6](#).<sup>231,232,238,239,240,241,242</sup> and <sup>243</sup> Resectability rates have ranged from 60% to 90%, and hospital mortality has ranged from 3.2% to 23%. Five-year survival rates have varied between 9% and 24%. The variability in rates of resectability, hospital mortality, and 5-year survival may have been related to differences in patient selection, surgical expertise, and the retrospective nature of most of these studies. More instructive to review are the survival results achieved by the surgical arms of randomized trials comparing various preoperative regimens to surgical resection alone. The most recent of these trials was the North American Intergroup trial that compared chemotherapy followed by surgery with surgery alone.<sup>244</sup> There were 467 eligible patients of whom 227 underwent primary surgical resection, the majority through a transthoracic approach. One hundred six patients had squamous cell cancer (47%) and 121 had adenocarcinoma (53%). Hospital mortality was 6%. Major complications occurred in 26% of patients. Overall survivals at 1, 2, and 3 years were 60%, 37%, and 26%, respectively. Actuarial 5-year survival was 20%. There was no difference in outcome between patients with adenocarcinoma and those with epidermoid cancer. In a separate trial performed by Walsh et al.,<sup>245</sup> 113 patients were randomized to receive either surgery alone or chemoradiation followed by transthoracic esophagectomy. Hospital mortality in the control arm was 2%, and the 3-year survival was 6%. Bossett et al.<sup>246</sup> performed a randomized trial comparing transthoracic esophagectomy alone with radiotherapy followed by esophagectomy. Three- and 5-year survival rates in the surgery alone arm were 38% and 22%, respectively. Finally, Law et al.<sup>247</sup> reported on 147 patients with squamous cell carcinoma randomized to either chemotherapy followed by esophagectomy or esophagectomy alone. There were 73 patients in the control arm, and nearly all underwent resection by a transthoracic approach. Hospital mortality was 8.7%. Survival rates at 2 and 5 years were 31% and 10%, respectively.

**TABLE 33.2-6.** Transthoracic Esophagectomy for Esophageal Cancer

Local recurrences following standard transthoracic resections have been reported in 30% to 60% of patients. Most of the data regarding local recurrences have been obtained from surgical control arms of various randomized trials. Gijnoux et al. <sup>248</sup> reported the incidence of local recurrence in a study comparing surgical resection alone with preoperative radiotherapy. Local recurrences were observed in 67% of patients in the surgery alone arm compared with 47% of individuals in the experimental arm. Similarly Nygaard et al. <sup>249</sup> reported a 35% local recurrence rate following resection alone in a four-arm randomized trial comparing resection with preoperative chemotherapy, preoperative radiotherapy, and preoperative chemoradiation. In the Intergroup trial comparing esophagectomy alone with chemotherapy followed by esophagectomy,<sup>244</sup> the local recurrence rate in the control arm was 31% among 135 patients who received a complete (R0) resection. An additional 68

patients had R1 or R2 resections. The overall local failure rate (persistent or recurrent disease) in all 227 patients in the control arm was 61%. In the previously mentioned randomized trial reported by Law et al.,<sup>247</sup> 21% of patients developed local recurrence, while an additional 10% had both local and distant recurrences; thus local recurrence was a component of treatment failure in 31% of patients in this study.

### **Comparison of Transhiatal and Transthoracic Esophagectomy**

Several retrospective studies have shown little difference in the operative mortality and morbidity between transhiatal and transthoracic esophagectomy with limited lymph node dissection. Rindani et al.<sup>250</sup> reviewed the results from 44 series published between 1986 and 1996. Thirty-three articles described results of 2675 patients who underwent transhiatal resection, whereas 29 articles reported results of transthoracic resections performed in 2808 patients. Thirty-day mortality was 6.3% after transhiatal and 9.5% after transthoracic esophagectomy. Major pulmonary and cardiovascular morbidity was similar in both groups. Transhiatal esophagectomy was associated with a higher incidence of anastomotic leaks (16% vs. 10%), anastomotic strictures (28% vs. 16%), and recurrent laryngeal nerve injury (11% vs. 5%). Overall 5-year survival was 24% after transhiatal esophagectomy and 26% following transthoracic resection.

Two randomized trials have compared transthoracic with transhiatal resections. Chu et al.<sup>231</sup> reported on 39 patients with carcinoma of the lower third of the esophagus who were prospectively randomized to receive either a transhiatal (n = 25) or a transthoracic resection (n = 19). There were no significant differences between the groups in terms of blood loss, postoperative ventilatory requirements, cardiopulmonary complication rates, and mean hospital stay. Median survival was 16.0 months after transhiatal esophagectomy and 13.5 months after transthoracic resection. Goldminc et al.<sup>233</sup> prospectively randomized 67 patients to receive either a transhiatal (n = 32) or transthoracic esophagectomy. There were no differences between the two groups with respect to hospital mortality, morbidity, incidence of pulmonary complications, or long-term survival.

In summary, survival rates achieved with the surgical transhiatal esophagectomy are comparable with those reported for standard transthoracic resection. However, radical lymph node dissections have not been performed in any of the aforementioned series; hence the survival results reflect the effect of the surgical incision rather than the extent of lymphadenectomy.

### **En Bloc Esophagectomy**

The deep location of the esophagus within the narrow confines of the mediastinum and the lack of a well-defined mesentery have generally precluded the application of *en bloc* resection to patients with esophageal carcinoma. In 1963, Logan described results pertaining to 250 patients who underwent *en bloc* resection for cancer of the cardia, noting a 16% 5-year survival.<sup>251</sup> Although that survival rate was remarkable at the time, the 21% operative mortality limited a wider adoption of the procedure. Skinner reintroduced the technique in 1969, which was later modified and applied to cancer of the thoracic esophagus.<sup>252</sup> The basic principle of the operation is extirpation of the tumor-bearing esophagus within a wide envelope of adjoining tissues that include both pleural surfaces laterally and the pericardium anteriorly where these structures are intimately related to the esophagus. The lymphatics wedged dorsally between the esophagus and the aorta, and the thoracic duct throughout its mediastinal course, are resected *en bloc* with the specimen. This posterior mediastinectomy necessarily results in a complete mediastinal node dissection from the tracheal bifurcation to the esophageal hiatus. Additionally, an upper abdominal lymphadenectomy is performed including the common hepatic, celiac, left gastric, lesser curvature, parahiatal, and retroperitoneal nodes. The purpose of this extended resection is to maximize locoregional control of the primary tumor; local recurrence rates following *en bloc* esophagectomy are reported to be less than 10%.<sup>253,254</sup> This is a strikingly low local failure rate compared with those observed following transhiatal or standard transthoracic resections, or chemoradiation delivered with curative intent.<sup>255</sup>

Critics have argued that the *en bloc* procedure is associated with a high operative mortality and morbidity without an apparent survival advantage. In fact, in the earliest report by Skinner,<sup>252</sup> the operative mortality for 80 patients with cancer of the cardia treated by *en bloc* resection was 11%, and the 5-year survival was only 18%. However, in more recent series, hospital mortality has ranged between 2% and 7%,<sup>48,256,257</sup> and several investigators have reported survival rates exceeding those achievable by standard resection. Lerut et al.<sup>48</sup> reported their experience with 129 patients who had an R0 resection for cancer of the thoracic esophagus. Approximately two-thirds of patients had squamous cell cancer, and one-third had adenocarcinoma of the esophagus. Resection was accomplished by the *en bloc* technique in 54 patients, with a hospital mortality of 7.5%. Survival was significantly better following *en bloc* resection compared with standard resection (48% vs. 41%;  $P = .002$ ). Interestingly, multivariate analysis showed that the survival advantage after *en bloc* resection was apparent only in patients with nodal metastasis ( $P = .005$ ). Furthermore, patients with stage III tumors had a 5-year survival of 22% after *en bloc* resection, compared with 13% after standard resection ( $P = .05$ ). Hagen et al.<sup>256</sup> reported similar results in a smaller group of patients with adenocarcinoma of the distal esophagus and gastroesophageal junction. *En bloc* resection was performed in 30 patients, and transhiatal resection was done in 16 patients. Overall survival was significantly better after *en bloc* resection (41% vs. 14%;  $P = .001$ ). A survival advantage was observed in patients with early lesions (T1 and T2) in whom the 5-year survival was 75% versus 21% in favor of *en bloc* resection. Similarly, patients with transmural (T3) tumors and five or fewer positive nodes had a significantly better survival after *en bloc* resection (27% vs. 9%).

An important criticism of most of these studies is the failure to clearly define the criteria used to stratify patients to receive one procedure versus another. For example, in the study by Hagen et al.,<sup>256</sup> patients receiving transhiatal esophagectomies were significantly older or more debilitated than those undergoing *en bloc* resections. Preferential inclusion of early-stage patients into the *en bloc* groups may have biased survival outcomes. Arguably some early-stage patients undergoing *en bloc* resections might have had similarly favorable outcomes following a more limited procedure.

Altorki et al.<sup>257</sup> reported on 155 patients who underwent resection for carcinoma of the esophagus between 1988 and 1998. During the first 4 years of the study, standard transthoracic resections were performed in nearly all patients; thereafter *en bloc* resections were carried out preferentially in nearly all patients. The overall hospital mortality was 5.1% and did not vary significantly by procedure (*en bloc*, 4.8%; standard transthoracic, 5.7%). Overall 5-year survival was 40% in the *en bloc* group. Node-negative patients had 5-year survival rates of 67% following *en bloc* resection and 27% after standard esophagectomy. Interestingly, the mean number of resected nodes per patient in node-negative patients was significantly higher after *en bloc* resection (36 vs. 20 per patient;  $P = .03$ ) suggesting that the extended procedure may improve the accuracy of staging in esophageal cancer patients. Conceivably, some *node-negative* patients were understaged during standard resections, resulting in apparently worse survival relative to similarly staged patients who had undergone *en bloc* resections. Survival was also significantly better after *en bloc* resection in patients with nodal metastases (33% vs. 13%;  $P = .002$ ). Five-year survival was significantly higher in patients with stage III disease treated by *en bloc* resection (34% vs. 11%;  $P = .007$ ). This survival advantage was noted despite an analysis of variance showing no difference between the groups in terms of age, gender, performance status, tumor size, cell type, or number of positive nodes per patient. The 5-year survival rate (11%) in stage III patients undergoing standard resection in this series is similar to those reported in other series following similarly limited resections, suggesting no obvious selection bias in favor of *en bloc* resection. The survival advantage conferred by *en bloc* esophagectomy in patients with stage III disease confirms previous observations by Lerut et al.<sup>48</sup> Furthermore, the 7.8% (8 of 109) local recurrence rate observed following *en bloc* esophagectomy in Altorki's trial is dramatically less than those observed following transhiatal or standard transthoracic resections.

### **Three-Field Lymphadenectomy**

Three-field lymph node dissection for carcinoma of the esophagus has been practiced by Japanese surgeons since the early 1980s. This effort was initially prompted by studies showing that the cervical lymph nodes were the site of tumor recurrence in 30% to 40% of patients in whom a curative resection had been performed.<sup>258</sup> The extended procedure included dissection of the cervical, mediastinal, and upper abdominal nodes in patients with carcinoma of the thoracic and abdominal esophagus. In 1991, Isono et al.<sup>259</sup> reported the results of a nationwide study on three-field dissections performed at 35 institutions throughout Japan. Nearly 1800 patients underwent esophagectomy with three-field lymph node dissection, whereas 2800 underwent two-field dissection. The following observations were made:

- Approximately one-third of patients had previously unsuspected metastases in cervical lymph nodes. The prevalence of cervical nodal metastases was highest for upper third tumors (40%), but even patients with lower third cancers had a 20% probability of metastatic carcinoma involving the cervical lymph nodes.
- The frequency of nodal metastases increased with depth of tumor penetration through the esophageal wall. Patients with intramucosal carcinoma had a 30% probability of nodal metastases, while invasion into the submucosa, muscularis propria, or adventitia signaled a 50%, 60%, and 80% probability of nodal disease, respectively. Interestingly, a statistically higher prevalence of nodal metastases was observed after three-field lymph node dissection in patients with T1 and T2 tumors, but not in those with more advanced disease.
- The cervical lymph nodes most frequently involved with metastatic carcinoma were the nodal chains along the recurrent nerves, as well as the deep cervical nodes along the posterior aspect of the internal jugular vein. Supraclavicular nodal disease was infrequent and was associated with a distinctly poor outcome.

Collectively, these observations indicate that a large number of patients will be inaccurately staged after *en bloc* resection with isolated mediastinal and abdominal lymphadenectomy. Approximately one-third of patients will have their tumor, node, metastasis (TNM) stage upstaged as a result of the extended procedure. Although

most surgeons readily concede that extended lymphadenectomy improves tumor staging, many question its effect on the survival of patients with locally advanced esophageal cancer.<sup>260</sup> However, Japanese surgeons have provided a compelling argument for a positive effect of three-field lymph node dissection on survival in these individuals. Akiyama et al.<sup>261</sup> reported their experience with 717 patients in whom an R0 resection was performed using either a two-field (n = 393) or three-field technique (n = 324).<sup>261</sup> Five-year survival in node-negative patients was 84% after the three-field procedure compared with 55% after two-field lymphadenectomy ( *P* = .004). Furthermore, in patients with node-positive disease, the 5-year survival rate was 43% in patients receiving three-field dissections, compared with 28% for patients undergoing two-field dissections ( *F* = .008), indicating that the improved survival rates observed in patients receiving extended lymphadenectomies were not simply due to stage migration. Similar results have been reported by a number of Japanese surgeons.<sup>262,263 and 264</sup> Significantly, most studies have reported 5-year survivals of 25% to 30% in patients with positive cervical lymph nodes. These impressive data suggest that the recurrent laryngeal nodes should be considered a regional (N1) rather than a distant (M1) site of disease for tumors of the intrathoracic and abdominal esophagus. Indeed, lymphoscintigraphy studies using radiolabeled colloid injected into the midthoracic esophagus have routinely demonstrated tracer uptake within the upper mediastinal and cervical nodes as well as the left gastric lymph nodes.<sup>265,266</sup>

In spite of the intriguing results reported by Japanese surgeons, most European and North American oncologists have viewed three-field dissection with skepticism. There are several reasons that might explain the lack of enthusiasm for the procedure:

- There is a prevailing concept among western surgeons that patients with carcinoma of the esophagus have systemic disease at the time of presentation. Cure following resection has often been considered a chance phenomenon dependent more on the biologic behavior of the tumor than on the surgical strategy pursued.
- Three-field lymph node dissection has been associated with a definite, albeit a statistically insignificant, increase in hospital morbidity. Foremost among the potential complications is injury to one or both recurrent nerves, reported in up to 70% of patients, some of whom have required tracheostomy and prolonged mechanical ventilation.<sup>263</sup> Furthermore, at least one study examined the quality of life following esophagectomy with three-field lymph node dissection with particular emphasis on the effect of vocal cord paralysis.<sup>264</sup> Twenty percent of patients reported severe hoarseness, restricted food intake, and reduced exercise tolerance up to 60 months postoperatively.
- Nearly all of the Japanese data are from retrospective studies comparing surgical therapies delivered over two decades. Two randomized studies have been reported.<sup>267,268</sup> Nishihira et al.<sup>267</sup> randomized 62 patients with squamous cell carcinoma of the esophagus to receive a two-field or three-field lymph node dissection. Hospital deaths occurred in 3% after two-field dissection and in 7% after three-field lymphadenectomy. There were no differences between the two groups in 5-year survival or recurrence rates. In another trial, Kato et al.<sup>268</sup> randomized 150 patients to receive transthoracic esophagectomy with either two-field or three-field lymph node dissection. Hospital mortality and morbidity were comparable in both groups; a significantly higher 5-year survival was observed in patients who underwent a three-field dissection (48% vs. 33%).

Altorki et al.<sup>38</sup> reported the only experience with this procedure in North America. Esophagectomy with a three-field node dissection was performed in 34 patients, 10 of whom had adenocarcinomas. Hospital mortality and morbidity were 2.3% and 35%, respectively. Recurrent nerve injury occurred in 6% of patients. An average of 60 nodes were resected per patient; 70% of these individuals had nodal metastases, most of which were within the lesser gastric curve, paraesophageal, and recurrent laryngeal nodes. Cervical nodal metastases were present in 30% of patients regardless of cell type or location of the primary tumor within the esophagus. With a median follow-up of 42 months, 3-year and 5-year survival was 46%. Node-negative patients had a 77% 5-year survival, whereas those with nodal metastases had a 5-year survival of 33%. Three of the ten patients with metastases involving cervical or recurrent laryngeal nodes were disease free a minimum of 3 years after operation. Local recurrence was observed in two patients.

Lerut et al.<sup>269</sup> reported the only European experience with esophagectomy and three-field lymph node dissection. Thirty-eight patients underwent the procedure with no hospital mortality. Overall survival rates at 3 and 5 years were 45% and 37%, respectively. Patients with nodal metastases had a 27% 5-year survival; individuals with cervical node disease had a 20% 5-year survival. The patterns of nodal metastases observed by Altorki and Lerut are similar to those reported by Japanese investigators and appear independent of tumor histology. The potential survival advantage offered by three-field dissection in esophageal cancer patients (particularly those with adenocarcinoma) is encouraging given the limited efficacy of chemotherapy and radiation in these individuals.

## CHEMOTHERAPY

Five-year survival rates for esophageal cancer patients resected at most major centers in the United States range from 15% to 20%.<sup>270,271</sup> Although radical esophagectomy may salvage some patients with locally advanced carcinomas, the vast majority of individuals succumb to their disease, suggesting that most patients have occult metastases at presentation. Studies of patterns of recurrence, and data from autopsy series confirm the potential for tumor spread to all organs.<sup>41,272,273,274 and 275</sup> These data have provided the rationale for using systemic therapy in conjunction with surgery, radiation, or both in patients with apparently localized disease or as the primary treatment for patients with clinically evident disseminated disease.

Until fairly recently, standard criteria of treatment response required a bidimensional lesion that could be serially measured. For the esophageal cancer patient with metastatic disease, treatment response can be reliably assessed using pulmonary, soft tissue, and liver nodules as indicators. CT, magnetic resonance imaging, and double-contrast barium esophagography, which are typically used to assess response in patients with disease limited to the esophagus, only provide unidimensional measurements of the primary.<sup>276,277</sup> Endoscopy with brushings and biopsy may be performed to confirm a clinical complete response; however, biopsy is subject to sampling error and is not a reliable indicator of complete histologic resolution of disease.

A variety of single agents and combination regimens have been evaluated in patients with recurrent or metastatic carcinoma of the esophagus. These patients often have a high tumor burden and poor performance status with little prospect for prolongation of survival. Phase II clinical trials in this population have identified drugs with activity,<sup>278</sup> and they have been integrated into combined modality regimens for the treatment of earlier stage disease.

The accumulated experience with chemotherapy to date is almost entirely in patients with squamous cell histology. Due to the rising incidence of adenocarcinoma of the esophagus, gastroesophageal junction, and cardia in the United States,<sup>3</sup> patients with this histology now make up two-thirds of referrals for chemotherapy. Only recently have trials with new agents and combined modality regimens included both histologies.

### Chemotherapy for Palliation of Recurrent and Metastatic Disease

**SINGLE AGENTS.** Studies of single agents are summarized in [Table 33.2-7](#).<sup>279,280,281,282,283,284,285,286,287,288,289,290,291,292,293,294,295,296,297,298,299,300,301 and 302</sup> The cumulative response rate for any one drug is low (on the order of 15% to 30%), and there is no indication of survival benefit. Symptomatic improvement, if reported, is brief. Response data for many of the older drugs have come from broad phase I and II trials conducted in the early 1970s, which included small numbers of esophageal cancer patients. Bleomycin, 5-fluorouracil (5-FU), mitomycin, and cisplatin (CDDP) have been used most often because of their single-agent activities and their additive or synergistic effects with radiation. Because of the potential for pulmonary toxicity, bleomycin is no longer included in combination regimens, having been replaced by 5-FU. Similarly, mitomycin is less often used because of its toxicity profile, which includes hemolytic-uremic syndrome and cumulative myelosuppression.

Drug	Dose	No. of Patients	Response	Partial Response	Complete Response
Bleomycin	10-20 mg/m <sup>2</sup> (10-20 mg/m <sup>2</sup> day 1 or 2)	86	5	15	25-28
Fluorouracil	30 mg/m <sup>2</sup> (30-40 mg/m <sup>2</sup> )	27	5	15	24
	30 mg/m <sup>2</sup> (30-40 mg/m <sup>2</sup> )	36	5	16	30
Mitomycin	10 mg/m <sup>2</sup> (10-15 mg/m <sup>2</sup> )	15	5	15	24-27
Doxorubicin	40-60 mg/m <sup>2</sup> (40-60 mg/m <sup>2</sup> )	25	5	16	25-28
Metastasis	10 mg/m <sup>2</sup> (10-15 mg/m <sup>2</sup> )	47	5	16	25
Cisplatin	10-20 mg/m <sup>2</sup> (10-15 mg/m <sup>2</sup> )	12	5	16	24-25-28
	10 mg/m <sup>2</sup> (10-15 mg/m <sup>2</sup> )	27	5	15	24
Dactinomycin	1-4 mg/m <sup>2</sup> (1-4 mg/m <sup>2</sup> )	41	5	16	25-27
Megestrol	400-700 mg/m <sup>2</sup> (400-700 mg/m <sup>2</sup> )	41	5	16	25-28
Fluorouracil	10-20 mg/m <sup>2</sup> (10-15 mg/m <sup>2</sup> )	36	5	16	30
Fluorouracil	20 mg/m <sup>2</sup> (10-15 mg/m <sup>2</sup> )	51	5 and 4	16	30

**TABLE 33.2-7.** Trials of Single Agents with Activity in Carcinoma of the Esophagus

5-FU has remained an important drug for the treatment of gastrointestinal malignancies. One study<sup>284</sup> using a protracted infusion schedule for 6 weeks in patients with newly diagnosed esophageal cancer reported an 85% response rate that contrasts with an Eastern Cooperative Oncology Group trial<sup>285</sup> in which a 15% response rate was observed in previously treated patients given intermittent bolus 5-FU.

There are seven trials pertaining to cisplatin as a single agent in esophageal cancer patients,<sup>286,289,290,291,292,293</sup> and 294 six of which used doses ranging from 50 to 120 mg/m<sup>2</sup> every 3 to 4 weeks. The cumulative response rate in patients with metastatic or recurrent disease was 21%.<sup>286,289,290,291,292</sup> and 293 Administration of the drug as a single bolus dose once every 3 weeks or in a divided dose over 5 days every 3 weeks appeared to be equally efficacious. Employing a more dose-intense schedule of cisplatin (120 mg/m<sup>2</sup> on day 1 and 15), Miller et al.<sup>294</sup> observed a 73% response rate in 15 patients before surgery. Although no complete responses were observed, these data suggest that sensitivity to chemotherapy is greater in the newly diagnosed patient.

A randomized phase II trial of cisplatin alone and cisplatin in combination with 5-FU in 92 patients with metastatic squamous cell carcinoma of the esophagus was reported by the European Organization for Research and Treatment of Cancer (EORTC).<sup>293</sup> An 18% response rate was observed in 45 patients receiving single-agent cisplatin at a dose of 100 mg/m<sup>2</sup> every 3 weeks. Although the response rate in the combination therapy arm was 36%, survival was similar for both groups. No studies of single-agent cisplatin have been performed in patients with adenocarcinoma of the esophagus.

Two investigational agents have demonstrated moderate activity in squamous cell carcinoma of the esophagus. These are the vinca alkaloid vindesine<sup>295,296</sup> and 297 and the polyamine synthesis inhibitor mitoguazone (methyl-GAG).<sup>298,299</sup> and 300 Responders included patients previously treated with cisplatin-based combination chemotherapy.

Vinorelbine, a semisynthetic vinca alkaloid that inhibits microtubule assembly, has been approved for use in lung cancer. It has less neurotoxicity compared with vincristine and vinblastine; neutropenia is dose limiting. The EORTC reported a 20% response rate in chemotherapy-naive patients with metastatic squamous cell cancer of the esophagus.<sup>301</sup> In a subsequent trial,<sup>303</sup> vinorelbine was combined with cisplatin in 57 patients with metastatic squamous cell cancer resulting in a 32% response rate and 6-month median duration of response. Vinorelbine has not been evaluated in patients with adenocarcinoma of the esophagus.

The taxane paclitaxel is the first entirely new compound to be tested in both adenocarcinoma and squamous cell carcinoma of the esophagus. Paclitaxel promotes the stabilization of microtubules and is a cycle-specific agent affecting cells in the G<sub>2</sub>/M phase. Paclitaxel also enhances radiation effects that may be both concentration and schedule dependent.<sup>304</sup> The only trial of single-agent paclitaxel in esophageal cancer used the maximum tolerable dose of 250 mg/m<sup>2</sup>, derived from initial phase I trials using a 24-hour infusion schedule.<sup>302</sup> A 34% response rate was observed in 33 patients with adenocarcinoma, and a 28% response rate was noted in 18 patients with squamous cell carcinoma of the esophagus. The overall response rate was 32%. All patients had good performance status, were chemotherapy-naive, and had distant metastases. The dose-limiting toxicity of paclitaxel is myelosuppression, primarily neutropenia. There are no completed studies using either shorter or longer infusion schedules such as 1, 3, and 96 hours.

Drugs that have been adequately tested in squamous cell cancer of the esophagus and have response rates of less than 5% are the methotrexate analogues, dichloromethotrexate<sup>305</sup> and trimetrexate,<sup>306,307</sup> and etoposide,<sup>308,309</sup> ifosamide,<sup>310,311</sup> and carboplatin.<sup>312,313,314</sup> and 315 Carboplatin has been studied in both adenocarcinoma and squamous cell carcinoma patients using a fixed dose schedule of 300 to 400 mg/m<sup>2</sup> in individuals with normal renal function. In contrast to the activity observed in phase II evaluations of cisplatin, responses were observed in only 3 of 59 chemotherapy-naive patients who received carboplatin. Therefore, substitution of carboplatin for cisplatin is not recommended when treating patients with either adenocarcinomas or squamous cell carcinomas of the esophagus.

### Combination Chemotherapy

Only in more recent years have combination regimens been evaluated in patients with adenocarcinoma. Older trials (before the mid-1990s) and those from Europe have almost exclusively been limited to patients with squamous cell carcinomas. Because esophageal cancer is a relatively uncommon malignancy, many studies have included patients treated preoperatively as well as those with recurrent or metastatic disease, and some have also included patients with locally advanced, unresectable neoplasms. In addition to the variation in patient populations, more recent trials have often limited eligibility to patients with no prior chemotherapy and performance status of 0 or 1. Thus, it is difficult to compare treatment efficacies reported from these phase II trials.

The results of platinum-based combination chemotherapy regimens are detailed in [Table 33.2-8](#).<sup>293,303,316,317,318,319,320,321,322,323,324,325,326,327</sup> and 328 Most series have had small numbers of patients and therefore 95% confidence intervals have been large. Nearly all responses have been partial, with only an occasional clinical complete response. Duration of response has been variable but on average has ranged from 3 to 6 months.

Regimen	Enrolled Patients	Response Rate (%)	Median Response Duration (mo)	Response	
Cisplatin + fluorouracil	17	5	17	0 mo	304
Cisplatin + fluorouracil + doxorubicin	31	5	16	5 mo	317,318
Cisplatin + fluorouracil + methotrexate	40	5	19	6 mo	319,320
Cisplatin + mitomycin + doxorubicin	30	5	48	5 mo	321
Cisplatin + mitomycin + methotrexate	36	5	11	17 wk	322
Cisplatin + 5-FU	40	5	16	6 mo	323,324
Carboplatin + mitomycin	16	5	0	0 mo	325
Cisplatin + mitomycin	17	5	12	4 mo	326
5-FU + mitomycin	17	5 and 8	30	4.5 mo	327,328
Cisplatin + 5-FU + mitomycin	36	5 and 8	16	39 mo	327
Thiothymidine acid + mitomycin	11	5	0	0 mo	329
Cisplatin + etoposide	40	5	48	7 mo	330
Paclitaxel (8h) + cisplatin q3wk	30	5 and 8	44	3.9 mo	331
Paclitaxel (3h) + cisplatin q3wk	30	5	12	0 mo	332
Paclitaxel (3h) + cisplatin q3wk + 5-FU	30	5	17	0 mo	333
Paclitaxel (3h) + cisplatin + 5-FU q3wk	40	5 and 8	48	1.7 mo	334
Interferon-α + cisplatin q3wk + 5-FU	35	5 and 8	17	4.5 mo	335
Interferon-α + cisplatin q3wk + 5-FU	35	5	18	0 mo	336

**TABLE 33.2-8.** Selected Combination Chemotherapy for Recurrent and Metastatic Carcinoma of the Esophagus

Trials in the 1980s testing three-drug regimens such as cisplatin, bleomycin, and vindesine<sup>317,318</sup> and cisplatin, mitoguazone, and vindesine<sup>321</sup> or vinblastine<sup>322</sup> yielded response rates of 30% to 40% in epidermoid cancer patients. Toxicity was primarily moderate myelosuppression. Bleomycin and mitoguazone were replaced by 5-FU, which has synergistic activity with cisplatin.

The two-drug combination of cisplatin (100 mg/m<sup>2</sup> day 1) and 5-FU (1000 mg/m<sup>2</sup>/d continuous infusion for 96 to 120 hours) is the regimen most commonly used to treat patients with either squamous or adenocarcinoma histology. A 35% response rate has been observed in patients with metastatic, recurrent, or locally advanced, incurable squamous cell cancer of the esophagus.<sup>293,323</sup> Higher response rates (in the 40% to 60% range) have been reported from trials administering two to three cycles of cisplatin and 5-FU as neoadjuvant therapy before surgery. The difference in response rates may be related to better performance status, nutrition, and smaller volume disease in the surgical candidates. Attempts to substitute carboplatin for cisplatin have been unsuccessful; in a phase II trial of carboplatin and vinblastine,<sup>324</sup> investigators from Memorial Sloan-Kettering Cancer Center observed no responses in 16 patients even though 11 with advanced, inoperable cancers were previously untreated, and 15 had Karnofsky performance scores of 70% or better.

Three trials using interferon-α<sub>2a</sub> as a biomodulator of 5-FU suggested possible benefit.<sup>325,326</sup> and 327 Preclinical data had indicated synergistic cytolytic activity when interferon was combined with 5-FU, possibly due to interferon-mediated stimulation of thymidine phosphorylase, which increases the conversion of 5-FU to its active metabolite, fluorodeoxyuridylate. Ilson and associates<sup>327</sup> treated 26 incurable esophageal cancer patients with interferon-α<sub>2a</sub> (3 million U subcutaneously daily), cisplatin (100 mg/m<sup>2</sup> day 1), and continuous infusion 5-FU (750 mg/m<sup>2</sup>/d for 5 days) recycled every 28 days; the complete and partial response rates were 50%, and the duration of response ranged from 11 to 74 weeks. Treatment responses were observed in 8 of 11 with squamous cell carcinoma (73%; 95% confidence interval, 47% to 99%) and 5 of 15 adenocarcinoma patients (33%; 95% confidence interval, 9% to 57%). The combination of 13-*cis* retinoic acid and interferon-α<sub>2a</sub>, however,

had no activity.<sup>328</sup>

Despite the lack of single-agent activity for etoposide, the Rotterdam Esophageal Cancer Study Group<sup>329</sup> reported a 48% response rate in patients with unresectable or metastatic squamous cell carcinoma. This experience using cisplatin (80 mg/m<sup>2</sup> day 1) and etoposide (100 mg/m<sup>2</sup> intravenously on days 1 to 2 and 200 mg/m<sup>2</sup> orally on days 3 to 5 every 4 weeks) served as the basis for a phase III evaluation of this regimen in the preoperative setting.<sup>330</sup>

Combination regimens including paclitaxel have been evaluated in esophageal cancer patients. In three phase II trials of paclitaxel and cisplatin, response rates ranged from 44% to 52%; activity was comparable in both histologic types.<sup>331,332</sup> and<sup>333</sup> Ilson and associates<sup>331</sup> evaluated paclitaxel administered by 24-hour infusion in doses of 200 to 250 mg/m<sup>2</sup> with growth factor support combined with cisplatin (75 mg/m<sup>2</sup>). Toxicity (primarily myelosuppression) was severe, leading to one or more hospitalizations in 50% of patients and five treatment-related deaths; as such, this particular regimen cannot be recommended. Van der Gaast and associates from Rotterdam reported two separate trials.<sup>332,333</sup> The first evaluated escalating doses of 3-hour infusion paclitaxel (100 to 200 mg/m<sup>2</sup>) combined with a fixed dose of cisplatin (60 mg/m<sup>2</sup>) administered every 2 weeks.<sup>332</sup> A 52% response rate was observed in 59 patients. Doses of paclitaxel above 180 mg/m<sup>2</sup> caused dose-limiting neurotoxicity. The second trial evaluated a weekly regimen of cisplatin (70 mg/m<sup>2</sup>) and 3-hour paclitaxel infusion.<sup>333</sup> A preliminary report indicated that the maximum tolerable dose of paclitaxel was 100 mg/m<sup>2</sup>/week, and that the response rate in 22 adenocarcinoma patients was 50%. The antitumor activity reported for these three regimens was comparable, but toxicities varied considerably.

The three-drug combination of paclitaxel, 175 mg/m<sup>2</sup> (3-hour infusion), combined with cisplatin (20 mg/m<sup>2</sup>/d × 5) and 5-FU (1000 mg/m<sup>2</sup>/d continuous infusion × 120 hours) was evaluated in 60 patients at four centers.<sup>331</sup> A 48% response rate was reported (56% in patients with squamous cell cancers and 46% in adenocarcinoma patients); significantly more complete responses were observed in patients with squamous cell carcinomas. Toxicity was severe, resulting in hospitalizations for 48% of patients, primarily for severe stomatitis, fever, and neutropenia. The addition of paclitaxel to the established cisplatin and 5-FU regimen did not raise the response rate sufficiently to warrant further evaluation in a larger comparative trial.

It is clear that the optimal dose and scheduling of paclitaxel in combination with other active drugs remains to be determined. In general, shorter infusion schedules of paclitaxel result in less myelotoxicity, but more neurotoxicity when this taxane is combined with cisplatin. The regimen of paclitaxel and carboplatin has not been tested in esophageal cancer. However, because of the lack of activity of carboplatin as a single agent or in combination with other agents used to treat esophageal cancer, it should not be substituted for cisplatin until appropriate clinical trials have been performed.

A new regimen under evaluation in esophageal cancer patients is the combination of irinotecan and cisplatin administered in low dose on a weekly schedule.<sup>334</sup> *In vitro* studies have demonstrated sequence-dependent synergy for cisplatin followed by irinotecan, which prevents removal of cisplatin-induced DNA-interstrand cross-links. Two trials have yielded encouraging results with a regimen of cisplatin (30 mg/m<sup>2</sup>) followed by irinotecan (65 mg/m<sup>2</sup>) administered weekly for 4 weeks, repeated every 6 weeks.<sup>335,336</sup> Ilson and associates<sup>335</sup> observed a 57% response rate in 35 patients [12 of 23 (52% response) in adenocarcinoma patients and 8 of 12 (66% response) in patients with squamous cell cancers]; median duration of response was 4.2 months.<sup>335</sup> Dysphagia and global quality of life were improved in the majority of patients. Ajani and associates<sup>336</sup> observed a 51% response rate using the same regimen in 25 adenocarcinoma patients, but recommended reduction of the irinotecan dose to 50 mg/m<sup>2</sup> in previously treated patients. Toxicity in both studies consisted of myelosuppression and diarrhea in a minority of patients. Diarrhea was ameliorated with prophylactic use of antidiarrheal agents, dose reduction, or both.

In summary, more recent trials of combination regimens that have included paclitaxel or irinotecan appear to have higher response rates than previous regimens; however, duration of response remains brief for esophageal cancer patients, and some trials have been reported only in preliminary abstract form and consist of small numbers of evaluable patients. In addition, the toxicities associated with many of these phase II single-institution experiences have been excessive.

Further follow-up of early reports and additional patient trials using the most promising regimens are needed. Based on the available data, the standard regimen of cisplatin and infusional 5-FU remains the recommended first-line treatment for patients with recurrent or metastatic disease of either histology. No specific paclitaxel-based regimen has yet emerged as more efficacious and less toxic than cisplatin/5-FU; however, alternative dosing schedules are currently under investigation.

### Preoperative Chemotherapy

Nearly three-fourths of patients in the West present with locally advanced (stages IIB and III) disease, and the poor survival rates achieved with surgery alone have provided the impetus for the evaluation of preoperative chemotherapy in resectable esophageal cancer patients.

The potential benefits of induction chemotherapy include downstaging the disease to facilitate surgical resection, improvement in local control, and eradication of micrometastatic disease. Esophagectomy following induction therapy enables comprehensive pathologic assessment of treatment response, which may be important in selecting patients for postoperative adjuvant therapy. The disadvantages of preoperative chemotherapy include the potential selection of drug-resistant clones and the delay in definitive treatment with the risk of further spread of disease. These are important concerns because approximately 50% of patients do not respond to current chemotherapeutic regimens.

Trials evaluating chemotherapy followed by surgery in esophageal cancer patients have been underway since the late 1970s. Stimulated by the promising results of cisplatin-based induction chemotherapy trials in patients with locally advanced oropharyngeal cancers, phase II trials using similar regimens were conducted in esophageal cancer patients in parallel with studies evaluating concurrent chemoradiation followed by surgery or chemoradiation as definitive therapy. Encouraging results with cisplatin and bleomycin,<sup>316</sup> with or without the addition of a vinca alkaloid<sup>317,337</sup> or mitoguazone,<sup>338</sup> and later with cisplatin and 5-FU,<sup>339,340,341,342</sup> and<sup>343</sup> led to randomized trials initiated in the 1980s. For squamous histology, the response rate to cisplatin (100 mg/m<sup>2</sup> day 1) and 5-FU (1000 mg/m<sup>2</sup>/d for 96 or 120 hours) every 3 weeks ranged between 42% and 66%, with 0% to 10% pathologic complete response rates; curative resection rates ranged from 40% to 80%, and median survival rates ranged from 18 to 28 months.<sup>339,340,341,342</sup> and<sup>343</sup> In these trials, two or three cycles of chemotherapy were administered before resection. A barium esophagogram and CT scans were used to initially stage patients and to assess response to induction therapy.

Five randomized trials evaluating preoperative chemotherapy in esophageal cancer patients are summarized in [Table 33.2-9](#).<sup>244,249,330,344,345</sup> Four of the trials enrolled only patients with squamous cell carcinoma.<sup>249,330,344,345</sup> The Scandinavian trial reported by Nygaard et al.<sup>249</sup> involved randomization to one of four treatment arms: surgery alone, radiotherapy followed by surgery, two courses of induction cisplatin and bleomycin followed by surgery, and all three modalities in sequence. No improvement in survival was noted in patients in the two treatment arms that included chemotherapy in this study.

Series	Treatment	Histology	% of Patients	Median Survival (mo)	Survival (%)
Nygaard <sup>249</sup>	Cisplatin + bleomycin + surgery	SCC	38	18	3
	RT + surgery	SCC	40	18	11
Ajani <sup>336</sup>	Cisplatin + irinotecan + 5-FU + surgery	SCC	25	18	9
	Cisplatin + irinotecan + 5-FU + surgery + adjuvant cisplatin + irinotecan	SCC	25	18	9
Ilson <sup>331</sup>	Cisplatin + 5-FU + surgery	SCC	34	18	3
	Regimen	SCC	34	18	3
Ajani <sup>336</sup>	Cisplatin + 5-FU + surgery + adjuvant cisplatin + 5-FU	SCC/adenocarcinoma	33	18	20
	Regimen	SCC/adenocarcinoma	33	18	20
Ilson <sup>331</sup>	Cisplatin + paclitaxel + 5-FU + surgery	SCC	31	18	11
	Regimen	SCC	31	18	11

**TABLE 33.2-9.** Randomized Trials of Preoperative Chemotherapy

In a study performed at the National Cancer Institute, Roth et al.<sup>344</sup> compared the combination of cisplatin, bleomycin, and vindesine for three courses followed by surgery, with surgery alone in 39 esophageal cancer patients. Six months of postoperative adjuvant cisplatin and vindesine were planned for patients in the

preoperative chemotherapy arm. A 47% major response rate including one pathologic complete response was documented using barium esophagogram and CT scans. Resectability rates were similar in the two groups, but a higher percentage of patients in the preoperative chemotherapy group had negative surgical margins. Responders to chemotherapy had significantly longer survival than nonresponders (median, 20 vs. 6.2 months;  $P = .008$ ). However, 3-year survival rates in the two treatment groups were not significantly different. All recurrences included distant metastases; the local recurrence rate was low (6.9%). Weight loss of greater than 10% was associated with poor survival in a multivariate analysis of potential prognostic variables.

A multicenter trial from Germany reported by Schlag et al.<sup>345</sup> compared preoperative cisplatin and 5-FU (three cycles) and surgery with surgery alone. The trial was stopped early after only 46 patients were enrolled because of a substantial increase in operative morbidity and mortality in the chemotherapy group. Response to chemotherapy was documented with serial CT scans, barium esophagogram, and endoscopy before treatment and before surgery. A 41% major response rate was observed, including pathologic complete response in two patients. There was no difference in median survival in the overall comparison; however, responders to preoperative chemotherapy survived longer than nonresponders (13 vs. 5 months).

The small numbers of patients enrolled in these three trials and the lack of prospective randomized controlled data in patients with adenocarcinoma of the esophagus led the U.S. Gastrointestinal Intergroup to mount a multicenter trial. Trial 0113 registered 467 patients with resectable disease to receive either three cycles of cisplatin and 5-FU followed by surgery and then two cycles of the same chemotherapy as adjuvant treatment for those who had a curative resection, or immediate surgery.<sup>244</sup> In contrast to other trials, barium esophagogram was the only test required to assess clinical response to preoperative chemotherapy. Thus, it is not surprising that only a 19% response rate was reported. Survival and patterns of failure were the major study end points. No differences were observed between the surgery control arm and the preoperative cisplatin and 5-FU arm in terms of curative resection rate (59% vs. 62%), treatment mortality (6% vs. 7%), overall median survival (16.1 vs. 14.9 months), or 3-year survival (26% vs. 23%). Furthermore, the median survival of patients who had a curative resection was the same in both treatment groups (27.4 vs. 25.0 months). The patterns of failure were also similar between groups (local recurrence 31% vs. 32%, and distant recurrence 50% vs. 41% in the surgery alone versus chemosurgery arms, respectively). Tumor histology did not influence response to treatment. As reported in the Roth trial,<sup>344</sup> pretreatment weight loss was a significant predictor of poor outcome in this study.

The failure of the large, well-controlled Intergroup 0113 trial to show benefit from the addition of cisplatin and 5-FU to surgery suggests either that this strategy does not work as had been theorized or that the induction chemotherapy agents and surgical techniques have not been optimized. Hence, the efficacy of any preoperative chemotherapy regimen in the treatment of resectable esophageal cancer patients remains unproven; as such, induction chemotherapy should not be routinely considered for these individuals unless administered in the context of well-designed, prospective, randomized clinical trials.

Kok and associates<sup>330</sup> reported preliminary results of a trial involving patients with squamous cell cancers. This study, which represents the only positive randomized trial in the literature, differed from the other trials reviewed previously in that patients in the preoperative chemotherapy arm were evaluated for response after two courses; nonresponders went on to surgery, whereas responding patients received two more courses of chemotherapy before surgery. The regimen consisted of cisplatin (80 mg/m<sup>2</sup> day 1) and etoposide (100 mg/m<sup>2</sup> intravenously on days 1 to 2 and 200 mg/m<sup>2</sup> orally on days 3 to 5). At a median follow-up for surviving patients of 15 months, the median survival of preoperative chemotherapy patients was significantly longer than those randomized to immediate surgery (18.5 vs. 11.0 months;  $P = .002$ ). These data raise the question of possible benefit from more intensive therapy than delivered in other trials and also demonstrate the potential relevance of identifying patients with chemosensitive tumors. A final report with further follow-up is awaited.

In conclusion, although a survival advantage has been demonstrated for definitive chemoradiation compared with radiotherapy alone,<sup>346</sup> four of five randomized trials of chemotherapy followed by surgery versus surgery alone have shown no benefit from this sequence of treatments. As such, more recent trials have focused on the evaluation of preoperative concurrent chemoradiation strategies that may have a greater likelihood of achieving histologic complete response and improving long-term survival in esophageal cancer patients.

### **Postoperative Adjuvant Chemotherapy**

Widespread dissemination of disease is the primary cause of death in esophageal cancer patients. As such, considerable efforts are underway to identify novel chemotherapeutic agents and to intensify exposure to agents with documented activity in this disease. Administering chemotherapy after surgery to patients who have already received chemotherapy or chemoradiation preoperatively has not been easily achieved in phase II<sup>338,339</sup> and phase III trials<sup>244,344</sup>; only 38% of patients who were candidates for adjuvant cisplatin and 5-FU in Intergroup trial 0113 received the two planned courses.<sup>244</sup>

Adjuvant chemotherapy in patients who have had surgery alone as their primary curative treatment is more feasible from the standpoint of patient tolerance, but it remains unclear whether current agents confer a survival advantage. The Japanese Oncology Group has studied this question in three separate randomized trials.<sup>347,348</sup> and <sup>349</sup> One study compared postoperative radiotherapy (50 Gy) to postoperative adjuvant chemotherapy (two courses of cisplatin and vindesine) in 258 patients following curative resection.<sup>347</sup> No differences were observed in survival (44% vs. 42% at 5 years), time to recurrence, or site of recurrence. Because these results could be interpreted as showing an equivalent beneficial effect from adjuvant chemotherapy and adjuvant radiotherapy, a second trial of surgery alone compared with surgery followed by two courses of adjuvant cisplatin and vindesine was conducted.<sup>323</sup> A total of 205 resected patients were randomized after stratification for regional node involvement. At a median follow-up of 59.2 months, the 5-year survival rate was 45% in the control arm, and 48% in the adjuvant treatment arm, indicating no survival benefit from this adjuvant chemotherapy regimen.

More recently, these investigators have reported preliminary results of a third trial.<sup>349</sup> The study design was the same as that previously described, except that the chemotherapy was changed to cisplatin and 5-FU for two courses after curative resection. A total of 242 patients were randomized with stratification for N0/1 status. At a median follow-up of 40.4 months, the estimated 5-year disease-free survival rate was 46% for the control group and 58% for chemotherapy patients ( $P = .05$ ); survival rates were 77% versus 82% in node-negative patients ( $P = .3$ ), and 35% versus 53% in node-positive patients ( $P = .06$ ) in the control and adjuvant arms, respectively. Overall survival rates were 51% for controls and 61% for chemotherapy patients ( $P = .3$ ). These data suggest that adjuvant chemotherapy may decrease the rate of development of distant metastases in patients with positive regional nodes. It is unlikely that two courses of chemotherapy would be sufficient to have a major effect on micrometastatic disease; thus, it is not surprising that more significant differences in survival did not emerge from this trial. However, the improvement in disease-free survival that approached statistical significance is intriguing, and further evaluation of adjuvant chemotherapy in both histologic types of esophageal cancer should be performed.

The Eastern Cooperative Oncology Group is currently conducting a phase II trial (E8296) evaluating adjuvant cisplatin and paclitaxel for four courses in patients with resected, node-positive adenocarcinomas of the esophagus, gastroesophageal junction, and cardia. A comparison with matched controls from a contemporary surgical series is planned.

The role of postoperative adjuvant chemotherapy or chemoradiation is currently undefined. There are no clear data indicating that administration of postoperative adjuvant chemotherapy will prolong survival, particularly for patients who have undergone a curative resection and have negative nodes. However, patients who have positive margins of resection should be considered for postoperative radiation. Those who have had R0 resections but have regional nodal metastases (stages IIB and III) should be enrolled in clinical trials evaluating adjuvant treatments.

### **RADIATION THERAPY**

Considerable controversy exists as to the ideal therapeutic approach for esophageal cancer. The Patterns of Care study examined 400 patients treated at 61 academic and nonacademic radiation oncology practices to determine practice patterns in the United States from 1992 to 1994.<sup>350</sup> During that time period, treatment approaches included primary combined modality therapy in 54%, radiation alone in 20%, preoperative combined modality therapy in 13%, postoperative combined modality therapy in 8%, postoperative radiation in 4%, and preoperative radiation in 1%. Various oncology groups have published treatment guidelines; however, there is still no consensus at present.<sup>351</sup> Because the effect of histology has not been adequately assessed, it is reasonable to treat both squamous cell cancers and adenocarcinomas in a similar manner.

### **Primary Therapy**

Primary therapy of esophageal cancer is either surgical or nonsurgical. Although the overall results of these approaches are similar, the patient populations selected for treatment with each modality are usually different, resulting in a potential selection bias against nonsurgical therapy. Patients with poor prognostic features, including those with comorbid conditions, or unresectable or metastatic disease, are more commonly selected for treatment with nonsurgical therapy. Furthermore,

**FIGURE 33.2-5.** Phase III Intergroup trial Radiation Therapy Oncology Group 85-01 for patients with squamous cell and adenocarcinoma of the esophagus selected for a nonoperative approach. 5-FU, 5-fluorouracil; CDDP, cisplatin; RT, radiation therapy.

Patients who were randomized to receive combined modality therapy had a significant improvement in median survival (14 vs. 9 months) and 5-year survival (27% vs. 0%;  $P < .0001$ ).<sup>366</sup> There was a clear plateau in the survival curve such that with a minimum follow-up of 5 years, the 8-year survival was 22%.<sup>346</sup> Histology did not significantly influence the results with 21% of patients with squamous cell carcinomas ( $n = 107$ ) alive at 5 years compared with 13% of patients with adenocarcinoma ( $n = 23$ ;  $P = NS$ ). Although African Americans had larger primary tumors (all of which were squamous cell cancers), there was no difference in their survival compared with whites.<sup>369</sup> The incidence of local failure as the first site of failure (defined as local persistence plus recurrence) was also decreased in the combined modality arm (47% vs. 65%). The protocol was closed early due to the positive results; however, following this early closure, an additional 69 patients were treated with the same combined modality therapy regimen. In this nonrandomized combined modality group, the 5-year survival was 14% and local failure rate was 52%.

Combined modality therapy not only improves the results compared with radiation alone, but is also associated with a higher incidence of toxicity. In the 1997 report of the RTOG 85-01 trial, patients who received combined modality therapy had a higher incidence of acute grade III toxicity (44% vs. 25%) and acute grade IV toxicity (20% vs. 3%) compared with radiation therapy alone. Including the one treatment-related death (2%), the incidence of total acute grade III+ toxicity was 66%.<sup>366</sup> The 1999 report examined late toxicity; the incidence of late grade III+ toxicity was similar in the combined modality arm compared with the radiation alone arm (29% vs. 23%).<sup>346</sup> However, grade IV+ toxicity remained higher (10% vs. 2%, respectively). Interestingly, the nonrandomized combined modality therapy group experienced a similar incidence of late grade III+ toxicity (28%), but a lower incidence of grade IV toxicity (4%), and there were no treatment-related deaths.

Based on the positive results from the RTOG 85-01 trial, the conventional nonsurgical treatment for esophageal carcinoma is combined modality therapy. Notwithstanding, the local failure rate in RTOG 85-01 combined modality therapy arm was 45%; therefore, new approaches such as intensification of combined modality therapy, including escalation of the radiation dose, have been pursued in an attempt to help improve these results.

**INTENSIFICATION OF COMBINED MODALITY THERAPY.** The phase II Intergroup trial 0122 (Eastern Cooperative Oncology Group PE289/RTOG 90-12) was designed to intensify the RTOG 85-01 combined modality arm.<sup>370</sup> The development of the neoadjuvant chemotherapy approach used in Intergroup 0122 was based, in part, on the results of a randomized trial of preoperative radiation therapy (55 Gy) versus preoperative chemotherapy (5-FU, cisplatin, vindesine) from Memorial Sloan-Kettering Cancer Center. This trial revealed that the resectability (65% vs. 58%), objective response (64% vs. 55%), and local failure (15% vs. 6%) rates with either preoperative radiation therapy or preoperative chemotherapy were similar.<sup>371</sup> Both the chemotherapy and radiation therapy in Intergroup 0122 were intensified as follows: (1) the 5-FU continuous infusion (1000 mg/m<sup>2</sup>/24 hours) was increased from 4 days to 5 days; (2) the total number of cycles of chemotherapy was increased from four to five cycles; (3) three cycles of full-dose neoadjuvant 5-FU and cisplatin were delivered before the start of combined modality therapy; and (4) the radiation dose was increased from 50.0 to 64.8 Gy.

The final results of the Intergroup trial 0122 have been reported.<sup>370</sup> For the 38 eligible patients, the primary tumor response rates were 47% complete and 8% partial; 3% had stable disease. The first site of clinical failure was local in 39% of patients and distant in 24% of individuals. For the total patient group, there were six deaths during treatment of which 9% (4 of 45) were treatment related. The median survival was 20 months and the 5-year actuarial survival was 20%. Therefore, this intensive neoadjuvant approach did not appear to offer a benefit compared with conventional doses and techniques of combined modality therapy. However, the higher radiation dose (64.8 Gy) was tolerable and is being further tested in Intergroup trial 0123, which is the replacement trial for RTOG 85-01 ( Fig. 33.2-6).

**FIGURE 33.2-6.** Phase III Intergroup trial 0123 (Radiation Therapy Oncology Group 94-05) for patients with squamous cell or adenocarcinoma of the esophagus. 5-FU, 5-fluorouracil; CDDP, cisplatin; RT, radiation therapy.

A limited number of phase II trials have tested the use of induction chemotherapy before radiation therapy or combined modality therapy. Valerdi et al.<sup>362</sup> reported the results of 40 patients with clinical stage II and III squamous cell cancers who received two cycles of neoadjuvant cisplatin, vindesine, and bleomycin (days 1 and 29) followed by 60 Gy. In contrast with Intergroup 0122, no chemotherapy was delivered with the radiation therapy. The pathologic complete response rate was 53%. With a median follow-up of 78 months, the local failure rate was 62%, median survival was 11 months, and the 5-year actuarial survival was 15%. These results are similar to those obtained with the RTOG 85-01 combined modality arm, with the exception of the higher treatment-related death rate of 5%.

Using a five-drug neoadjuvant regimen, Roca and colleagues<sup>372</sup> treated 55 patients (54 with squamous cell) with bolus cisplatin, 5-FU, leucovorin, bleomycin, and mitomycin C for 15 days followed by 60 Gy plus concurrent 5-FU, leucovorin, and cisplatin. No maintenance chemotherapy was delivered. All anatomic sites within the esophagus were acceptable, and 53% of patients had clinical stage III disease. Although the treatment-related mortality was only 4% and the 3-year survival was 35%, the local failure rate was 42%, which was similar to the 45% reported in the RTOG 85-01 combined modality therapy arm.

In summary, neoadjuvant chemotherapy, as delivered in the previously mentioned trials, does not appear to improve the results of combined modality therapy. New trials using paclitaxel (Taxol)-based induction chemotherapy are in progress.<sup>373</sup>

**INTENSIFICATION OF THE RADIATION DOSE.** Another approach to dose intensification of combined modality therapy involves increasing the radiation dose above 60 Gy. There are two methods by which to increase the radiation dose to the esophagus: brachytherapy and external-beam radiation.

### Brachytherapy

Intraluminal brachytherapy allows the escalation of the dose to the primary tumor while protecting the surrounding dose-limiting structures such as the lung, heart, and spinal cord.<sup>374</sup> A radioactive source is placed intraluminally via endoscope or a nasogastric tube. Brachytherapy has been used both as primary therapy (usually as a

palliative modality),<sup>375,376,377 and 378</sup> as well as boost following external-beam radiation therapy or combined modality therapy.<sup>375,379,380 and 381</sup> It can be delivered by high dose-rate or low dose-rate.<sup>382</sup> Although there are technical and radiobiologic differences between the two dose rates, there are no clear therapeutic advantages.

As a single therapy, brachytherapy is used as a palliative modality and results in a local control rate of 25% to 35% and a median survival of approximately 5 months.<sup>375,376,377 and 378</sup> In the randomized trial from Sur et al.<sup>376</sup> there were no significant differences in local control or survival with high dose-rate brachytherapy compared with external-beam radiation. Jager et al.<sup>377</sup> treated 88 patients with 15 Gy, and 67% had improvement of dysphagia at 4 to 6 weeks and 47% had complete restoration of swallowing.

A major limitation of brachytherapy is the effective treatment distance. The primary isotope is <sup>192</sup>Ir, which is usually prescribed to treat to a distance of 1 cm from the source. Therefore, any portion of the tumor that is greater than 1 cm from the source receives a suboptimal radiation dose. This limitation has been confirmed by pathologic analysis of treated specimens.<sup>383</sup>

More encouraging results have been reported from series combining brachytherapy with external-beam or combined modality therapy; however, it is not clear if this advantage is due to the therapy or a selection bias in favor of patients treated in the curative setting as opposed to those treated for palliation only. In a phase II trial reported by Calais et al.,<sup>379</sup> a total of 53 patients with clinically unresectable adenocarcinoma or squamous cell carcinoma of the esophagus received 60 Gy plus three cycles of concurrent 5-FU, cisplatin, and mitomycin C followed by high dose-rate intraluminal brachytherapy (5 Gy/week × 2). With a median follow-up of 39 months, the 3-year and 5-year actuarial survivals were 27% and 18%, respectively. Severe late toxicity occurred in 11%. One patient died of treatment-related toxicity. Two patients (4%) developed a fistula; however, both were due to tumor progression. Swallowing function was reported as good in 75%. The local failure rate was 43% (23 of 53).

Other trials of brachytherapy following external-beam radiation or combined modality therapy have reported less favorable results. Schraube and associates<sup>381</sup> treated 54 patients with 60-Gy external-beam radiation followed by a 14-Gy brachytherapy boost, observing a median survival of 8 months and a 2-year overall survival of 10%. Major toxicity was seen in 15%. Using a similar treatment regimen in 35 patients with squamous cell carcinomas, Akagi et al.<sup>380</sup> reported a 26% local failure rate, a 5-year survival of 35%, and a 26% incidence of late complications. Moni et al.<sup>375</sup> reported a 62% local failure rate and 2-year survival of 27% in 21 patients with primary, nonmetastatic disease. However, for the total group of 47 patients there was a 36% grade III+ complication rate including a 17% incidence of fistula.

The trial by Yorozu et al.<sup>384</sup> was limited to a more favorable subset of patients with clinical T1 to T2 disease. A total of 125 patients received 40- to 60-Gy external-beam radiation followed by a 8- to 24-Gy high dose-rate brachytherapy boost. With a median follow-up of 3.1 years, the 5-year survival was 26% and local failure was 44%. Esophageal ulcers occurred in 41% and were fatal in 6% of patients.

In the RTOG 92-07 trial, 75 patients with squamous cell cancers (92%) or adenocarcinomas (8%) of the thoracic esophagus received the RTOG 85-01 combined modality regimen (5-FU, cisplatin × 4 with concurrent 50 Gy) followed by a boost during cycle 3 of chemotherapy with either low dose-rate (19 patients) or high dose-rate (56 patients) intraluminal brachytherapy.<sup>385</sup> The choice of the dose rate was at the discretion of the investigator. Due to low accrual, the low dose-rate option was discontinued and the analysis was limited to patients who received the high dose-rate treatment. High dose-rate brachytherapy was delivered in weekly fractions of 5 Gy during weeks 8, 9, and 10. Following the development of several fistulas, the fraction delivered at week 10 was discontinued. Although the complete response rate was 73%, with a median follow-up of only 11 months, local failure as the first site of failure occurred in 27% of patients. Acute toxicity included 58% grade III, 26% grade IV, and 8% grade V (treatment-related death). The cumulative incidence of fistula was 18% per year and the crude incidence was 14%. Three of the six treatment-related fistulas were fatal. Given the significant toxicity, this treatment approach should be used with caution.

The American Brachytherapy Society has developed guidelines for esophageal brachytherapy.<sup>386</sup> For patients treated in the curative setting, brachytherapy should be limited to tumors less than or equal to 10 cm with no evidence of distant metastasis. Contraindications include tracheal or bronchial involvement, cervical esophagus location, or stenosis that cannot be bypassed. The applicator should have an external diameter of 6 to 10 cm. If combined modality therapy is used (defined as 5-FU-based chemotherapy plus 45 to 50 Gy), the recommended doses of brachytherapy are 10 Gy in 2 weekly fractions of 5 Gy each for high dose-rate, and 20 Gy in a single fraction at 4 to 10 Gy/h for low dose-rate. The doses should be prescribed to 1 cm from the midsource. Lastly, brachytherapy should be delivered after the completion of external-beam radiation, and not concurrently with chemotherapy.

In summary, in the palliative setting, intraluminal brachytherapy is an effective modality for decreasing symptoms such as dysphagia and bleeding. In patients treated in the curative setting, the addition of brachytherapy does not appear to improve results compared with radiation therapy or combined modality therapy alone. Therefore, the benefit of adding intraluminal brachytherapy to radiation or combined modality therapy remains unclear.

### External-Beam Therapy

There are limited data examining the tolerance of external-beam doses of greater than or equal to 60 Gy when delivered concurrently with chemotherapy. In a separate toxicity analysis from Coia and associates,<sup>359</sup> the results of 90 patients with clinical stages I to IV squamous and adenocarcinomas of the esophagus were reported; the incidence of grade III toxicity was 22%, and grade IV toxicity was 6%. There were no treatment-related deaths.

Calais et al.<sup>387</sup> reported the results of 53 patients with clinically unresectable disease who received 5-FU, cisplatin, and mitomycin C plus 65 Gy. The full dose of radiation could be delivered in 96% of patients. The incidence of World Health Organization grade III+ toxicity was 30%, and the overall 2-year survival was 42%. It should be noted that the chemotherapy in this trial was not delivered at doses adequate to treat systemic disease.

On the encouraging side, almost all patients in both the Intergroup 0122 and the Calais trials (96% and 94%, respectively) who started radiation therapy were able to complete the full dose (64.8 to 65.0 Gy). Therefore, this higher dose of radiation was considered tolerable and was used in the experimental arm of the Intergroup esophageal trial 0123 (RTOG 94-05). Intergroup 0123 is the follow-up trial to RTOG 85-01. In this trial, patients with either squamous cell or adenocarcinomas who are selected for a nonsurgical approach are randomized to a slightly modified RTOG 85-01 combined modality regimen with 50.4 Gy versus the same chemotherapy with 64.8 Gy (see Fig. 33.2-6).

The modifications to the original RTOG 85-01 combined modality therapy arm include (1) using 1.8 Gy fractions to 50.4 Gy rather than 2 Gy fractions to 50 Gy; (2) treating with 5-cm proximal and distal margins for 50.4 Gy rather than treating the whole esophagus for the first 30 Gy followed by a cone-down with 5-cm margins to 50 Gy; (3) not beginning cycle 3 of 5-FU and cisplatin until 4 weeks following the completion of radiation therapy rather than 3 weeks; and (4) delivering cycles 3 and 4 of chemotherapy every 4 weeks rather than every 3 weeks. The Intergroup 0123 opened in late 1994 and was closed to accrual in 1999 when an interim analysis revealed that it was unlikely that the high-dose arm would achieve a superior survival compared with the standard-dose arm.

In addition to increasing the total dose, radiation can be intensified by accelerated fractionation or hyperfractionation. Selected series using these approaches are summarized in Table 33.2-12.<sup>355,388,389 and 390</sup> Although these approaches are reasonable, most series report an increase in acute toxicity without any clear therapeutic benefit. These regimens remain investigational.

Series	Number	Histology	Treatment	Results	Toxicity
Gearty <sup>388</sup>	11	NS	60 Gy (1.8 Gy/fraction) + 5-FU/CCP	100% survival; 40% local control	15% grade III
Jones <sup>389</sup>	11	NSC	50 Gy (1.8 Gy/fraction) + 5-FU/CCP × 4	100% survival; 75% local control	30% grade III

CCP, cisplatin; 5-FU, fluorouracil; NS, information not reported in the manuscript; NSC, squamous cell carcinoma.

**TABLE 33.2-12.** Selected Series of High-Dose Accelerated Fractionation/Hyperfractionated Combined Modality Therapy

### Palliation of Dysphagia with Radiation Therapy

Dysphagia is a common problem in patients with esophageal cancer. Not only is it the most frequently presenting symptom, but it can remain a problem up to the time of the patient's death. Many of the series that have examined palliation are retrospective, and most do not use objective criteria to define and assess this symptom. Some have not reported the number of patients presenting with dysphagia or the percentage who were palliated until the time of death. Furthermore, few series have carefully examined other variables that may have influenced results such as histology, stage, and location of the primary tumor.

As seen in [Table 33.2-13](#), a limited number of series have examined the palliative effects of radiation alone [365,391,392,393](#) and [394](#) or combined modality therapy. [360,361,393,395,396](#) and [397](#) Overall, external-beam radiation therapy alone palliates dysphagia in approximately 70% to 80% of patients.

Series	Total Number	Palliation of Dysphagia <sup>a</sup>	
		At the End of Treatment (%)	Duration of Palliation
<b>RADIATION THERAPY ALONE</b>			
Wara <sup>365</sup>	105	80	6 mo average
Petrovich <sup>366</sup>	135	87	24% at 6 mo 18% at 9 mo 35% at 12 mo
Rosner <sup>391</sup>	89	70	—
Casper <sup>392</sup>	127	71	84% until death
Whittington <sup>393</sup>	35	—	5% at 9 mo
<b>COMBINED MODALITY THERAPY</b>			
Cota <sup>394</sup>	102	88	67-100% until death
Seitz <sup>395</sup>	35	100 <sup>b</sup>	—
Whittington <sup>396</sup>	36	—	87% by actuarial
Nguyen <sup>397</sup>	6	100	—
Coia <sup>398</sup>	25	88	88% until death
Urbas <sup>399</sup>	37	—	Median 5 mo
Esquivel <sup>400</sup>	25	84	—

<sup>a</sup>See text for the definition and the number of patients presenting with dysphagia.  
<sup>b</sup>Patients had dilation or myotomy/striptom administration/gastric laser at the start of therapy.

**TABLE 33.2-13.** Palliation of Dysphagia with External-Beam Radiation Therapy with or without Chemotherapy

The most comprehensive and carefully performed analysis of swallowing function in patients receiving combined modality therapy is from Coia et al. [398](#) Using a swallowing score modified from O'Rourke et al., [399](#) Coia et al. analyzed 102 patients treated with three 5-FU-based combined modality regimens. Before the start of therapy, 95% of patients had some degree of dysphagia. Within 2 weeks following the start of treatment, 45% had improvement in dysphagia and by the completion of the 6-week therapy, 83% had improvement. Overall, 88% had an improvement in dysphagia. The median time to maximum improvement was 4 weeks (range, 1 to 21 weeks), and all but two patients were able to swallow at least soft or solid foods at the time of maximum symptomatic improvement.

Variables such as treatment intent, histology, and tumor location were examined. All of the 25 patients treated with curative intent who survived more than 1 year were able to eat soft or solid foods following treatment. The benign stricture rate (defined as a stricture in the absence of recurrent disease) was 12%. Ninety-one percent of patients treated in the noncurative setting had an initial improvement in swallowing, and 67% were palliated until death. Histology and stage had no effect on the rate of palliation; however, patients with distal third lesions had significant improvement in dysphagia compared with individuals with upper or middle third tumors (95% vs. 79%;  $P < .05$ ).

Intraluminal brachytherapy achieves palliation of dysphagia in 40% to 90% of patients. [375,376,377](#) and [378](#) Because it is usually prescribed to 1 cm from the source, it may not sufficiently treat gross disease. There is a selection bias against brachytherapy since it is commonly used for patients who have either failed to respond to external-beam radiation or who are medically unfit to travel for daily outpatient treatment. Even accounting for these selection biases, given its limited effective range, brachytherapy has not proven to be as successful as external-beam radiation in treating the entire tumor volume.

In summary, external-beam radiation therapy, either alone or in combination with chemotherapy, palliates dysphagia in approximately 80% of patients, one-half of whom are palliated until death. If a patient requires rapid palliation (within a few days), alternative approaches such as laser or stent are recommended, since external-beam radiation with or without chemotherapy requires at least 2 weeks to obtain palliation. However, palliation achieved by external-beam therapy is more durable than that obtained by other palliative modalities since it treats the problem (the gross tumor mass), not just the symptom. If external-beam radiation is not possible, then brachytherapy should be considered.

### Acute and Long-Term Toxicity of Radiation Therapy

The toxicity of radiation therapy is a function of total dose and technique of administration, as well as chemotherapy exposure. There are limited toxicity data in patients who received conventional doses of radiation therapy. Essentially all patients experience lethargy and esophagitis commencing 2 to 3 weeks after the start of radiation; these symptoms begin to resolve 1 week after the completion of therapy.

The most carefully documented acute radiation-related toxicity data are from the control arm of RTOG 85-01 in which patients received radiation therapy alone to a dose of 64 Gy. [255,366](#) The incidence of acute grade III toxicity was 25%, and grade IV toxicity was 3%; the incidence of long-term grade III+ toxicity was 23% and grade IV+ was 2%. [346](#) There were no treatment-related deaths.

As with surgery, radiation therapy can produce esophageal strictures. The total incidence of stricture (benign plus malignant) in patients receiving radiation therapy alone or radiation combined with chemotherapy is 20% to 40% in modern studies, and up to 60% in historical series [400](#); nearly one-half of these strictures are malignant since they are associated with local recurrence. The incidence of stricture is lower in series in which careful radiation techniques were used. For example, Coia et al. [398](#) noted that the incidence of benign stricture was 12% in a subset of 25 patients who were locally controlled and survived at least 1 year.

One series examined the functional results in patients who developed benign or malignant strictures. [399](#) Eighty patients received 45 to 56 Gy and 53% received some form of chemotherapy. Of the 24 patients (30%) who developed a benign stricture, 71% were able to tolerate a full or soft diet and required dilation with a median interval between dilations of 5 months. Therefore, even in the subset of patients who develop a benign stricture, dilation is effective in the majority of patients. In contrast, in the 28% of patients who developed a malignant stricture, dilation was unsuccessful and esophageal intubation was required.

The high incidence of fistulae reported in the RTOG 92-07 trial of combined modality therapy plus intraluminal brachytherapy (18% actuarial, 14% crude) has not been seen in series using radiation therapy or combined modality therapy without intraluminal brachytherapy. The incidence of other long-term grade III+ toxicities such as pneumonitis or pericarditis is 5%. If appropriate radiation doses and techniques are used, spinal cord myelitis should not occur.

### TREATMENT-RELATED DEATHS

The issue of treatment-related deaths in patients receiving combined modality therapy is complex. Although the incidence was only 2% in RTOG 85-01, subsequent trials have reported a higher treatment-related mortality (i.e., 9% in Intergroup 0122 and 8% in RTOG 92-07). This mortality is lower than the 10% to 15% incidence reported in the historical surgical series, although only slightly higher than the 6% reported in the surgical control arm of Intergroup 0113. [244](#) It is interesting to note that as the mortality with surgery has decreased, there has been a corresponding increase in the treatment-related mortality reported in the nonoperative trials. As previously discussed, this may be related, in part, to selection bias against patients treated with the nonoperative approach. Only a randomized trial of surgical versus nonsurgical therapy can address this issue.

### COMPARISON OF DEFINITIVE CHEMORADIATION AND SURGERY

Appropriate randomized trials comparing chemoradiation and surgery have not been performed. However, it is an important issue for the practicing oncologist and for

the establishment of standards of care. The positive results of RTOG 85-01, demonstrating a 27% 5-year survival rate for patients treated with definitive chemoradiation compared with no survivors after treatment with radiotherapy alone, are a major advance. Without a doubt, this treatment option has influenced the selection of patients for surgical management because it provides an alternative for restoring swallowing function in patients with locally advanced disease for whom resection would likely be palliative.

For patients with earlier stage disease that appears resectable, definitive chemoradiotherapy may also be appropriate treatment; however, prospective trials comparing this approach with surgery, stratified for histology and stage have yet to be performed. Nonetheless, contemporary series suggest that the nonsurgical approach offers a survival rate that is the same or better than that achievable with surgery alone in most medical centers. For example, the median and 5-year survival rates in the surgical control arm of Intergroup 0113 trial were 16 months and 20%, respectively, <sup>244</sup> and in the surgical control arm of the Dutch trial by Kok et al. <sup>330</sup> the median survival rate was 11 months. The incidence of local recurrence (local failure plus local persistence of disease) as the first site of failure was 45% in RTOG 85-01 and 39% in Intergroup 0122. Although local recurrence as the first site of failure in Intergroup 0113 was 31%, this analysis was limited to patients who underwent a complete resection with negative margins (R0 resection). Since an additional 30% of patients had residual local disease, if one was to score these patients as having local persistent disease (as was done in the RTOG 85-01 analysis), the comparable local failure rate with surgery alone was 30% + 31% = 61%. The treatment-related mortality was also similar (2% in RTOG 85-01 and 6% in Intergroup 0113).

In summary, the local failure, survival, and treatment-related mortality of definitive chemoradiation as administered in RTOG 85-01 and those observed following surgery alone appear comparable. Despite these observations, it is clear that both approaches have limited success; as such trials combining all three modalities (surgery plus preoperative chemotherapy and radiotherapy) have been initiated.

## TREATMENT IN THE SETTING OF A TRACHEOESOPHAGEAL FISTULA

The presence of a malignant tracheoesophageal fistula is an unfavorable prognostic feature; however, occasionally patients may survive for a prolonged period of time. Historically, radiation therapy was believed to be contraindicated due to concerns of exacerbating the fistula as the tumor responded. There have been several reports that challenge these views. In a Mayo Clinic series, <sup>401</sup> ten patients with malignant tracheoesophageal fistula received 30 to 66 Gy external-beam radiation, with a median survival of 5 months. None of these patients experienced an enlarged or more debilitating fistula following radiation. Arlington and Bohorquez <sup>402</sup> described a patient who developed a fistula while receiving external-beam radiation to a total dose of 56.5 Gy, which healed 2 months following the completion of radiation.

Although the experience is limited, data suggest that radiation may not necessarily increase the severity of a malignant tracheoesophageal fistula, and it can be administered safely. Due to the poor prognosis of this group of patients, it is unclear if it improves outcome particularly in individuals who may also be palliated by stents. <sup>403,404</sup> and <sup>405</sup>

## ADJUVANT THERAPY

### Adjuvant Radiation Therapy without Chemotherapy

The rationale of adjuvant radiation therapy is based on the patterns of failure following potentially curative surgery in patients with clinically resectable disease. Unfortunately, few surgical series report these data. The incidence of local failure in the surgical control arms from the preoperative radiation therapy randomized trials from Mei et al. <sup>406</sup> and Gignoux and coworkers <sup>248</sup> was 12% and 67%, respectively. The local failure rate in the surgical control arm from the postoperative radiation therapy randomized trial from Teniere et al. <sup>407</sup> was 35% for patients with negative local regional lymph nodes and 38% for patients with positive local regional lymph nodes. The surgical control arm of Intergroup 0113 <sup>244</sup> provides a modern, more relevant baseline for the results of surgery alone. As previously discussed there was a 31% local failure in patients with a R0 resection and a total local failure rate (including the additional 30% of patients with persistent disease) of 61%. Although the majority of patients with esophageal cancer succumb to distant metastases, the incidence of local failure following transhiatal or standard transthoracic resection is high enough to warrant the evaluation of adjuvant radiation therapy.

### Preoperative Radiation Therapy

Six randomized trials of preoperative radiation therapy for patients with clinically resectable disease are summarized in [Table 33.2-14](#). <sup>248,249,406,408,409</sup> and <sup>410</sup> The series performed by Launois et al., <sup>408</sup> Gignoux et al., <sup>248</sup> and Nygaard et al. <sup>249</sup> were limited to patients with squamous cell carcinoma. Patients with both squamous cell carcinoma and adenocarcinoma were included in the series by Arnott et al. <sup>409</sup>; the histologies of the esophageal cancers treated in the series by Huang et al. <sup>410</sup> and Mei et al. <sup>406</sup> were not indicated.

Series	Type	Number	Resectable (%)		Local Failure (%)		5-Year Survival (%)	
			Preop	Postop	Preop	Postop	Preop	Postop
Mei <sup>406</sup>	SCC + adenocarcinomas	170	200	20	12	12	17	1
Gignoux <sup>248</sup>	SCC	250	200	20	12	67	12	1
Nygaard <sup>249</sup>	SCC	180	200	25	12	12	12	1
Launois <sup>408</sup>	SCC	100	400	30	70	12	12	1
Huang <sup>410</sup>	SCC	100	400	30	12	12	12	1
Arnott <sup>409</sup>	SCC	200	400	30	12	12	12	1

SC, squamous cell carcinoma; Aden, adenocarcinoma; Preop, preoperative; Postop, postoperative.

**TABLE 33.2-14.** Randomized Trials of Preoperative Radiation Therapy for Esophageal Cancer

Overall, preoperative radiation therapy did not increase resectability, and only two series reported local failure rates. Although Mei and colleagues <sup>406</sup> reported no difference in local failure, Gignoux et al. <sup>248</sup> observed a significant decrease in local failure in patients who received preoperative radiation therapy compared with those treated by surgery alone (46% vs. 67%, respectively).

Two trials have reported an improvement in survival in patients receiving preoperative radiation therapy, although the significance of these observations is debatable. In a previously described four-arm randomized trial, Nygaard et al. <sup>249</sup> observed that the 48 patients who received preoperative radiation therapy without chemotherapy had a 20% 3-year survival compared with 5% survival in control patients; however, this did not reach statistical significance. Huang et al. <sup>410</sup> also reported improved survival in surgical patients treated with preoperative radiation therapy relative to surgical controls (46% vs. 25%, respectively); however, formal statistical analysis was not performed. Furthermore, metaanalysis from the Oesophageal Cancer Collaborative Group showed no clear evidence of a survival advantage for preoperative radiation therapy. <sup>411</sup>

The aforementioned randomized preoperative radiation therapy trials used suboptimal designs. Conventional radiation therapy doses were not delivered, and some trials used split-course radiation. Furthermore, none of the trials allowed an adequate interval between completion of radiation therapy and surgery (in general, a 4- to 6-week interval is recommended). Consequently, radiation-related morbidity cannot be appropriately assessed in these trials.

The only study that allows analysis of the effect of radiation techniques is a randomized trial from France involving patients with squamous cell carcinomas who received combined modality therapy using continuous or split-course radiation. <sup>412</sup> The 95 patients who received continuous-course therapy had a significantly higher local control rate (57% vs. 29%), 2-year event-free survival rate (33% vs. 23%), and a borderline significant 2-year survival rate (37% vs. 23%) relative to patients treated with split-course radiation. Because it is less effective than continuous-course, split-course radiation is not recommended.

Series	Number	Local Failure (%)	Distant Failure (%)	Survival (%)		Mortality (%)
				3-year	5-year	
GP <sup>a</sup>						
Surgery	4	25	36	36	36	—
No surgery	36	27	22	36	25	—
Kavanagh <sup>b</sup>

No surgery	72	41	39	—	—	27

<sup>a</sup>Results limited to the 38 of 113 patients who had no clinical evidence of metastatic disease at the time of preoperative assessment.  
<sup>b</sup>36 died of disease in 3 years.  
<sup>c</sup>36 died of disease in 11 years.

**TABLE 33.2-17.** Selected Nonrandomized Series of Preoperative Combined Modality Therapy Plus Surgery for Esophageal Cancer

The results of selected phase II series in which patients have undergone preoperative combined modality therapy followed by a planned operation are summarized in [Table 33.2-16](#). Leichman and colleagues from Wayne State University<sup>424</sup> reported the results of 21 patients with squamous cell carcinomas. Patients received 30 Gy at 2 Gy/d, plus two cycles of concurrent 5-FU and cisplatin. Individuals with residual tumor at surgery received an additional 20 Gy postoperatively. Pathologic complete response rate was 37%, and the median survival was 18 months in the 19 patients who underwent an operation; a 27% operative mortality was observed. Forty-eight percent of patients required hyperalimentation during preoperative therapy. This pilot trial was expanded to a Southwest Oncology Group trial (8037) for patients with squamous cell carcinoma. Of 113 patients evaluated in this trial, only 71 underwent an operation. The pathologic complete response rate was 16%, and the operative mortality was 11%. Despite a 3-year actuarial survival rate of 16%, all patients were dead of disease within 4 years.<sup>425</sup>

Since these initial reports, a variety of treatment approaches have been examined. In most studies, pathologic complete response rates were approximately 25%. Intensive combined modality regimens using hyperfractionated radiation have been evaluated by Urba et al. and Forastiere and associates<sup>426,427</sup> and<sup>428</sup> from the University of Michigan, as well as Shahab and colleagues<sup>429</sup> from Ellis Fischel Cancer Center, and Adelstein et al.<sup>430</sup> Some of these regimens achieved higher pathologic complete response and survival rates, usually with corresponding increases in acute toxicity. For example, Raoul et al.<sup>431</sup> reported a 56% complete pathologic response rate and a 52% 3-year survival rate, but a 63% incidence of grade III+ acute toxicity. In the series by Adelstein et al.,<sup>432</sup> patients received preoperative accelerated fractionation (1.5 Gy twice a day to 45 Gy) plus 5-FU and cisplatin. The 27% complete response and 44% 3-year survival rates observed in this trial were comparable with those reported in other series using conventional fractionation; however, the 18% surgical mortality was higher.

In addition to the different treatment schedules, variable surgical techniques have been used in these trials. For instance, investigators from the University of Michigan performed transhiatal resections exclusively, whereas others preferentially did Ivor-Lewis procedures. Transhiatal esophagectomy is thought to be a more conservative operation relative to the Ivor-Lewis procedure, although as previously discussed, both operations appear to be inferior to *en bloc* esophagectomy in terms of achieving local control and improving survival in esophageal cancer patients.

More conventional doses of chemotherapy and radiation therapy techniques have been advocated by Stahl et al.,<sup>433</sup> Jones and colleagues,<sup>434</sup> Forastiere et al.,<sup>435</sup> and Bates and associates.<sup>436</sup> In addition, these investigators have sought to determine if preoperative endoscopy with biopsy can accurately assess response to treatment, and whether achievement of pathologic complete response following chemoradiation improves overall survival. Bates et al.<sup>436</sup> reported a 65% 3-year survival rate in patients who achieved a pathologic complete response, compared with a 25% survival rate in those who did not. Forastiere and associates<sup>435</sup> reported 2-year survival rates of 78% for pathologic complete responders compared with 46% for those having residual tumor in the resected esophagus ( $P = .006$ ); in a previous trial with long-term follow-up,<sup>427</sup> these investigators observed 5-year survival rates of 60% and 32% for pathologic complete responders and those with residual disease following induction therapy, respectively. These nonrandomized data suggest that with aggressive induction chemoradiation therapy, patients who are downstaged to pathology-negative status may have a survival advantage. In addition, the fact that long-term survival was observed in 25% to 30% of patients with residual tumor in the resected specimen suggests that surgery was an important component of the multimodality regimens. Bates et al.<sup>436</sup> noted a 41% false-negative rate with preoperative endoscopy and biopsy, indicating that this technique cannot reliably determine the need for further therapy. Furthermore, Jones and colleagues<sup>437</sup> reported that CT scan had a sensitivity of 65%, specificity of 33%, a positive predictive value of 58%, and a negative predictive value of 41% in evaluating pathologic response following preoperative combined modality therapy in esophageal cancer patients. EUS may have similar limitations,<sup>218,219</sup> although FDG PET may prove to be a useful noninvasive means to assess response to induction therapy.<sup>223</sup> Thus, at present, no methods short of surgical resection accurately determine which patients have achieved pathologic complete response following induction chemoradiation therapy.

In some trials, patients have been selected for surgery based on their overall medical status and response to preoperative therapy (see [Table 33.2-17](#)). Gill and colleagues<sup>396</sup> evaluated the role of surgery following combined modality therapy consisting of two cycles of 5-FU and cisplatin and radiation therapy. The study was biased in that only those patients with more favorable prognoses were selected for surgery. Although the differences were not statistically significant, the local failure and distant failure rates were higher in the patients who underwent surgery compared with those who did not. Using a similar approach of limiting surgery to those patients who responded to preoperative therapy and delivering higher radiation doses to nonresponders, Kavanagh and associates<sup>438</sup> reported that patients who underwent surgery had a lower local failure rate (24% vs. 44%); however, there were no differences in distant failure or median survival. The 1992 to 1994 Patterns of Care<sup>439</sup> survey study reported a significant improvement in survival of patients selected to receive preoperative combined modality therapy compared with combined modality therapy alone.

### Randomized Trials

There have been three randomized trials comparing preoperative combined modality therapy with surgery alone in patients with clinically resectable disease ([Table 33.2-18](#)).<sup>245,440,441</sup> The series from Le Prise et al.<sup>442</sup> is not included since patients received sequential rather than concurrent chemotherapy plus radiation.

Series	Number	Stage	Treatment	Pathologic Complete Response (%)		Survival (%)		Local Failure (%)
				3-year	5-year	3-year	5-year	
Urb <sup>a</sup>	100	T1S adenocarcinoma	Preoperative CRT	29	1.6y	32	27	—

Leu <sup>c</sup>	20	SCC	Preoperative CRT	5	3 mo	3	—	—
			Surgery	1	3 mo	3	—	—

CRT, combined modality therapy; SCC, squamous cell carcinoma.  
<sup>a</sup>3-year survival rates and 30% mortality rates.  
<sup>b</sup>30%.

**TABLE 33.2-18.** Randomized Trials of Preoperative Combined Modality Therapy for Esophageal Cancer

Urba and associates from the University of Michigan<sup>440</sup> randomized 100 patients (75% with adenocarcinoma) to preoperative cisplatin (20 mg/m<sup>2</sup> days 1 to 5 and 17 to 21), vinblastine (1 mg/m<sup>2</sup> days 1 to 4 and 17 to 20), 5-FU (300 mg/m<sup>2</sup>/24 hours days 1 to 21), and concurrent radiation therapy (1.5 Gy twice a day to 45 Gy), followed on day 42 by a transhiatal esophagectomy versus surgery alone. Preliminary analysis with a median follow-up of 1.82 years in surviving patients revealed no benefit in median survival (1.46 vs. 1.48 years) or estimated 2-year survival (41% vs. 36%) of preoperative combined modality therapy. Subsequent analysis with a median follow-up of 5.2 years in the 19 living patients revealed that preoperative combined modality therapy did not improve median survival (1.41 vs. 1.46 years); however, univariate analysis demonstrated a borderline significant improvement in 3-year survival (32% vs. 15%;  $P = .07$ ). This survival benefit reached statistical significance

( $P = .04$ ) with multivariate analysis. Furthermore, a significant decrease in local recurrence (19% vs. 39%;  $P = .04$ ) was observed in patients receiving combined modality therapy.<sup>441</sup>

In a series from Dublin, Walsh et al.<sup>245</sup> reported a significant survival benefit with preoperative combined modality therapy. In this trial, 113 patients with adenocarcinoma of the midesophagus or distal esophagus (including the cardia) were randomized to two cycles (weeks 1 and 6) of 5-FU (15 mg/kg/24 hours days 1 to 5), cisplatin (75 mg/m<sup>2</sup> day 7), plus concurrent preoperative radiation therapy (2.67 cGy/d to 40 Gy) versus surgery alone. Resection was performed 8 weeks following the start of chemotherapy, and a variety of operations were allowed. Combined modality therapy was well tolerated. The incidence of acute grade III+ toxicity was 15%. The operative mortality was 9% in the multimodality treatment arm compared with 4% in surgery control arm. With a median follow-up in surviving patients of 18 months, a significant improvement in both median survival (16 vs. 11 months;  $P = .01$ ) and 3-year survival (32% vs. 6%;  $P = .01$ ) was observed in patients receiving preoperative therapy compared with those treated with surgery alone. A major criticism of this trial is the high operative mortality (9%) and the low 3-year survival rate (6%) in the surgical control arm. In the Intergroup 0113 (RTOG 89-11) trial the operative mortality and 3-year survival rates were 6% and 25%, respectively, in the surgical control arm.

The third randomized trial of preoperative combined modality therapy was reported by Bosset et al.<sup>246</sup> from the EORTC. A total of 282 patients with clinically resectable (stages I and II) squamous cell carcinomas were randomized to preoperative combined modality therapy versus surgery alone. The preoperative regimen included 3.7 Gy  $\times$  5 followed by a 2-week rest and another 3.7 Gy  $\times$  5. Chemotherapy was limited to cisplatin, 80 mg/m<sup>2</sup>, 0 to 2 days before starting radiation therapy. With a median follow-up of 55 months, patients who received preoperative combined modality therapy had a significantly greater 3-year disease-free survival (40% vs. 28%) and local disease-free survival (relative risk, 0.6), yet had no improvement in median survival (19 months) or overall 3-year survival (36%) compared with patients treated with surgery alone. However, this combined modality therapy regimen was unconventional in design; not only was the radiation split course and delivered with unusually high doses per fraction, but the doses of chemotherapy were not adequate for systemic therapy.

Although two of the three randomized trials demonstrated a survival advantage, they are limited by small numbers of patients and short follow-up, hence their results should be interpreted with caution. To help clarify this controversy, the Intergroup has developed a randomized trial of preoperative combined modality therapy (Cancer and Leukemia Group B C9781), which is the follow-up trial to Intergroup 0113. The preoperative regimen is based on the combined modality arm from RTOG 85-01 and uses conventional 5-FU, cisplatin, and 50.4 Gy; the control arm is surgery alone since preoperative chemotherapy was not beneficial in Intergroup 0113.

Paclitaxel-based regimens have activity in patients with advanced esophageal cancer, and preoperative combined modality regimens using paclitaxel have achieved encouraging results<sup>420,421</sup> and <sup>422,443</sup>; however, an increase in acute radiation esophagitis has been seen in initial reports. Safran et al.<sup>422</sup> reported a 9% incidence of radiation esophagitis in patients receiving 3-hour paclitaxel infusion. More protracted infusions appear to be better tolerated; in an ongoing phase I dose escalation trial using 96-hour paclitaxel infusion plus cisplatin and 5040 cGy (reported in abstract form by Kelsen and associates<sup>373</sup>), no patients experienced grade III+ esophagitis at the 80 mg/m<sup>2</sup> dose level of paclitaxel. As with combined modality regimens in other gastrointestinal cancers, development of ideal regimens and schedules remains an active area of clinical investigation.

In summary, the efficacy of preoperative combined modality treatment for resectable esophageal cancer patients remains unclear. Although an apparent benefit has been seen in phase II trials that have used intensive regimens, significant toxicities have been observed. Whereas two of the three randomized trials revealed a survival advantage for combined modality treatment, in the study by Urba et al.<sup>440,441</sup> this advantage reached significance only by multivariate analysis, and the trial by Walsh et al.<sup>245</sup> had an unusually low survival rate in the surgical control arm. Both trials had relatively small numbers of patients and limited follow-up. Further maturation of these randomized trials, together with results of the Intergroup trial Cancer and Leukemia Group B C9781, may allow more definitive conclusions regarding the role of preoperative combined modality therapy. In the interim, preoperative combined modality therapy remains an investigational approach, results of which should be compared with the best results achievable by surgery alone in patients who have been optimally staged.

Due to selection bias, it is difficult to determine what is the best treatment for esophageal cancer. The standard of care is either surgery alone or primary combined modality therapy. The results of these two approaches appear similar, although no direct comparative trials have been performed.

### **Radiation Field Design and Treatment Techniques**

Similar to the expert surgical skills required for a successful esophagectomy, radiation field design for esophageal cancer requires careful techniques.<sup>444</sup> There are a number of sensitive organs that, depending on the location of the primary tumor, will be in the radiation field. These include but are not limited to skin, spinal cord, lung, heart, intestine, stomach, kidney, and liver. Minimizing radiation to these structures while delivering an adequate dose to the primary tumor and local regional lymph nodes requires patient immobilization and CT-based treatment planning for organ identification, lung correction, and development of dose-volume histograms.

Although CT can identify adjacent organs and structures, it may be limited in defining the extent of the primary tumor. To assess the consistency of target-volume delineation, Tai and colleagues sent sample cases with CT scans to 48 radiation oncologists throughout Canada and asked them to fill out questionnaires regarding treatment techniques as well as outline the boost target volumes.<sup>445</sup> There was substantial inconsistency in defining the planning target volume, both in the transverse and longitudinal dimensions. Therefore, in addition to a CT scan, barium swallow should be obtained at the time of radiation therapy simulation. The integration of other imaging modalities in radiation treatment planning such as esophageal ultrasound, PET scan, and magnetic resonance imaging are under active investigation.

At present, the standard radiation dose for patients selected for curative nonoperative combined modality therapy approach is 50.4 Gy at 1.8 Gy per fraction. The radiation field should include the primary tumor with 5-cm superior and inferior margins and 2-cm lateral margins. The primary local regional lymph nodes should receive the same dose. For cervical (proximal) primary tumors (defined as at or proximal to the carina), the treatment volume includes the bilateral supraclavicular nodes, and for distal gastroesophageal primaries the celiac axis nodes should be included. An example of a four-field technique for a distal esophageal cancer is seen in [Figure 33.2-7](#).

**FIGURE 33.2-7.** An example of a four-field technique for the treatment of a distal esophageal cancer.

For cervical primaries, patients are placed supine. Various field designs are possible and their choice depends on the geometry of the primary tumor in relation to the spinal cord. The spinal cord dose should be limited to 45 Gy. Field designs include a three-field technique (two anterior obliques and a posterior) or more commonly anteroposterior and posteroanterior to 39.6 to 41.4 cGy, followed by a left or right opposed oblique pair with photons plus an electron boost to the contralateral supraclavicular area, both to a total dose of 50.4 Gy. For midesophageal primary tumors patients are placed prone to help exclude the spinal cord from the radiation field and receive four fields (anteroposterior and posteroanterior and opposed laterals). For distal primaries patients are treated supine using the same four-field technique. Care should be taken to exclude as much of the normal stomach as possible, especially if the patient is receiving radiation therapy preoperatively. CT-based three-dimensional treatment planning should be performed and all fields treated each day. Dose-volume histograms help guide the radiation oncologist in choosing the radiation plan that minimizes the loss of normal organ function.

A variety of radiation treatment regimens may be used in the palliative setting. Since the goal is rapid amelioration of symptoms, the most common approach is to treat

anteroposterior and posteroanterior, including the primary tumor with 2-cm margins with ten 3-Gy fractions to a total dose of 30 Gy.

### **Tumor Markers and Predictors of Response to Combined Modality Therapy**

It would be helpful to predict tumors that have a higher likelihood of responding to radiation or combined modality therapy. In 38 patients with squamous cell carcinoma who received combined modality therapy with or without surgery, Sarbia et al.<sup>446</sup> observed that tumors without p53 expression and those with weak Bcl-XL expression had a higher response to chemotherapy (56% and 53%, respectively) than tumors positive for p53 or those having high-level Bcl-XL expression (30% and 32%, respectively;  $P = NS$ ). Following preoperative combined modality therapy, patients with p53-negative tumors had significantly better mean survivals compared with those whose tumors expressed p53 (31 vs. 11 months;  $P = .0378$ ). There was no prognostic effect of the expression of apoptosis-regulating genes. Using multivariate analysis, Pomp et al.<sup>447</sup> found that overexpression of p53 correlated with diminished survival in 69 patients with squamous or adenocarcinomas treated with radiation alone. In another study, Merchant et al.<sup>448</sup> found a correlation between decreasing phospholipid expression and increasing T stage and grade.

### **ENDOLUMINAL PALLIATION TECHNIQUES**

As previously discussed, surgery remains the standard of care for patients with resectable neoplasms; however, many esophageal cancer patients are inoperable due to locally advanced or distant metastatic disease. Although chemotherapy and radiation therapy are typically used to palliate unresectable disease, many individuals require additional measures to relieve dysphagia and pain. Esophageal dilation frequently can alleviate esophageal obstruction secondary to malignancy; however, results usually are temporary, and patients require repeated treatments. Lundell et al.<sup>449</sup> reported their experience with esophageal dilation in 41 esophageal cancer patients. Although complications were observed in less than 5% of these individuals, dysphagia recurred in all patients, and most dilations had to be repeated every 4 weeks.

Whereas in a strict sense surgery for locally advanced esophageal cancer can be considered palliative in nature, resection of esophageal carcinomas in the context of known distant metastases or the treatment of unresectable obstructing neoplasms using surgical bypass procedures presently cannot be advocated in light of data demonstrating safe and effective palliation by endoluminal stents, laser, or photodynamic therapy (PDT) techniques.<sup>450</sup> Orringer<sup>451</sup> reported results of bypass procedures in 37 patients with unresectable esophageal carcinomas, noting an operative mortality of 24%, an anastomotic leak rate of 19%, and effective palliation in only 25% of individuals. The average survival of patients leaving the hospital following esophageal bypass procedure was less than 6 months. In additional studies, Mannell et al.<sup>452</sup> evaluated 124 patients undergoing esophageal bypass for unresectable disease. Although 82% of patients experienced complete and durable palliation, hospital mortality was approximately 11%, and survival in these individuals was only 5 months. Holting et al.<sup>453</sup> compared results of 26 patients undergoing surgical bypass, with 45 patients undergoing endoscopic laser palliation. Although surgical patients tended to experience more sustained palliation, survival rates were comparable in both patient groups. In a more recent study, Segalin et al.<sup>454</sup> reported an operative mortality of 20% and median survival of 6 months for 49 patients undergoing esophageal resection for advanced metastatic disease. In contrast, 30-day mortality was 10%, and median survival was 4 months for 254 patients treated with intubation procedures. Laser therapy was performed in 50 patients with no operative mortality and a median survival of 4 months.

Although previous studies employing intubation techniques have reported high morbidity and mortality, current data indicate that expandable stents placed by endoscopic methods afford cost-effective and durable palliation in esophageal cancer patients. Rajman et al.<sup>455</sup> evaluated 101 patients with malignant dysphagia, 83 of whom experienced dysphagia secondary to esophageal cancer, and 13 of whom had digestive respiratory tract fistulas. The majority of strictures were in the distal third of the esophagus and most were secondary to exophytic tumors. The mean stricture length was approximately 7 cm. Initial stent placement was successful in 100 patients, and the vast majority experienced significant improvement in their dysphagia. Life-threatening complications were noted in approximately 8%; there were no procedure-related deaths. All digestive respiratory tract fistulas were successfully controlled by endoscopic stents. Ninety-nine patients died of their disease within a mean follow-up of 201 days. In an additional series, Cwikiel et al.<sup>456</sup> reported long-term results of 100 patients with malignant dysphagia treated with self-expanding Nitinol stents. Esophageal strictures were due to squamous cell carcinoma in 43 patients, adenocarcinoma in 18, anastomotic recurrence in 14, or extrinsic compression from mediastinal tumor in 14 individuals. One hundred six stents were placed in 100 patients. Complications included incomplete expansion due to stent twisting (four patients), stent migration (four patients), tumor ingrowth (17 patients), food impaction (five patients), fracture of stent wires (two patients), benign stricture (two patients), and tumor bleeding (four patients). Forty-seven patients experienced transient chest pain following deployment of the stent. Esophageal respiratory fistulas were observed in five patients, three of whom were successfully treated with additional stent placement. Ninety-seven patients experienced significant reduction in dysphagia; at the time of their deaths, 42 patients had no dysphagia, 39 had grade 1 dysphagia, 16 had grade 2 dysphagia, and 3 experienced grade 3 dysphagia.

Cantero et al.<sup>457</sup> compared results of 25 patients undergoing esophageal bypass with 30 patients treated with autoexpandable esophageal stents. Dysphagia was not relieved in 24% of surgical patients, and hospitalization for these patients ranged from 18 to 50 days; the hospital mortality was 24%. Survival in these patients was only 5.4 months. Twenty-eight of 30 individuals treated with esophageal stents experienced significant relief of dysphagia; hospitalization ranged from 5 to 12 days. A 6.6% mortality was observed for these individuals, and no deaths were related to technical difficulties. Mean survival for these patients was 6 months.

Although less commonly used, PDT has been advocated as an additional means to palliate obstructing esophageal carcinomas.<sup>458</sup> Lightdale et al.<sup>459</sup> reported results of a randomized multicenter trial evaluating PDT versus neodymium:yttrium-aluminum-garnet (Nd:YAG) laser treatment for palliation of dysphagia secondary to esophageal carcinomas. Two hundred thirty-six patients were evaluated, of whom 218 patients underwent treatment; 110 individuals received PDT, and 108 patients were treated with YAG laser. Significant improvement in dysphagia was noted in all patients without obvious differences between groups. Objective tumor responses were comparable but slightly improved with PDT. Esophageal perforations occurred in 1% of individuals following PDT treatment versus 7% of individuals treated with laser techniques. These results suggest that PDT and Nd:YAG laser are equally efficacious with regard to palliation of dysphagia, and that PDT may be associated with a relatively lower risk of acute perforations.

Maier et al.<sup>460</sup> reviewed their experience with 119 cases of unresectable esophageal cancers treated with endoluminal palliation techniques. Twenty-one patients required dilation and Nd:YAG laser obliteration before therapy; 44 patients received PDT followed by brachytherapy; 25 of these individuals also received external-beam radiation therapy. Seventy-five patients refused PDT and were treated with high-dose brachytherapy, 17 of whom also received external-beam radiation therapy. PDT was more successful than brachytherapy in relieving stenosis; significant relief of dysphagia was observed. The mean number of PDT treatments was four (range, one to seven); because of concerns regarding stricture formation and perforations, PDT was not repeated within 3 months. Major complications were noted in 9.2% of patients. Four esophageal perforations occurred that were treated by esophageal exclusion and mediastinal drainage techniques. Four esophageal respiratory fistulas were observed, all of which were treated with endoluminal stents. Mean overall survival was 7.7 months; a statistically significant difference in survival was observed for patients receiving PDT and external-beam therapy compared with those receiving brachytherapy alone.

Thus, current data indicate that esophageal stents, laser, or PDT can efficiently palliate obstructing esophageal cancers with far less morbidity and mortality than surgical bypass techniques. Relative contraindications to esophageal stenting include complete obstruction not allowing guidewire placement, noncircumferential tumor not enabling stabilization of the stent, esophageal dilation above the stenosis, or high cervical esophageal lesions. Although laser and PDT require more expertise, these modalities may either be used initially to palliate obstructing esophageal lesions or as an adjunct to treat tumor ingrowth, which occurs in 20% to 30% of stent patients. Endoluminal stenting, YAG laser, and PDT should be viewed as complementary modalities for palliation of unresectable, obstructing esophageal carcinomas.

### **TREATMENT RECOMMENDATIONS AND FUTURE DIRECTIONS**

Although individuals occasionally are diagnosed early due to participation in screening protocols, the vast majority of patients with esophageal cancer present with either locally advanced (stages IIB or III) or inoperable metastatic disease. Esophagectomy remains the standard of care for patients who can tolerate resection. Available data from well-designed prospective randomized trials do not support the routine use of induction chemotherapy in resectable patients. Furthermore, there are no convincing data that justify the routine use of chemotherapy following esophagectomy. Radiation therapy has no proven benefit as the sole modality in the induction setting, and current data indicate a potential benefit of this treatment modality in patients with positive resection margins, but not in completely resected individuals irrespective of nodal status. Limited data suggest that combined chemoradiation therapy may be beneficial in the induction setting in resectable patients, particularly in individuals achieving pathologic complete responses; surgery remains an important component of these aggressive protocols since no other modality enables accurate assessment of response to induction therapy, and no other intervention can enhance local control in this setting. However, further analysis of well-designed, prospective randomized trials is required before multimodality treatment can be considered the standard of care for individuals with resectable cancers. Data from Altorki et al.,<sup>36</sup> Lerut and colleagues,<sup>269</sup> and Akiyama and coworkers<sup>261</sup> indicate that *en bloc* esophagectomy, particularly with three-field lymphadenectomy, enhances the accuracy of staging and appears to improve local control and overall survival in esophageal cancer patients. If confirmed by other expert esophageal cancer surgeons, these results should be considered the standard against which all other treatments are compared. Patients with unresectable cancers should be

palliated with chemoradiation therapy in cooperative trials, such that toxicity and survival data can be evaluated in a rigorous manner. Considerable progress must be made in terms of enhancing the accuracy of staging to improve stratification of patients to appropriate prospective trials and minimize stage migration, which may obscure potential benefits of therapeutic interventions.

Although their prognostic significance remains unclear, mutations involving growth factor receptors, cyclin D1, Rb, p16, p53, and telomerase appear to be appropriate targets for intervention in esophageal cancers and their precursor lesions. Several novel compounds have been identified that specifically inhibit the tyrosine kinase activity of EGFR, or erbB2, and enhance the efficacy of conventional cytotoxic agents. Nguyen et al. (manuscript in preparation) observed that 17-allylamino geldanamycin mediated dose-dependent depletion of p185 protein expression and inhibited proliferation of cultured esophageal carcinoma cells overexpressing erbB-2. Interestingly, reduced doses of 17-allylamino geldanamycin that exhibited minimal inhibitory activity synergistically potentiated the effects of paclitaxel in esophageal cancer cells; enhanced paclitaxel sensitivity following 17-allylamino geldanamycin treatment coincided with cell-cycle arrest and apoptosis in these cells. Chemotherapeutic regimens that exploit these observations are currently under evaluation at the National Cancer Institute.

The Rb tumor suppressor pathway is disrupted by a variety of mechanisms in virtually all esophageal cancers, and gene transfer experiments have confirmed that restoration of this pathway significantly inhibits the malignant phenotype of esophageal cancer cells. <sup>140,155</sup> Flavopiridol is a synthetic flavone that inhibits several cyclin-dependent kinases (including cdk4 and cdk6), diminishes cyclin D1 and Bcl-2 expression, and induces cell-cycle arrest and apoptosis in a variety of cancer cells. <sup>461,462</sup> Data indicate that flavopiridol mediates profound cell-cycle arrest and apoptosis in esophageal cancer cells irrespective of histology or genotype; inhibition of cyclin D1, Rb, and p107 expression precedes the onset of apoptosis in these cells. <sup>463</sup> Additional studies have demonstrated that pretreatment of esophageal cancer cells with flavopiridol markedly enhances their sensitivity to paclitaxel, in part, by synchronizing them in G<sub>2</sub>M. <sup>464</sup> In addition to being a novel agent for the treatment of esophageal cancers, flavopiridol may be a potential chemoprevention agent since it effectively targets three mutational events (i.e., cyclin D1 overexpression, as well as Rb and p16 inactivation) that are known to occur early during multistep esophageal carcinogenesis.

Approximately 50% of esophageal cancers exhibit loss of p16 expression due to promoter hypermethylation. <sup>179,181</sup> Studies by Weiser et al. <sup>465</sup> have shown that the demethylating agent, 5-aza-2'-deoxycytidine (DAC) at low doses induces p16 expression in cancer cells. Furthermore, these investigators have observed that the novel histone deacetylase inhibitor, depsipeptide FR901228, enhances DAC-mediated growth arrest and apoptosis in esophageal cancer cells irrespective of histology or tumor suppressor gene status. Additional studies have demonstrated that sequential DAC and depsipeptide treatment enhances NY-ESO-1 expression in esophageal cancer cells and enables their recognition by HLA-restricted cytolytic T cells specific for this cancer testis antigen. <sup>466</sup> Clinical trials designed to evaluate the ability of DAC and depsipeptide to mediate target gene induction and apoptosis in esophageal carcinomas and augment antitumor immunity in patients with these malignancies are underway in the Surgery Branch, National Cancer Institute. Evaluation of these agents, as well as other novel compounds targeting p53 mutations and telomerase expression in cancer cells, <sup>246,467</sup> may ultimately enable evolution of more precise and efficacious treatment regimens for highly lethal esophageal neoplasms.

## INTRODUCTION

Adenocarcinoma of the stomach has been the leading cause of cancer death worldwide through most of the twentieth century. It now ranks second only to lung cancer with an estimated 755,500 new cases diagnosed annually around the world. The incidence of this disease has gradually decreased in many parts of the world, principally because of changes in diet, food preparation, and other environmental factors. The declining incidence has been dramatic in the United States, where this disease ranks fourteenth as a cause of cancer deaths. It is estimated that 21,900 new cases are diagnosed annually, with approximately 13,500 deaths per year.<sup>1,2</sup> With the exception of just a few countries in the world, the prognosis for this disease remains poor. The overall 5-year survival rate in the United States and most of the Western world ranges from 5% to 15%. The explanations for these poor results are multifactorial. The lack of defined risk factors and specific symptomatology, and the relatively low incidence, have contributed to the late stage of onset seen in most Western countries. In Japan, where gastric cancer is endemic, patients are diagnosed at an early stage, which is reflected in the excellent 50% 5-year survival rate.

Although the incidence of gastric cancer has decreased dramatically over the last century, the decline has been limited to cancers below the gastric cardia. The number of newly diagnosed patients with proximal gastric and gastroesophageal junction adenocarcinomas has increased markedly since the mid-1980s.<sup>3,4</sup> and<sup>5</sup> The disturbing fact is that these are thought to be biologically more aggressive than distal tumors and more complex to treat. The only proven, potentially curative treatment is surgical resection of all gross and microscopic disease. Even after a "curative" gastrectomy, disease recurs in both regional and distant sites in at least 80% of patients. Efforts to improve these poor results have focused on developing effective pre- and postoperative systemic and regional adjuvant therapies. It is generally accepted that patients with chemoresponsive tumors are more likely to have a survival advantage. Consequently, a greater emphasis is being placed on predicting chemoresponsiveness in gastric cancer. This chapter details the current thinking regarding the origins, treatment, and prevention of this universal health problem.

## EPIDEMIOLOGY

In 1965, Laurén<sup>6</sup> described two distinct histologic types of stomach adenocarcinoma: intestinal and diffuse, which provided a model to better understand the etiology and epidemiology of the disease.<sup>7</sup> The intestinal variant arises from precancerous areas, such as gastric atrophy or intestinal metaplasia within the stomach; occurs more commonly in men than in women; is more frequent in an older population; and represents the dominant histologic type in areas where stomach cancer is epidemic, suggesting a predominantly environmental etiology. The diffuse form does not typically arise from recognizable precancerous lesions. It represents the major histologic type in endemic areas; occurs slightly more frequently in women and in younger patients; and has a higher association with familial occurrence (blood type A), suggesting a genetic etiology.<sup>8</sup> Changes in the incidence of gastric cancer within populations over time or between geographically distinct populations appear to reflect a difference or change in the incidence of the intestinal form.<sup>9,10</sup> and<sup>11</sup>

The highest incidences of stomach cancer can be found in Japan, South America, Eastern Europe, and portions of the Middle East. In most countries, the mortality rate approximates the incidence; in Chile and Costa Rica, the mortality rates for gastric cancer exceed 40 per 100,000 population. In contrast, low-incidence areas, such as New Zealand and Australia, have mortality rates of less than 10 per 100,000.<sup>12</sup> In Japan, despite the epidemic incidence of gastric cancer, a decline has been seen in mortality rates since the 1970s as a result of mass screening.<sup>13</sup>

The studies of migrant populations from areas of high to low risk have produced evidence of environmental influences on the development of gastric cancer.<sup>9,14,15,16,17</sup> and<sup>18</sup> Among Japanese migrating from the highest risk prefectures in Japan to Hawaii, the risk of stomach cancer persisted even when a Western-style diet was adopted. The high risk of stomach cancer also was observed in second-generation offspring who continued to consume a Japanese-style diet but was low in those adopting a Western-style diet.<sup>16</sup> In the population of Polish migrants living in the United States for 10 years or more, the incidence of gastric cancer decreased and

became intermediate between the countries of origin and adoption.<sup>15</sup> These studies suggest that environmental exposure in early life is essential in determining risk but that other environmental or cultural factors may be continually influencing the predisposition to cancer.

In the United States, stomach cancer occurs at a higher incidence in men than in women (ratio of approximately 2:1). It is more frequent in black men than in white men (1.5:1). Starting at the fourth decade, the incidence of stomach cancer increases with advancing age and has a peak incidence in the seventh decade in men and a slightly later peak incidence in women.<sup>12,19</sup> The mortality rate for stomach cancer has decreased from 31.5 per 100,000 for white men in 1935 to 7.8 per 100,000 for all U.S. men in 1983. However, this decline in mortality simply reflects the decrease in the incidence of the disease, and relative 5-year survival rates have not changed considerably.

One of the most striking epidemiologic observations has been the increasing incidence of adenocarcinomas involving the proximal stomach and distal esophagus.<sup>3,4,20,21</sup> In 1991, Blot and colleagues,<sup>3</sup> reviewing the National Cancer Institute's Surveillance, Epidemiology, and End Results database, reported that, during the period 1976 to 1987, a shift to proximal gastric lesions was noted. The annual increase in proximal gastric lesions was 4.3% for white men, 4.1% for white women, 3.6% for black men, and 5.6% for black women. This annual rate of increase on a percentage basis is greater than that of lung cancer or melanoma. The incidence of adenocarcinoma elsewhere in the stomach was approximately the same or slightly lower. By 1984 to 1987, cancers of the cardia made up 47% of all gastric cancers in white men. European investigators have reported similar data.<sup>22</sup> This trend is worrisome, because proximal gastric cancers are thought to have a poorer prognosis, stage for stage, compared with distal cancers.<sup>23,24,25</sup> and <sup>26</sup> The etiologic basis for this rising trend is being aggressively pursued. Increasing prevalence of obesity in the United States may be one factor contributing to this trend. Elevated body mass index<sup>27,28</sup> and caloric consumption<sup>29</sup> have been associated with adenocarcinoma of the distal esophagus and gastric cardia. Gastroesophageal reflux disease may be another risk factor. A population-based, case-control study performed in Sweden found that, for persons with recurrent symptoms of reflux, as compared to those without such symptoms, the odds ratio was 7.7 [95% confidence interval (CI), 5.3 to 11.4] for esophageal adenocarcinoma and 2.0 (95% CI, 1.4 to 2.9) for adenocarcinoma of the gastric cardia.<sup>30</sup> Others have found tobacco use to be associated with these tumors at these sites.<sup>31</sup> Gammon et al.<sup>32</sup> observed an increased odds ratio of 2.4 (95% CI, 1.7 to 3.4) for cigarette smokers. Conversely, aspirin and nonsteroidal antiinflammatory drug use has been associated with a lower risk of esophageal and cardia cancers,<sup>33</sup> implicating inflammation in the etiology of this disease.

## ETIOLOGY AND PATHOGENESIS

It is generally accepted that the carcinogenic process leading to the intestinal-type cancers takes many years to develop into invasive adenocarcinoma. Many studies have investigated the role of diet in association with the development of stomach cancer, concluding that the consumption of raw (uncooked) vegetables, fruit, citrus fruit, and high fiber are inversely related to stomach cancer risk.<sup>14,18,34,35</sup> Dietary factors that may be associated with an increased risk of stomach cancer are listed in [Table 33.3-1](#). Antioxidants, which can prevent the conversion of nitrates to nitrosamine, appear to be protective. Diets rich in vitamins A and C<sup>14,36</sup> and micronutrients such as selenium, zinc, copper, iron, and manganese may lower the risk of gastric carcinoma.<sup>37</sup>

Associated Factors
Nutritional
High salt consumption
High nitrate consumption
Low dietary vitamins A and C
Poor food preparation (cooked, salt cured)
Lack of refrigeration
Poor drinking water (well water)
Chemical
Nifedipine
Cadmium
Cigarette smoking
Helicobacter pylori infection
Gastric mucin
N-nitrosamines
Fiber gastric surgery for benign gastric ulcer disease
Genetic Factors
Type A blood
Familial adenomatous polyposis
Hereditary nonpolyposis colorectal cancer
Li-Fraumeni syndrome
Preexisting lesions
Adenomatous gastric polyps
Chronic atrophic gastritis
Dysplasia
Intestinal metaplasia
Mucosa's disease

**TABLE 33.3-1.** Factors Associated with Increased Risk of Developing Stomach Cancer

The incidence of cancers affecting the gastric body and antrum is inversely related to socioeconomic status, which probably reflects a number of social, occupational, or cultural factors.<sup>18</sup> A higher incidence has been associated with the practice of smoking or salting meat and fish and a low incidence with the use of refrigeration and better food preparation. The use of well water, which may contain high concentrations of nitrates or *Helicobacter pylori*, has been shown to be a risk factor for gastric cancer.<sup>38,39</sup> Smoking has been reported to increase the relative risk, whereas no consistent data have supported that alcohol consumption affects the incidence of stomach cancer.<sup>35</sup>

Correa and colleagues<sup>9</sup> have proposed a model for the pathogenesis of intestinal-type gastric cancer. Normal mucosa, either through environmental or other factors, becomes atrophied in association with impaired gastric acid secretion and an increased gastric pH. Subsequent bacterial overgrowth results in further mucosal injury directly or via the bacterial production of nitrites or N-nitroso compounds from dietary nitrates.<sup>38</sup> In laboratory animals, the ability of chronically administered oral N-nitroso compounds to produce intestinal metaplasia and subsequent carcinoma has been well described.<sup>40,41</sup> In humans, this mechanism is supported by the observation of a high prevalence of chronic atrophic gastritis and intestinal metaplasia in populations with a high incidence of gastric cancer and the association of gastric cancer with pernicious anemia.<sup>10,42,43</sup> and <sup>44</sup>

The Epstein-Barr virus genome has been identified in human gastric cancers with lymphoepithelioid features.<sup>45,46</sup> This is an uncommon finding that has been associated with tumors of younger patients (younger than 35 years), tumors located in the cardia, or in stump carcinomas.<sup>47,48</sup> The frequency in Japan is estimated to be approximately three times that of North America.<sup>49</sup>

The data in support of radiation exposure increasing the risk of gastric cancer come from the Japanese atomic bomb reports.<sup>50</sup> An initial analysis of patients irradiated for peptic ulcer disease followed through 1962 showed no significant tumor increase. A subsequent study of 2049 irradiated patients and 763 medically managed patients was undertaken in 1984 to estimate the risk of cancer due to gastric irradiation. A relative risk of 3.7 was found for stomach cancer.<sup>51</sup>

The occurrence of gastric carcinoma clustered in families suggests the existence of a genetic susceptibility to cancer of the stomach. Estimates of familial clustering of gastric cancer range from 1%<sup>52</sup> to 15% of all gastric cancers.<sup>52,53</sup> The most celebrated example of the genetic predisposition toward stomach cancer is illustrated in the Bonaparte family: Napoleon, his father, and his grandfather all died of gastric carcinoma.<sup>54</sup> Gastric cancer occurs with increased frequency in family members diagnosed with hereditary nonpolyposis colorectal cancer and Li-Fraumeni syndrome. In 1998, Guilford et al.<sup>55</sup> identified an E-cadherin germline mutation present in three Maori kindreds with familial gastric cancers in New Zealand. The potential role for this mutated intracellular adhesion protein in the susceptibility of diffuse-type cancers also was documented in non-Maori families of European and Korean descent.<sup>56</sup> Shinmura et al.<sup>52</sup> studied DNA from 13 proband cases of familial gastric cancer and concluded that DNA mismatch repair, mutated p53, and E-cadherin genes did not contribute to the observed familial clustering.

## PRIOR GASTRIC SURGERY AND GASTRIC CANCER

In 1922, Balfour<sup>57</sup> made the original observation that an association existed between the development of gastric cancer and previous partial gastrectomy for benign disease. A gastric stump cancer arises in the gastric remnant no less than 5 years after partial gastrectomy to distinguish a *de novo* gastric stump cancer from a locally recurrent tumor that was not recognized at the original operation.<sup>58</sup> Two metaanalyses have been published that indicate an increased risk of gastric stump cancer in patients with partial gastrectomy.<sup>59,60</sup> The increased risk is observed only after a latency period of at least 15 years, is increased in patients operated on for gastric but not for duodenal ulcer, and is slightly higher in women than in men. The type of reconstruction does not appear to influence the relative risk of developing gastric stump cancer. Baas et al.<sup>48</sup> compared 26 stump carcinomas with 24 conventional stomach cancers and found that RNA *in situ* hybridization for Epstein-Barr virus was positive in nine stump carcinomas versus two carcinomas in the nonoperated stomach, suggesting etiologic differences between stump carcinoma and

cancers arising in the intact stomach.

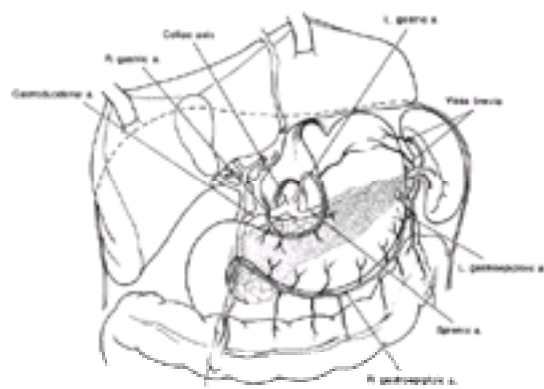

Because histamine-2 receptor antagonists suppress gastric acid secretion, it has been suggested that chronic use of these agents may predispose the gastric epithelium toward malignant degeneration. However, the only increased risk of stomach cancer in histamine-2 receptor antagonist users has been restricted to patients who had started treatment within 5 years before the diagnosis of stomach cancer.<sup>61,62</sup> This suggests that there may have been a misdiagnosis in some patients rather than a causal role for the drug.

### ***Helicobacter pylori* and Gastric Cancer**

In 1982, Marshall and Warren first isolated *H pylori* from biopsies of gastric epithelium. The role for *H pylori* in initiating mucosal injury and the subsequent development of chronic atrophic gastritis is well known.<sup>40,63</sup> In patients who had undergone resection for intestinal-type gastric cancer, the presence of *H pylori* has been identified in noncancerous tissue in almost 90% of patients, compared with 32% with the diffuse form of gastric cancer.<sup>64</sup> Several studies have reported a significant association between *H pylori* infection and gastric cancer,<sup>65,66</sup> and<sup>67</sup> particularly for tumors in the distal stomach.<sup>68</sup> The risk of developing gastric cancer correlated with increasing *H pylori* immunoglobulin G antibody levels and was higher when the time interval between the diagnosis of *H pylori* infection and gastric cancer was more than 10 years. Parsonnet and colleagues<sup>65</sup> found a particularly strong association between *H pylori* infection and stomach cancer in women and blacks. The intestinal and diffuse types of stomach adenocarcinoma, as well as gastric lymphoma, were associated with *H pylori* infection. However, others have found a significantly higher incidence of *H pylori* infection in patients with intestinal but not diffuse-type gastric cancer.<sup>69</sup> Although *H pylori* has been classified as a class I carcinogen, the incidence of *H pylori* infection in matched controls in these studies was between 61% and 76%, indicating that most people with *H pylori* infection do not develop stomach cancer and that other contributing factors are important in its pathogenesis. It has been shown that *H pylori* isolates that possess the *cagA* gene are more virulent in nature and produce significant amounts of gastritis and epithelial injury. Patients with *cagA* *H pylori* infection have a slightly higher risk of developing stomach cancer than those with *cagA*-negative strains.<sup>70</sup> Further research may define whether characteristics of certain subtypes of *H pylori* or unique characteristics of its host promote malignant transformation. At the present time, antibiotic therapy in *H pylori*-positive patients should be reserved for those with proven ulcer disease or nonulcer dyspepsia in whom other measures have been unsuccessful.

### **ANATOMIC CONSIDERATIONS**

The stomach begins at the gastroesophageal junction and ends at the pylorus (Fig. 33.3-1). Above it lie the diaphragm and left lobe of the liver; before it is the abdominal wall; and below it are the transverse colon, mesocolon, and greater omentum. Behind and to the sides are the spleen, pancreas, left adrenal gland, left kidney, and splenic flexure of the colon. Cancers arising from the proximal greater curvature may directly involve the splenic hilum and tail of pancreas, whereas more distal tumors may invade the transverse colon. Proximal cancers may extend into the diaphragm, spleen, or the left lateral segment of the liver.

**FIGURE 33.3-1.** Blood supply to the stomach and anatomic relationships of the stomach with other adjacent organs likely to be involved by direct extension of a large gastric malignancy.

The blood supply to the stomach is extensive and is based on vessels arising from the celiac axis (see Fig. 33.3-1). The right gastric artery, arising from the hepatic artery, and the left gastric artery, arising from the celiac axis directly, course along the lesser curvature. Along the greater curvature are the right gastroepiploic artery, which originates from the gastroduodenal artery at the inferior border of the proximal duodenum, and the left gastroepiploic artery, branching from the splenic artery laterally. The short gastric arteries (vasa brevia) arise directly from the splenic artery and make a relatively small contribution to the blood supply to the proximal portion of the stomach. The preservation of any of these vessels in the course of a subtotal gastrectomy for carcinoma is not necessary (nor possible if the operation is performed correctly), and the most proximal few centimeters of remaining stomach are well supplied by collateral flow from the lower segmental esophageal arcade. The rich submucosal blood supply of the stomach is an important factor in its ability to heal rapidly and produce a low incidence of anastomotic disruption.

The venous supply of the stomach tends to parallel the arterial supply. The venous efflux ultimately passes the portal venous system and is reflected in the fact that the liver is a primary site for distant metastatic spread.

The lymphatic drainage of the stomach is extensive, and distinct anatomic groups of perigastric lymph nodes have been defined according to their relationship to the stomach and its blood supply. There are six perigastric lymph node groups: along the greater curvature are the subpyloric and gastroepiploic nodes, and along the lesser curvature are the suprapyloric and the lesser curvature lymph nodes. Proximally are found the right and left pericardial nodes. The second echelon (extraperigastric) nodes include the common hepatic, left gastric, splenic hilum, and splenic artery lymphatics, which drain into the celiac and periaortic lymphatics. Proximally are the lower esophageal lymph nodes; extensive spread of gastric cancer along the intrathoracic lymph channels may be manifested clinically by a metastatic lymph node in the left supraclavicular fossa (Virchow's node) or left axilla (Irish's node). As the submucosal lymphatic supply of the stomach becomes extensively involved with tumor, other routes of lymphatic drainage may be recruited. Tumor spread to the lymphatics in the hepatoduodenal ligament can extend along the falciform ligament and result in subcutaneous periumbilical tumor deposits known as *Sister Mary Joseph's nodes*.

### **PATHOLOGY AND TUMOR BIOLOGY**

Approximately 95% of all malignant gastric neoplasms are adenocarcinomas, and in general, the term *gastric cancer* refers to adenocarcinoma of the stomach. Other malignant tumors are very rare and include squamous cell carcinoma, adenoacanthoma, carcinoid tumors, and leiomyosarcoma.<sup>71</sup> Although no normal lymphoid tissue is found in the gastric mucosa, the stomach is the most common site for lymphomas of the gastrointestinal tract. The increased awareness of association between mucosa-associated lymphoid tissue lymphomas and *H pylori* may explain, in part, the rise in incidence.<sup>72</sup> The differentiation between adenocarcinoma and lymphoma can sometimes be difficult but is essential because staging, treatment, and prognosis are different for each disease.<sup>73</sup>

### **HISTOPATHOLOGY**

Several staging schemas have been proposed based on the morphologic features of gastric tumors. The Borrmann classification divides gastric cancer into five types depending on macroscopic appearance. Type I represents polypoid or fungating cancers, type II encompasses ulcerating lesions surrounded by elevated borders, type III represents ulcerated lesions infiltrating the gastric wall, type IV are diffusely infiltrating tumors, and type V are unclassifiable cancers.<sup>74</sup> The gross morphologic appearance of gastric cancer and the degree of histologic differentiation are not independent prognostic variables.<sup>75,76</sup> Ming<sup>76</sup> has proposed a histomorphologic staging system that divides gastric cancer into either a prognostically favorable expansive type or a poor prognosis infiltrating type. Based on an analysis of 171 gastric cancers, the expansive-type tumors were uniformly polypoid or superficial on gross appearance, whereas the infiltrative tumors were almost always diffuse. Grossly ulcerated lesions were equally divided between the expanding or infiltrative forms. Broder's classification of gastric cancer grades tumors histologically from 1 (well differentiated) to 4 (anaplastic). Bearzi and Ranaldi<sup>77</sup> have correlated the degree of histologic differentiation with the gross appearance of 41 primary gastric cancers seen on endoscopy. Ninety percent of protruding or superficial cancers were well differentiated (Broder's grade 1), whereas almost one-half of all ulcerated tumors were poorly differentiated or diffusely infiltrating (Broder's grades 3 and 4).

The most widely used classification of gastric cancer is by Laurén.<sup>6</sup> It divides gastric cancers into either intestinal or diffuse forms. This classification scheme, based on tumor histology, effectively characterizes two varieties of gastric adenocarcinomas that manifest distinctively different pathology, epidemiology, and etiologies. The intestinal variety represents a differentiated cancer with a tendency to form glands. In contrast, the diffuse form exhibits very little cell cohesion and has a predilection for extensive submucosal spread and early metastases. Although the diffuse-type cancers are generally associated with a worse outcome than the intestinal type, this finding is not independent of tumor, node, metastasis (TNM) stage.

## PATTERNS OF SPREAD

Carcinomas of the stomach can spread by local extension to involve adjacent structures and can develop lymphatic metastases, peritoneal metastases, and distant metastases. These extensions can occur by the local invasive properties of the tumor, lymphatic spread, or hematogenous dissemination. The initial growth of the tumor occurs by penetration into the gastric wall, extension through the wall, and involvement of an increasing percentage of the stomach. The two modes of local extension that can have a major therapeutic impact are tumor penetration through the gastric serosa, where the risk of tumor invasion of adjacent structures or peritoneal spread is increased, and involvement of lymphatics. Zininger<sup>78</sup> has evaluated the spread in the gastric wall and has found a wide variation in its extent. Tumor spread is often through the intramural lymphatics or in the subserosal layers. Local extension can also occur into the esophagus or the duodenum. Duodenal extension is principally through the muscular layer by direct infiltration and through the subserosal lymphatics, but is not generally of great extent. Extension into the esophagus occurs primarily through the submucosal lymphatics.

Local extension does not occur solely by radial intramural spread but also by deep invasion through the wall to involve adjacent structures. Extension can occur through the gastric serosa to involve omentum, spleen, adrenal gland, diaphragm, liver, pancreas, or colon. Data from several large older series indicated that 60% to 90% of patients had primary tumors penetrating the serosa or invading adjacent organs and that at least 50% had lymphatic metastases.<sup>79,80</sup> Of the 1577 primary gastric cancer cases admitted to Memorial Sloan-Kettering Cancer Center between July 1, 1985, and June 30, 1998, 60% of the 1221 resected cases had evidence of serosal penetration, and 68% had positive nodes. Lymph node metastases were found in 18% of pT1 lesions after R0 resection in 941 patients. This rate increased significantly to 60% in pT2 lesions. The highest incidence of lymphatic metastasis was seen in tumors diffusely involving the entire stomach. Tumors located at the gastroesophageal junction also had a high incidence relative to other sites. The pattern of nodal metastases also varies depending on the location of the primary site (Table 33.3-2), with the left gastric artery nodes being consistently at increased risk for nodal metastases regardless of tumor location.

	Upper Third (%)	Middle Third (%)	Lower Third (%)
Paraesophagus	22	9	4
Lesser or greater curvature	25	36	37

**TABLE 33.3-2.** Pattern of Nodal Metastases from Gastric Cancer

Gastric cancer recurs in multiple sites, both locoregionally and systemically (Table 33.3-3). The literature reveals disagreements over failure patterns (Table 33.3-4); these disagreements are likely related to the patient cohorts accepted for evaluation, the time at which failure was determined, and the method of determination of failure patterns. In two older autopsy series, the rate of locoregional failure [defined as tumor in perigastric tissues (e.g., in the retroperitoneal “gastric bed,” perigastric lymph nodes, gastric remnant)] after potentially curative resection was 40% to 80%.<sup>81,82</sup> Many patients had multiple sites of local failure. Shiu and coworkers<sup>79</sup> found a 23% local recurrence rate in 169 patients treated for carcinoma of the body of the stomach.

**TABLE 33.3-4.** Failure Patterns in Gastric Cancer Patients

Gunderson and Sosin<sup>83</sup> reanalyzed the reoperation series performed by Wangenstein at the University of Minnesota, where patients had a second-look laparotomy after resection of the primary tumor. This type of analysis is valuable because it can demonstrate the early (and perhaps most treatable) modes of failure rather than simply showing diffuse metastatic disease at autopsy. Sixty-nine percent of patients had evidence of a locoregional recurrence, and 42% of patients had peritoneal seeding. Most of the local failures were located in the gastric bed (81%), although recurrences also occurred in the anastomosis or stump (39%) or in the regional lymph nodes (63%). A trial from the British Stomach Cancer Group found an incidence of local failure in patients treated with surgery alone to be 37 of 69 (54%).<sup>84</sup> A series evaluating local failure patterns reported by Landry and coworkers<sup>85</sup> showed a total locoregional failure rate of 38%, with most of the local recurrences in the gastric bed, the anastomosis, or the gastric stump. The incidence of local failure increased when the primary disease extended through the gastric wall or when lymph nodes were involved at the initial surgery. Liver metastases occurred in 30% of patients and peritoneal seeding in 23%. Extraabdominal failure was relatively rare and

occurred in 13% of patients.

Some newer series suggest a higher incidence of peritoneal seeding as a failure pattern. Wisbeck et al. <sup>82</sup> evaluated autopsy and clinical records of 85 patients who died of gastric cancer. Sixteen patients had a resection with curative intent; 15 of these developed a locoregional recurrence, eight developed peritoneal seeding, and seven developed lung metastases. Of the entire cohort, 40 of 85 (47%) developed peritoneal seeding. Ajani and colleagues <sup>86</sup> treated 25 patients with preoperative chemotherapy. At the time of surgery, eight had peritoneal carcinomatosis, and it developed subsequently in an additional five patients. Because imaging studies were not done routinely postoperatively, they could not accurately determine the risk of locoregional failure. These data suggest that increased attention to methods of controlling local and regional disease as well as systemic disease is needed to improve long-term results.

## CLINICAL PRESENTATION

### SIGNS AND SYMPTOMS

Most patients with gastric cancer are diagnosed with advanced-stage disease, and this is reflected in the vague, nonspecific symptoms that characterize the disease. Patients may have a combination of signs and symptoms, such as weight loss, anorexia, fatigue, or epigastric discomfort, none of which unequivocally indicates gastric cancer. The clinical significance of weight loss in gastric cancer should not be underestimated. Dewys and colleagues <sup>87</sup> has shown that, in 179 patients with advanced, nonmeasurable gastric cancer, more than 80% of patients had a greater than 10% decrease in body weight. Patients with weight loss had a significantly shorter survival than those without weight loss.

In some patients, symptoms may suggest the presence of a lesion in specific locations. A history of dysphagia may indicate the presence of a tumor in the cardia with extension through the gastroesophageal junction. A complaint of early satiety is actually a very infrequent symptom of gastric cancer, but is indicative of a diffusely infiltrative tumor that has resulted in loss of distensibility of the gastric wall. Persistent vomiting is consistent with an antral carcinoma obstructing the pylorus. Significant gastrointestinal bleeding is uncommon with gastric cancer; however, hematemesis does occur in approximately 10% to 15% of patients. However, many patients are diagnosed after the development of ascites, jaundice, or a palpable mass, indicating extensive and incurable disease.

Because the transverse colon is held in close proximity to the stomach by the gastrocolic ligament, it is a potential site of malignant fistula and large bowel obstruction from a gastric primary. Diffuse peritoneal spread of disease frequently produces other sites of intestinal obstruction. A large ovarian mass (Krukenberg's tumor) or a large peritoneal implant in the pelvis (Blumer's shelf), which can produce symptoms of rectal obstruction, may be felt on pelvic or rectal examination. Nodular metastases in the subcutaneous tissue around the umbilicus or in peripheral lymph nodes represent areas in which tissue diagnosis can be established with minimal morbidity.

### SCREENING

Mass screening programs for gastric cancer have been most successful in high-risk areas, especially in Japan. <sup>88</sup> A variety of screening tests have been studied in Japanese patients, with a sensitivity and specificity of approximately 90%. <sup>89</sup> They frequently include the use of double-contrast barium radiographs or upper endoscopy. <sup>88</sup> The yield in screened populations has been substantial; in some Japanese studies, up to 40% of newly diagnosed patients have early gastric cancer, and up to 60% of patients actively participating in routine mass screening programs have the disease. <sup>88</sup> This is clinically important because, as discussed below in [Pathologic Staging and Prognosis](#), early gastric cancer has a very high cure rate when treated surgically. However, the fact that gastric cancer remains the number one cause of death in Japan may reflect the limitations of a mass screening program when the entire population at risk is not effectively screened. Newer studies have verified that a low serum pepsinogen I/II ratio can be used to better select patients at increased risk for atrophic gastritis and gastric cancer. <sup>90</sup>

## PRETREATMENT STAGING

### TUMOR MARKERS

Carcinoembryonic antigen (CEA) is elevated in approximately one-third of primary gastric cancer patients. <sup>91</sup> The sensitivity of CEA is low, but when elevated, the level does generally correlate with stage. Combining CEA with other markers, such as the sialylated Lewis antigens CA19-9 or CA50, can increase the sensitivity over CEA alone. <sup>92,93 and 94</sup> A large study evaluated the prognostic significance of serum levels of CEA (n = 237), a-fetoprotein (n = 164), human chorionic gonadotropin-b (b-HCG) (n = 165), CA19-9 (n = 64), and CA125 (n = 104), as well as tissue staining for C-erb B-2 (n = 160) and b-HCG (n = 160). In a multivariate analysis, only serum b-HCG <sup>34</sup> IU/L (hazard ratio, 1.7; 95% CI, 2.8 to 1.1) and CA125 <sup>350</sup> U/mL (hazard ratio, 2.2; 95% CI, 4.2 to 1.2) had prognostic significance. Elevated serum b-HCG and CA125 in gastric cancer before chemotherapy may reflect not just tumor burden but aggressive biology, however, these findings must be compared to other known preoperative markers of stage, such as endoscopic ultrasonography (EUS) T and N stage. <sup>95</sup>

### ENDOSCOPY

Upper endoscopy is used routinely for the initial diagnosis and staging of gastric adenocarcinoma and should be performed in any patient with localized disease for which surgical treatment is anticipated. Numerous reports have demonstrated diagnostic accuracy of more than 95% for advanced disease. <sup>96,97</sup> The size, location, and morphology of the tumor, including the proximal and distal extent of spread, as well as other mucosal abnormalities, should be carefully evaluated. Decreased distensibility of the stomach, abnormal peristaltic activity, or abnormal pyloric function may indicate extensive submucosal infiltration or extramural extension of tumor into the vagi. The likelihood of a positive yield on biopsy is greater than 95% when six to ten tissue samples are obtained. <sup>96</sup> Detecting the faint mucosal irregularities usually associated with early gastritis-like carcinomas can be enhanced by endoscopic dye spraying with vital dyes, such as 0.1% indigocalmin. This technique has been used extensively in Japan with good success.

EUS has been used extensively to stage the depth of invasion and regional lymph node extent in potentially operable gastric cancer. EUS uses a high-frequency (7.5 or 12 MHz) transducer at the end of an endoscope and allows highly accurate staging of the depth of invasion of the primary tumor (T stage) and is more accurate than a computed tomographic (CT) scan for staging T and N status. <sup>95,98</sup> Although it appears more useful than a CT scan for detecting perigastric lymph node metastases, the overall accuracy of EUS for assessing all regional nodes is less satisfactory. Because CT may identify metastases to distant nodes and sites, such as the liver, ovaries, and peritoneum, CT and EUS are best used as complementary tests. EUS has become an invaluable tool to assess which early gastric cancers are candidates for endomucosal resection, a curative treatment in properly selected patients <sup>99,100</sup> (see [Treatment of Local Disease](#), below).

### COMPUTED TOMOGRAPHY

Once gastric cancer is suspected, a barium study or flexible upper endoscopy with biopsy is performed. After the diagnosis is established, staging procedures involve careful physical examination, routine blood screening tests, and abdominal and chest CT scanning. <sup>101</sup> Barium contrast studies have limited accuracy for determining resectability, but by using double-contrast techniques, a positive diagnosis of lesions between 5 and 10 mm can be made in 75% of patients. <sup>102</sup> CT of the chest, abdomen, and pelvis is useful for assessing the lateral extension of the tumor and presence of systemic metastases. <sup>103</sup> However, up to 50% of patients have more extensive disease at laparotomy than was predicted by preoperative CT. <sup>104</sup> With newer triphasic spiral CT scanning methods, greater emphasis has been placed on identifying low-volume disease and predicting the T stage. Takao et al. <sup>105</sup> reported an accuracy for spiral CT of 82% for staging T status in advanced gastric cancer and 15% in early gastric cancer by obtaining images with the stomach filled with water. Few Western centers routinely apply these techniques, and without them the accuracy of T staging is generally poor.

### POSITRON EMISSION TOMOGRAPHY

Whole body [<sup>18</sup>F]fluorodeoxyglucose (FDG) positron emission tomography (PET) is being applied increasingly in the evaluation of gastrointestinal malignancies. The positron-emitting <sup>18</sup>F-labeled analogue of 2-deoxyglucose, 2-[<sup>18</sup>F]-fluoro-2-deoxyglucose is readily transported into cells by either type I or II hexose transporters. Once in the cell, the analogue is phosphorylated into FDG-6-phosphate, which in most tumor tissues is not metabolized further. The preferential accumulation of positron-emitting FDG by tumor cells has been used successfully to image human tumors. Several studies have documented improved efficacy of detecting recurrent colorectal and hepatic (primary and metastatic) tumor sites, with a sensitivity ranging from 92% to 100% and an accuracy of 90% to 96%. <sup>106</sup> Results from a study in esophageal cancer demonstrated that PET could detect 20% of metastases missed by CT. <sup>107</sup> Little information regarding the use of FDG-PET in the management of

gastric cancer is available. In a pilot study begun here at Memorial Sloan-Kettering Cancer Center, we set out to assess the feasibility of FDG-PET imaging in gastric cancer patients. Fifteen patients were performed on 14 gastric cancer patients with various stages of disease. One hundred forty-five lesions were imaged with concurrent histologic confirmation. The preliminary results show FDG-PET to have a sensitivity of 60%, specificity of 100%, and an overall accuracy of 94% in identifying gastric cancer. The most consistent finding has been uptake in the primary tumor, indicating a possible role in treatment response assessment as well as for staging.

## LAPAROSCOPY

The introduction of fiberoptic, video-assisted laparoscopy in the early 1980s added a means of direct and immediate assessment of the abdominal cavity without the morbidity of a laparotomy. Comparative studies of CT and laparoscopy have consistently shown laparoscopy to provide additional information that was not seen by preoperative CT imaging. In a study of 103 consecutively staged gastric cancer patients, laparoscopy had an accuracy of 94% when compared to what was found at laparotomy. Disease missed by CT was mostly peritoneal metastases. The rate of detecting occult M1 disease by this method ranges from 13% to 37%.<sup>108,109,110,111,112</sup> and<sup>113</sup> Patients without clinically significant bleeding or obstruction that are found to have occult metastatic disease are incurable and may benefit from participation in new treatment protocols. Use of induction chemotherapy and selective resection of responding patients is an attractive alternative to immediate resection. Contrary to previously held dogma, most stage IV patients rarely develop significant symptoms from the primary tumor before death. None of the 24 patients with metastatic disease discovered at laparoscopy who were followed until death required subsequent laparotomy for complications of the primary tumor.<sup>109</sup> Because CT may identify metastases to distant sites (liver, adrenal glands, and ovaries), thus avoiding an operation, CT, EUS, and laparoscopy are all considered complementary tests.

The development of laparoscopic ultrasonographic probes has added a third dimension to the laparoscopic examination.<sup>114</sup> Laparoscopy with laparoscopic ultrasonography, although more invasive than EUS, is superior in identifying unsuspected metastases to liver and lymph nodes. Considering the low morbidity and significantly shorter hospital stay,<sup>109,112</sup> laparoscopy, whenever feasible, should eliminate the need for patients undergoing laparotomy without resection.

## PATHOLOGIC STAGING AND PROGNOSIS

As with other neoplasms, the uniform and accurate staging of gastric cancer is essential to meaningfully predict prognosis and assess response to treatment. The R classification indicates the amount of residual disease left after tumor resection.<sup>115</sup> *RC* indicates no gross or microscopic residual disease; *R1* indicates microscopic residual disease, and *R2* signifies gross residual disease. This is an obvious but most important prognostic factor, but it was not always indicated in the past, making interpretation of survival results difficult.

The International Union Against Cancer (UICC) and American Joint Committee on Cancer (AJCC) TNM classification for stomach cancer is shown in [Table 33.3-5](#). The depth of tumor invasion ([Fig. 33.3-2](#)) determines T stage. The relationship between T stage and survival is well defined ([Fig. 33.3-3](#)). The General Rules for Gastric Cancer Study in Surgery and Pathology was published in English in 1995 by the Japanese Research Society for Gastric Cancer.<sup>74</sup> The definition of the primary tumor stage based on the depth of invasion and the presence and extent of serosal invasion is shown in [Table 33.3-6](#). T stage is further divided into mucosa (m), submucosa (sm), and muscularis propria (pm). The subserosa (ss) and S1 tumors have been reclassified to further stratify the degree and type of serosal invasion. INFa is a subserosal tumor with expansive growth, INFb is a subserosal tumor with intermediate-type growth, and INFg is a subserosal tumor with infiltrating growth. S2 and S3 are now defined as either se (cancer cells exposed to the peritoneal cavity), si (cancer cells infiltrating neighboring tissue), or sei (the coexistence of se and si).<sup>74</sup> Survival results based on T stage are fairly consistent among Japan, Europe, and the United States<sup>116,117,118,119,120</sup> and<sup>121</sup> (see [Table 33.3-6](#)).

**TABLE 33.3-6.** Survival after Curative Resection for Gastric Cancer with Respect to Depth of Invasion

The AJCC/UICC N stage was changed in 1997 to reflect the number of involved lymph nodes. Tumors with one to six involved nodes are classified as pN1; 7 to 15 involved nodes are pN2, and more than 15 involved nodes is N3. Survival decreases dramatically as the number of metastatic lymph nodes increase. The N stage survival rate based on the number of nodes involved is shown in [Figure 33.3-4](#) for 941 R0 gastric cancer patients treated at Memorial Sloan-Kettering Cancer Center. The previous classification was based on the localization of lymph node metastases. An analysis of 477 R0 resected node-positive cases from the German Gastric Cancer Study compared survival using both staging systems. This new 1997 AJCC further separated the survival of patients categorized by the old N definition ([Fig. 33.3-5](#)). Survival was significantly changed in the old N2 group by applying the new N stage classification.<sup>122</sup> Differences between the two staging systems were not as great for N1 patients. Within the groups with one to six, 7 to 15, and more than 15 involved nodes, the location of metastatic lymph nodes did not significantly alter the prognosis. The new classification can now be applied in surgical trials with fewer methodologic problems, and it seems more reproducible provided that a minimum of at least 15 lymph nodes are examined. Several studies have assessed quantitative involvement of lymph nodes and survival after resection for gastric cancer and found that survival with up to three to four metastatic lymph nodes is better than with more extensive lymph node involvement.<sup>121,123</sup> Once nodal metastases are found, Japanese survival statistics are better than those seen in Western patients<sup>123</sup> ([Table 33.3-7](#)). Possible explanations for this observation include a potential difference in the biology of the tumor between the two patient populations or that the Japanese are removing and analyzing more lymph nodes, resulting in stage migration. The new AJCC/UICC requirement that a minimum of 15 nodes be removed and analyzed may minimize these differences.

**TABLE 33.3-7.** Survival after Resection for Gastric Cancer with Respect to Lymph Node Status

Under the current staging system, the presence of more than 15 perigastric lymph node metastases is classified as N3 disease, which is staged as M1. The Japanese staging system extensively classifies 18 lymph node regions into four N categories depending on their relationship to the primary tumor as well as anatomic location. The careful and complete prosection of the operative specimen may often be performed by the attending surgeon or designated surgical resident. Involvement with N1 and N2 lymph node groups represent regional disease, which is encompassed by the D2 lymphadenectomy, whereas N3 and N4 lymph nodes are considered distant metastases. In addition, the presence and extent of intraabdominal metastases to the peritoneum and liver are categorized ([Table 33.3-8](#)).

N0	No serosal invasion
N1	Suspected serosal invasion
N2	Definite serosal invasion
N3	Adjacent organ involvement
N1	Perigastric lymph nodes
N2	Lymph nodes around the left gastric artery, common hepatic artery, splenic artery, and celiac axis
N3	Lymph nodes in the hepatoduodenal ligament, posterior aspect of pancreas, and root of mesentery
N4	Paraortic and middle colic lymph nodes
P0	No peritoneal metastases
P1	Adjacent peritoneal involvement
P2	A few scattered metastases to distant peritoneum
P3	Many distant peritoneal metastases
H0	No liver metastases
H1	Metastases limited to one lobe
H2	A few bilateral metastases
H3	Numerous bilateral metastases

III	N2, N3-4, P0, H0
IV	N3, N4-5, P1-3, H1-3

**TABLE 33.3-8.** Japanese Surgical Staging System for Gastric Cancer

Stage for stage, considerable disparity exists between the survival of patients with stomach cancer in Japanese and Western series. Wanebo and coworkers <sup>124</sup> have reported on the results of a tumor registry survey in 1982 and 1987 of 18,365 U.S. patients. In the entire cohort, 18% of patients were stage I, 16% stage II, 36% stage III, and 30% stage IV. Although early diagnosis, a higher incidence of intestinal-type tumors, and the use of radical surgery in Japan may explain these differences, in part, a major contributing factor may be the extensive and meticulous surgical and pathologic staging of gastric cancer in Japan. Several reports from the United States, Japan, and Europe have demonstrated similar survival results by applying more similar surgical and pathologic staging techniques. <sup>125,126</sup> and <sup>127</sup> The 1997 AJCC TNM survival curves are shown in [Figure 33.3-6](#) for R0-resected patients.

**FIGURE 33.3-6.** Kaplan-Meier curves of disease-specific survival according to the 1997 American Joint Committee on Cancer system. Stage 0 (n = 16) A; IA (n = 139) B; IB (n = 133) C; II (n = 206) D; IIIA (n = 239) E; IIIB (n = 130) F; IV (n = 81) G. (From the Memorial Sloan-Kettering Cancer Center Department of Surgery Prospective Gastric Cancer Database.)

Although not a formal component of stage grouping, the histopathologic grade and type and, when available, the peritoneal lavage cytology status should be recorded. The presence of free peritoneal cancer cells has been shown by a number of investigators to be an M1 equivalent. <sup>128,129,130</sup> and <sup>131</sup> Burke et al. <sup>132</sup> found no survivors beyond 18 months among stage III patients with positive peritoneal lavage.

## TREATMENT OF LOCALIZED DISEASE

### ENDOSCOPIC MUCOSAL RESECTION

It has been shown that a subset of early gastric cancers can undergo an R0 resection without lymphadenectomy or gastrectomy. The Japanese have popularized endoscopic mucosal resection of early gastric cancers that meet specific criteria. This approach involves the submucosal injection of fluid to elevate the lesion to facilitate complete mucosal resection. The technique is suitable for lesions that have a low metastatic potential. <sup>133</sup> These include well-differentiated, superficial type IIa or IIc lesions that are generally smaller than 3 cm in diameter and located in an easily manipulated area. Tumors invading the submucosa are at increased risk for metastasizing to lymph nodes and are not appropriate for endoscopic resection. Takekoshi et al. <sup>134</sup> reported a series of 308 endoscopic resections for early cancer. Forty-four patients had residual or recurrent lesions after endoscopic mucosal resection. All recurrences were resected, and no patients died of gastric cancer. In experienced hands, endoscopic mucosal resection is a suitable alternative to gastrectomy for favorable early gastric cancer.

### SURGERY

The only potentially curative treatment for localized gastric cancer is complete surgical resection. The principles that guide operative management are based on the Halstedian belief that gastric cancer progresses from mucosa to submucosa where it then invades into lymphatics. From there, lymph node involvement occurs but before the disease reaches the systemic circulation. Clearly this is an oversimplified view of tumor progression; however, support for this theory comes from the strong correlation between depth of invasion and the extent and number of lymph node metastases. Others have argued that epithelial cancers can metastasize directly into the systemic circulation, thus bypassing lymph nodes. <sup>20</sup> Molecular factors, which govern invasion and metastases, differ from one tumor to the next, such that even some early gastric cancers do recur and are fatal after curative surgery. <sup>135</sup> In general, the success of an R0 resection is directly dependent on stage as determined by the TNM system. It is well accepted that surgery carries a high cure rate for stage IA and IB cancers and much poorer results for stages IIIA and IIIB. Disagreement exists among surgeons with respect to the appropriate extent of resection, because improved outcome has not been conclusively linked with more radical surgery. Current areas of discussion include the potential therapeutic benefit from extended lymphadenectomy, the routine use of total versus subtotal gastrectomy for tumors of the body or antrum, and prophylactic splenectomy.

#### Extended Lymphadenectomy

The Japanese Research Society for Gastric Cancer proposed a standardized D2 resection for patients undergoing curative gastrectomy. As radical surgery for gastric cancer has become uniformly accepted in Japan, the operative mortality rate for D2 resection has declined and 5-year survival after curative resection has improved. Many large retrospective reports from Japan, other Asian countries, and specialty centers in the West advocate a D2 lymphadenectomy for patients with resectable gastric cancer. <sup>136</sup> Maruyama and colleagues <sup>117</sup> have reported results from more than 20,000 cases from a nationwide registry in Japan for three periods: 1963 to 1966, 1969 to 1973, and 1971 to 1985. The 30-day operative mortality rate declined from 3.8% in the first period to 1.0% in the latest. When patients were compared with respect to stage, depth of tumor invasion, presence of serosal invasion, and N1 or N2 nodal metastases, improved survival was noted in the most recent period compared to the first. However, radical (D2) resection did not improve survival for patients with extranodal disease, such as peritoneal metastases, distant lymph node metastases (N3-4), or diffusely infiltrating carcinomas (linitis plastica). Takeda and coworkers <sup>137</sup> also have reported that 5-year survival improved from 21% to 46% in 166 patients undergoing total gastrectomy with curative intent for tumors with positive serosal invasion when a D2 lymphadenectomy was performed compared with 62 patients in whom no systematic lymphadenectomy was performed. Kodama and colleagues <sup>138</sup> have compared survival in 254 patients undergoing simple resection with 454 patients undergoing extensive regional lymph node dissection (ELD) for gastric carcinoma. The therapeutic effect of ELD was greatest in patients with serosal invasion (T3) or with positive lymph node metastases; patients with T1, T2, T4, or N0 disease did not show a benefit from ELD. In all of these studies, outcomes of patients operated on in different periods were compared, and it is possible that other factors could have influenced survival. In a series of 486 patients who underwent curative (D2) resection for gastric cancer, Sowa and coworkers <sup>139</sup> demonstrated that tumor size and depth of penetration were directly related to the incidence of lymph node metastases in gastric cancer and that the rate of skip metastases was less than 1%. In this study, as well as in others, <sup>140</sup> T1-2 lesions had metastases limited to perigastric lymph nodes in 15% to 40% of patients, suggesting that, in cases of less-advanced cancers, a systematic lymphadenectomy may be

needed to clear all nodal disease.

Reports have also come from the United States and Europe that are mostly retrospective series advocating D2 lymphadenectomy for gastric cancer. <sup>141</sup> Keller and colleagues,<sup>142</sup> reporting for the German Stomach Cancer TNM Study Group, recommended systematic lymphadenectomy for resectable gastric cancer because occult lymph node metastases were pathologically identified two to three times more frequently than when no systematic lymphadenectomy was performed. Roder et al. <sup>143</sup> reported the results of the German Gastric Carcinoma Study, in which the treatment of 1999 patients was prospectively recorded and assessed in a systematic, uniform manner. They demonstrated a survival advantage after D2 lymphadenectomy for stage II and IIIA tumors. The issue of stage migration was dismissed on the basis that both the standard and extended lymph node dissection groups had far more than the recommended 15 lymph nodes examined. In a retrospective analysis of 210 patients, Shiu et al. <sup>121</sup> found that, if their lymphadenectomy encompassed one echelon of pathologically uninvolved nodes beyond the level of nodal metastases, survival was significantly improved over those with a less extensive lymphadenectomy (60% vs. 25%, respectively). Irvin and Bridger <sup>144</sup> have reported a similar 60% 5-year survival rate in 22 patients undergoing curative D1 resection, but all 22 had pathologically negative nodes (T1–3,N0).

Because of the technical difficulty of an extended lymphadenectomy, some authors have addressed the possibility of using selective lymph node dissection in gastric cancer with macroscopically suspicious nodes. In one series, however, the mean size of metastatic lymph nodes in 370 patients undergoing D2 gastrectomy was 7 mm,<sup>145</sup> and others have reported that surgeons could correctly diagnose metastatic involvement by intraoperative macroscopic examination in only 20% of patients.<sup>142,145</sup> Noguchi and colleagues<sup>146</sup> have reported that, although a direct correlation exists between lymph node size and the frequency of metastases, 30% of all metastases to lymph nodes occur in nodes smaller than 3 mm in size. Therefore, it is unlikely that selective lymphadenectomy based on gross appearance of lymph nodes is feasible or appropriate.

The need for and extent of lymphadenectomy necessary for patients with early gastric cancer, defined as primary tumors limited to the mucosa or submucosa, is controversial.<sup>147,148,149,150</sup> and <sup>151</sup> Risk factors for lymph node metastases have been identified for intramucosal tumors <sup>133,152</sup> in early gastric cancer. Some have advocated selective lymphadenectomy, particularly when other favorable factors exist, such as a primary tumor of small size (less than 1.5 cm), protruded-type tumor (Borrmann type I), and tumors confined to the mucosa.<sup>145</sup> Hochwald et al. <sup>152</sup> analyzed 165 early gastric cancers for clinical and pathologic factors associated with a low incidence of lymph node metastases. Tumor size [relative risk (RR), 4.8; 95% CI, 4.0 to 5.5], depth of invasion (RR, 3.4; 95% CI, 2.9 to 4.0), and the presence of venous invasion (RR, 3.3; 95% CI, 2.8 to 3.8) were all independently associated with having positive nodes. However, of the 47 tumors smaller than 4.5 cm in size and limited to the mucosa only, 4% had lymph node metastases. Kurihara et al. <sup>153</sup> found that when submucosal carcinomas were classified into three categories according to depth of invasion by dividing the submucosal (sm) layer into three equal parts—sm1, sm2, and sm3—the incidence of lymph node metastasis increased from 2% to 12% and 20%, respectively. With the availability of EUS and mucosal strip biopsy techniques such as endoscopic mucosal resection, informed decisions can be made regarding the risk of lymph node metastases and need for lymphadenectomy. The approach to early gastric cancer is evolving into one of selective management. The favorable long-term results of endoscopic mucosal resection suggest that lymphadenectomy is not needed in properly selected cases. <sup>134</sup>

For advanced cancers, considerable debate continues as to whether the routine use of an extensive *en bloc* resection of second-echelon lymph nodes (D2 resection) is superior to a more limited lymphadenectomy of the perigastric lymph nodes (D1 resection). Four prospective randomized trials have now been completed on this subject. Dent et al. <sup>154</sup> reported the first prospective randomized trial of D1 versus D2 gastrectomy from Cape Town, South Africa ( [Table 33.3-9](#)). At surgery, only 43 patients of 403 explored were randomized to receive either D2 or D1 gastrectomy. They found no difference in 5-year survival rates. <sup>155</sup> Patients undergoing D2 resection had a significantly longer operating time, greater transfusion requirement, and longer hospital stay. A second single-institution, prospective, randomized trial comparing D1 subtotal gastrectomy to D3 total gastrectomy (omentectomy, splenectomy, distal pancreatectomy, lymphadenectomy of celiac axis, and porta hepatis) in 55 patients with antral cancer was reported from Hong Kong. <sup>156</sup> The length of hospitalization and morbidity was significantly increased in the D3 group. Median survival was significantly shorter than for D1 resection patients. In Japan and in specialty centers in the West, however, where extended D2 resection is performed routinely, operative mortality is minimal and does not appear to be related to the extent of lymphadenectomy. <sup>117,157,158</sup> Given the small sample sizes, these trials lacked the statistical power needed for meaningful interpretation of survival results.

**TABLE 33.3-9.** Prospective Randomized Trial Comparing D1 versus D2–3 Resection for Potentially Curable Gastric Carcinoma

In 1989, two major randomized trials were conducted to further address the D2 controversy. In the United Kingdom, the Medical Research Council (MRC) conducted a trial that accrued 737 patients, with 400 patients randomized into two equal arms at the time of laparotomy. Postoperative morbidity was significantly greater in the D2 group (46% vs. 28%;  $P < .001$ ). Hospital mortality was an alarming 13% for the D2 group and 6% for D1 ( $P < .04$ ; 95% CI for D2, 4% to 11%).<sup>159</sup> The excess morbidity and mortality seen in the D2 group was associated with the routine use of distal pancreatectomy and splenectomy, which proponents of the D2 lymphadenectomy would point out is not required for adequate lymph node clearance. In a follow-up publication, Cuschieri et al. <sup>160</sup> reported that the 5-year survival rates were 35% for D1 resection and 33% for D2 resection (difference, -2%; 95% CI, -12% to 8%). Both overall and recurrence-free survival were the same. The authors concluded that their findings indicated that the classic Japanese D2 lymphadenectomy offered no survival advantage over the D1. The question of whether D2 resection without pancreaticosplenectomy is better than standard D1 resection could not be dismissed by the results of this trial.

The Dutch Gastric Cancer Group conducted a subsequent larger and rigorously monitored trial. In this study, 996 patients were entered and 711 were randomized (380 in the D1 group and 331 in the D2 group). In an effort to assure quality control, all operations were monitored. Initially, this oversight was done by a Japanese surgeon who trained a group of Dutch surgeons who, in turn, acted as supervisors during surgery at any one of the 80 participating centers. A number of observations were made from this trial. Despite the extraordinary efforts made to ensure quality control of the two types of lymph node dissection, both noncompliance (not removing all lymph node stations) and contamination (removing more than was indicated) occurred, thus blurring the distinction between the two operations. <sup>161</sup> The postoperative morbidity was again higher in the D2 group (43% vs. 25%,  $P < .001$ ). The mortality rate also was significantly higher in the D2 group (10% vs. 4%,  $P = .004$ ), and these patients required a longer hospitalization. <sup>162</sup> Pancreaticosplenectomy also was performed *en passant* in the D2 group as part of the classic operation.

In summary, the D2 operation is a systematic approach toward the removal of high-risk perigastric lymph nodes. Most retrospective single-center reports indicate that the routine use of extended lymphadenectomy for potentially curable gastric cancer can be performed safely. Four published prospective randomized trials have not shown a survival advantage for the D2 lymph node dissection and do not support the routine use of extended D2 gastrectomy. A modified D2 operation avoiding pancreaticosplenectomy will provide superior staging information and may avoid the added morbidity and mortality associated with the additional organ resection. The advanced stage of disease at surgery in most patients remains the key determinant of survival. If there is a survival benefit from the D2 lymphadenectomy, it is limited to those with few lymph node metastases.

### Total versus Subtotal Gastrectomy

Ideally, the extent of gastric resection should provide the optimal cancer procedure with the minimal attendant morbidity. The rationale for the routine use of total gastrectomy is presumably based on the appreciation that extensive intramural extension of tumor may be present and that simultaneous multiple gastric cancers have been reported.<sup>163</sup> Although older retrospective data do suggest that survival is improved with total gastrectomy compared with subtotal gastrectomy, <sup>81</sup> current evidence does not support this finding. <sup>164</sup> Three prospective randomized trials have addressed this question for the treatment of distal gastric cancers. <sup>156,164,165</sup> A French cooperative prospectively randomized trial of total gastrectomy versus subtotal gastrectomy has reported data on postoperative morbidity, mortality, and

5-year survival. One hundred sixty-nine patients with adenocarcinoma of the antrum who were operated on with curative intent were included for analysis.<sup>164</sup> The groups were well matched for the usual prognostic variables. The overall complication rate and postoperative mortality rate was 32% and 1.3% for total gastrectomy and 34% and 3.2% for subtotal gastrectomy, respectively. No difference was found in cumulative 5-year survival between groups. The second single institution prospective randomized trial, as reported above in the [Extended Lymphadenectomy](#) section, compared subtotal gastrectomy and D1 lymphadenectomy with total gastrectomy and D3 lymphadenectomy in 55 patients with antral cancers from Hong Kong.<sup>156</sup> No survival advantage was found after the more extensive resection. Bozzetti et al.<sup>166</sup> reported the 5-year survival rates from a multicenter randomized Italian trial conducted by the Italian Gastrointestinal Tumor Study Group. The median follow-up was 72 months after subtotal gastrectomy (range, 2 to 125 months) and 75 months after total gastrectomy (range, 7 to 113 months). The 5-year survival rate was 65.3% after subtotal gastrectomy and 62.4% after total gastrectomy for gastric cancer. The data support the use of subtotal gastrectomy for the treatment of advanced distal tumors, provided a 5-cm gross negative margin can be achieved.

Other series have reported an operative mortality after total gastrectomy, ranging from 4% to 18%, and that anastomotic leak is responsible for up to 50% of these operative deaths.<sup>167,168</sup> and <sup>169</sup> Others have argued that the functional results after total gastrectomy may be slightly worse than with distal subtotal gastrectomy.<sup>170,171</sup> and <sup>172</sup> Moreover, the ability to completely dissect paracardial lymph nodes is not related to the extent of gastric resection.<sup>173</sup> Therefore, although routinely used by many, total gastrectomy should not be considered the initial option in patients in whom a 5-cm gross proximal margin can be obtained with a subtotal resection.

Carcinomas arising in the proximal one-third of the stomach have a worse prognosis than distal gastric lesions.<sup>24,25,121</sup> Total gastrectomy has traditionally been the procedure of choice for proximal tumors. Review of the prospective gastric database at Memorial Sloan-Kettering Cancer Center from July 1985 to August 1995 identified 391 patients with proximal gastric cancers. Ninety-eight of these patients underwent either a total or proximal gastrectomy exclusively through an abdominal approach. Patients undergoing esophagogastrectomy were excluded. Patients were matched for clinical and pathologic factors. The length of hospital stay was the same for patients undergoing resection for proximal gastrectomy (16.5 days; range, 8 to 55 days) and for total gastrectomy (18 days; range, 8 to 48). Postoperative mortality for proximal gastrectomy (6.0%) and total gastrectomy (3.0%) were not significantly different. The overall 5-year survival rate for proximal gastric cancer was 43% and was 41% for total gastrectomy. Total and proximal gastrectomy have similar time to first recurrence, and the pattern of recurrence was the same. As was found for distal tumors, the extent of resection for proximal gastric cancer does not affect long-term outcome.

The functional sequelae and postoperative mortality of proximal gastric resection are considered to be worse than for total gastrectomy. In a series of 89 patients reported by Buhl and associates<sup>174</sup> who were treated with total gastrectomy, distal gastric resection, or proximal gastric resection, the latter group had a higher incidence of dumping, heartburn, and reduced appetite. In addition, quality of life and capacity to work were reduced in patients with proximal gastric resection. The Norwegian Stomach Cancer Trial has prospectively studied the incidence of postoperative complications and mortality in more than 1000 consecutive patients undergoing surgery for gastric cancer.<sup>175</sup> The postoperative mortality rate in more than 760 patients undergoing resection was 8.3% and was highest in patients undergoing proximal resection (16%) compared with total gastrectomy (8%), subtotal gastrectomy (10%), or distal resection (7%). Factors significantly related to the incidence of postoperative complications included advancing age, male gender, no antibiotic prophylaxis, and splenectomy. Similar to the postoperative mortality, the complication rate was highest for proximal resections (52%), followed by total gastrectomy (38%), subtotal resection (28%), and distal resection (19%). Therefore, for proximal lesions, it appears that total gastrectomy using a variety of reconstructive options may provide better functional results, but this observation has not been tested in a prospective randomized fashion.<sup>175a</sup> There appear to be fewer complications and a lower operative mortality after total gastrectomy for the treatment of proximal gastric cancers.

### Prophylactic Splenectomy

Several authors have critically evaluated the value of routine splenectomy during gastric resection for tumors not adjacent to or invading the spleen.<sup>175,176,177,178,179</sup> and <sup>180</sup> In a multivariate analysis of more than 250 patients who underwent total gastrectomy with curative intent, no correlation was found between splenectomy and survival.<sup>177</sup> The Norwegian Stomach Cancer Trial has demonstrated a higher complication rate with the use of splenectomy in their prospective trial (42% vs. 27%).<sup>175</sup> In Sasako's analysis of potential risk factors in patients from the Dutch multicenter randomized study of D1 versus D2 lymphadenectomy, splenectomy was the most important risk factor for developing a complication (RR, 2.13; 95% CI, 1.44 to 3.16).<sup>175b</sup> The consensus from the literature is that prophylactic splenectomy increases morbidity and mortality without an apparent survival benefit.<sup>177,179,180,181</sup> and <sup>182</sup>

## TECHNIQUE OF OPERATION

Beginning with laparoscopy allows for careful intraoperative staging of disease. Inspection for the presence of ascites; hepatic metastases; peritoneal seeding; disease in the pelvis, such as a "drop" metastasis; or ovarian involvement should be performed. Once distant metastases have been ruled out depending on the location of the lesion, a bilateral subcostal incision or a midline abdominal incision can be used to gain adequate exposure to the upper abdomen. The stomach should be inspected to assess the location and extent of tumor. The size and location of the primary tumor dictates the extent of gastric resection. A D2 lymphadenectomy sparing the spleen and pancreas can be done safely and provides an excellent specimen for surgical and pathologic staging, but this procedure should only be performed by or with an experienced surgeon.

The D2 subtotal gastrectomy commences with mobilization of the greater omentum from the transverse colon. After the omentum is mobilized, the anterior peritoneal leaf of the transverse mesocolon is incised along the lower border of the colon, and a plane is developed down to the head of the pancreas. The infrapyloric lymph nodes are dissected, and the origin of the right gastroepiploic artery and vein are ligated. With a combination of blunt and sharp dissection, the plane of dissection continues on to the anterior surface of the pancreas, extending to the level of the common hepatic and splenic arteries. This maneuver can be tedious, but theoretically it provides additional protection against serosal spread of tumor to the local peritoneal surface.

The right gastric artery is ligated. At this point, the duodenum is divided distal to the pylorus. The stomach and omentum are then reflected cephalad. The gastrohepatic ligament is divided close to the liver up to the gastroesophageal junction. Dissection is then continued on the hepatic artery toward the celiac axis. Once near the celiac axis, the lymph node-bearing tissue is dissected until the left gastric artery is visualized and can be divided at its origin. The proximal peritoneal attachments of the stomach and distal esophagus can then be incised, and the proximal extent of resection is chosen.

For tumors of the mid- and proximal stomach, dissection of the lymph nodes along the splenic artery and splenic hilum is important. This technique is not indicated for antral tumors, given the low rate of splenic hilar nodal metastases seen with these tumors. The stomach is then divided 5 cm proximal to the tumor, which dictates the extent of gastric resection. Despite the fact that the entire blood supply of the stomach has been interrupted, a cuff of proximal stomach invariably shows good vascularization from the feeding distal esophageal arcade. When feasible, most surgeons prefer to anastomose jejunum to stomach versus esophagus because of the technical ease and excellent healing. Reconstruction using a variety of techniques has been described and is a matter of personal choice ([Fig. 33.3-7](#)).

**FIGURE 33.3-7.** Variations in types of reconstruction after total or subtotal gastrectomy include (left to right) the Roux-en-Y, Braun, and Lawrence techniques.

## ADJUVANT THERAPY

## RATIONALE FOR ADJUVANT THERAPY

As already mentioned, the prognosis for patients with gastric cancer is, to a large extent, dependent on the stage of the disease at the time of diagnosis. Patients with early-stage gastric cancer (Tis; T1N0M0; or shallow penetrating T2N0M0) have a good to excellent prognosis, with cure rates exceeding 70% to 80% after operation alone. After curative surgery, however, patients with locally advanced cancers without nodal metastases (T3N0 gastric cancers) have an at least 50% chance of dying within 5 years; lymph node metastases have an even more ominous prognosis. Although 80% to 90% of American patients fall in the high-risk group, preoperative identification of patients at low risk for recurrence is difficult. Newer preoperative staging techniques, such as laparoscopy, have been demonstrated to be highly sensitive and specific in identifying patients with intraabdominal metastatic tumor, particularly in the peritoneal cavity. However, these techniques still have a relatively low sensitivity for separating deeply penetrating T2 from T3 tumors, as well as a low sensitivity for identifying metastatic lymphadenopathy. Therefore, for patients who have more than early-stage gastric cancer (deeply penetrating T2 or T3 tumors and patients with lymph node metastasis), the use of systemic therapy early in the treatment plan is rational in a disease in which a high propensity is seen for systemic failure with or without local recurrence. Neoadjuvant chemotherapy (also known as *preoperative* or *primary chemotherapy*) is an attractive concept in diseases such as gastric cancer for which complete resection of the primary tumor is often difficult or impossible, and because systemic dissemination at the time of diagnosis is common. A more traditional approach to adjuvant therapy is the use of postoperative treatment.

## POSTOPERATIVE TREATMENT

Table 33.3-10 summarizes the results of a number of prospective randomized trials of postoperative chemotherapy in gastric cancer. These studies date back to the 1960s. Two early trials from the Veterans Administration Surgical Oncology Group investigated the use of thiotepa or 5-fluorodeoxyuridine (FUDR) after surgical resection.<sup>183,184</sup> Both were negative.

TABLE 33.3-10. Intravenous Adjuvant Therapy for Gastric Cancer: Selected Phase III Trials

### Nitrosourea-Containing Regimens

Four studies have used a combination of 5-fluorouracil (5-FU) and the nitrosourea methyl chloroethylcyclohexyl nitrosourea (CCNU) as adjuvant therapy after gastric resection. It should be noted that, in advanced disease, 5-FU and methyl CCNU had only modest effectiveness, and this combination was an inferior arm in a randomized trial in patients with advanced disease (see Table 33.3-10). The Gastrointestinal Tumor Study Group randomly assigned patients to either no additional treatment or to 18 months (originally 2 years) of methyl CCNU and 5-FU.<sup>185</sup> At a final analysis, the survival curves reached statistical significance in favor of the chemotherapy arm. However, an identical study using 5-FU and methyl CCNU performed during the same period by the Eastern Cooperative Oncology Group using the same dose and schedule and including a group of 180 patients (89 controls, 91 treated) demonstrated no difference in disease-free or overall survival rate (median survival, 32.7 and 36.6 months; 2-year survival rate, 57% for both groups)<sup>186</sup> (see Table 33.3-10). A third study by the Veterans Administration Surgical Oncology Group using the same agents on a different schedule was also negative.<sup>187</sup>

Estrada and colleagues<sup>188</sup> studied the use of 12 to 18 months of methyl CCNU, 5-FU, and doxorubicin or observation in a small group of 66 evaluable patients after resection. At 5 years, no difference was noted in disease-free survival (29% treated vs. 34% observed) or overall survival (29% vs. 37%). Two treatment-related deaths were reported. Most current adjuvant or neoadjuvant studies do not include a nitrosourea.

### Mitomycin-Containing Regimens

A series of trials have involved the use of mitomycin (see Table 33.3-10). One Spanish trial investigated the use of high-dose mitomycin C alone after surgical resection. In this study, only 33 patients received chemotherapy; 37 patients were in a control group. A striking difference in survival was noted (seven relapses in the treatment arm, 23 in the control arm;  $P < .001$ ). The chemotherapy dose schedule was mitomycin C, 20 mg/m<sup>2</sup> once every 6 weeks for four doses. An update continues to show a significant survival advantage for the mitomycin-treated group.<sup>189</sup> However, this study has not been confirmed by other mitomycin-containing trials.

In a larger study,<sup>190</sup> evaluable patients were randomized after gastrectomy to receive (within 7 days of surgery) mitomycin C, 10 mg/m<sup>2</sup> monthly for six doses, plus oral uracil and ftorafur (UFT) or to expectant observation. With a median follow-up of 3.1 years, no difference was noted in disease-free or overall survival between treatment and control groups (median survival for patients receiving chemotherapy, 2.3 years; for observation, 2.6 years). This study does not confirm the role of mitomycin C in the adjuvant setting. However, although the total dose was similar (80 mg/m<sup>2</sup> vs. 60 mg/m<sup>2</sup>), the dose intensity was different.<sup>191</sup> Allum and coworkers<sup>192</sup> reported the results of a three-arm randomized trial comparing postoperative 5-FU and mitomycin C with or without cyclophosphamide, 5-FU, vincristine, and methotrexate induction compared with surgery only. The study allowed entrance up to 12 weeks after surgery. The surgery-only group received saline every 3 weeks; 140 patients received 5-FU and mitomycin C plus a 5-day induction course of cyclophosphamide, 5-FU, vincristine, and methotrexate; 141 patients received 5-FU and mitomycin C alone. Therapy was continued for 2 years. With a median follow-up of 100 months, the median survival was 15.5 months; no significant difference was noted between the treated or control groups.

Japanese studies involving mitomycin also have been reported. Nakajima et al.<sup>193</sup> treated a group of 243 patients who received either mitomycin C, 5-FU, plus cytosine arabinoside or a similar regimen in which 5-FU was replaced by ftorafur, with the control patients having surgery only. No statistical differences in survival were seen at 5 years, although 5-year survival for the chemotherapy patients was somewhat better than for the control group ( $P = .09$ ). Subgroup analyses indicated significant differences in survival for those with earlier stage disease (stages I and II), but these were retrospective and unplanned. More recently, Nakajima and colleagues<sup>194</sup> have reported the results of another, larger trial performed in Japan. Five hundred seventy-nine patients with early-stage gastric cancer (T1 or T2 lesions) were stratified and randomized to receive postoperative chemotherapy or observation. The treatment plan involved mitomycin C, 1.4 mg/m<sup>2</sup>, twice weekly for 3 weeks after surgery in conjunction with FU, 167.7 mg/m<sup>2</sup>, also given twice weekly for 3 weeks. This was followed by 18 months of oral UFT given 300 mg daily. The primary end point was survival. Two hundred eighty-eight patients received treatment and 285 were followed expectantly. Slightly more than one-half of the patients had lymph node-negative tumors. With a median follow-up of 72 months, the overall 5-year survival rate was 82.9% for those in the control group and 85.8% for those in the treatment group ( $P = .17$ ; hazard ratio, 0.738). The authors of this study concluded that this regimen has no survival benefit in patients with serosa-negative, surgically resected gastric cancer.

A preliminary report in patients with advanced gastric cancer has compared a cisplatin, epirubicin, and FU combination to a combination of mitomycin, epirubicin, and FU. Although the initial report indicated an advantage to the mitomycin-containing arm, at the presentation itself no advantage was reported.<sup>195</sup> Most current adjuvant or neoadjuvant studies do not include mitomycin.

### Anthracycline-Containing Regimens

The uses of several doxorubicin-containing combination chemotherapy adjuvant regimens have been reported (see Table 33.3-10). Coombes and colleagues<sup>196</sup>

studied 315 patients with curatively resected gastric cancer who were randomized to receive FU, doxorubicin (Adriamycin), and mitomycin (FAM) or no postoperative therapy. Two hundred eighty-one patients were evaluable for analysis. Chemotherapy could be started as late as 6 weeks from surgery. Twenty-six percent of patients in the control arm had N2 disease versus 18% in the treated group, but this difference was not statistically significant. With a median follow-up of 68 months, 56% of patients in the treated arm and 61% of those in the control arm had a recurrence in disease. No significant difference was reported in disease-free survival or overall survival (FAM, 45.7%; control, 35.4%). A number of subgroup analyses were performed, the most positive of which was an effect for patients with T3 or T4 tumors who had positive lymph nodes ( $P = .07$  in favor of the FAM group). This, however, was an unplanned subgroup analysis. Three FAM patients died from suspected treatment-related complications. In a second FAM study, the Southwest Oncology Group also failed to note an improvement in survival for the treated group.<sup>197</sup> Both groups of investigators concluded that chemotherapy, including FAM, when given in the adjuvant setting, should be used only in an investigational setting.

Krook and colleagues<sup>198</sup> used a different doxorubicin-containing combination in the adjuvant setting. After curative resection, 125 evaluable patients were randomized to either observation alone or to three cycles of 5-FU, 250 mg/m<sup>2</sup>/d, for 5 days plus doxorubicin, 40 mg/m<sup>2</sup>, on day 1. Treatment began between 4 and 6 weeks after resection. No differences were noted in overall survival between the two groups (median survival of observation group, 31 months; treatment group, 36 months). The 5-year survival rate was almost identical (33% vs. 32%). Two treatment-related deaths, both related to sepsis during leukopenia, were reported.

The FU, doxorubicin (Adriamycin), and methotrexate (FAMTX) regimen has been extensively studied in patients with advanced metastatic disease, and in randomized trials it was superior to regimens such as FAM.<sup>198</sup> There is one random assignment trial from the Netherlands comparing neoadjuvant FAMTX to surgery alone. Fifty-six eligible and evaluable patients were entered: 27 were randomized to receive FAMTX before surgery and 29 to undergo surgery only. In the FAMTX plus surgery treatment group, 15 of 27 (56%) had curative resections versus 18 of 29 (62%) in the surgery-only arm. Forty-four percent of treated patients could not complete the planned four courses of FAMTX due to disease progression or toxicity. Response evaluation after chemotherapy was possible in 25 patients: two complete responses, six partial responses. The difference in curative resectability rate was 6.5% (95% confidence interval -32% to +19%) in favor of surgery only. The authors concluded that more active regimens than FAMTX will be required for future randomized trials.

Neri et al.<sup>199</sup> used a regimen containing epirubicin, FU, and leucovorin for patients with stage III disease. Chemotherapy was given for 7 months. Fifty-five patients were followed expectantly, and 48 received chemotherapy. The median survival rate for patients receiving therapy (20.4 months) was superior to those undergoing observation (13.6 months;  $P = .01$ ). At an average of 36 months of follow-up, 25% of patients receiving adjuvant therapy were alive compared to 13% of those being followed expectantly. Although these results are encouraging, they are at odds with the study by Krook et al.<sup>198</sup> in a similar number of patients. Use of this regimen should still be considered experimental, and it requires a larger confirmatory trial.

Tsavaris et al.<sup>200</sup> performed a small randomized trial in which epirubicin was substituted for doxorubicin to create the FU, epirubicin, and mitomycin (FEM) regimen. Eighty-four patients were randomized to receive three cycles of FEM or no treatment. Recurrence or death occurred in 64% of patients receiving FEM versus 81% of the control group; however, this difference was not statistically significant.

### Cisplatin -Containing Regimens

Although cisplatin-containing combinations have undergone extensive studies in patients with advanced metastatic disease, as discussed below (see [Palliative Treatment of Gastric Cancer](#)), currently no randomized trials are available in which patients with curative resections of gastric cancer were postoperatively and randomly assigned to receive or not receive a cisplatin-based regimen.

### METAANALYSIS OF ADJUVANT CHEMOTHERAPY TRIALS

Earle and Maroun<sup>201</sup> presented the preliminary results of a metaanalysis involving 12 trials performed in Western countries. It was not clear that individual patient data was obtained. In this analysis, the crude odds ratio for death for patients receiving adjuvant therapy was 0.81 (0.67 to 0.98) with a relative risk of 0.94 (0.88 to 1.01). These authors concluded that the survival benefit from these trials in patients undergoing curative resections was small. In an earlier analysis, Hermans et al.<sup>202</sup> reviewed 11 trials reported since 1980. In these studies, surgery was followed by postoperative chemotherapy or by observation alone. A total of 2096 patients were studied. The odds ratio was 0.88 (0.78 to 1.08), which was not statistically significantly superior to observation alone. In a later brief report by the same authors, two additional trials were added to this database that indicated a slight benefit to postoperative adjuvant therapy.

In both cases, the metaanalysis performed involved a variety of chemotherapy regimens, most of which had FU in common. They were a review of the literature, rather than a pooled analysis of individual patient data. Furthermore, the number of patients involved is relatively small in comparison to the metaanalysis in breast cancer, for example. Gastric cancer overviews to date suggest a modest benefit for older chemotherapeutic regimens. Almost all of these trials are seriously handicapped by their statistical design: With a small number of patients accrued, only very large differences could be expected to show a statistical benefit. Particularly as newer, potentially more effective chemotherapy regimens are developed, a high priority should be placed on designing trials that have adequate numbers of patients who are carefully staged so that the trials have appropriate power to allow an assessment of benefit.

### INTRAPERITONEAL CHEMOTHERAPY

The rationale for the use of intraperitoneal therapy after resection of primary gastric cancer is based on the high risk of peritoneal metastasis as a component of first failure. Autopsy series and second-look laparotomy series have reported that up to 50% of patients have clinically evident peritoneal carcinomatosis as a site (sometimes the only site) of failure. The pharmacokinetic rationale for intraperitoneal therapy has been well described. Drug concentrations within the peritoneal cavity are severalfold to one to two logs higher than concentrations that can be achieved after oral or intravenous treatment. Clinical support for the use of intraperitoneal chemotherapy also comes from other tumors. For example, a decrease of all sites of failure in patients receiving adjuvant colon cancer treatment using intravenous FU plus oral levamisole was reported; the only exception was peritoneal recurrence. In ovarian cancer, a large randomized trial demonstrated a small but statistical and clinically significant survival advantage for women receiving a portion of their therapy intraperitoneally. Thus, as is the case for many abdominal malignancies, a strong rationale exists for maximizing the effectiveness of currently available antineoplastic agents by using intraperitoneal treatment as a portion of the adjuvant therapy.

During the 1990s, an increasing number of reports have summarized data on the use of immediate postoperative intraperitoneal therapy for patients with gastric cancer. Interpretation of this data is hampered, however, by the retrospective nature of some of these trials. In addition, most prospective studies are pilot or phase II, involving small numbers of patients and testing feasibility. Last, even the small number of phase III trials reported to date are severely underpowered, making definitive conclusions regarding the use of intraperitoneal therapy, at this point, impossible. [Table 33.3-11](#) lists selected reports involving intraperitoneal chemotherapy given as adjuvant treatment in the postoperative setting. Although the database is limited, several themes are clear. The technique most commonly used is to administer intraperitoneal treatment (with or without hyperthermia) at the end of resection of all gross disease. Intraperitoneal chemotherapy is delivered in the operating room or recovery room or, at the latest, within several days of resection. In the latter case, this involves placement of an intraperitoneal catheter with therapy started soon after operation and given for repeated courses. No randomized comparative studies of the two techniques are available. The theoretical advantage of immediate intraoperative treatment is better distribution, whereas the theoretical advantage of intraperitoneal therapy via an implanted catheter is the ability to give repeated courses. Both techniques also have been used with established peritoneal carcinomatosis, but it is even harder to draw conclusions regarding this patient population. A fluorinated pyrimidine (FU or FUDR) or mitomycin C is usually part of the treatment plan.

Study	Regimen	Number of Patients	Median Survival	2-F Survival Rate (%)	P Value
Hajbara et al. <sup>203</sup>	Mitomycin C	24	>5 y	49	.81
	Control	23	1.2 y	27	
Rosen et al. <sup>204</sup>	Mitomycin C	46	79.6	35	.41
	Control	45	51.6	35	
Schiesl et al. <sup>205</sup>	Cisplatin	31	15 mo	38	.85
	Control	33	12 mo	36	
Santner et al. <sup>206</sup>	Cisplatin	33	17	33	.6
	Control	34	16	30	
Yu et al. <sup>207</sup>	Mitomycin-FU	123	35	38.7*	.2
	Control	123	35	35.9*	

FU, fluorouracil; NS, not stated.  
\*Five-year survival.

**TABLE 33.3-11. Intraperitoneal Therapy for Gastric Cancer: Phase III Trials**

In preclinical studies, Archer and Grey<sup>203</sup> used a rat model to demonstrate that intraperitoneal chemotherapy is capable of treating both peritoneal and liver micrometastasis. In a second study, Murthy and coworkers<sup>204</sup> demonstrated in a mouse model that the frequency of tumor formation at sites of surgical trauma in the peritoneum ranged from 28% to 82%, depending on the type of incisions made in the peritoneal cavity, as opposed to a 33% rate of peritoneal tumors in nonoperated mice. Data from several animal models indicate that the risks of peritoneal implantation and intraabdominal tumor spread immediately after laparotomy are high.<sup>205,206</sup> Clinically, a randomized trial in colon cancer by Sugarbaker and colleagues<sup>207</sup> demonstrated a marked decrease in peritoneal metastasis with intraperitoneal chemotherapy when compared with intravenous treatment, but showed no change in survival.

During the late 1980s and early 1990s, one of the most extensively used intraperitoneal agents in gastric cancer was mitomycin C. As is the case for all intraperitoneal therapy in gastric cancer, however, the small number patients involved hamper interpretation of this data. The initial promising study of Hajiwara and colleagues<sup>308</sup> indicated a marked improvement in survival for patients randomized to intraperitoneal therapy compared to those receiving no postoperative treatment. Mitomycin was adsorbed to a carbon-containing solution and infused immediately after the end of the operative procedure. In this study, 24 patients received treatment with mitomycin and 25 were observed after operation. A highly significant difference in favor of the intraperitoneally treated group was found (2-year survival, 68.6% vs. 26.9%; the difference was maintained at 3 years). This study sparked a number of reports, some of which are included in [Table 33.3-11](#). Retrospective reviews using higher-dose mitomycin with or without activated charcoal raised concerns regarding toxicity, with some studies indicating a high risk of intraabdominal toxicity leading to an increase in perioperative mortality. To more definitively test the hypothesis that intraperitoneal mitomycin offered benefit, Rosen and colleagues<sup>208</sup> reported their results using a similar technique. Ninety-one patients were randomly assigned to resection followed by observation or resection followed by carbon-adsorbed mitomycin C, 50 mg, given intraperitoneally. The study was stopped prematurely when an interim analysis revealed a marked increase in postoperative complications (25% vs. 16%) and an increased perioperative mortality (11% for patients receiving intraperitoneal therapy vs. 2% for the control arm). No survival advantage was noted at the time of the interim analysis, and the trial was closed. This randomized trial, plus the phase II and retrospective data, indicate that intraperitoneal mitomycin C, particularly in higher dosages of 25 to 50 mg, given with or without activated charcoal and with or without hyperthermia may be associated with a marked increase in toxicity with only questionable improvement in survival.

Regimens that do not contain mitomycin C also have been studied. These primarily involve the use of fluorinated pyrimidines (either FU or floxuridine), usually given with leucovorin or other agents (e.g., cisplatin) or both. Mitomycin in lower doses also has been used with FU. Phase II studies performed in the United States at single institutions by Crookes et al.<sup>209</sup> and Atiq et al.<sup>210</sup> indicated that postoperative intraperitoneal therapy using fluorinated pyrimidines could be given with safety. However, unusual toxicity has occasionally been noted. Atiq and colleagues<sup>210</sup> from Memorial Sloan-Kettering Cancer Center reported the results of a phase II study involving intraperitoneal cisplatin and FU plus systemic FU in high-risk patients having undergone potentially curative resections with gastric cancer. Thirty-five patients (most with stage IIIA or IIIB tumors) received intraperitoneal cisplatin, 25 mg/m<sup>2</sup>, on days 1 to 4 and FU, 750 mg/m<sup>2</sup>, as a single dose. Each drug was given daily for 4 days in a row for up to five cycles on a once a month basis. FU systemically as a continuous 24-hour infusion was given simultaneously. With a median follow-up of 24 months, 51% of patients remained alive and free of disease. Toxicity was acceptable. An unusual side effect of sclerosing encapsulating peritonitis was noted in 15% of patients. Further investigation revealed that solutions containing FU had a pH of greater than 8.5. The authors speculated that this resulted in hydrolysis of cisplatin to a reactive alkylating species. To avoid further sclerosing encapsulating peritonitis, the authors subsequently avoided mixing cisplatin and FU together before administration. No further episodes of sclerosing encapsulating peritonitis were seen. In a further update of this trial with a minimum follow-up of 42 months, 40% of patients remain alive and free of disease.

Yu et al.<sup>211</sup> reported the results of a randomized trial in which 248 patients were randomly assigned to receive intraperitoneal therapy or to observation. Patients receiving intraperitoneal chemotherapy were given mitomycin C on postoperative day 1 and FU on postoperative days 2 to 5. The study included patients with all stages of disease (I to IV). As is the case in other mitomycin-containing trials, morbidity and mortality were higher in the experimental arm (postoperative mortality, 5.6% vs. 0.8%). No statistical difference was noted in overall survival for the investigation arm (38.7% vs. 29.3%; *P* = .219), although an unplanned subset analysis showed a benefit for patients with stage II or III disease.

Similarly, Sautner and colleagues<sup>185</sup> performed a small, randomized phase III trial using intraperitoneal cisplatin as a single agent. Cisplatin, 90 mg/m<sup>2</sup>, was given intraperitoneally once a month. Therapy began 2 to 4 weeks after surgery. This study also allowed entrance of patients with documented peritoneal metastasis so that not all those treated were in the adjuvant setting. No difference was reported in survival for patients receiving or not receiving additional treatment. The authors concluded that intraperitoneal cisplatin as a single agent had no significant impact on recurrence.

### CONTINUOUS HYPERTHERMIC PERITONEAL PERFUSION

Continuous hyperthermic peritoneal perfusion (CHPP) for the treatment or prophylaxis of peritoneal carcinomatosis usually is administered during exploratory laparotomy after a primary tumor resection in patients who have established carcinomatosis or who are considered at high risk for developing peritoneal disease. CHPP takes advantage of the favorable pharmacokinetics that can be achieved with intraperitoneal chemotherapy<sup>212</sup> and the established synergistic cytotoxicity of hyperthermia and chemotherapy.<sup>213,214</sup>

Most of the initial clinical experiences came from Japanese investigators who administered CHPP to patients in whom peritoneal seeding was identified at the time of gastric resection for cancer.<sup>215,216,217</sup> and <sup>218</sup> The therapeutic agent administered into the perfusate was usually mitomycin C (10 mg/mL). Steady-state concentrations of mitomycin C were approximately tenfold higher in the perfusate compared with serum. With the significant hyperthermia, a mild increase in hepatic transaminases was noted after treatment. However, the studies did confirm that CHPP could be safely administered after a major extirpative procedure.

Fujimoto and coworkers<sup>219</sup> and Gilly and colleagues<sup>220</sup> reported that malignant ascites could be palliated effectively with CHPP. Fujimoto's group reported that five of six patients with malignant ascites secondary to recurrent gastrointestinal cancer had resolution of the ascites after undergoing tumor resection and CHPP; all five patients were without evidence of recurrent disease at a mean follow-up of 12.8 ± 5 months. Gilly's group reported that nine of ten patients had no evidence of recurrent ascites on ultrasound obtained 2 months after CHPP. Fujimura and colleagues<sup>218</sup> treated 31 patients with peritoneal carcinomatosis secondary to recurrent gastric cancer with cisplatin and mitomycin C administered via CHPP. In 12 of 31 patients who underwent a second-look operation, four had a complete response and one had a partial response to treatment. However, it is important to appreciate that CHPP is only effective in treating small-volume peritoneal disease. Yonemura and coworkers<sup>216</sup> introduced CHPP with 30 mg mitomycin C and 300 mg cisplatin as prophylactic treatment for peritoneal recurrence after curative resection of 79 advanced gastric cancers. Survival was compared to that of 81 patients treated during the same period. Prolonged survival was reported in the subgroup of patients with tumors that penetrated the serosa. No increase in morbidity or mortality was reported between the two groups.<sup>216</sup>

Several multiarm studies have evaluated the efficacy of prophylactic or therapeutic CHPP administered immediately after resection for gastric cancer reported primarily from centers in Japan<sup>218,221</sup> ([Table 33.3-12](#)). In a report by Koga and coworkers<sup>221</sup> of a subset of 47 patients who had histopathologic evidence of serosal invasion, the 3-year survival rate in the CHPP-treated group was better than in the control group, but not significantly. In the same study, a larger CHPP-treated cohort did have a significantly better 5-year survival rate compared with historically matched controls. In patients who underwent major gastric resection, the incidence of an anastomotic leak or the length of postoperative ileus was affected by CHPP treatment. Fujimoto and colleagues<sup>222</sup> reported that overall survival was significantly longer in patients treated with CHPP; in the subgroup analysis, the beneficial effect was observed in patients with and without documented peritoneal seeding. Peritoneal disease was the major contributing cause of death in patients who did not receive CHPP. In a three-arm randomized trial reported by Fujimura and colleagues,<sup>218</sup> the efficacy of CHPP was compared with continuous normothermic peritoneal perfusion and surgery alone in patients with gastric cancer and serosal invasion undergoing resection with curative intent. In the two perfusion groups, survival was significantly better compared with the group receiving surgery alone. Hamazoe and colleagues<sup>223</sup> reported that survival was slightly better in 42 patients treated prophylactically with CHPP compared with 40 untreated control patients. Several centers in the United States and Europe are currently evaluating the feasibility of CHPP for patients with peritoneal carcinomatosis.<sup>224,225,226,227</sup> and <sup>228</sup>

**TABLE 33.3-13. Neoadjuvant Therapy for Locally Advanced Gastric Cancer: Selected Phase II and Phase III Trials**

Another technique for predicting outcome early in the treatment course involves the use of PET scanning. A decrease in F-18 fluorodeoxyglucose uptake has been proposed as an early marker for objective regression in patients receiving systemic chemotherapy for locally advanced or metastatic disease.<sup>238</sup> Although preliminary studies with PET in gastric cancer have now been reported, definitive, large-scale trials correlating survival outcome with change in PET scan are still awaited.

Although assessing the degree of tumor regression is difficult, phase II studies of neoadjuvant chemotherapy have demonstrated that such treatment can be given with acceptable toxicity and with no apparent increase in operative morbidity or mortality. Several phase II pilot studies have been reported using this approach (see [Table 33.3-13](#)). Ajani and colleagues<sup>239</sup> at the M. D. Anderson Cancer Center performed a single-arm phase II trial involving 48 patients who had gastric cancers that were potentially operable. Etoposide, doxorubicin, and cisplatin chemotherapy was given for three courses before operation followed by two planned postoperative courses. Eighty-five percent of patients underwent operation, and 77% had potentially curative resections. Toxicity, primarily due to neutropenia, was substantial but generally manageable. One chemotherapy-related death was reported. In a second study, Ajani and colleagues<sup>86</sup> used a similar regimen of cisplatin, FU, and etoposide for two preoperative and three postoperative courses. One postoperative death was reported. All patients underwent operation, and 72% had potentially curative resections. The most common site for recurrent disease was peritoneal carcinomatosis either found at surgery or developing subsequently. Lowy et al.<sup>240</sup> summarized the long-term results of these and a third sequential phase II trial. A total of 83 patients were treated. All the studies involved the use of cisplatin-based therapy. Seventy-three percent of patients underwent R0 resections. Although response to therapy can be difficult to interpret, 4% of patients had pathologic complete remissions. Response to chemotherapy as assessed clinically was thought to be an independent predictor of survival.

Leichman and colleagues<sup>241</sup> reported the initial results of a trial in which 38 patients with resectable gastric tumors received two cycles of a preoperative chemotherapy regimen involving 5-FU, 200 mg/m<sup>2</sup>/d, given over 3 weeks with weekly intravenous leucovorin, 20 mg/m<sup>2</sup>, and monthly cisplatin, 100 mg/m<sup>2</sup>. Postoperative intraperitoneal therapy involved FUDR, 3000 mg total dose, daily for 3 days plus cisplatin, 200 mg/m<sup>2</sup>, with intravenous sodium thiosulfate. Ninety-two percent of patients underwent laparotomy; 87% of patients had resection. Postoperative intraperitoneal therapy was possible in 68% of study patients. One treatment-related death was reported. Prestudy clinical tumor staging (by CT and endoscopy) was not provided. Postoperative staging showed 14 patients with either stage 0 (one patient) or stage I disease. An additional seven patients had stage II tumors. Crookes et al.<sup>209</sup> reported the long-term results of this phase II study. In the final report, a total of 59 patients were included. A 71% R0 resection rate was noted. The operative mortality was 5%. Median survival of this group of patients was estimated to exceed 4 years. Because these patients did not undergo preoperative laparoscopy or EUS, however, they may have included patients with both locally advanced and earlier-stage tumors.

Kelsen and coworkers<sup>236</sup> performed two trials involving preoperative chemotherapy followed by postoperative intraperitoneal treatment. The first study used the FAMTX regimen preoperatively and gave postoperative intraperitoneal FU and cisplatin.<sup>236</sup> Fifty-six evaluable patients were identified by EUS as having advanced disease; most had stage IIIA or IIIB tumors. Toxicity was tolerable, the major side effect was myelosuppression leading to hospitalization for neutropenic fever on at least one occasion in 60% of patients. Down-staging occurred in 51% of patients. The operability rate was 89%, and the resectability rate was 74% (61% curative, 20% palliative). With a median follow-up of 28 months, the median duration of survival for all patients was 15.3 months.

In a follow-up study, the same group of investigators treated a group of 35 patients with preoperative cisplatin and FU chemotherapy for two cycles followed by postoperative intraperitoneal floxuridine plus leucovorin. All patients underwent pretreatment laparoscopy and EUS, and all had T3 or lymph node–positive tumors. Preoperative toxicity was tolerable, without any increase in operative morbidity or mortality. The R0 resection rate was 82%, and the estimated median duration of survival was 22.5 months. Fink and colleagues<sup>242</sup> treated a group of 49 patients with preoperative cisplatin, FU, and leucovorin (PLF). The R0 resection rate was 76%. Median duration of survival for all patients was 36 months, and at a median follow-up of 28 months, the median survival for the R0-resected patients had not been reached.<sup>242</sup>

Alexander and coworkers<sup>243</sup> treated 22 patients with locally advanced gastric cancer with three cycles of 5-FU, leucovorin, and interferon followed by resection and three cycles of postoperative consolidation therapy. The response rate to neoadjuvant therapy was 38%, and 18 patients (82%) underwent resection with curative intent. Endoscopic tumor biopsies were obtained in 13 patients before and during cycle two of neoadjuvant chemotherapy, and thymidylate synthase (TS) levels were quantitated by Western blot. Pretreatment TS levels in tumor were significantly higher in responders versus nonresponders. After exposure to 5-FU, levels of free TS were significantly lower, and the percentage of TS complexed with 5-FU was significantly higher in responders. These preliminary data indicate that quantification of TS in tumor may provide a method to select patients most likely to respond to 5-FU–based chemotherapy.

Kang et al.<sup>244</sup> reported the preliminary results of a small randomized trial of neoadjuvant cisplatin, etoposide, and FU therapy versus surgery alone. Fifty-three patients received preoperative chemotherapy, and 54 underwent immediate operation. No significant difference was noted in operability rate (89% vs. 100%), resection rate (71% vs. 61%), or in median survival (33 vs. 32 months). All of these trials have demonstrated that preoperative chemotherapy can be given safely without an increase in operative morbidity or mortality when experienced surgeons perform the operation. Most studies are single-institution trials, and all investigators have emphasized the need for multiinstitutional prospective studies to test the hypothesis that preoperative treatment will improve outcome as measured by overall survival. Although it is unclear as to whether one chemotherapy regimen, including cisplatin-based treatment, is markedly superior to another (as discussed in [Palliative Treatment of Gastric Cancer](#), below), almost all preoperative regimens do involve this agent. The identification of the taxanes docetaxel and paclitaxel and, more recently, of the camptothecin irinotecan as active agents in the treatment of this disease has led to the introduction of these agents into newer neoadjuvant regimens.

Larger-scale phase III trials with a surgery-only control arm are now under way, and additional studies are in the advanced planning stage. A European group, led by the United Kingdom MRC, is currently performing a randomized trial with a projected accrual of 500 patients. The investigational arm involves preoperative chemotherapy with epirubicin, cisplatin, and FU (ECF) followed by operation versus operation alone. Three preoperative courses are delivered, followed by operation within 6 weeks of completing chemotherapy. An additional three courses of postoperative ECF is planned. This study is still accruing patients. Phase II pilot trials are nearing completion in the United States preliminary to a large-scale randomized study. These pilot trials include neoadjuvant chemotherapy using cisplatin, taxotere, and FU followed by surgery followed by intraperitoneal chemotherapy; a second study uses neoadjuvant chemoradiation with cisplatin, FU, and taxotere plus concurrent radiation followed by resection. Last, the Eastern Gastric Oncology Group is performing a study of cisplatin and taxotere therapy followed by surgery followed by postoperative chemoradiation therapy. It is anticipated that the control arm in the next intergroup trial will be the best arm of the Intergroup 116 study (discussed later, in [Adjuvant Radiation and Chemoradiation Therapy](#)), in which patients having undergone curative resection for gastric cancer were randomized to observation or chemoradiation therapy using FU and leucovorin as the chemotherapeutic agents.

In summary, neoadjuvant approaches involving preoperative chemotherapy with or without postoperative intraperitoneal treatment are now under way in the United States and in Europe. To date, the data indicate no increase in operative morbidity or mortality. Because evaluating the primary tumor is difficult, down-staging can only be estimated. The approach, although promising, requires definitive randomized phase III trials before firm conclusions regarding the value of this technique are established.

## ADJUVANT RADIATION AND CHEMORADIATION THERAPY

Few studies have evaluated radiation therapy alone (with no concomitant chemotherapy) as an adjuvant to surgical resection of gastric cancer. Most of the studies that have evaluated radiation therapy as an adjuvant have used concomitant 5-FU chemotherapy.

Some of the earliest data on radiation therapy of gastric cancer comes from the Mayo Clinic, where studies were performed in the 1960s on the use of radiation therapy and 5-FU in a variety of gastrointestinal malignancies. Although these reports were based on patients with locally advanced tumors, they laid the groundwork for the subsequent adjuvant studies. Childs and colleagues<sup>245</sup> reported a study of patients with advanced gastric cancer who were randomized to either radiation therapy alone to a dose of approximately 4000 cGy or radiation therapy combined with 5-FU as a radiation sensitizer (bolus 5-FU for 3 days, 15 mg/kg/d). This study showed a significant improvement in survival with the combination of 5-FU and radiation compared with radiation alone. Because the dose of 5-FU was extremely low, most people have interpreted these data as showing an advantage to 5-FU as a radiation sensitizer. This observation also is consistent with the data that have been obtained in other gastrointestinal sites, such as rectal and pancreatic cancer, for which 5-FU has improved survival when combined with radiation therapy. The British Stomach Cancer Group study randomized patients to postoperative radiation therapy; postoperative chemotherapy with FAM; or surgery alone. At 5-year follow-up, no

significant difference was seen among any of the three arms, but the local recurrence rate was decreased by the use of radiation therapy (54% with surgery alone vs. 32% with radiation therapy,  $P < .01$ ).<sup>246</sup>

Two studies used chemotherapy plus concurrent radiation. In one study, however, incompletely resected patients were included. Dent and colleagues<sup>247</sup> treated 142 patients who were randomly assigned to no additional therapy or to 2000 cGy given in eight treatments over 10 days plus FU, 12.5 mg/kg, daily for 4 days immediately before the beginning of radiation. A second cycle was given on day 28. Patients in "division one" had no residual gross disease but may have had incomplete resection. The control group had 31 patients, and the chemotherapy/radiation group had 35 patients. No difference in survival between the two groups was reported. Moertel and coworkers<sup>247a</sup> from the Mayo Clinic have reported the results of a randomized trial of radiation therapy (3750 cGy in 24 fractions) plus 5-FU (15 mg/kg  $\times$  3) versus surgery alone for poor prognosis patients, including those with scirrhous carcinomas, metastases to regional lymph nodes, invasion of adjacent structures, or tumors originating in the cardia. Eighty percent of patients had positive nodal disease, and approximately 25% had invasion of adjacent structures. The treated patients had a 5-year survival rate of 20% versus a 4% 5-year survival rate in the surgery-only controls. However, the issue is confused by the fact that ten patients who were randomized to adjuvant treatment refused therapy. In this small cohort of patients, the 5-year survival rate was 30%. Locoregional recurrence was decreased from 54% in the surgery-alone arm to 39% in the combined modality arm. The survival results in these studies are also similar to those reported in nonrandomized series, such as that by Slot and colleagues,<sup>248</sup> in which 57 patients with poor prognostic factors received postoperative radiation therapy to a dose of 30 to 50 Gy combined with 5-FU. The 5-year survival rate was 26%, with 16 patients having a locoregional recurrence as their first sign of relapse.

Although others have evaluated other combinations of chemotherapy with radiation therapy,<sup>249,250</sup> no advantage has been shown to date with any drug regimen besides 5-FU when combined with chemotherapy. The data suggest that, for patients with nodal positivity, serosal involvement, or close or positive surgical resection margins, postoperative radiation therapy may be of value. This approach has been studied in the United States in a national intergroup trial (INT 116) evaluating two cycles of chemotherapy with 5-FU and leucovorin followed by radiation therapy to a dose of 4500 cGy with concurrent chemotherapy. Intergroup 116 involved a total of 556 evaluable patients, 275 of whom were followed expectantly after operation, and 281 who were randomly assigned to receive postoperative chemoradiation therapy. All patients had undergone an R0 resection. The type of lymphadenectomy was not mandated by the study protocol. Postoperative chemoradiation therapy involved the use of FU and leucovorin chemotherapy and 45 Gy of external-beam radiation therapy. One cycle using the Mayo Clinic regimen of FU, 425 mg/m<sup>2</sup>, and leucovorin, 20 mg/M<sup>2</sup>, for 5 consecutive days was followed by concurrent chemoradiation. Doses were decreased during radiation to FU, 400 mg/M<sup>2</sup>, and leucovorin, 20 mg/M<sup>2</sup>, daily for 4 days during week 1 of radiation, and for 3 days at the end of radiation. One month after the completion of radiation, additional chemotherapy using FU, 425 mg/M<sup>2</sup>, and leucovorin, 20 mg/M<sup>2</sup>, daily for 5 days was given for two additional cycles. This data has been presented in abstract form. The two arms were well balanced for important prognostic indicators. Eighty-five percent of patients had lymph node metastases. With close attention to detail, especially to radiation therapy treatment planning, toxicity was tolerable, although three (1%) toxic deaths on the experimental arm were reported. Postoperative adjuvant chemoradiation therapy resulted in a significant improvement in both disease-free and overall 3-year survival rates. The median survival was improved from 26 months for the surgery-only group to 40 months for those receiving chemoradiation. Three-year survival was 41% for surgery only and 52% for postoperative chemoradiation ( $P = .03$ ; hazard ratio, 1.28) (J. McDonald, personal communication). If the final report confirms these initial data, postoperative chemoradiation using FU and leucovorin will become the standard of care for resected R0 patients able to tolerate such treatment.

To try to increase the total radiation dose that can safely be delivered, newer radiation approaches have been tried. An approach that has been investigated at a few centers is intraoperative electron-beam radiation therapy. In this technique, pioneered by Abe and Takahashi,<sup>251</sup> patients receive a single dose of high-energy electrons delivered to the tumor bed at the time of gastrectomy. Because most of the radiosensitive normal structures can be moved from the radiation beam, the risk of producing significant bowel complications is reduced. In a nonrandomized trial, Abe has demonstrated an improved 5-year survival rate in patients with locally advanced disease (usually because of posterior infiltration) who were treated with intraoperative radiation therapy (20%).<sup>251a</sup> A small randomized trial of a similar approach at the National Cancer Institute<sup>252</sup> did not demonstrate any significant survival advantage, although it did demonstrate an improvement in local control compared with surgery alone. A number of phase II trials have been performed that demonstrate the feasibility of this approach in a large number of centers, but these trials do not allow any conclusions regarding efficacy<sup>251,252,253</sup> and<sup>254</sup> (Table 33.3-14).

Stage	5-Y Survival			
	Surgery		Surgery + IORT	
	Number of Patients	%	Number of Patients	%
I	43	93	20	88.1
II	11	54.5	18	77.6
III	38	36.8	19	44.6
IV (no distant metastases)	18	0	27	19.5

**TABLE 33.3-14.** Gastric Cancer: Surgery Alone versus Surgery and Intraoperative Radiation Therapy (IORT), Japan

## TECHNIQUE OF RADIATION THERAPY

In general, the presence of normal tissues close to the tumor mass limits the radiation dose that can be delivered safely. The spinal cord, kidneys, small bowel, and liver are all in close proximity and cannot be entirely avoided. In addition, the stomach itself is a radiation-sensitive tissue, and high doses (more than 5000 cGy) to a functional stomach produce a significant incidence of ulceration and bleeding.

When irradiating the upper abdomen, a number of acute side effects from therapy may occur, including nausea, weight loss, and fatigue. With properly planned radiation fields, the nausea is not generally severe, but given the prolonged course of radiation, if careful attention is not given to the patient's nutritional status, the therapy can end up producing more harm than good. Usually, a combination of antiemetics, multiple small feedings, and nutritional supplements are sufficient to control the side effects of treatment, but on occasion, feeding tubes are useful. If patients cannot maintain their weight before the initiation of radiation therapy, they usually have difficulty with the therapy. The other acute side effects are relatively minor and easily managed. The possible late side effects that must be considered include damage to spinal cord, liver, kidney, and stomach.

Late liver and renal failure or radiation-induced spinal cord transection are all possible complications from excess irradiation, but if proper attention is paid to these structures during treatment planning, a clinical problem should rarely develop. The tolerance dose of the stomach itself is on the order of 5000 cGy, so those doses above this level have a real risk of producing gastric ulceration.

It is common for at least one kidney to be required in the radiation field to a high dose (more than 3000 cGy), which produces a very high chance of significant renal injury, usually to the left kidney. Studies have demonstrated<sup>255</sup> that, for a patient with baseline renal function that is within normal range, treating one kidney to high dose has a very low likelihood of producing renal injury that adversely affects the patient's quality of life. The compensatory hypertrophy of the unirradiated kidney results in adequate renal function, and the risk of renovascular hypertension is very low. If the equivalent of one kidney can be eliminated from the radiation field and the patient starts with a relatively normal creatinine clearance, then the patient should tolerate the radiation course adequately in regard to the kidneys. Standard radiation tolerance doses should be observed for the other normal tissues mentioned previously.

If radiation therapy is being used as an adjuvant or with curative intent, the patterns of spread of the tumor must be considered in planning the radiation field. In contrast to many other tumor sites, a standard radiation field is often inappropriate in treatment of gastric cancer because the spread patterns relate to the site of origin and the extension that is found on preoperative imaging studies and at surgery. The lymphatic pattern of spread has already been discussed, and this pattern greatly influences the radiation fields that are appropriate. Although one usually wishes to encompass much of the stomach (or the gastric bed), for tumors that originated and remained limited to the gastric antrum, it is not necessary to irradiate the entire cardia of the stomach and to extend the radiation field to encompass the lower esophagus, but it is necessary to treat the periduodenal lymph nodes. Similarly, for tumors originating in the cardia, it is essential that the field extend up into the esophagus and that there is full coverage of the bed of the gastric cardia and fundus, but one can safely avoid irradiating the periduodenal nodes. Often, a local failure from gastric cancer occurs from posterior extension of the primary tumor onto the pancreas and into other retroperitoneal tissues. Therefore, full coverage

of these areas of posterior invasion is essential. An example of a typical radiation field is shown in [Figure 33.3-8](#). The radiation fields are primarily anteroposterior fields, although lateral and oblique fields can be very useful for the final boost. If lateral fields are used for a substantial portion of the large-field treatment, then care must be taken to avoid treating large segments of the liver to doses higher than 2000 or 2500 cGy.

**FIGURE 33.3-8.** Typical treatment field for postoperative radiation therapy of a tumor of the body of the pancreas. This field encompasses the entire tumor bed and virtually all regional lymphatic sites. For tumors that are located more proximally or distally in the stomach, the fields can be shaped to avoid regions at lower risk (see text).

The total radiation dose to be used is determined primarily by the tolerance of the normal tissues mentioned above. Generally, a dose of 4500 cGy given at 180 cGy/d has a minimal chance of producing significant late complications. At doses higher than 5000 cGy, the risk of late complications increases, and doses greater than this should be limited to very small volumes. As mentioned above, the data strongly suggest that the combination of 5-FU and radiation is more effective than radiation alone. Although the optimal method of drug administration is not known, it is appropriate to use, as a minimum, 3 days of bolus 5-FU during the first and last week of radiation therapy.

### PALLIATIVE TREATMENT OF GASTRIC CANCER

Since the late 1970s, many chemotherapeutic agents have been studied in gastric cancer. Although reports of very high response rates with some of the newer combination chemotherapy regimens have been published, the median survival of patients with advanced cancer continues to be dismal.

### SINGLE-AGENT CHEMOTHERAPY

The objective response rates reported for single agents in patients with gastric cancer are shown in [Table 33.3-15](#). FU is the most extensively studied single agent in this disease, with an overall objective response rate of 21%.<sup>256,257</sup> The two most commonly used schedules for administering 5-FU as a single agent are daily intravenous injections for 5 consecutive days, repeated every 4 to 5 weeks, and weekly intravenous injections. Both schedules have similar response rates and toxicity profiles. The major side effects of 5-FU are mucositis, diarrhea, myelosuppression, and (using a continuous infusion) the hand-foot syndrome. 5-FU has been a common element in most combination chemotherapy regimens for gastric cancer.

Drug	Number of Patients	Response Rate (%)
<b>Antimetabolites</b>		
5-Fluorouracil	410	21
Methotrexate	28	12
Tiazofurin	26	15
Tegafur	15	0
<b>Oral antineoplastic</b>		
5-FU	100	20
S-1	51	40
Epirubicin (oral)	21	10
Capecitabine (oral)	34	37
Fluorouracil (oral)	17	19
<b>Antibiotics</b>		
Mitomycin C	213	30
Doxorubicin	141	17
Epirubicin	80	10
<b>Heavy metals</b>		
Cisplatin	150	19
Carboplatin	41	5
<b>Taxanes</b>		
Paclitaxel	100	17
Docetaxel	120	21
<b>Chemopreventives</b>		
Etoposide	40	25
Vincristine	23	0

**TABLE 33.3-15.** Chemotherapeutic Agents

Mitomycin C, an antitumor antibiotic, also has been extensively used in the treatment of gastric cancer, especially in Japan. The overall objective response rate for mitomycin C has been approximately 30%.<sup>258,259</sup> and <sup>260</sup> Its greatest toxicity is delayed and cumulative myelosuppression, so the drug is usually given on an intermittent basis every 4 to 8 weeks.

Doxorubicin (Adriamycin), an anthracycline antibiotic, also has been studied. In 141 evaluable patients with advanced disease, it had an overall response rate of 17%.<sup>258,259,261</sup> Doxorubicin is a potent agent with significant but manageable early side effects. Its most critical toxicity is irreversible myocardial damage. Several groups have studied cisplatin. As a single agent, it is reported to produce major responses in 19% of patients, including those previously treated.<sup>262,263</sup> and <sup>264</sup>

Several new agents have been identified as having substantial activity in advanced gastric cancer. As shown in [Table 33.3-15](#), the taxanes paclitaxel and docetaxel have both undergone phase II trials. For paclitaxel, both 3-hour and 24-hour infusions given every 3 weeks have been studied. Overall, approximately 20% of patients have had major objective regressions, primarily partial remissions. It is unclear as to whether a substantial difference exists between the two schedules. Response also has been seen in patients who have received prior chemotherapy. Similar data exists for docetaxel. The overall response rate is approximately 20% to 25%, with most studies having used an every 3-week dosing schedule. The two taxanes have not yet been compared in prospective randomized studies. Irinotecan, a new agent in the treatment of patients with colorectal cancer, also has single-agent activity in gastric cancer. Responses have been reported in both previously treated and untreated patients.

Both of these new classes of agents have now been used in multidrug combinations as described in the following sections. In addition to the identification of the taxanes and irinotecan, interest is increasing in oral fluorinated pyrimidine therapy. In this case, although the agents being studied are not of a new class but rather are FU prodrugs, ease of administration and the mimicking of chronic infusional therapy is of interest. UFT has been the most well-studied oral fluorinated pyrimidine. Responses in 20% to 30% of patients have been reported. Fewer data are available for S-1, although in one study, an unusually high response rate of 49% was reported. Also shown in [Table 33.3-15](#) are newer agents studied since 1996 that have not demonstrated antineoplastic activity.

### COMBINATION CHEMOTHERAPY

Numerous attempts have been made to develop more effective combination chemotherapy regimens using known active drugs; some trials also have included other agents that did not have substantiated activity. Both phase II and prospective randomized phase III trials have been reported ([Table 33.3-16](#) and [Table 33.3-17](#)). In general, results from multicenter phase III trials have had lower response rates than single-institution phase II studies for the same drug regimens.<sup>230,261,265,266,267,268,269,270,271,272</sup> and <sup>272a</sup> Several combination chemotherapy regimens have shown response rates in the range of 30% to 50%, usually in phase II studies.

Drug	Enthalpy Points	Response Rate (%)	95% Confidence Limits	Median Survival (mo)
5-FU (M2)	68	30	21-39	6.6
5-FU (M1)	100	28	20-36	—
5-FU+mito (M3) (FAM)	141	25	19-31	13.1
5-FU+CCNU (M4)	19	6	0-12	6.4
5-FU+CCNU (M5)	25	16	6-26	6.3
5-FU+epi (M6)	171	32	25-39	5.4
5-FU+epi (M7)	6	0	0-7	9
5-FU+epi (M8)	6	0	0-7	16
5-FU+CCNU (M9)	20	10	3-17	13.1
5-FU+CCNU (M10)	6	0	0-7	6.8
5-FU+mito (M11)	100	28	19-37	16.2 (best)
5-FU+epi (M12)	171	32	25-39	6.4
5-FU+epi (M13)	6	0	0-7	11.8
5-FU+epi (M14)	6	0	0-7	13.1

TABLE 33.3-17. Prospective Randomized Trials of Combination Chemotherapy in Advanced Gastric Cancer

FAM AND FAM VARIANTS

The FAM combination was widely used in the 1980s (see Table 33.3-16). In the initial report of this regimen, 26 of 62 patients (42%) achieved a partial response; no complete responses were reported.<sup>273</sup> The median duration of response was 9 months; the median survival for the whole group was 5.5 months, although the median survival for responding patients was 12.5 months. Results using FAM have since been reported in more than 650 patients in various dose schedules with a cumulative response rate of 30%; the complete remission rate has been 2%.<sup>260</sup> The median remission duration is 5 to 10 months. Other studies have used variants of the FAM regimen (e.g., increased doxorubicin dose). The overall response rate of 28% for such modified regimens is similar to the response rate reported in patients treated with the original FAM combination. The median survival of patients treated on FAM variants was also identical to those treated on the original FAM regimen.<sup>260</sup>

In a review of Japanese studies, Ogawa<sup>274</sup> reported a cumulative response rate of 36% in 356 patients with a combination of 5-FU, mitomycin C, and cytarabine. The mean survival was reported as 16 to 20 months. In a randomized trial of 5-FU alone versus 5-FU, mitomycin, and cytarabine, however, Cocconi and colleagues<sup>257</sup> found no statistical difference among the response rate, duration of response, or median survival in the two arms.

In a phase III trial, the North Central Cancer Treatment Group compared single-agent 5-FU to 5-FU plus doxorubicin and to FAM<sup>275</sup> (see Table 33.3-17). The primary end point of this study was survival. The median survival of all patients was 29 weeks. The investigators also did not notice any significant differences in the palliative effect among these three treatment regimens.

Cisplatin -Based Chemotherapy

Although many phase II studies have been performed during the 1990s involving a variety of cisplatin-containing and non-cisplatin-containing combinations, only a few phase III randomized studies have been reported. Most of these trials involve relatively small numbers of patients, so that the ability to make definitive statements of superiority of one treatment over the other is limited.

The *in vitro* synergy between cisplatin and 5-FU, the activity of cisplatin as a single agent in gastric cancer, and the bone marrow toxicity of mitomycin led several investigators to replace mitomycin in the FAM combination with cisplatin. The cumulative overall response rate for this FAP regimen was 34%, with 5% of the patients achieving complete remission.<sup>260,268,276</sup> Cisplatin and doxorubicin were given in doses of 60 to 100 and 30 to 60 mg/m<sup>2</sup> per cycle, respectively. 5-FU dose and schedule also varied in individual trials.

To assess the individual contribution of cisplatin, methyl CCNU, and triazinate in combination with 5-FU and doxorubicin, the Gastrointestinal Tumor Study Group performed a prospective randomized trial comparing FAP, FAME [FU, doxorubicin (Adriamycin), and methyl CCNU], and FAT [5-FU, doxorubicin (Adriamycin), triazinate].<sup>276</sup> The primary end point was survival. Of 249 patients studied, 38% had measurable disease and were evaluable for response. The response rates for FAP, FAME, and FAT were 19%, 15%, and 20%, respectively. Median survival rates were 31 weeks (FAP), 24 weeks (FAME), and 30 weeks (FAT). Severe toxicity was seen in 69% of patients treated with FAP, 62% on FAME, and 42% on FAT.

Cunningham and coworkers<sup>277</sup> substituted epirubicin, an analogue of doxorubicin that, in preclinical studies, has less cardiac toxicity with equivalent tumor activity to doxorubicin, for doxorubicin in the ECF regimen in one report. Ten of 14 evaluable patients (71%) achieved an objective response. In a second trial involving 52 evaluable patients, the response rate was 37%, with a 17% complete remission rate.<sup>278</sup> Median durations of survival were not reported. The Italian Oncology Group for clinical research performed a randomized phase III trial comparing the FAM regimen to a cisplatin, epirubicin, leucovorin, and FU (PELF) regimen.<sup>279</sup> Nonhematologic toxicity was significantly more frequent with PELF compared with FAM, including two treatment-related deaths. PELF had a significantly higher response rate (43%) than did FAM (15%). The median duration of survival was not significantly different. Waters et al.<sup>279a</sup> reported the long-term results of a randomized trial in which ECF was compared to the FAMTX combination. This is one of the largest phase III trials in advanced gastric cancer reported.

In phase II studies led by Cunningham and colleagues,<sup>277</sup> ECF had a high response rate with acceptable toxicity. FAMTX had been shown in earlier trials to be superior to FAM, which was one of the standards of the early 1980s. In the randomized MRC study,<sup>279b</sup> 126 patients received ECF and 130 patients received FAMTX. The overall response rate for ECF was significantly higher than that of FAMTX (46% vs. 21%). Median survival was also longer for ECF (8.7 vs. 6.1 months). In the update, long-term survival was presented. At 2 years, 14% of patients receiving ECF were alive versus 5% of FAMTX patients. In an earlier trial, Kim and colleagues<sup>279c</sup> compared FU and cisplatin to FU alone and to the FAM regimen. This smaller trial had 54 to 57 patients per arm. The response rate to the cisplatin-containing combination was 51%, significantly better than the 25% to 26% for the non-cisplatin-containing arms. The median duration of survival of 8.5 months was almost identical to the median duration of survival for ECF.

Barone and colleagues<sup>279c</sup> compared a cisplatin, epirubicin, and etoposide combination to FU plus leucovorin. In this small study, 32 patients received cisplatin-containing therapy and 33 received FU plus leucovorin. Response rates were similar (22% vs. 18%, respectively), as was median survival. The 2-year survival rate was 14% for patients receiving cisplatin, epirubicin, and etoposide compared to 3% of those receiving 5-FU plus leucovorin. The Turkish Oncology Group<sup>279c</sup> compared two cisplatin-containing combinations: etoposide, epirubicin, cisplatin versus FU, epirubicin, and cisplatin; 20% of patients responded to the etoposide, epirubicin, and cisplatin regimen versus 15% to FU, epirubicin, and cisplatin. Median survival rates were short (6 vs. 5 months). Thus, to date, epirubicin- and cisplatin-containing combinations have been reported to have higher response rates and, in some trials, a survival advantage.

## Cisplatin -Etoposide Variants

Because of evidence that etoposide and cisplatin may be synergistic and that the combination of the two may be helpful in overcoming multidrug resistance,<sup>280,281</sup> these drugs have been combined in many tumors. Two phase II trials of etoposide and cisplatin in advanced gastric cancer (including gastroesophageal junction adenocarcinoma) showed an 18% response rate in 79 evaluable patients. Kelsen and colleagues<sup>282</sup> reported only one major objective regression in 33 evaluable patients. Cisplatin at a dose of 60 mg/m<sup>2</sup> was given on days 1 and 29 and every 6 weeks thereafter, with etoposide given at a dose of 100 mg/m<sup>2</sup> on days 3, 5, 7, and 31, 33, and 35. Toxicity was generally tolerable. In the second trial, Elliott and coworkers<sup>283</sup> saw 13 responses in 46 evaluable patients. Etoposide was given at a dose of 130 mg/m<sup>2</sup>/d × 3 plus cisplatin, 45 mg/m<sup>2</sup>/d, on days 2 and 3. Both drugs were given by continuous intravenous infusion, and the cycles were repeated every 4 weeks. Most patients experienced severe toxicity. The median duration of response was 4 months.

Preusser and colleagues<sup>284</sup> used the combination of etoposide, doxorubicin, and cisplatin (EAP) and reported a 64% response rate in 67 patients, with a complete remission rate of 21%. Including patients with locoregional tumor treated in a separate trial, Wilke and colleagues<sup>285</sup> treated 145 patients with EAP, resulting in a cumulative response rate of 57%. Analyzing response as a function of extent of disease, patients with locoregional tumor had a response rate of 73%, with a 29% complete remission rate, as opposed to those with metastatic disease who had a response rate of 49% with a complete remission rate of 8%. Similarly, the median survival time for patients with locally advanced disease was 17 months in comparison with 8.5 months for those with metastatic disease. In four subsequent phase II trials of EAP involving 173 evaluable patients, a cumulative response rate of 53% and a complete remission rate of 6% has been seen.<sup>286,287</sup> However, in each of the subsequent trials after the initial study reported by Preusser, a treatment-related death rate of 10% to 14% with EAP was noted.

In part because EAP caused severe toxicity in older patients, Wilke and colleagues,<sup>288</sup> devised a combination chemotherapy regimen of etoposide, leucovorin, and FU (ELF) for patients older than 65 years with advanced gastric cancer. The rationale for this combination was that 5-FU and etoposide are active agents in gastric cancer that are well tolerated and have no cumulative organ toxicity, the dose limiting toxicity being overlapping myelosuppression; etoposide and 5-FU are synergistic and are not cross-resistant; and leucovorin enhances the cytotoxicity of FU in other tumors. Fifty-one patients older than 65 years of age or with cardiac disease were treated. The overall response rate was 53%, including 12% complete remissions. The response rate in patients with locally advanced disease was 70% compared with 49% in patients with distant metastases. The median duration of response was 9.5 months. Twenty percent of patients experienced grade 3 or 4 myelosuppression; however, nonhematologic toxicity was generally mild. The authors recommended ELF as a suitable regimen for high-risk patients (advanced age or cardiac risk factors).

## Fluorouracil, Doxorubicin (Adriamycin), and Methotrexate

The concept of biochemical modulation of 5-FU involves the use of agents designed to increase the pool of phosphoribosylpyrophosphate in tumor cells, resulting in increased 5-FU ribonucleotide metabolites, thereby increasing the effectiveness of 5-FU-directed tumor kill. This approach led Klein<sup>289</sup> to study sequential high-dose methotrexate followed by 5-FU in combination with doxorubicin (Adriamycin) (the FAMTX regimen) in advanced gastric cancer. The interval between methotrexate and 5-FU is 1 hour in the original FAMTX regimen. Klein reported a response rate of 59% in 100 evaluable patients, with a complete remission rate of 12% and a treatment-related mortality rate of 3%. In a review of his experience,<sup>289</sup> Klein noted a 6% long-term (more than 5 years) survival rate for patients receiving FAMTX.

Kelsen and colleagues<sup>290</sup> reported the results of a randomized trial comparing EAP to FAMTX in advanced gastric cancer. The response rates were similar. Three patients (10%) had complete remission rates in the FAMTX arm; no complete remissions were seen with EAP. Although no significant differences were reported in the response rate, EAP was significantly more toxic than FAMTX for neutropenia, anemia, and thrombocytopenia. Most important, four treatment-related deaths (13%) were noted on the EAP arm as opposed to none on the FAMTX arm ( $P = .04$ ). In view of the significant toxicity difference, the study was closed. The median durations of survival of all patients was similar (FAMTX, 7 months; EAP, 6 months). The authors concluded that FAMTX was at least as active as EAP but was significantly less toxic.

The European Organization for Research and Treatment of Cancer published the results of a multicenter prospective randomized trial comparing FAMTX with FAM<sup>291</sup> (see Table 33.3-17). The response rate of 41% for FAMTX was significantly superior to the 9% response rate for FAM ( $P < .0001$ ). Five complete responders were reported in the FAMTX arm compared with none on the FAM regimen. Survival among FAMTX patients was also superior (42 weeks compared with 29 weeks for FAM;  $P = .004$ ). The toxic death rate of the two combinations was similar (FAMTX, 4%; FAM, 3%). At 1 year, 41% of FAMTX versus 22% of FAM patients were alive. None were surviving at the 2-year mark on FAM, whereas 9% of the patients survived on the FAMTX arm. Severe hematologic toxicity was seen in more patients on FAM than on the FAMTX regimen. As noted previously, in a randomized trial performed by Cunningham and colleagues,<sup>277</sup> ECF was superior to FAMTX in terms of response rate, quality of life, and survival.

The European Organization for Research and Treatment of Cancer has performed a randomized trial of FAMTX versus ELF versus cisplatin and 5-FU. In a preliminary result of this study, 274 eligible patients were randomized.<sup>291</sup> No significant difference was found in severe toxicity (World Health Organization scale 3 or 4+) between the three arms. The response rates in the subgroups of patients with measurable disease in the preliminary report also showed no significant difference. Median survival was 7 to 8 months. The analysis was preliminary because not all patients had been fully assessed.<sup>292</sup>

In summary, as is the case for adjuvant trials, few adequately powered, large-scale phase III studies have been performed comparing one regimen with another. From the point of view of median survival, little substantial difference exists between one regimen and another, particularly in those in which both arms include cisplatin. However, it is of note that 2-year survival rates of 10% to 15% have been reported in several series reporting longer-term data, indicating that at least some patients have substantial palliative benefit. Although some investigators have proposed that one regimen be considered the standard of care, as yet no convincing data shows that one cisplatin and FU-containing combination is markedly better than another.

The identification of several new classes of agents with substantial single-agent activity (the taxanes and irinotecan) and new modalities of treatment (including newer approaches, such as immunotherapy, angiogenesis blockade, monoclonal antibody chemotherapy combinations, and manipulation of molecular biologic targets) should be vigorously pursued. Their inclusion in multidrug combinations may lead to further improvements in palliation, and eventually to cure, when these agents are used in the multimodality setting. Several large-scale randomized trials are currently under way comparing, for example, docetaxel and cisplatin-containing treatment to "standard" cisplatin and FU or, alternatively, irinotecan and cisplatin-containing therapy to cisplatin and FU.

## PREDICTING RESPONSE

The development of techniques that will allow physicians to choose those individual chemotherapeutic agents that are most likely to work in the individual patient is a high priority. It is particularly important because currently available cytotoxic chemotherapy for gastric cancer has only modest to moderate effectiveness, with objective regressions in 25% to 40% of all patients treated, and toxicities can be substantial. Earlier *in vitro* assays have not proven to have adequate sensitivity; however, several studies suggest that molecular analysis of tumor tissue might be a more accurate measure to predict outcome. The hypothesis is that levels of expression of target molecules, or of molecules associated with the mechanism of action of an individual agent, are associated with response or resistance.

Several new techniques for molecular analysis are being studied to allow individualization of therapy. These include immunohistochemical stains for expression of the molecular marker of interest (such as TS) or use of reverse transcriptase-polymerase chain reaction technology to measure relative gene expression. In gastric cancer, a substantial amount of data involves the use of relative gene expression of messenger RNA. For example, in trials from the University of Southern California and Memorial Sloan-Kettering Cancer Center, studies have been performed in patients with locally advanced but not metastatic gastric cancer. Although response has been used in the outcome analysis in several of these trials, it should be recognized that response assessment in locoregional gastric cancer can be difficult; survival is a firmer end point. Lenz and colleagues<sup>293</sup> and Metzger et al.<sup>294</sup> from the same group reported an analysis of a subgroup of patients receiving neoadjuvant cisplatin and FU chemotherapy followed by resection and intraperitoneal FUDR chemotherapy. Response and survival were correlated with molecular markers in 38 evaluable patients. Those with low levels of relative TS and ERCC1 (excision repair cross complementing gene; a marker for cisplatin sensitivity) had a significantly longer median and long-term survival than did patients with high levels of expression. Fata and colleagues<sup>294a</sup> evaluated the predictive value of TS, thymidylate phosphorylase, dihydropyrimidine dehydrogenase, and ERCC1 in inoperable gastric cancer patients undergoing surgery, without pre- or postoperative chemotherapy. This study addressed the question as to whether levels of expression of a molecular marker were independent predictors of outcome, or whether levels of gene expression were only important in the context of chemotherapy. In a preliminary assessment, patients with low relative gene expression of TS, TP, or ERCC1 did not have an improved outcome (either disease-free or overall survival). They noted that surgery-only patients with high TS gene expression, a marker that would predict resistance to chemotherapy, had a better survival compared to patients with low TS. This finding was persistent even in a multivariate analysis adjusting for stage.

Conversely, patients receiving cisplatin and FU preoperative chemotherapy with low TS were more likely to have better outcome. Several other groups also have investigated the use of similar molecular markers. Boku and colleagues<sup>295</sup> used immunohistochemistry to measure TS, p53, vascular endothelial growth factor, and glutathione S-transferase. Thirty-nine patients in this study had unresectable disease and received cisplatin plus FU. Patients with immunohistochemistry negative for TS (indicating low expression) had a higher response rate and survived longer than patients with positive stains, as did those negative for p53, BCL2, and glutathione S-transferase. Conversely, patients with vascular endothelial growth factor–positive tumors had a higher response rate. A multivariate analysis indicated that a combination of favorable molecular phenotypes had a greater impact on survival than did performance status or other clinical parameters.

Resistance to chemotherapy has been reported by many investigators to be associated with mutations of the p53 oncogene. Several such studies have been performed in gastric cancer. Cascinu and colleagues<sup>296</sup> performed immunohistochemistry on pretreatment endoscopic biopsies in 30 patients with locally advanced but not metastatic disease. As is the case in other studies in this group of patients, assessing response can be difficult. With this caveat, 16 of 30 patients had high levels of p53 expression by immunohistochemistry. Ten of 12 responding patients had p53-negative tumors. These authors concluded that mutation of p53 oncogene confers resistance to chemotherapy. On the other hand, Ikeguchi et al.<sup>297</sup> found no relationship between p53 status and intraperitoneal chemotherapy, nor did Yeh and colleagues.<sup>298</sup> A definitive study in which adequate numbers of patients with advanced gastric cancer receive the same chemotherapy irrespective of their molecular marker profile and are followed prospectively has not yet been performed. Such studies have been proposed for other tumors (such as colorectal cancer). The identification of molecular markers measured by immunohistochemistry, by reverse transcriptase-polymerase chain reaction, or by other techniques that could predict outcome would be a substantial improvement in directing therapy.

## CHEMOTHERAPY VERSUS BEST SUPPORTIVE CARE

During the late 1980s and early 1990s, considerable debate occurred over whether chemotherapy for patients with advanced gastric cancer had any advantages over best supportive care. This issue is of importance, not only in addressing the options for standard care treatment for patients with advanced disease, but in the implication that effective systemic therapy given in the palliative setting may lead to an increase in cure rate for patients with localized, high-risk, potentially curable tumors. Four randomized trials have been reported in which patients were assigned to either chemotherapy and best supportive care or best supportive care alone. In all of these trials, the option for the initiation of chemotherapy at the time of symptomatic or objective progression was at the discretion of the treating physician. Although these studies have relatively small numbers of patients (recognizing the difficulty of performing such studies and that, in several cases, the study was stopped when benefit was seen in the chemotherapy-receiving arm), the data are fairly consistent. Patients randomized to receive best supportive care alone, even when allowed to receive chemotherapy at a later date, have a median survival of 3 to 5 months. Patients randomized to immediate chemotherapy had a median survival of 9 to 11 months. More impressive is 1- and 2-year survival when reported. As shown in [Table 33.3-18](#), the 1-year survival rate is 35% to 40% for patients receiving chemotherapy versus approximately 10% for those randomized to best supportive care. The 2-year survival rate is 6% to 10% for patients receiving chemotherapy versus 0% of patients with initial observation. These data strongly support the conclusion similar to that of other malignancies, such as colorectal and breast cancer, that systemic chemotherapy has a real although modest effect on survival in patients with advanced disease. Furthermore, the results support the use of systemic cytotoxic chemotherapy as part of multimodality therapy in patients with less-advanced but high-risk cancers. None of the regimens used in the best supportive care trials included cisplatin nor, of course, the more recently identified active agents paclitaxel, docetaxel, and irinotecan. As already discussed, however, reports on longer-term follow-up of randomized chemotherapy trials also show 5% to 15% of patients living for longer than 2 years.

Regimen	Number of Patients	Median Survival (mo)	Survival Rate (%)	
			1Y	2Y
FAMTX	30	10	40	6
BSC	10	3	10	0
FEMTX	17	12	—	—
BSC	19	3	—	—
EtopLF	10	10	—	—
BSC	8	4	—	—
ELF	52	10.2	34.6	9.6
BSC	51	5	7.8	0

A, doxorubicin (Adriamycin); BSC, best supportive care; E, epirubicin; etop, etoposide; F, fluorouracil; L, leucovorin; MTX, methotrexate. (Modified from Wis J. The treatment of advanced gastric cancer. *Semin Oncol* 1996;23:397, with permission.)

## SURGERY FOR PALLIATION

Because the survival for patients with advanced gastric cancer is so poor, any proposed operation should have a good chance of providing sustained symptomatic relief while minimizing the attendant morbidity and need for prolonged hospitalization. Ekbohm and Gleysteen<sup>299</sup> have reviewed the results of palliative resection versus intestinal bypass (gastrojejunostomy) in 75 patients with advanced gastric cancer. The most frequent symptoms for which patients underwent operation included pain, hemorrhage, nausea, dysphagia, or obstruction. Operative mortality was 25% for gastrojejunostomy, 20% for palliative partial or subtotal gastrectomy, and 27% for total or proximal palliative gastrectomy. The most common and often fatal complication was anastomotic leak. After gastrojejunostomy, 80% of patients had relief of symptoms for a mean of 5.9 months compared with palliative resection, which provided relief of symptoms in 88% of patients for a mean of 14.6 months. Although the duration of palliation was significantly longer after resection ( $P < .01$ ), the selection criteria for resection versus bypass were not controlled, and some bias against performing a palliative resection in high-risk patients with more advanced disease may have occurred. Meijer and colleagues<sup>300</sup> also have reported a retrospective analysis of 51 patients undergoing either palliative intestinal bypass or resection. In 20 of 26 patients (77%) undergoing resection, palliation was considered moderate to good with a mean survival of 9.5 months. After gastroenterostomy, some palliation was noted in 8 of 25 patients (30%), and survival was 4.2 months. Butler and colleagues<sup>167</sup> have presented the results of total gastrectomy for palliation in 27 patients with advanced gastric cancer. Operative mortality was only 4%, whereas morbidity occurred in 48% of patients. Median survival was 15 months, with a survival rate of 38% at 2 years. This substantial survival rate at 2 years reflects the fact that, although all patients were symptomatic before surgery, only one-half had stage IV disease. Patients with linitis plastica present a very difficult therapeutic challenge. Resection may provide palliation of symptoms; however, survival after total gastrectomy is exceedingly poor, ranging from 3 months to 1 year.<sup>301</sup>

Bozzetti and colleagues<sup>302</sup> have reviewed the outcomes of 246 patients with advanced gastric cancer who underwent simple exploratory laparotomy alone, gastrointestinal bypass, or palliative resection at the National Cancer Institute of Milan. When survival was compared in patients with similar type and extent of disease, a consistent trend was seen for improved median survival with palliative resection in patients with local spread (4.4 vs. 8 months) and distant spread of disease (3 vs. 8 months). Boddie et al.<sup>303</sup> has reported similar results in 45 patients undergoing palliative resection at the M. D. Anderson Cancer Center for advanced gastric cancer. Operative mortality for resection was 22%. In 21 patients who had undergone a palliative bypass procedure, survival was significantly shorter than for those undergoing resection ( $P < .01$ ).

In select patients with symptomatic advanced gastric cancer, resection of the primary disease appears to provide symptomatic relief with acceptable morbidity and mortality, even in the presence of macroscopic residual disease. The criteria for deciding which patients may benefit from palliative operation have not been established, and the data available represent retrospective analyses of patients selected for operation. The choice of procedure in these studies may have been influenced by differences in opinion regarding the value of palliative surgery in patients with such a grave prognosis.

## RADIATION FOR PALLIATION

To date, no studies have evaluated the use of radiation therapy in patients with locally recurrent or metastatic carcinoma of the stomach. Its use is likely to be limited to palliation of symptoms, such as bleeding or controlling pain secondary to local tumor infiltration. Although minimal data are available, radiation therapy seems to be fairly effective (from anecdotal experience) in controlling bleeding, as is true in other sites. This can often be accomplished at relatively low radiation doses. Pain from local tumor invasion can also be palliated, although the doses required are higher (4000 cGy). On rare occasions, a case may arise of a patient with a focal local recurrence without metastases who would be amenable to relatively high-dose radiation therapy to try to prolong survival or in whom radiation therapy would be given as an adjuvant to surgical resection. At present, however, no data support such an approach.

## INTRODUCTION

Cancer of the exocrine pancreas continues to be a major unsolved health problem, with approximately 28,200 deaths per year in the United States and 50,000 deaths per year in Europe (excluding the former USSR).<sup>1,2</sup> In the United States in the year 2000, pancreatic cancer is expected to be the fourth leading cause of cancer-related death for both men and women and to be responsible for close to 5% of all cancer-related deaths.<sup>1</sup> Because of difficulties in diagnosis, the aggressiveness of pancreatic cancers, and the lack of effective systemic therapies, generally fewer than 5% of patients with adenocarcinoma of the pancreas survive 5 years after diagnosis.<sup>3,4</sup> Thus, incidence rates and mortality rates are virtually identical.

## EPIDEMIOLOGY

In the United States, the incidence of pancreatic cancer steadily increased for several decades but has leveled off since the late 1970s, with 28,300 new cases (2% of all cancer diagnoses) estimated in the year 2000.<sup>1</sup> Studies evaluating this trend suggest that the decreased incidence is due to a steady decline in the rate for white men, which peaked during the period of 1970 to 1974. By contrast, rates for white women, African American men, and African American women have not fallen and may have increased slightly.<sup>4</sup> In Japan, the incidence of pancreatic cancer increased sharply from 1.8 per 100,000 in 1960 to 5.3 per 100,000 in 1985.<sup>5,6</sup>

Overall, pancreatic cancer incidence and mortality statistics are similar for the United States and Western Europe. Between 1989 and 1991, mortality rates for pancreatic cancer in the United States were 10 per 100,000 for men and 7.2 per 100,000 for women.<sup>7</sup> Although the overall mortality rates in industrialized societies appear similar, geographically and ethnically dissimilar populations show considerable differences in mortality rates from pancreatic cancer. In Europe, for the time period of 1985 to 1989, mortality rates ranged from 5.3 per 100,000 in Spain to 10.3 per 100,000 in Hungary and Czechoslovakia.<sup>2</sup> Spain, Portugal, and Greece recorded an extremely low mortality rate of 3 per 100,000 among men.<sup>2</sup> The reasons for these regional differences and the changing incidence of pancreatic cancer remain obscure, but they might possibly be related to the trend of a declining smoking rate.<sup>8</sup>

## ETIOLOGIC FACTORS

Investigations have identified a number of factors that may contribute to the pathogenesis of pancreatic cancer. Current estimates suggest that approximately 30% of pancreatic cancer cases are due to cigarette smoking.<sup>9,10</sup> Studies that have explored the dose-response relationship have shown that the risk of pancreatic cancer increases as the amount and duration of smoking increase and that long-term smoking cessation (more than 10 years) reduces risk by approximately 30% relative to the risk of current smokers.<sup>9,11</sup> Application of molecular epidemiologic techniques that are being developed for lung cancer may provide greater specificity in linking tobacco exposure with the development of pancreatic cancer<sup>12,13</sup> and may facilitate the study of chemopreventive strategies.<sup>14</sup>

Data regarding the effect of coffee consumption and excessive alcohol consumption appear to be conflicting. For each of these factors, a few studies have suggested an increased risk of pancreatic cancer,<sup>11,15,16,17</sup> and 18 but the majority of studies conducted during the 1990s have failed to consistently demonstrate such a risk.<sup>11,17,19,20,21,22</sup> and 23 In some cases, significant methodologic problems may have confounded interpretation of the data, leading to erroneous conclusions.<sup>20</sup>

Diabetes mellitus has been long associated with pancreatic cancer; however, not all studies have supported such a relationship,<sup>24</sup> and the precise mechanism has yet to be defined. Diabetes mellitus has been implicated as both an early manifestation of pancreatic carcinoma<sup>25,26,27</sup> and 28 and a predisposing factor.<sup>22,29,30,31</sup> and 32 It is known that pancreatic cancer can induce peripheral insulin resistance,<sup>33,34</sup> and 35 and the argument that long-standing diabetes mellitus is also a risk factor for pancreatic cancer is supported by a cohort study showing that, after an initial hospitalization for diabetes, patients had an increased risk of developing pancreatic cancer and that this risk persisted for more than a decade.<sup>36</sup> However, the increased risk was limited to patients with non-insulin-dependent diabetes or patients whose diabetes was diagnosed after 40 years of age.<sup>36</sup> Metaanalysis of studies published between 1975 and 1994 showed that pancreatic cancer occurred with increased frequency in patients with long-standing diabetes.<sup>36</sup> The mechanisms underlying the association between pancreatic cancer and diabetes are obscure; however, the diabetic state seems to enhance the growth of pancreatic cancer in animal models.<sup>37</sup>

A series of reports have validated the epidemiologic association between chronic pancreatitis and pancreatic cancer,<sup>38,39,40,41</sup> and 42 but the magnitude of the risk of pancreatic cancer attributable to pancreatitis remains controversial.<sup>43</sup> Pathologic and molecular biologic studies have begun to explore the relationship between both

hereditary and nonhereditary chronic pancreatitis and pancreatic cancer.<sup>44</sup> Pathologic examination of lesions along the pancreatic duct has revealed a spectrum of mucous cell hyperplasias (papillary and nonpapillary hyperplastic lesions and atypical hyperplastic lesions currently termed *pancreatic intraepithelial neoplasia*) in patients with chronic pancreatitis and patients with pancreatic cancer.<sup>45</sup> The identification of mutations in the *K-ras* oncogene, a mutation found almost universally in established pancreatic cancers, in regions of mucous cell hyperplasia in patients with chronic pancreatitis provided the first molecular link between chronic inflammation and the initiation of multistep pancreatic carcinogenesis.<sup>46</sup> Calculation of a general estimate of population-attributable risk has suggested that chronic pancreatitis may explain as many as 5% of pancreatic cancer cases.<sup>47</sup>

The emergence of the importance of inherited genetic syndromes in gastrointestinal tract neoplasia has led to closer investigation of the potential role for heritable factors in pancreatic cancer. Considerable progress in our understanding of familial pancreatic cancer has been made since the late 1990s.<sup>48,49</sup> Currently, it is estimated that possibly as many as 5% to 8% of pancreatic cancer cases are associated with a familial predisposition.<sup>32,50</sup> Several hereditary disorders predispose persons to both endocrine and exocrine pancreatic cancer. These include the multiple endocrine neoplasia type 1 syndrome,<sup>51,52</sup> hereditary pancreatitis,<sup>44,53</sup> hereditary nonpolyposis colon cancer/Lynch syndrome II,<sup>54</sup> von Hippel-Lindau syndrome,<sup>55</sup> ataxia-telangiectasia,<sup>56</sup> and the familial atypical multiple mole melanoma syndrome.<sup>57,58</sup> and<sup>59</sup> In addition, case reports and formal epidemiologic studies have suggested the possibility of familial aggregations of pancreatic cancer outside the context of these rare familial syndromes.<sup>60,61</sup> and<sup>62</sup>

Through the establishment of large familial pancreatic cancer registries,<sup>48,53</sup> progress has been made in understanding the specific genetic alterations responsible for the familial aggregation of pancreatic cancer in some families. Genetic testing of kindreds with increased rates of pancreatic cancer has revealed germline mutations in genes known to be important in pancreatic carcinogenesis: *p16 (CDKN2)*,<sup>56,58</sup> *BRCA2*,<sup>63</sup> and *STK11/LKB1*,<sup>64</sup> but not *Smad4*.<sup>65</sup> Evaluation of approximately 30 extended families with presumed familial pancreatic cancer has suggested that transmission is consistent with an autosomal dominant pattern<sup>66</sup> and that even second-degree relatives of patients from these families are at increased risk.<sup>48</sup> Interestingly, unlike for other familial gastrointestinal cancers (e.g., colon cancer in familial polyposis coli), the age at onset, tumor histopathology, and overall survival for patients with familial pancreatic cancer are often the same as those for patients with sporadic cancers.<sup>49,54,63</sup>

Presently, the management of individuals documented to be at increased risk of pancreatic cancer is extremely controversial.<sup>67</sup> Options range from close observation to aggressive surgical intervention<sup>68</sup>; the optimal surveillance and surgical strategies have yet to be defined. However, continued study of patients with familial pancreatic cancer and their families is expected to provide insight into the critical molecular genetic abnormalities leading to familial pancreatic cancer. These genetic abnormalities may then provide new perspectives on the process of pancreatic carcinogenesis for patients with sporadic pancreatic cancer and provide opportunities for early detection and chemoprevention.<sup>69,70</sup>

## PATHOLOGY AND MOLECULAR PATHOGENESIS

### CELLULAR PATHOLOGY

The normal pancreatic architecture is characteristic of a secretory gland: A background of acinar cells accounts for approximately 80% of the cell number and volume of the gland; 1% to 2% is clusters of islet cells; 10% to 15% is single-layered, cuboidal ductal cells; and a sparse interlacing network of blood vessels, lymphatics, nerves, and collagenous stroma is present. This architecture is markedly altered in carcinoma, in which the predominant histologic feature is a dense collagenous stroma with atrophic acini, remarkably preserved islet cell clusters, and a slight to moderate increase in the number of ducts, both of normal appearance and cancerous. The diagnosis of ductal adenocarcinoma rests on the identification of mitoses; nuclear and cellular pleomorphism; discontinuity of ductal epithelium; and evidence of perineural, vascular, or lymphatic invasion.<sup>71</sup>

Ninety-five percent of malignant neoplasms of pancreatic origin arise from the exocrine portion of the gland and have light-microscopic features consistent with those of adenocarcinomas.<sup>71</sup> Much more infrequent are tumors arising from the islets of Langerhans' (endocrine) cells of the pancreas. Primary nonepithelial tumors of the pancreas (e.g., lymphomas or sarcomas) are extremely rare. A current view of the histologic classification of exocrine pancreatic neoplasms is presented in [Table 33.4-1](#).

<b>Malignant</b>
Ductal adenocarcinoma*
Mucinous cystadenocarcinoma
Acinar carcinoma
Unclassified large cell carcinoma
Small cell carcinoma
Pancreatoblastoma
<b>Uncertain malignant potential</b>
Intraductal papillary mucinous tumor
Mucinous cystadenoma
Papillary cystic neoplasm
<b>Benign</b>
Serous cystadenoma*

\*Variants include adenosquamous carcinoma, pleomorphic giant cell carcinoma, mucinous adenocarcinoma, and oncoclast-like giant cell carcinoma.  
\*May exhibit uncontrolled local tumor growth, causing the designation design to be questioned.

**TABLE 33.4-1.** Histologic Classification of Epithelial Tumors of the Exocrine Pancreas

Extensive "preneoplastic" lesions have been demonstrated in the pancreatic ducts adjacent to frankly invasive cancers with a higher frequency than was seen in a matched control population without pancreatic cancer.<sup>72</sup> Furthermore, clinical studies have documented progression of lesions from mild dysplasia to high-grade dysplasia<sup>73</sup> and from high-grade dysplasia to infiltrating ductal adenocarcinoma.<sup>74</sup> Finally, the identification of mutated *K-ras*, a genetic change found in the majority of patients with invasive pancreatic cancer,<sup>75,76</sup> and<sup>77</sup> in papillary and dysplastic papillary ductal lesions has provided further evidence that these hyperproliferative states are the precursors of infiltrative ductal carcinoma. Current evidence supports the general hypothesis that progression of the ductal lesions is characterized by the accumulation of additional genetic and biochemical changes. For example, preneoplastic ductal lesions can be shown to harbor mutations in genes that are typically altered in invasive pancreatic carcinoma, including *P16* and *P53*.<sup>78,79</sup> and<sup>80</sup> Activated telomerases can also be found.<sup>81,82</sup> Interestingly, other malignancies that can masquerade as pancreatic cancer, such as carcinoma of the ampulla of Vater, only infrequently contain a mutated *K-ras* oncogene.<sup>83</sup> At present, however, accurate identification of high-risk patient subsets who are destined to develop invasive cancer and thus are candidates for intervention is not possible.

### ONCOGENES AND TUMOR SUPPRESSOR GENES

Studies using archival human pancreatic tumor tissue and human pancreatic cancer cell lines have identified a number of characteristic genetic abnormalities associated with pancreatic cancer. As described previously, these studies have revealed specific point mutations at codon 12 of the *K-ras* oncogene in 75% to 90% of pancreatic adenocarcinoma specimens.<sup>75,76</sup> and<sup>77</sup> The *ras* protein is an important signal-transduction mediator for receptor protein tyrosine kinases. Signaling is initiated by the recruitment of guanine nucleotide exchange proteins that promote hydrolysis of guanosine triphosphate (GTP) to guanosine diphosphate (GDP). *Ras* bound to GTP is maintained in an active configuration that triggers other enzymatic second messengers, such as the *raf*, phosphatidylinositol, and protein kinase C pathways, which leads to nuclear signals resulting in cellular division and proliferation. The mutated *ras* oncogene is not able to convert GTP to inactive GDP, resulting in a constitutively active *ras* protein product, unregulated cellular proliferation signals, and susceptibility to transformation.<sup>84</sup> The *K-ras* mutation in pancreatic carcinogenesis is proposed to be an early event in pancreatic tumor progression.<sup>85</sup>

Data suggest that up-regulation of vascular endothelial growth factor (VEGF) occurs as a result of the activation of mutations of the *ras* oncogene.<sup>86</sup> VEGF is an endothelial cell-specific mitogen that promotes angiogenesis in solid tumors. Angiogenesis is essential for tumors to grow larger than 1 mm<sup>3</sup>, and angiogenesis must occur for metastasis formation and growth. Overexpression of VEGF has been demonstrated in several tumors, and VEGF messenger RNA has been shown to be overexpressed in a Syrian hamster pancreatic cancer cell line.<sup>87,88</sup> Therefore, *ras* mutations may contribute to pancreatic carcinogenesis not only by promoting tumor cell proliferation but also indirectly by stimulating tumor angiogenesis. The available data also suggest that *ras* and *src* oncogenes mediate their effects on gene

expression partly by activating the transcription factors AP-1 and Rel/NF- $\kappa$ B. These transcription factors have been shown to up-regulate a number of genes whose protein products play important roles in tumor invasion, angiogenesis, and metastasis<sup>88,90</sup> and are relevant to pancreatic cancer carcinogenesis.<sup>91,92</sup> Other proangiogenic factors, such as interleukin-8, are also up-regulated by AP-1 and NF- $\kappa$ B.<sup>93,94</sup> In addition, the tumor suppressor genes *p53* and *p16* have been shown to regulate the expression of VEGF.<sup>95,96</sup> Numerous agents that inhibit angiogenesis are currently undergoing testing in phase I and II clinical trials in patients with various types of cancer in the United States.<sup>97,98</sup>

Additional genetic alterations in human pancreatic cancer have been described, many by Kern and colleagues<sup>99,100,101,102</sup> and<sup>103</sup> at Johns Hopkins University. Their studies have been facilitated by xenograft enrichment of human tumors obtained at the time of surgical resection.<sup>99</sup> Pieces of the fresh human tumors are implanted subcutaneously in athymic nude mice, and the resulting tumors are harvested when they have grown to 1 cm in diameter. This allows the neoplastic cells to expand while preventing similar expansion of contaminating stromal cells. Subsequent molecular studies can then be performed on a population of pure tumor cells. Using this technology, three chromosomal loci with homozygous deletions have been identified in pancreatic ductal carcinomas. They are appropriately termed *DPC* (deleted in pancreatic cancer) 1/2, 3, and 4. *DPC1/2* is located on chromosome 13q12 (the region of the *BRCA2* gene),<sup>100</sup> *DPC3* (*p16/MTS-1*) on chromosome 9q21,<sup>101</sup> and *DPC4* on chromosome 18q21.1.<sup>102,103</sup> *DPC4* (*Smad4*), the most recently discovered tumor suppressor gene, is an important component of the transforming growth factor- $\beta$  signaling pathway that normally down-regulates the growth of epithelial cells, stimulates differentiation, and promotes apoptosis.<sup>104,105</sup> Loss of this important growth regulatory pathway contributes to unregulated cell growth.<sup>106,107</sup> *DPC4* was found to be homozygously deleted in 30% of pancreatic carcinomas and inactivated through loss of heterozygosity and intragenic mutation in another 20% of the cases studied.<sup>108</sup>

The p16 protein belongs to a class of cyclin-dependent kinase (CDK)-inhibitory proteins (including p21/WAF1/Cip1) and inhibits the cyclin D1/CDK-4 complex that normally acts to phosphorylate the retinoblastoma (Rb) protein. Inactivation of *p16* leads to hyperphosphorylated Rb, loss of cell-cycle control, and unregulated cell growth. Allelic deletions involving *p16* have been found in 85% of human pancreatic tumor xenografts.<sup>101</sup> The second p16 allele is inactivated by three mechanisms: point mutations in 40% of cases,<sup>101,109</sup> deletion of the second allele in 40%,<sup>110</sup> and promoter silencing through hypermethylation of the p16 promoter in 15%.<sup>111</sup> Interestingly, *p16* mutations also have been detected in 30% to 50% of melanoma-prone kindreds. A report of 19 families with a history of melanoma in at least two first-degree relatives found pancreatic cancer only in families with germline *p16* mutations.<sup>58</sup> Patients with malignant melanoma in the cancer registries of the Surveillance, Epidemiology, and End Results program were followed to determine the incidence of pancreatic cancer in this cohort. Nearly twice as many pancreatic cancers as expected were found in patients diagnosed with malignant melanoma before age 50, and the pancreatic cancer incidence was more than twice that expected in female melanoma patients younger than 50 years.<sup>112</sup>

The tumor suppressor gene *p53* is critical to normal cellular function, and its amino acid sequence is highly conserved among many species. After DNA damage, p53 protein levels increase because of posttranslational changes in protein stability. The normal p53 response to DNA damage leads to both cell-cycle arrest and apoptosis. The *p53* gene is the most commonly mutated gene in human cancer. Seventy percent of pancreatic adenocarcinomas have loss of *p53* function.<sup>56,108</sup> Inactivation of *p53* function occurs through loss of one p53 allele and mutational inactivation of the other. Mutations in the *p53* sequence are more frequently seen in poorly differentiated tumors, and patients whose tumors have a *p53* intragenic frameshift deletion experience a significantly reduced disease-free survival (compared to those with other mutations or wild-type *p53*).<sup>113</sup> However, this type of relationship has not been documented in all studies.<sup>114</sup>

Based on the frequency with which mutations in *K-ras*, *p53*, and *p16* are found, a model of pancreatic carcinogenesis has been suggested whereby the malignant clone evolves from cells driven by a dominant oncogene (*K-ras*) with subsequent deregulation of cell growth precipitated by abnormal cell-cycle control resulting from mutations in *p53*, *p16*, or both.<sup>115,116</sup>

Exactly how the increasingly complex molecular alterations described thus far in human pancreatic cancer interact during pancreatic carcinogenesis is still unclear. However, *in vitro* studies designed to correct these alterations may lead to novel treatment strategies and improve our understanding of the relative roles of these changes in pancreatic cancer biology.

## CLINICAL SIGNS AND SYMPTOMS

The lack of obvious clinical signs and symptoms delays diagnosis in most patients with pancreatic cancer. Jaundice, due to extrahepatic biliary obstruction, is present in approximately 50% of patients at diagnosis and is associated with a less advanced stage of disease than are other signs or symptoms.<sup>117</sup> Small tumors of the pancreatic head may obstruct the intrapancreatic portion of the bile duct and cause the patient to seek medical attention when the tumor is still localized and potentially resectable. In the absence of extrahepatic biliary obstruction, few patients present with potentially resectable disease.

The pain typical of locally advanced pancreatic cancer is a dull, fairly constant pain of visceral origin localized to the region of the middle and upper back. The pain is due to tumor invasion of the celiac and mesenteric plexus. Vague, intermittent epigastric pain occurs in some patients; its etiology is less clear. Fatigue, weight loss, and anorexia are common, even in the absence of mechanical gastric outlet obstruction. Pancreatic exocrine insufficiency due to obstruction of the pancreatic duct may result in malabsorption and steatorrhea. Although malabsorption and mild changes in stool frequency are common, diarrhea occurs infrequently.

Glucose intolerance is present in the majority of patients with pancreatic cancer.<sup>118,119</sup> and<sup>120</sup> Although the exact mechanism of hyperglycemia remains unclear, both altered  $\beta$ -cell function and impaired tissue insulin sensitivity are present.<sup>118,121</sup> The importance of islet cell function to the development of exocrine cancer is suggested by the work of Bell and Stayer,<sup>122</sup> who demonstrated that pretreatment of hamsters with streptozocin and the resulting destruction of islet cells prevented the induction of pancreatic cancer in these animals by the carcinogen N-nitrosobis-(2-oxopropyl) amine. This work was substantiated by studies in Chinese hamsters, which demonstrated that only genetically diabetic animals did not develop cancers in response to this carcinogen.<sup>123</sup>

In the absence of jaundice, patient complaints are nonspecific, as are clinical signs on physical examination. However, important staging information with direct implications for therapy can be obtained from the physical examination. This information includes performance status, cardiopulmonary function, and the presence or absence of left supraclavicular adenopathy and ascites.

## NATURAL HISTORY AND PATTERNS OF TREATMENT FAILURE

Rational anticancer therapy for solid malignancies is based on accurate knowledge of the natural history and patterns of treatment failure for each tumor type. Pancreatic cancer spreads early to regional lymph nodes, and subclinical liver metastases are present in the majority of patients at the time of diagnosis, even when findings from imaging studies are normal. Patient survival depends on the extent of disease and performance status at diagnosis.<sup>124</sup> The extent of disease is best categorized as resectable, locally advanced, or metastatic. Patients who undergo surgical resection for localized nonmetastatic adenocarcinoma of the pancreatic head have a long-term survival rate of approximately 20% and a median survival of 13 to 20 months (Table 33.4-2).<sup>125,126,127,128,129,130,131,132,133,134,135,136,137,138</sup> and<sup>139</sup> As is discussed later (see [Treatment of Potentially Resectable Disease](#)), survival is clearly maximized by combining surgery with either preoperative or postoperative 5-fluorouracil (5-FU)-based chemotherapy and radiation therapy (chemoradiation). However, disease recurrence after a potentially curative pancreaticoduodenectomy remains common, as illustrated in Table 33.4-3.<sup>133,134</sup> and<sup>135,137,140,141,142,143,144,145,146,147,148</sup> and<sup>149</sup> Local recurrence occurs in up to 86% of patients who undergo surgery alone; local-regional tumor control is maximized with combined-modality therapy in the form of chemoradiation and surgery.<sup>124</sup> With improved local-regional disease control, liver metastases become the dominant form of tumor recurrence and occur in 25% to 53% of patients after potentially curative combined-modality treatment.<sup>124</sup>

<sup>b</sup>Survival adjacent to resective resection therapy.  
 Mean.

Standardized criteria also are needed for the pathologic analysis of pancreaticoduodenectomy specimens to allow accurate interpretation of reported survival statistics. Retrospective pathologic analysis of archival material does not allow accurate assessment of margins of resection or number of lymph nodes retrieved. However, these are the most accurate predictors of outcome. In studies by Yeo et al.,<sup>135,138</sup> positive resection margin status, lymph node metastases, poorly differentiated tumor histology, and tumor size of 3 cm or greater were the tumor characteristics that most strongly predicted disease recurrence and short survival duration. To determine which patient subsets may benefit from the most aggressive treatment strategies, accurate pathologic staging and histologic assessment of response are mandatory.

At the University of Texas M. D. Anderson Cancer Center, the surgeon and pathologist evaluate each specimen first by frozen-section examination of the common bile duct transection margin and the pancreatic transection margin.<sup>156</sup> The retroperitoneal margin, defined as the soft tissue margin directly adjacent to the proximal 3 to 4 cm of the superior mesenteric artery (SMA),<sup>157</sup> is evaluated by permanent-section examination. This can be done either by taking a 2- to 3-mm full-face (*en face*) section of the margin or by inking the margin and sectioning the tumor perpendicular to the margin. The retroperitoneal margin must be evaluated or accurately inked at the time of tumor resection by the pathologist and surgeon; identification of the retroperitoneal margin is not possible later. A positive bile duct or pancreatic transection margin is treated with re-resection; however, this is not possible in the retroperitoneum, where the aorta and SMA origin limit the extent of surgical resection.

Samples of multiple areas of each tumor, including the interface between the tumor and adjacent uninvolved tissue, are submitted for paraffin-embedded histologic examination (five to ten blocks). Sections 4- $\mu$ m thick are cut and stained with hematoxylin and eosin. Final pathologic evaluation of permanent sections includes a description of tumor histology and differentiation; gross and microscopic evaluation of the tissue of origin (pancreas, bile duct, ampulla of Vater, or duodenum); and assessments of maximum transverse tumor diameter, lymph node status, and the presence or absence of perineural, lymphatic, and vascular invasion. When segmental resection of the SMV is required, the area of presumed tumor invasion of the vein wall is serially sectioned and examined in an attempt to discriminate benign fibrous attachment from direct tumor invasion. In patients who received preoperative chemoradiation, the grade of treatment effect is assessed on permanent sections using the grading schema developed by Cleary and reported by Evans et al.<sup>158</sup>

The method for classifying subsets of regional lymph nodes in pancreaticoduodenectomy specimens<sup>156</sup> is based on the work of Cubilla et al.<sup>159</sup> The soft fibrofatty tissue containing regional lymph nodes is divided into six regions as outlined on an anatomic pathology dissection board.<sup>156</sup> If lymph nodes are not identified, fat or other potentially neoplastic tissue is submitted for microscopic examination. Staley and colleagues<sup>156</sup> have demonstrated that the number of lymph nodes identified in the surgical specimen is increased by the use of a standardized system of specimen analysis. The dissection board used at our institution provides a simple means of improving lymph node identification and documenting the location of histologically confirmed lymph node metastases.<sup>156</sup> The Japanese staging system involves extremely detailed analysis of margins and lymph node groups but is not a practical system for widespread application.<sup>160</sup> As the use of multimodality treatment strategies for pancreatic cancer becomes more common, it will be even more important to standardize pathologic assessment of tumor specimens.

Maintaining an active pancreatic tumor banking program is critical to the ongoing success of translational research programs. Only through the coordinated efforts of such interdisciplinary programs will new treatments advance from the laboratory to clinical practice. Pathologists should routinely bank tumors for collaborative research efforts. At the M. D. Anderson Cancer Center, small sections of normal pancreas (when possible) and tumor are collected immediately for RNA extraction, and additional samples are snap frozen in liquid nitrogen and stored at  $-80^{\circ}\text{C}$ . A representative section of tumor and normal tissue is routinely fixed in 70% ethyl alcohol for paraffin block processing, and a hematoxylin and eosin–stained slide is made.

## PRETREATMENT DIAGNOSTIC STUDIES

### TUMORS OF THE PANCREATIC HEAD AND PERIAMPULLARY REGION

Few anatomic regions in the human body cause greater confusion and controversy regarding appropriate diagnostic evaluation and treatment than does the periampullary region. The reasons for this are unclear because the differential diagnosis of extrahepatic biliary obstruction is limited to a malignant neoplasm (of the pancreas, bile duct, ampulla of Vater, or duodenum), a benign stricture (usually due to pancreatitis), and choledocholithiasis. Benign tumors of the periampullary region are exceedingly rare and therefore need not be considered in this differential diagnosis. Unlike for tumors in other parts of the gastrointestinal tract, the diagnostic algorithm cannot be separated from the treatment plan—diagnosis and treatment represent a continuum. Patients often receive diagnostic studies and treatment based more on established lines of physician referral than on sound knowledge of the natural history and current therapies for periampullary cancer. This fact is largely responsible for the variability in diagnostic and treatment recommendations: Typically, surgeons favor surgery, gastroenterologists favor endoscopically placed stents, and radiologists favor transhepatic stents.

#### General Principles

The recommended diagnostic evaluation for a patient with extrahepatic biliary obstruction and presumed cancer of the head of the pancreas is based on the following three principles.

**LAPAROTOMY SHOULD BE THERAPEUTIC, NOT DIAGNOSTIC.** If the primary tumor cannot be resected completely, surgery (pancreaticoduodenectomy) for pancreatic cancer offers no survival advantage. However, only 30% to 50% of patients who undergo operation with curative intent have their tumors successfully removed; the remaining patients are found to have unsuspected liver or peritoneal metastases or local tumor extension to the mesenteric vessels.<sup>128,161,162</sup> Therefore, the majority of patients who undergo surgical exploration for presumed cancer of the pancreatic head receive no survival benefit; however, the laparotomy results in a perioperative morbidity rate of 20% to 30%, a mean hospital stay of 1 to 2 weeks, and a median survival after surgery of only 6 months.<sup>161,163,164</sup> Furthermore, in patients whose tumors are resected with positive margins ([Table 33.4-6](#)),<sup>129,131,133,134</sup> and <sup>135,146,165,166,167</sup> and <sup>168</sup> the survival duration is less than 1 year and is no different from the survival duration achieved with palliative chemotherapy and irradiation in patients who have locally advanced, unresectable disease.<sup>150,153</sup> Therefore, in contrast to the case for selected patients with colorectal or gastric cancer, no data support palliative (positive-margin) resection for adenocarcinoma of the pancreas.

**TABLE 33.4-6.** Median Survival for Patients Who Underwent Surgical Resection for Adenocarcinoma of the Pancreas and Were Found to Have a Positive Margin of Resection

**RESECTABILITY SHOULD BE DETERMINED PREOPERATIVELY.** Accurate preoperative assessment of resectability increases resectability rates and minimizes positive-margin resections. A common misconception in pancreatic tumor surgery is that resectability is determined best at laparotomy. In fact, however, resectability is most accurately determined preoperatively by imaging studies, not at the time of “exploratory” laparotomy.<sup>124,139,157,169</sup> Surgeons declare a tumor to be unresectable at the time of laparotomy when unsuspected liver metastases, peritoneal implants or, most commonly, locally advanced disease is found. The term *locally advanced* is often poorly defined, leaving the patient, the medical oncologist, and the radiation oncologist without a clear understanding of why the primary tumor was not resected.<sup>170</sup> At the time of surgical exploration for pancreatic head cancer, a Kocher maneuver (mobilization of the pancreatic head and duodenum from their retroperitoneal attachments) is the first procedure performed to assess the relationship of the tumor to the SMA by palpation. However, the presumed accuracy of this

maneuver to assess SMA involvement evolved before the development of contrast-enhanced CT, and no anatomic basis exists for the maneuver's use as a determinant of resectability. Direct intraoperative assessment of the extent of retroperitoneal tumor growth in relation to the SMA origin is not completed until the final step in tumor resection, after gastric and pancreatic transection, when the surgeon is committed to resection even if all of the tumor cannot be safely removed.

Data from the M. D. Anderson Cancer Center have demonstrated improved rates of resectability and low rates of margin positivity when high-quality CT is combined with the use of objective preoperative criteria for resectability.<sup>139,149,157</sup> The CT criteria for resectability are (1) the absence of extrapancreatic disease, (2) a patent superior mesenteric–portal vein (SMPV) confluence (assuming the technical ability to resect isolated involvement of the SMV or SMPV confluence), and (3) no direct tumor extension to the celiac axis or SMA. Patients whose tumors are deemed unresectable by these radiologic criteria are not considered candidates for a potentially curative resection.

Fuhrman and colleagues<sup>157</sup> studied 145 consecutive patients referred for pancreaticoduodenectomy because of a presumed or biopsy-proven periampullary cancer. Thin-section, contrast-enhanced CT was performed on all patients, and only 42 patients fulfilled the criteria for resectability. Thirty-seven of the 42 patients were able to undergo pancreaticoduodenectomy, for a resectability rate of 88%. Final pathologic evaluation of the retroperitoneal margin was used to confirm the accuracy of the CT criteria in predicting resectability. No patient had a grossly positive margin of resection, and only 5 of 25 patients with adenocarcinoma of pancreatic head origin were found to have a microscopic focus of adenocarcinoma at the retroperitoneal margin. This was despite the fact that many patients had undergone a previous nontherapeutic laparotomy before referral and that nine patients required resection of the SMV or SMPV confluence. In contrast, the intraoperative use of the Kocher maneuver is much less effective in determining resectability. Robinson and colleagues<sup>170</sup> studied 29 patients who underwent a successful pancreaticoduodenectomy after a previous unsuccessful laparotomy during which the pancreatic tumor was judged to be unresectable. Incorrect assessment of resectability (at the time of the Kocher maneuver) was the reason why 17 of the 29 patients did not undergo resection at their first laparotomy. The data thus demonstrate that, unlike intraoperative palpation, contrast-enhanced CT can accurately assess the relationship of the tumor to the SMA and celiac axis; this tumor-vessel relationship should be the main focus of the staging (preoperative) radiologic evaluation.

**PALLIATIVE LAPAROTOMY SHOULD BE AVOIDED WHEN POSSIBLE.** In patients with locally advanced or metastatic pancreatic cancer, operation for palliation is rarely needed. Multiple studies have compared operative biliary decompression and endoscopic stent placement in patients with jaundice due to malignant obstruction of the intrapancreatic portion of the common bile duct.<sup>171,172 and 173</sup> The higher initial morbidity and mortality rates and longer hospital stay associated with operative biliary bypass are countered by the higher frequency of hospital readmission for stent occlusion and cholangitis with endoscopic stent placement. Physicians typically advocate either surgery or endoscopic stenting; however, a selective approach based on the patient's extent of disease and performance status is more appropriate. Patients with liver metastases or ascites have a median survival of less than 6 months, making endoscopic stent placement an obvious choice. Patients with locally advanced disease treated with chemoradiation have a median survival of 10 to 12 months, with 20% surviving 2 years.<sup>152,153</sup> Patients with a superior performance status at diagnosis often survive longer, yet it is difficult in most patients to predict, at diagnosis, the tempo of disease progression. Clearly, one would like to avoid operation (with its morbidity and often lengthy recovery period) in patients with rapidly progressive disease. Similarly, one would like to have a durable means of biliary decompression in patients who are expected to survive longer than 6 to 9 months. Therefore, in patients with locally advanced nonmetastatic disease, it is reasonable to proceed with endoscopic stent placement and reserve operative biliary bypass for patients who survive long enough to experience stent occlusion. As is discussed later (see the section [Palliative Methods of Biliary and Gastric Decompression](#)), innovations in stent construction and the development of the expandable 10-mm metal stent have improved patency rates and resulted in more widespread application of stenting. Data from Raikar and colleagues<sup>174</sup> at the Mayo Clinic have demonstrated that endoscopic stenting for unresectable pancreatic cancer provides an equivalent duration of survival with a reduced cost and shorter hospital stay than operative biliary decompression, despite the need for subsequent stent exchanges.

### Computed Tomography and Endoscopic Retrograde Cholangiopancreatography

Improved CT technology has resulted in CT being the study of choice to determine the extent of disease and resectability status in patients with pancreatic cancer. Image resolution has improved considerably with the use of dynamic scanning, whereby intravenous contrast material is delivered by an automatic injector. The development of helical or spiral scanning has improved scan speed through continuous rotation of the x-ray tube around the gantry. This allows the entire pancreas to be imaged during the bolus phase of contrast enhancement. In addition, scan data can be processed to display images in three-dimensional and multiplanar formats. Helical CT performed with contrast enhancement and a thin-section technique can accurately assess the relationship of the low-density tumor to the celiac axis, SMA, and SMPV confluence. However, design of the scanning protocol and interpretation of scans must be done by experienced radiologists who understand the clinical importance of accurate staging and assessment of resectability in patients with pancreatic cancer. A completed CT scan report should contain the following information necessary to determine resectability: (1) the presence or absence of extrapancreatic metastatic disease, (2) the patency of the SMV and SMPV confluence and their relationship to the tumor, and (3) the relationship of the tumor to the celiac axis and SMA. If such information is not apparent from review of the scans or the report, the study should be repeated.

Our diagnostic schema, based on high-quality CT, appears in [Figure 33.4-1](#). A patient is deemed to have locally advanced, unresectable disease when clear evidence on the CT scans shows encasement of the SMA or celiac axis or occlusion of the SMPV confluence. The accuracy of CT in predicting unresectability is well established; current technology has eliminated the use of laparotomy to assess local tumor resectability.<sup>175,176 and 177</sup> If a low-density mass is not seen on CT scans, patients with extrahepatic biliary obstruction undergo diagnostic and therapeutic endoscopic retrograde cholangiopancreatography (ERCP). A malignant obstruction of the intrapancreatic portion of the common bile duct is characterized by the double-duct sign (proximal obstruction of the common bile and pancreatic ducts), which can often be accurately differentiated from choledocholithiasis and the long, smooth tapering bile duct stricture seen with chronic pancreatitis. To prevent cholangitis in patients who undergo diagnostic ERCP in the setting of extrahepatic biliary obstruction, endoscopic stents are routinely placed. Endoscopic stent placement also is done in patients with elevated bilirubin levels who are enrolled in preoperative chemoradiation protocols.

**FIGURE 33.4-1.** Management algorithm used at the M. D. Anderson Cancer Center for patients with suspected or biopsy-proven (from previous laparotomy before referral) adenocarcinoma of the pancreatic head. Accurate radiographic imaging allows patients to be staged as having resectable, locally advanced, or metastatic disease (see text). In patients with locally advanced or metastatic disease, biopsy confirmation of malignancy is mandatory before the initiation of specific anticancer therapy. Similarly, before initiation of neoadjuvant chemoradiation, cytologic confirmation of malignancy is required. The development of endoscopic ultrasonography (EUS)-guided fine-needle aspiration (FNA) has greatly simplified tissue acquisition in patients with localized, nonmetastatic pancreatic cancer. Angiography is performed selectively and is largely limited to patients who have undergone a previous biliary bypass involving the common bile duct to define hepatic arterial anatomy before reoperative pancreaticoduodenectomy. Laparoscopy should be considered before opening the abdomen in patients with potentially resectable disease. CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography.

### Endoscopic Ultrasonography and the Role for Pancreatic Biopsy

Accurate staging and biliary decompression are achieved with CT and ERCP in the majority of patients. Endoscopic ultrasonography (EUS)-guided fine-needle aspiration (FNA) is currently the procedure of choice for obtaining a cytologic diagnosis of malignancy. Pretreatment confirmation of malignancy is mandatory in all patients with locally advanced or metastatic disease before treatment with systemic therapy or external-beam radiation therapy (EBRT) and is being considered more commonly in patients with localized, potentially resectable disease because of the growing popularity of neoadjuvant therapy. Reports of EUS-guided FNA of the pancreas have demonstrated its accuracy and safety.<sup>178,179 and 180</sup> When biopsy material is interpreted by an experienced cytopathologist, false-positive results should

not occur. However, false-negative results may be common, resulting in negative predictive values as low as 40%.<sup>178</sup> In a patient who presents with extrahepatic biliary obstruction, has a malignant-appearing stricture of the intrapancreatic portion of the common bile duct, and has no history of recurrent pancreatitis or alcohol abuse, the absence of a mass on CT or EUS should not exclude the possibility of a carcinoma of the pancreas or bile duct. Similarly, negative results of EUS-guided FNA should not be interpreted as definitive proof that a malignancy does not exist. The results of EUS, with or without FNA, should be considered in the context of the clinical situation and as a complement to CT and ERCP findings.

Although pretreatment pancreatic biopsy is frequently used, physicians should be cautioned about the use of intraoperative pancreatic biopsy. In patients with resectable disease, there is no indication for routine intraoperative pancreatic biopsy, and as stated, the use of preoperative EUS-guided FNA should be limited to those patients receiving preoperative chemoradiation in whom cytologic confirmation of malignancy is needed. In contrast to the minimal risk of FNA, a risk of peritoneal dissemination of tumor cells resulting from surgical manipulation and intraoperative large-needle biopsy is supported by data from Staley et al.<sup>148</sup> Having undergone a previous laparotomy with tumor biopsy before definitive pancreaticoduodenectomy was the only factor associated with an increased risk of local-regional tumor recurrence in their study. Furthermore, intraoperative pancreatic biopsy has been associated with significant complications, such as pancreatitis, pancreatic fistula, and hemorrhage.<sup>170</sup> Nevertheless, because of the perceived risk of tumor dissemination due to preoperative FNA (a common concern when CT-guided FNA was popular), patients with presumed periampullary or pancreatic neoplasms are often brought to the operating room for planned intraoperative diagnostic biopsy before extirpative surgery. If the frozen-section findings are negative, many surgeons do not proceed with tumor resection because of concerns about performing such an extensive operation for benign disease.<sup>170,181</sup> In contrast, most experienced pancreatic surgeons believe that preoperative or intraoperative pancreatic biopsy is unnecessary, because a negative biopsy in the appropriate clinical setting is likely due to sampling error and therefore should not influence the decision to proceed with pancreaticoduodenectomy.<sup>182,183,184</sup> and <sup>185</sup> In the absence of choledocholithiasis found at ERCP or a history of pancreatitis, obstruction of the intrapancreatic portion of the common bile duct is almost always secondary to malignancy. If the decision to perform pancreaticoduodenectomy is based on high-quality images obtained by CT and ERCP and on an accurate clinical history, it is extremely unlikely that pancreaticoduodenectomy will be performed for benign disease. Furthermore, if the preoperative FNA result is benign or nondiagnostic, it is a mistake to assume that the patient does not have cancer or that a tissue diagnosis can be obtained at surgery before complete tumor resection. The diagnosis of a malignant obstruction of the intrapancreatic portion of the common bile duct should be accurately established by high-quality images obtained by CT, ERCP, and EUS; unnecessary and preventable patient morbidity occurs when laparotomy, pancreatic biopsy, or both are used as diagnostic studies because of the physician's failure to obtain state-of-the-art pretreatment imaging.

### **Laparoscopy and Angiography**

During the 1990s, laparoscopy has been used in patients with radiologic evidence of localized disease to detect extrapancreatic tumor not seen on CT scans, thereby allowing laparotomy to be limited to patients with localized disease. Studies by Cuscheri<sup>186</sup> and Warshaw et al.<sup>187</sup> have demonstrated the value of laparoscopy in detecting liver and peritoneal metastases not seen on CT scans. This favorable initial experience with laparoscopy in the identification of subclinical metastatic disease has led to a policy of routine laparoscopy in the staging of pancreatic adenocarcinoma in many centers.<sup>188,189</sup> and <sup>190</sup> However, it is important to remember that 70% to 80% of patients with pancreatic cancer present with locally advanced or metastatic disease; if laparoscopy is done early in the diagnostic sequence, it will have a very high yield of positive findings. If laparoscopy is performed after high-quality contrast-enhanced CT, the yield will likely be much lower. For example, Conlon and colleagues<sup>188</sup> evaluated 115 patients with periampullary tumors thought to be resectable based on CT. All patients underwent careful laparoscopic examination, including inspection of the lesser sac and biopsy of celiac, portal, or perigastric lymph nodes. Unresectable disease was found at laparoscopy in 41 (38%) of 108 evaluable patients. Sixty-one (91%) of the remaining 67 evaluable patients underwent pancreatic resection. Overall, however, only 53% of the initial 115 patients underwent resection. Although the authors did not describe the specific CT scanning protocol used to evaluate their patients, the low radiologic resectability rate in comparison to that achievable with high-quality CT suggests that optimal preoperative imaging was not used in all patients before laparoscopy.

Other, more recent investigations suggest that CT-occult extrapancreatic disease is uncommon, being found in only 4% to 15% of patients with tumors considered resectable after high-quality CT.<sup>139,191,192,193</sup> and <sup>194</sup> In a study by Rumstadt and colleagues<sup>192</sup> from the University of Heidelberg, 398 patients with pancreatic or periampullary cancer treated between 1990 and 1995 were evaluated preoperatively with high-quality CT, ERCP, and angiography. On the basis of this imaging evaluation, 194 patients were considered to have a high probability of resectability based on the absence of infiltration into adjacent tissue or distant metastases. Of these 194 patients, 172 (89%) underwent successful pancreaticoduodenectomy. Only 9 (5%) of the 194 patients thought to have resectable tumors were found to have occult metastatic disease at laparotomy. The authors concluded that only this small group of patients would have benefited from laparoscopy.

Contrast-enhanced helical CT allows accurate assessment of vital tumor-vessel relationships, remains the study of choice for detecting intraparenchymal liver metastases, and is less invasive and therefore less costly than laparoscopy (which still requires general anesthesia in most centers). CT remains the initial study of choice for determining whether a patient has potentially resectable, locally advanced, or metastatic disease; such clinical staging is critical for accurate treatment planning. Laparoscopy may prevent unnecessary laparotomy in approximately 10% of patients with presumed localized, potentially resectable pancreatic cancer. Laparoscopy before laparotomy (during a single anesthesia induction) is a reasonable approach in patients with biopsy-proven or suspected potentially resectable pancreatic cancer in whom a decision has been made to proceed with pancreaticoduodenectomy. However, data are not available to support the cost-effectiveness of laparoscopy's routine use as a staging procedure under a separate anesthesia induction before treatment planning. Furthermore, laparoscopy should not be used to compensate for inadequate CT imaging.

Contrast-enhanced helical CT also has reduced the role of preoperative angiography. Angiography does not provide the detail that is needed to determine the anatomic relationship between the tumor and the SMA that is provided by high-quality contrast-enhanced CT. Angiography allows contrast enhancement of only the vessel lumen; the surrounding tumor and soft tissue cannot be evaluated. We limit the use of angiography to reoperative cases, in which identification of aberrant hepatic arterial anatomy may prevent iatrogenic injury during portal dissection when there is extensive scarring from a previous biliary procedure.<sup>195</sup> Tyler and Evans<sup>181</sup> reported a replaced or accessory right hepatic artery arising from the SMA in 26% of patients who underwent reoperative pancreaticoduodenectomy. Preoperative knowledge of this common anatomic variant may help prevent operative misadventure in the reoperative setting.

### **TUMORS OF THE PANCREATIC BODY AND TAIL**

Because adenocarcinomas of the pancreatic body and tail do not cause obstruction of the intrapancreatic portion of the common bile duct, early diagnosis is rare; virtually all patients have locally advanced or metastatic disease at the time of diagnosis. CT provides an excellent assessment of the relationship of the tumor to the celiac axis and the SMA origin. Arterial encasement is present in the majority of patients, except for the anecdotal patient who presents with upper gastrointestinal hemorrhage resulting from sinistral hypertension secondary to splenic vein occlusion by a small tumor. In the rare patient who appears to have resectable disease on CT (no arterial encasement and no extrapancreatic disease), laparoscopy before laparotomy is a logical approach because peritoneal metastases are frequently found.<sup>196,197</sup> The scant data available regarding surgical resection confirm the short survival and poor prognosis in this subgroup of patients.<sup>198,199</sup> Furthermore, the high 30-day hospital mortality rate (43%; 6 of 14 patients with adenocarcinoma) reported in a study from the Department of Veterans Affairs hospitals suggests that many of the patients taken to surgery have advanced disease and a poor performance status.<sup>200</sup> Accurate preoperative imaging and a selective approach to surgical therapy minimizes treatment-related morbidity and mortality and maximizes the length and quality of patient survival.

### **TREATMENT OF POTENTIALLY RESECTABLE DISEASE**

#### **PREOPERATIVE AND POSTOPERATIVE CHEMORADIATION**

EBRT and concomitant 5-FU chemotherapy (chemoradiation) were shown in several studies to prolong survival in patients with locally advanced adenocarcinoma of the pancreas.<sup>150,151,201</sup> Those data were the foundation for a prospective randomized study of adjuvant chemoradiation (500 mg/m<sup>2</sup>/d of 5-FU for 6 days and 40 Gy of radiation) after pancreaticoduodenectomy conducted by the Gastrointestinal Tumor Study Group (GITSG); that trial also demonstrated a survival advantage from multimodality therapy compared with resection alone (20 months vs. 11 months).<sup>141,202</sup> However, owing to a prolonged recovery, 5 (24%) of the 21 patients in the adjuvant chemoradiation arm could not begin chemoradiation until more than 10 weeks after pancreaticoduodenectomy, despite the fact that the only patients likely to be considered for protocol entry were those who recovered rapidly from surgery and had a good performance status. Similar findings have been reported from the European Organization for Research and Treatment of Cancer (EORTC).<sup>203,204</sup> and <sup>205</sup> In 1987, the EORTC initiated trial 40891 comparing adjuvant 5-FU-based chemoradiation after pancreatectomy with surgery alone. Between 1987 and 1995, 218 patients were randomized to receive either chemoradiation (40 Gy in a split course and 5-FU given as a continuous infusion at a dose of 25 mg/kg/d during EBRT) or no further treatment after pancreaticoduodenectomy for adenocarcinoma of the pancreas or periampullary region. Patients were recruited from 29 centers in Europe, one in France, and three in the Netherlands. Analysis was performed on 207 of the patients, 114 (55%) of whom had pancreatic cancer. Eleven patients were deemed ineligible for analysis because of extensive local disease with incomplete resection. The median survival duration was 24.5 months for those who received adjuvant therapy and 19 months for those who received surgery alone ( *P* = .2); for

patients with pancreatic cancer, the median survival was 17.1 months for those who received adjuvant therapy compared with 12.6 months for those who received surgery alone ( $P = .099$ ). Concerns over trial design, methodology, and data interpretation include the following:

1. The precise anatomic (pathologic) distinction between pancreatic and periampullary adenocarcinoma was not defined, and the high proportion of periampullary (nonpancreatic) tumors is unexplained.
2. Patients were considered for enrollment in this trial after recovery from pancreaticoduodenectomy; despite this selection bias, 21 (20%) of 104 evaluable patients randomized to receive chemoradiation did not receive intended therapy owing to patient refusal, medical comorbidities, or rapid tumor progression.
3. No assessment of the retroperitoneal margin of resection was performed, and therefore no mechanism to assess the completeness of surgical resection was available. Furthermore, although the method of follow-up was not defined (raising the concern that sites of recurrent disease were underestimated), tumor recurrence in the pancreatic bed was a site of first progression in 20% of patients. This finding, combined with the short survival in the observation arm (12 months for patients with pancreatic adenocarcinoma), suggests that many patients underwent incomplete resection.
4. Although the survival differences for the subset of patients with pancreatic cancer were not significant ( $P = .099$ ), the wide confidence interval (relative risk, 0.7; 95% confidence interval, 0.5–1.1) does not exclude the possibility of a clinically meaningful improvement in survival in the chemoradiation arm that was not apparent because of the small sample size.

Despite these concerns, the authors concluded that postoperative adjuvant chemoradiation should not be considered standard therapy after pancreaticoduodenectomy for cancer.<sup>204</sup>

Two additional trials of postoperative adjuvant therapy after pancreaticoduodenectomy are ongoing: the European Study Group of Pancreatic Cancer (ESPAC)-1 trial and a Radiation Therapy Oncology Group (RTOG) trial. The ESPAC-1 trial is a four-arm study incorporating a two-by-two factorial design to compare adjuvant chemoradiation (40 Gy in a split course and 5-FU), adjuvant chemotherapy (5-FU and folinic acid), chemoradiation followed by chemotherapy, and observation alone after pancreaticoduodenectomy for pancreatic and periampullary carcinomas.<sup>206,207</sup> More than 40 centers in nine countries are participating in this study, which began accrual in 1994. In July 1998, the RTOG activated the first American phase III cooperative group study of postoperative adjuvant therapy for resected pancreatic adenocarcinoma since the GITSG trial.<sup>208</sup> Patients are randomized to receive either gemcitabine or 5-FU to be given before and after 5-FU–based chemoradiation.

Despite the selection bias involved in the enrollment of patients into postoperative adjuvant therapy studies, prospective and retrospective data suggest an improved survival duration with the addition of postoperative adjuvant chemoradiation after pancreaticoduodenectomy (Table 33.4-7).<sup>133,139,140 and 141,149,167,202,209,210,211,212 and 213</sup> The most compelling data reported of late come from Yeo and colleagues<sup>167</sup> at Johns Hopkins University, who reviewed all patients who underwent pancreaticoduodenectomy for adenocarcinoma of the pancreatic head during a 4-year period. One hundred twenty patients received adjuvant chemoradiation, and 53 underwent pancreaticoduodenectomy alone. The median survival for those who received adjuvant therapy was 19.5 months, compared with 13.5 months for the group who received surgery alone.

TABLE 33.4-7. Chemoradiation Studies in Patients with Resectable Pancreatic Cancer

A survival advantage was also demonstrated for patients treated with adjuvant combination chemotherapy (5-FU, doxorubicin, and mitomycin C) after pancreatectomy.<sup>214</sup> The median survival was 23 months in the 30 patients randomized to receive adjuvant therapy, compared to 11 months in the 31 patients treated with surgery alone. Forty-six additional patients were ineligible after surgery, attesting to the difficulty in performing multiinstitutional protocol-based research involving as complex a surgical procedure as pancreaticoduodenectomy. The toxicity of the surgery and chemotherapy was significant; only 24 of 30 patients received chemotherapy, and only 13 of those received all six planned courses of chemotherapy. A previous pilot study of adjuvant 5-FU, doxorubicin, and mitomycin C using a different schedule of administration found similar toxicity and therefore questioned the use of adjuvant combination chemotherapy, even of moderate toxicity, after pancreatectomy.<sup>145</sup>

The risk of delaying or not receiving postoperative adjuvant therapy,<sup>167,203,214,215</sup> combined with small published experiences of successful pancreatic resection after EBRT,<sup>216,217 and 218</sup> prompted many institutions to initiate studies in which chemoradiation was given preoperatively.<sup>158,219</sup> Results of these and other studies have suggested specific advantages of preoperative versus postoperative chemoradiation, including the following considerations<sup>124</sup>: (1) Because chemotherapy and radiation are given first, delayed postoperative recovery has no effect on the delivery of multimodality therapy<sup>139,149</sup>; (2) pancreaticojejunal anastomotic leaks, the most common major complication after pancreaticoduodenectomy, are decreased in patients who receive preoperative chemoradiation<sup>220</sup>; (3) the high frequency of positive-margin resections that have been reported supports the concern that the retroperitoneal margin of excision, even when negative, may be only a few millimeters—surgery alone is thus inadequate local therapy for most patients<sup>134,167</sup>; and (4) patients with disseminated disease evident on restaging studies after chemoradiation are not subjected to laparotomy.<sup>149</sup>

In patients who receive chemoradiation before planned pancreaticoduodenectomy, repeat staging CT after chemoradiation reveals liver metastases in approximately 25%.<sup>139,149</sup> If these patients had undergone pancreaticoduodenectomy at the time of diagnosis, it is probable that the liver metastases would have already been present subclinically; these patients would therefore have undergone a major surgical procedure only to have liver metastases found soon after surgery. In the M. D. Anderson Cancer Center trials, patients who were found to have disease progression at the time of restaging had a median survival of only 7 months.<sup>124</sup> The avoidance of a lengthy recovery period and the potential morbidity of pancreaticoduodenectomy in patients with such a short expected survival duration represents a distinct advantage of preoperative over postoperative chemoradiation. Furthermore, when delivering multimodality therapy for any disease, it is beneficial, when possible, to deliver the most toxic therapy last, thereby avoiding morbidity in patients who experience rapid disease progression not amenable to currently available therapies.

The survival advantage for the combination of chemoradiation and surgery compared with surgery alone (see Table 33.4-7) likely results from improved local-regional tumor control. Because of the poor rates of response to 5-FU–based systemic therapy in patients with measurable metastatic disease, it is unlikely that 5-FU–based chemoradiation regimens significantly impact the development of distant metastatic disease. Data from the M. D. Anderson Cancer Center support this belief.<sup>148,149</sup> Staley and colleagues<sup>48</sup> reported on 39 consecutive patients who underwent pancreaticoduodenectomy and intraoperative electron-beam radiation therapy (IOERT; 10 Gy) for adenocarcinoma of the pancreatic head after preoperative infusional 5-FU (300 mg/m<sup>2</sup>/d, 5 days per week) and EBRT (50.4 Gy). Thirty-eight patients were evaluable for analysis of patterns of treatment failure; one perioperative death occurred. Overall, 38 recurrences were found in 29 patients; eight recurrences (21%) were local-regional (pancreatic bed, peritoneal cavity, or both), and 30 (79%) were distant (lung, liver, bone). The liver was the most frequent site of tumor recurrence, and liver metastases were a component of treatment failure in 53% of patients (69% of all patients who had recurrences). Fourteen patients (37% of all patients; 48% of patients who had recurrences) had liver metastases as their only site of recurrence. Isolated local or peritoneal recurrences were documented in only four patients (11%). In contrast, previous reports of pancreaticoduodenectomy alone for adenocarcinoma of the pancreas documented local recurrence in 50% to 80% of patients.<sup>134,142,147</sup> The improvement in local-regional control with preoperative chemoradiation was seen despite the fact that 14 of 38 evaluable patients had undergone laparotomy with tumor manipulation and biopsy before referral for chemoradiation and reoperation. If these 14 patients are excluded, only two patients (8%) experienced local or peritoneal recurrence as any component of treatment failure. However, the chemoradiation program was associated with gastrointestinal toxic effects (nausea, vomiting, and dehydration) that required hospital admission in one-third of patients.<sup>148</sup> In addition, the multicenter Eastern Cooperative Oncology

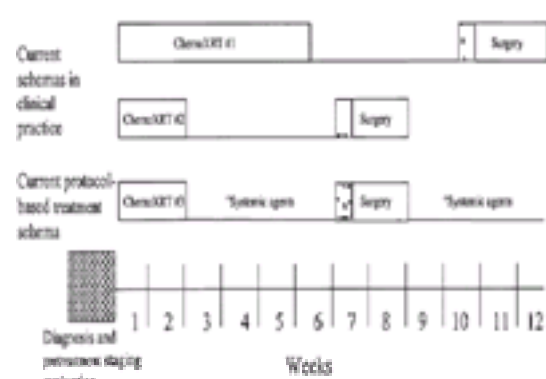

Group trial documented the need for hospital admission in 51% of patients during or within 4 weeks of completing chemoradiation.<sup>213</sup> These findings led to a change in the delivery of radiation therapy and 5-FU at the M. D. Anderson Cancer Center. A rapid-fractionation program of chemoradiation was designed to avoid the gastrointestinal toxicity seen with standard-fractionation chemoradiation (5.5 weeks) while attempting to maintain the excellent local tumor control achieved with multimodality therapy.<sup>149</sup> In a study of the revised regimen, rapid-fractionation chemoradiation was delivered over 2 weeks with 18-MeV photons using a four-field technique to a total dose of 30 Gy (3 Gy per fraction for ten fractions, 5 days per week). 5-FU was given concurrently by continuous infusion at a dosage of 300 mg/m<sup>2</sup>/d, 5 days per week. Restaging with chest radiography and abdominal CT was performed 4 weeks after completion of chemoradiation in preparation for pancreaticoduodenectomy. Thirty-five patients received this treatment, 27 were taken to surgery, and 20 (74%) underwent successful pancreaticoduodenectomy. Local tumor control and patient survival were equal to the results reported above with standard-fractionation (5.5 weeks) chemoradiation: Local-regional recurrence developed in only 2 (10%) of the 20 patients who underwent resection, and the median survival for all 20 patients was 25 months.<sup>149</sup>

Because of the large percentage of patients who develop distant metastatic disease, predominantly in the liver, the improved local-regional tumor control achieved with combined-modality therapy (chemoradiation and surgery) translates into only a small improvement in median survival. Therefore, more effective systemic agents are needed to both maximize radiation sensitization and treat microscopic extrapancreatic metastatic disease. One such potential agent is gemcitabine (2'-deoxy-2',2'-difluorocytidine; Gemzar), a deoxycytidine analogue capable of inhibiting DNA replication and repair. After a phase I study,<sup>221</sup> gemcitabine was evaluated in a multicenter trial of 44 patients with advanced pancreatic cancer.<sup>222</sup> Although only five objective responses were documented, the investigators noted frequent subjective symptomatic benefits, often in the absence of an objective tumor response. Toxicity appeared to be minor and included myelosuppression, particularly thrombocytopenia, as well as a flu-like syndrome and mild hemolytic-uremic syndrome. Based on these observations, gemcitabine was compared to 5-FU in previously untreated patients with advanced pancreatic cancer.<sup>223</sup> Patients treated with gemcitabine had a median survival of 5.65 months, compared to 4.41 months ( $P = .0025$ ) in those treated with 5-FU. Twenty-four percent of patients treated with gemcitabine were alive at 9 months, compared to 6% of patients treated with 5-FU. In addition, more clinically meaningful effects on disease-related symptoms (pain control, performance status, and weight gain) were seen with gemcitabine (24% of patients) than with 5-FU (5% of patients). Similar systemic effects and demonstrable disease responses were documented in patients who were treated with gemcitabine after experiencing disease progression while receiving 5-FU.<sup>224</sup>

Gemcitabine is also a potent radiation sensitizer of human pancreatic cancer cells *in vitro*, supporting studies examining its use *in vivo*. Laboratory studies suggest that the inhibitory effect of gemcitabine on DNA synthesis (when combined with irradiation) is prolonged in tumor compared to normal tissues.<sup>225</sup> This may provide a window of opportunity for the combination of gemcitabine and EBRT when delivered in a fractionated schedule. Such data provide the basis for the ongoing phase I studies of this drug-radiation combination in patients with locally advanced pancreatic cancer; gemcitabine (combined with EBRT) is being given in escalating doses weekly as a single agent,<sup>226</sup> in combination with 5-FU,<sup>227</sup> in combination with cisplatin,<sup>228</sup> at a fixed dose with escalating doses of EBRT,<sup>229</sup> and as a twice-weekly infusion with either standard-fractionation EBRT<sup>230</sup> or split-course EBRT.<sup>231</sup> Wolff and colleagues<sup>226</sup> from the M. D. Anderson Cancer Center have reported a phase I study of rapid-fractionation EBRT (30 Gy over 2 weeks, 3 Gy per fraction) and concomitant weekly gemcitabine in patients with locally advanced adenocarcinoma of the pancreatic head. Gemcitabine was given during the first 2 weeks of irradiation and continued weekly to complete a 7-week course of systemic therapy. The maximum tolerated dose of gemcitabine using this treatment schedule was 350 mg/m<sup>2</sup>/week. Dose-limiting toxicities included fatigue, anorexia, nausea, vomiting, and dehydration; febrile neutropenia occurred in only one patient. Future studies of gemcitabine-based chemoradiation will likely incorporate a fixed dose-rate schedule of administration because current data suggest an improved response rate with such a schedule.<sup>232</sup>

The results with gemcitabine for locally advanced and metastatic pancreatic cancer suggest that gemcitabine may be useful in patients with potentially resectable disease. Hoffman and colleagues<sup>233</sup> have reported a phase I study of preoperative standard-fractionation EBRT (50.4 Gy) and escalating weekly doses of gemcitabine (300 mg/m<sup>2</sup>, 400 mg/m<sup>2</sup>, 500 mg/m<sup>2</sup>) for potentially resectable pancreatic cancer. Eight (53%) of 15 patients required hospitalization after chemoradiation. Pancreaticoduodenectomy was completed in eight patients; so far, the histologic response to the preoperative therapy appears to be superior to that with prior chemoradiation combinations. No experience with adjuvant gemcitabine-based chemoradiation after pancreaticoduodenectomy has been published; acute and late toxic effects of this drug-radiation combination may be more significant than when it is used in the preoperative setting.

The evolution of multimodality therapy for patients with potentially resectable pancreatic cancer appears in [Figure 33.4-2](#). Future regimens will likely emphasize neoadjuvant therapy and capitalize on our expanding understanding of the molecular basis of metastasis, allowing conventional chemoradiation and surgery to be combined with systemic or regional delivery of novel agents that inhibit essential steps in tumor cell growth.

**FIGURE 33.4-2.** The evolution of multimodality neoadjuvant (preoperative) therapy for patients with potentially resectable adenocarcinoma of the pancreatic head. Current treatment schemas combine 5-fluorouracil (5-FU) chemoradiation (ChemoXRT) and pancreaticoduodenectomy. Short-course rapid-fractionation chemoradiation avoids the gastrointestinal toxicity of standard-fractionation chemoradiation and reduces overall treatment time. Future treatment schemas (currently being studied in the protocol setting) emphasize the importance of improving local and systemic disease control with more potent radiation-sensitizing agents and novel systemic therapies. n, restaging evaluation; ChemoXRT #1, 50.4 Gy, 1.8 Gy per fraction: 5-FU 300 mg/m<sup>2</sup>/d, M–F; ChemoXRT #2, 30 Gy, 3.0 Gy per fraction: 5-FU 300 mg/m<sup>2</sup>/d, M–F; ChemoXRT #3, 30 Gy, 3.0 Gy per fraction: with improved radiation-sensitizing agents (gemcitabine). <sup>a</sup>Systemic agents: novel systemic agents, such as inhibitors of angiogenesis, farnesyl-protein transferase, epidermal growth factor, and so forth.

## PANCREATICODUODENECTOMY

### Background

Current surgical treatment is based on the procedure of pancreaticoduodenectomy as described in 1935 by Whipple et al.<sup>234</sup> Their two-stage pancreaticoduodenectomy consisted of biliary diversion and gastrojejunostomy during a first operation and, after the patient recovered (approximately 3 weeks later), resection of the duodenum and pancreatic head. By 1941, the world experience totaled 41 cases, and the perioperative mortality rate was 30%.<sup>235</sup> Before 1940, the pancreatic remnant was not reanastomosed to the small bowel, and the high mortality rate was largely due to pancreatic fistula from the oversewn pancreatic remnant. In 1941, Whipple modified his reconstruction to include a pancreaticojejunostomy, with the entire procedure done in one operation. In 1946, Waugh and Clagett<sup>236</sup> from the Mayo Clinic described their modification of the one-stage procedure to its current form. The goals of surgical therapy outlined by Waugh and Clagett have not changed since that date: (1) there should be reasonable opportunity for cure, (2) the risk of death should not outweigh the prospects for cure, and (3) the patient should be left in as normal a condition as possible.<sup>236</sup>

### Surgical Mortality Rates

Advances in operative technique, anesthesia, and critical care have resulted in a 30-day in-hospital mortality rate of less than 2% for pancreaticoduodenectomy when performed at major referral centers by experienced surgeons.<sup>138,220,237</sup> At such centers, mortality rates remain less than 2% despite the use of multimodality therapy, the frequent need for complex vascular resection and reconstruction, and the referral of many patients after an initial unsuccessful attempt at tumor resection.<sup>238,239</sup> Mortality rates from other institutions, including university centers and the Department of Veterans Affairs hospitals, have been reported in the range from 7.8% to more than 10%.<sup>240,241,242</sup> and <sup>243</sup> Data from New York State have demonstrated that hospitals performing fewer than nine pancreatic resections per year have an unacceptably high perioperative mortality rate of 12%.<sup>244</sup> Data from Maryland and Ontario, Canada, also have demonstrated that increased patient volume is

associated with lower surgery-related mortality.<sup>245,246 and 247</sup> The most compelling data on the relationship of hospital volume to perioperative mortality and long-term survival after pancreaticoduodenectomy come from the Center for the Evaluative Clinical Sciences at Dartmouth Medical School.<sup>248,249</sup> Birkmeyer et al.<sup>248</sup> studied 7229 Medicare patients older than 65 years of age who underwent pancreaticoduodenectomy at 1772 hospitals between 1992 and 1995. The study population was divided into quartiles according to hospital volume, with high-volume centers defined as those that performed five or more pancreaticoduodenectomies per year. Forty high-volume hospitals (2%) performed 1541 (21%) of the 7229 pancreaticoduodenectomies. In-hospital mortality was 11% overall, 4% in high-volume hospitals, and 10% to 16% in medium-volume (two to five pancreaticoduodenectomies per year) and very low-volume (fewer than one pancreaticoduodenectomy per year) hospitals. These data suggest a linear relationship between surgical volume and outcome. Birkmeyer and colleagues suggested that more than 100 deaths per year could potentially be prevented by the referral of pancreatic cancer patients to high-volume hospitals. Furthermore, in an analysis of survival duration, after exclusion of perioperative deaths and adjustment for case mix, patients who underwent surgery at high-volume hospitals were less likely to experience late mortality.<sup>249</sup> The authors concluded that patients considering pancreaticoduodenectomy at low-volume hospitals should be given the option of referral to a high-volume center.

Patient outcome is optimized and costs minimized by the referral of patients requiring major pancreatic resections for malignant disease to centers with active multidisciplinary treatment programs.<sup>250</sup> However, because surgical resection benefits only patients who undergo a complete resection, it is essential that surgery be done only on patients with localized, potentially resectable pancreatic cancer. In the absence of significant innovations in systemic therapy, the only potential for major improvements in the quality of life of patients with pancreatic cancer lies in our ability to limit surgery-related morbidity to those patients most likely to benefit from surgical intervention (i.e., to avoid laparotomy in patients with unresectable disease). Therein lies the importance of determining resectability using strict CT criteria (see [Pretreatment Diagnostic Studies](#), earlier in this chapter).

### Technique

Pancreaticoduodenectomy as currently performed in the United States incorporates selected aspects of the traditional Whipple procedure and emphasizes the importance of removing all soft tissue to the right of the SMA.<sup>251</sup> The surgical resection is divided into six clearly defined steps,<sup>181,251</sup> the most important of which is step 6, during which the pancreas is divided and the specimen is removed from the SMPV confluence and the right lateral border of the SMA. This is performed by completely mobilizing the SMV and portal vein medially; the uncinate process is then dissected off of the SMV and its posteriorly located first jejunal branch. Only after full medial mobilization of the SMV can one identify the SMA (lateral to the SMV). The pancreatic head and all soft tissue to the right of the SMA are then removed with direct ligation of the inferior pancreaticoduodenal artery or arteries.

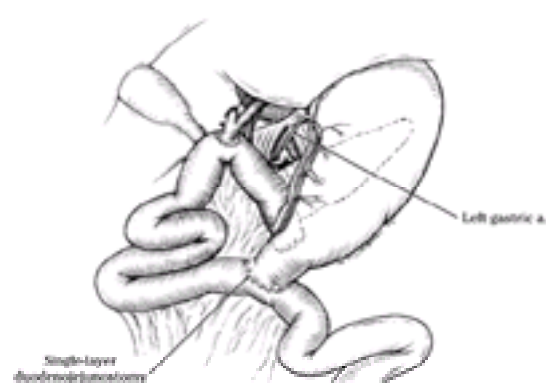

The high incidence of local recurrence after standard pancreaticoduodenectomy (see [Table 33.4-3](#)) mandates that close attention be paid to the retroperitoneal margin. The retroperitoneal margin is the soft tissue margin along the right lateral border of the proximal SMA. This margin contains the lateral portion of the mesenteric neural plexus that surrounds the artery. Importantly, perineural invasion involving the mesenteric plexus at the SMA origin and tumor cell infiltration of lymphatic vessels and connective tissue may extend beyond the confines of the palpable tumor in the pancreatic head and result in a microscopically positive retroperitoneal margin, even when all gross disease is easily resected.<sup>252,253 and 254</sup> A more extensive retroperitoneal dissection to the right of the SMA is not associated with greater operative morbidity and is necessary to obtain a negative retroperitoneal margin.<sup>124,157,238</sup> This important margin of resection is often confused with the soft tissue posterior to the pancreatic head and duodenum and anterior to the inferior vena cava (posterior pancreaticoduodenal region). Direct invasion of the inferior vena cava is uncommon, and removal of all tissue anterior to this vessel is easily accomplished. As is true for other solid tumors, adequate local-regional control of pancreatic cancer requires negative margins of excision, and the margin of greatest importance at the time of pancreaticoduodenectomy is the soft tissue margin along the proximal SMA (retroperitoneal margin). In addition, clear identification of the SMA avoids the potential for iatrogenic injury.

Segmental resection of the SMPV confluence is performed when the tumor is inseparable from the lateral wall of the SMV or portal vein.<sup>239</sup> Although an occasional patient may have such a small area of venous involvement that a saphenous vein patch is an obvious choice, the majority of patients with involvement of the SMPV confluence require segmental venous resection. The technical feasibility of portal vein resection was first reported by Fortner<sup>255</sup> in his large series of type I regional pancreatectomies that included routine portal vein resection. More recently, surgeons have reported the safety of pancreatectomy with *en bloc* resection of the SMPV confluence.<sup>256,257</sup> Fuhrman and colleagues<sup>238</sup> have demonstrated that invasion of the SMV or portal vein is not associated with histopathologic variables (margin and lymph node positivity) that suggest a poor prognosis. Their data imply that venous involvement is a function of tumor location rather than an indicator of aggressive tumor biology. Additional data from the M. D. Anderson Cancer Center have confirmed that patient survival is not affected by the need for venous resection at the time of pancreaticoduodenectomy.<sup>258</sup> In contrast to previous reports on venous resection, the preferred technique for resection of the SMPV confluence at M. D. Anderson involves preservation of the splenic vein–portal vein junction and use of an internal jugular vein interposition graft placed between the SMV and portal vein.<sup>195,239,257</sup>

It is important to emphasize the distinction between regional pancreatectomy and pancreaticoduodenectomy with segmental resection of the SMV or SMPV confluence. Venous resection is not an attempt to improve *en bloc* lymphatic and soft tissue clearance, as is performed in regional pancreatectomy. It is unlikely that larger local-regional resections (to the left of the SMA and celiac axis) in poorly selected patients with advanced disease will impact survival.<sup>195,258</sup> Venous resection should be performed only in carefully selected patients who have tumor adherence to the SMV or SMPV confluence but no evidence of tumor extension to the SMA or celiac axis. The rationale for venous resection and the anatomic difference between tumor invasion of venous and arterial structures have been reviewed.<sup>238,239,258</sup> Because the need for venous resection is unexpected in many patients and is discovered only after gastric and pancreatic transection, when nonresectional procedures are no longer an option, surgeons who perform pancreaticoduodenectomies should be familiar with standard vascular techniques for resection and reconstruction of the SMPV confluence.

### PYLORUS PRESERVATION

Preservation of the antropyloroduodenal segment in combination with pancreaticoduodenectomy ([Fig. 33.4-3](#)) was first described by Traverso and Longmire in 1978.<sup>259</sup> Since then, increasing numbers of pancreatic surgeons have used this modification of the procedure, particularly for patients with benign disease or small periampullary lesions. Proponents of the technique argue that preservation of the antropyloric pump mechanism results in improved long-term upper gastrointestinal tract function with associated salutary nutritional sequelae.<sup>132,135,260</sup> Physiologic studies suggest that pylorus preservation decreases intestinal transit time, lessens diarrhea (steatorrhea), normalizes glucose metabolism, and improves postoperative weight gain.<sup>261,262</sup> Detractors of pylorus-preserving pancreaticoduodenectomy counter that the reported improvements in gastrointestinal tract function and nutrition are small, if any, and that they come at the expense of an increased incidence of delayed gastric emptying during the early postoperative period.<sup>263,264</sup> Clinically significant long-term gastrointestinal dysfunction occurs in very few patients after standard pancreaticoduodenectomy with distal gastric resection.<sup>261</sup> Additionally, leaving the distal stomach and duodenum may compromise margins of excision, prevent adequate peripyloric lymphadenectomy, and negatively impact patient survival.<sup>130,263,265</sup> Published data to date involve retrospective comparisons that have yielded mixed results. Most investigators would agree that pylorus preservation should not be performed in patients with bulky tumors of the pancreatic head or with duodenal tumors involving the first or second portions of the duodenum.

**FIGURE 33.4-3.** Illustration of the completed reconstruction after pylorus-preserving pancreaticoduodenectomy.

However, a far greater body of literature exists on the use of pylorus preservation than on innovative, multimodality therapies for patients with localized pancreatic

cancer. The resection or retention of the pylorus is of much less significance than the proper selection of patients for pancreaticoduodenectomy and the status of the retroperitoneal margin after tumor resection. For example, three reports advocating pylorus preservation for malignant pancreatic and periampullary cancers reported positive resection margins in 25%, 29%, and 37% of patients.<sup>132,135,266</sup> In the presence of a positive margin of resection, patients do not survive long enough to receive a potential nutritional benefit (if one exists) from pylorus preservation.

#### ADJUVANT INTRAOPERATIVE ELECTRON-BEAM RADIATION THERAPY

Despite the use of postoperative adjuvant EBRT and 5-FU, the incidence of disease recurrence in the tumor bed has been reported to be as high as 50%.<sup>267</sup> This rate of local recurrence is likely due to the high incidence of residual macroscopic or microscopic disease at the resection margins and in the retroperitoneal soft tissues after pancreaticoduodenectomy and to the inability of 40 to 50 Gy of EBRT to control this level of tumor burden.<sup>134</sup> IOERT, which delivers a single large dose of radiation to the tumor bed at the time of surgery, has been used alone and in combination with postoperative EBRT to improve local control. With IOERT, the total radiation dose delivered to a tumor or tumor bed can be increased over the dose that can be given by EBRT because sensitive normal tissues are displaced from the radiation field during the surgical procedure. Furthermore, this single intraoperative dose is believed to be biologically equivalent to an external-beam radiation dose at least two to three times greater given by means of conventional fractionation.

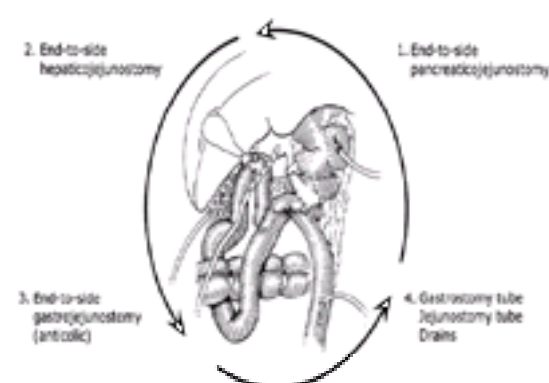

The data on the efficacy of pancreatic resection with IOERT alone or in combination with preoperative or postoperative EBRT are limited to retrospective or prospective single-institution studies and one small randomized trial.<sup>136,268,269,270,271</sup> and <sup>272</sup> The only reported prospective, randomized, controlled clinical trial of IOERT for resectable pancreatic cancer was performed at the U.S. National Cancer Institute beginning in 1980.<sup>272</sup> Twenty-four patients who underwent resection for pancreatic adenocarcinoma were randomized to receive IOERT (20 Gy) to the bed of the resected pancreas or observation. Patients in the IOERT group who had extrapancreatic tumor extension also received postoperative EBRT (45 to 55 Gy). Most patients had locally advanced disease that would be considered unresectable by conventional criteria. Patients underwent extensive extirpative surgery to remove all gross evidence of the primary tumor; the procedures frequently required vascular and adjacent organ resections, and this extent of surgical therapy resulted in considerable morbidity. The overall perioperative mortality rate was 27%, and the morbidity rate was 71%; the mortality and morbidity did not differ significantly between the IOERT and observation groups. The median survival of patients who received IOERT was 18 months, compared to 12 months for the observation group. Local recurrences occurred in all 12 patients (100%) in the observation group but in only 4 (33%) of 12 patients who received IOERT. One patient who received IOERT remained disease-free more than 15 years after therapy. Because of the small patient numbers, statistically significant survival differences were not reached between the IOERT and control groups.

More recently, investigators from the M. D. Anderson Cancer Center studied a regimen that included preoperative chemoradiation and IOERT. Patients with potentially resectable pancreatic cancer received preoperative EBRT (50.4 Gy in 28 fractions or 30 Gy in ten fractions) and concomitant protracted-infusion 5-FU (300 mg/m<sup>2</sup>/d) followed by pancreaticoduodenectomy and IOERT (10 to 20 Gy) to the resection bed.<sup>139,149</sup> Based on this group's experience, it appears that IOERT can be delivered with minimal morbidity after preoperative chemoradiation and pancreaticoduodenectomy. The median survival duration in their most recent study was 25 months.<sup>149</sup> Disease recurrence occurred in 70% of patients at a median follow-up of 37 months; 86% of recurrences were distant, and only 14% were local-regional.

The results of these studies show that IOERT can be combined safely with pancreaticoduodenectomy and contemporary chemoradiation protocols. Although local control appears improved by IOERT, marked improvements in survival have not been demonstrated. At present, IOERT should be limited to investigative protocols.

#### RECONSTRUCTION

After pancreaticoduodenectomy with or without IOERT, gastrointestinal reconstruction is performed in a counterclockwise direction ( Fig. 33.4-4).<sup>251,273</sup> The transected jejunum is brought through a small incision in the transverse mesocolon to the right or left of the middle colic vessels, and a two-layer, end-to-side, duct-to-mucosa pancreaticojejunostomy is performed over a small Silastic stent (if the pancreatic duct is not dilated). A two-layer anastomosis that invaginates the cut end of the pancreas into the jejunum can be performed if the pancreatic duct is not suitable for a duct-to-mucosa anastomosis. However, we prefer a duct-to-mucosa anastomosis. A single-layer biliary anastomosis is then completed, followed by an antecolic, end-to-side gastrojejunostomy constructed in two layers. Gastrostomy and feeding jejunostomy tubes are placed using the Witzel technique, and two closed-suction drains are placed.

**FIGURE 33.4-4.** Illustration of pancreatic, biliary, and gastric reconstruction after standard pancreaticoduodenectomy. The remaining pancreas is anastomosed to the jejunum; we prefer a direct duct-to-mucosa anastomosis of the pancreatic duct.

Gastrointestinal reconstruction after pancreaticoduodenectomy is associated with two recognized complications: leak at the pancreaticojejunostomy and delayed gastric emptying. Anastomotic leak from the biliary and gastric anastomoses should be very uncommon. Initial techniques for gastrointestinal reconstruction after pancreaticoduodenectomy involved simple closure of the pancreatic stump. Because of a high rate of pancreatic fistula formation, surgeons quickly switched to implantation of the pancreatic remnant into the jejunum.<sup>274</sup> A more recent alternative is implantation of the pancreatic remnant into the posterior wall of the stomach.<sup>275,276</sup> and <sup>277</sup> Regardless of the technique used, results appear dependent on the experience of the surgeon. With greater experience, the incidence of complications decreases.

Delayed gastric emptying is common after standard pancreaticoduodenectomy and may be more frequent with pylorus preservation.<sup>278</sup> The cause is multifactorial but largely related to denervation of the upper gastrointestinal tract during resection of the pancreatic head and attached soft tissues and nerves to the right of the SMA. Symptoms of nausea, vomiting, and postprandial fullness resolve in 4 to 12 weeks in virtually all patients. The routine placement of gastrostomy and jejunostomy tubes at the time of surgery avoids needless patient morbidity due to temporary gastric emptying dysfunction. Patients can be discharged while receiving enteral feeding (via the jejunostomy tube) and allowed to advance their oral diet as tolerated. In addition, such tube placement prevents the expense and potential complications associated with intravenous hyperalimentation in patients who require prolonged hospitalization because of perioperative or postoperative complications. Poor gastric emptying in the absence of other concomitant intraabdominal pathologic conditions should not be the cause of prolonged hospitalization.

#### TREATMENT DECISIONS: POTENTIALLY RESECTABLE DISEASE

The use of contrast-enhanced helical CT allows accurate assessment of local tumor resectability. High-quality CT with objective CT criteria for resectability has replaced exploratory laparotomy as a means of assessing resectability. Pancreaticoduodenectomy should be considered only in patients with a good performance status (Karnofsky scale, 70% or higher) and as part of a multimodality treatment program that includes either preoperative or postoperative chemoradiation. The modest survival rates seen with current treatments (see Table 33.4-2) argue strongly for enrollment of all patients into clinical trials of new combinations of surgery, chemoradiation, and newly developed systemic agents. Published perioperative mortality rates support the referral of patients with potentially resectable disease to centers that are experienced with the operative management of pancreatic cancer and that perform at least nine major pancreatic resections per year.<sup>244,248,249</sup>

#### PALLIATIVE METHODS OF BILIARY AND GASTRIC DECOMPRESSION

Debate over the best method of biliary decompression (surgical bypass or endoscopic stent) in patients with terminal pancreatic cancer stimulated a series of

prospective randomized trials.<sup>171,172 and 173</sup> These studies demonstrated that both methods are effective in relieving jaundice. Stenting is associated with lower initial morbidity and mortality rates and shorter hospital stays than operative bypass, but stent occlusion often results in the need for readmission to the hospital. Surgical biliary bypass provides a durable means of biliary decompression, but with greater initial morbidity. It is reasonable to assume that surgical complications are higher in patients with advanced disease and a poor performance status. In contrast, stent occlusion is more likely in patients with locally advanced or low-volume metastatic disease who survive long enough to experience this complication. Logic argues strongly for a selective approach to biliary decompression based on an accurate assessment of performance status and tumor burden.<sup>279</sup>

Patients with unresectable pancreatic cancer due to locally advanced or metastatic disease have a median survival of 6 months<sup>280</sup>; this duration of survival can be quite variable, ranging from 3 to 14 months depending on performance status and extent of disease. Laparotomy in this patient group is associated with a mortality rate of 2.5% to 5.0%, a morbidity rate of 20% to 30%, and a mean hospital stay of 10 to 14 days.<sup>161,280,281 and 282</sup> If one assumes that satisfactory recovery requires an additional 2 to 4 weeks, the patient with unresectable disease has invested 10% to 20% of overall survival time in achieving biliary drainage. Therefore, the incentive for the development of a less invasive method of biliary decompression is obvious. Technological advances in stent construction have now made endoscopic stent placement the procedure of choice in patients with advanced pancreatic cancer.<sup>174,283,284</sup> In patients with metastatic disease, whose survival duration is rarely longer than 6 to 9 months, biliary obstruction should be managed with outpatient endobiliary stent placement; this avoids the morbidity, hospital stay, and prolonged recovery period associated with operative biliary bypass. Stent occlusion is minimized with the use of large-caliber polyethylene stents (10.0 or 11.5 Fr.) without side holes; these stents reduce sludge and improve patency compared with smaller stents. Expandable 10-mm metal stents further decrease bacterial colonization and biofilm formation, resulting in improved patency compared with polyethylene stents<sup>285,286</sup>; however, that improved patency comes at a higher initial cost.

Patients with locally advanced, nonmetastatic pancreatic cancer have a median survival of 10 to 14 months (with current chemotherapy and chemoradiation regimens); endoscopic biliary decompression (even with an expandable metal stent) is associated with an increased incidence of stent occlusion as survival duration increases. Currently consensus has not been reached on how to manage an obstructed bile duct in patients with locally advanced, unresectable, nonmetastatic pancreatic cancer who have a good performance status. The desire to avoid palliative surgery (biliary bypass) that provides no anticancer therapy is balanced by the need for durable biliary decompression without the risk of recurrent cholangitis secondary to stent occlusion. This controversy is best illustrated by two publications from the same institution: one supports endobiliary stenting,<sup>174</sup> whereas the other supports operative bypass.<sup>279</sup>

We use a selective approach to biliary decompression. Outpatient endoscopic stenting is performed in all patients who are not candidates for pancreaticoduodenectomy. In patients with a life expectancy of 3 to 5 months (i.e., those with poor performance status or liver or peritoneal metastases), an 11.5-Fr. polyethylene stent is placed. In patients with a life expectancy of 6 to 12 months (i.e., those with locally advanced, nonmetastatic disease), a self-expanding metal stent is preferred. However, patients who develop early stent occlusion or migration or who by clinical criteria appear to do poorly with endoscopic biliary decompression are quickly referred for operative biliary bypass. A multidisciplinary approach to these patients is critical—the medical oncologist, gastroenterologist, and surgeon must communicate and avoid overly dogmatic approaches to palliative care.

Operative biliary bypass is routinely performed in patients who are brought to the operating room for planned pancreaticoduodenectomy and are found to have locally advanced or extrapancreatic metastatic disease. In such patients, a biliary-enteric bypass is performed. Previous studies have demonstrated no difference in outcome between cholecystojejunostomy and choledochojejunostomy.<sup>161</sup> However, the gallbladder should not be used for biliary decompression in the setting of acute or chronic gallbladder disease, cephalad tumor extension, or prolonged stent placement before surgery. In patients with a previous endoscopic stent, hypertrophy and fibrosis of the wall of the bile duct may make the cystic duct–common bile duct junction unsuitable for biliary decompression. Our choice for biliary bypass at the time of surgery is a Roux-en-Y choledochojejunostomy. The gallbladder is removed and the common bile duct transected. The endoscopic stent (if present) is removed, the distal bile duct is closed, and an end-to-side choledochojejunostomy is created with a single layer of interrupted monofilament sutures.

In patients with unresectable disease, laparoscopic cholecystojejunostomy represents another alternative for biliary decompression.<sup>287,288,289 and 290</sup> We use this technique in patients with locally advanced, nonmetastatic disease in whom attempted endoscopic stenting has been unsuccessful. Tumors of the uncinate process or the inferior aspect of the pancreatic head that extend to the root of the mesentery often deform the ampulla of Vater, making endoscopic cannulation difficult. Laparoscopic biliary decompression is an attractive option in these patients. Because laparoscopically assisted cholecystojejunostomy depends on a patent cystic duct–common bile duct junction, it is important not to consider this form of biliary decompression in patients with large tumors that extend cephalad to the porta hepatis.

Patients with symptomatic jaundice and ascites present a unique technical challenge. A subset of these patients have such advanced disease (and poor performance status) that pain control and hospice care are all that is indicated. For the occasional patient who presents with jaundice and the rapid onset of ascites and requires palliative treatment, we prefer endoscopic stent placement followed by early peritoneovenous shunting if an initial attempt at diuretic therapy is unsuccessful. If endoscopic stenting is not technically possible, laparoscopic cholecystojejunostomy is a reasonable alternative in the absence of high-volume carcinomatosis. Transhepatic biliary drainage with an internal-external catheter is not advised in patients with ascites because the ascitic fluid leaks around the catheter at the skin entrance site. In patients with malignant ascites, the surgeon should avoid using transabdominal catheters and making large abdominal incisions because of the risk of ascitic leak.

The subject of prophylactic gastrojejunostomy is not as relevant to the current surgical management of patients with pancreatic cancer as it was before the 1990s. Accurate preoperative imaging has increased resectability rates so that fewer patients are found to have unresectable disease at surgery. Advocates of prophylactic gastrojejunostomy state that the procedure can be performed safely, is not associated with postoperative delayed gastric emptying, and prevents subsequent gastric outlet obstruction in 10% to 20% of patients.<sup>161,280</sup> Detractors argue that concomitant gastric bypass at the time of therapeutic biliary bypass significantly increases operative morbidity, that the incidence of subsequent gastric outlet obstruction (in patients who receive only a biliary bypass) is much less than 10%, and that, if clinically evident gastric outlet obstruction does occur, it is usually a manifestation of end-stage disease.<sup>281,291,292 and 293</sup> Lillemoe et al.<sup>294</sup> from Johns Hopkins University reported on a prospective randomized trial of prophylactic gastrojejunostomy in patients with adenocarcinoma of the pancreatic head and periampullary region. Patients found to have unresectable disease and not to have intraoperative evidence of impending gastric outlet obstruction (such patients were excluded from analysis) at the time of laparotomy were randomly assigned to receive either a prophylactic gastrojejunostomy or no further surgery. Subsequent gastric outlet obstruction developed in 8 (19%) of the 43 patients who did not receive a gastric bypass, compared to 0 of 44 patients who received a gastrojejunostomy. Postoperative delayed gastric emptying occurred in 2% of patients in both groups, and the mean survival duration (8.3 months) was identical in both groups. Furthermore, no perioperative deaths occurred, and the mean hospital stay was approximately 8 days; again, no difference was noted between groups. The authors concluded that a retrocolic gastrojejunostomy should be performed routinely when a patient with pancreatic or periampullary cancer is found at operation to have unresectable disease. It appears that high-volume referral centers can perform palliative surgical biliary and gastric bypass procedures with low morbidity and mortality; however, these results may not be easily translated to low-volume centers with less experience. For example, a review of patients at 74 Department of Veterans Affairs hospitals from 1987 to 1991 concluded that prophylactic gastric bypass should be performed in patients with locally advanced, nonmetastatic pancreatic cancer, but the 30-day operative mortality rate (15% to 20%) was unacceptably high for palliative surgery in patients with such a short anticipated survival.<sup>295</sup>

In contrast to the data from Johns Hopkins University, Espat et al.<sup>296</sup> from Memorial Sloan-Kettering Cancer Center reported a low incidence of gastric outlet obstruction in patients with advanced pancreatic cancer. These investigators reported the longitudinal follow-up of 155 patients with pancreatic adenocarcinoma who were found to have locally advanced or metastatic disease at the time of staging laparoscopy (for presumed localized disease by CT). The median survival was 6.2 months for those with metastatic disease and 7.8 months for those with locally advanced disease; these survival durations support the authors' contention that the patients did not have high-volume metastatic disease at the time of laparoscopy. At a median follow-up of 6 months (81% of patients had died of disease), only 3 (2%) of 155 patients had undergone a subsequent open surgical procedure. Gastrojejunostomy for symptomatic gastric outlet obstruction was performed in two of these three patients. Two additional patients underwent elective gastric bypass (one was performed laparoscopically) at the time of biliary bypass. One additional patient required a percutaneous gastrostomy tube for poor gastric emptying during the terminal phase of his disease. Raikar et al.<sup>174</sup> from the Mayo Clinic also reported a low incidence of subsequent gastric outlet obstruction in patients with unresectable pancreatic cancer who had endoscopic biliary decompression. In their study, only 1 (3%) of 34 patients treated with endoscopic biliary decompression required surgical bypass for gastric outlet obstruction. These two nonrandomized studies do not support the practice of routine prophylactic gastric bypass.

The apparent differences in the incidences of gastric outlet obstruction in the above studies are not readily explained. In general, we do not perform prophylactic surgery in patients with pancreatic cancer. If a patient is found to have unresectable disease during surgery for planned pancreaticoduodenectomy, we consider gastrojejunostomy when clinical symptoms or anatomic findings suggest impending obstruction. However, in patients with locally advanced or limited metastatic disease with good performance status, the Johns Hopkins data<sup>294</sup> (based on a prospective randomized trial) would support the creation of a retrocolic

gastrojejunostomy.

## TREATMENT OF LOCALLY ADVANCED DISEASE

Approximately 40% of the 28,600 patients diagnosed with ductal adenocarcinoma of the pancreas in 1999 presented with unresectable but nonmetastatic disease. Because these patients' tumors are unresectable by a Whipple procedure or total pancreatectomy owing to invasion of the portal or mesenteric vessels and they have no clinically demonstrable metastases, radiotherapeutic approaches frequently have been used. These approaches have included EBRT, with and without 5-FU chemotherapy; IOERT; and, more recently, EBRT with new chemotherapeutic (radiosensitizing) agents.

### EXTERNAL-BEAM IRRADIATION WITH OR WITHOUT 5-FLUOROURACIL

In all except one study, conventional EBRT combined with 5-FU chemotherapy has been shown to improve survival in patients with locally advanced unresectable pancreatic cancer compared to irradiation alone or chemotherapy alone ( [Table 33.4-8](#)).<sup>151,201,297,298</sup> The most favorable median survival duration and 2-year survival rate for EBRT plus 5-FU were approximately 10 months and 12%, respectively. When interpreting the GITSG trials of this combination, it is important to remember that all patients were entered in the GITSG studies after laparotomy, at which time the disease was deemed unresectable by the operating surgeon. The significant morbidity reported with palliative pancreatic surgery<sup>295</sup> suggests that only patients with a high performance status could have recovered rapidly enough to be eligible for these studies. Thus, although surgical staging provided a more uniform study population, it also introduced significant selection bias: Only rapidly recovering patients were considered for treatment. Comparison of future findings to these data must take into account this selection bias.

Study	Number of Patients	Median Survival (mo)	Local Failure in Eligible Patients (%)	2-Y Survival Rate (%)
<b>Mayo Clinic<sup>297</sup></b>

**TABLE 33.4-8.** Prospective Randomized Studies of Radiation Therapy and Chemotherapy for Locally Advanced Unresectable Pancreatic Cancer

Because of the limited tolerance of normal tissue in the upper abdomen (liver, kidney, spinal cord, and bowel) to EBRT, total doses of only 45 to 54 Gy, in 25 to 30 fractions, have usually been given. For an unresectable lesion, this dose of radiation is inadequate, as demonstrated by the high rates of tumor progression and poor survival seen in both prospective and retrospective studies. For example, the Mayo Clinic reported a local failure rate of 72% for 122 patients with unresectable pancreatic cancer treated with an EBRT dose of 40 to 60 Gy.<sup>299</sup>

Because surgical resection of the primary tumor remains the only potentially curative treatment for pancreatic cancer, preoperative irradiation has been studied to assess its ability to convert locally unresectable pancreatic cancer to resectable disease ( [Table 33.4-9](#)).<sup>230,300,301,302,303,304</sup> and <sup>305</sup> In a study from the New England Deaconess Hospital,<sup>304</sup> 16 patients with locally advanced unresectable pancreatic cancer were treated with 45 Gy of EBRT and infusional 5-FU to enhance resectability. Of these 16 patients, only two (13%) were able to undergo resection. Similarly, investigators from Duke University reported that only 2 (8%) of 25 patients with locally advanced pancreatic cancer treated with 45 Gy of EBRT and 5-FU (with or without cisplatin or mitomycin C) subsequently underwent complete resection with negative margins.<sup>300</sup> These and other studies (see [Table 33.4-9](#)) indicate that it is unlikely that neoadjuvant chemoradiation can convert unresectable lesions to resectable ones and thereby increase the number of patients potentially cured with combined-modality therapy. It is important to remember that as one loosens the definition of a locally advanced pancreatic cancer, results appear more optimistic. If, however, one maintains a strict (CT) definition of locally advanced pancreatic cancer that includes only arterial involvement (low-density tumor inseparable from the SMA or celiac axis on contrast-enhanced CT) or SMV or SMPV confluence occlusion, successful down-staging to allow complete surgical resection will be rare with currently available chemotherapy or chemoradiation techniques.

### INTRAOPERATIVE ELECTRON-BEAM RADIATION THERAPY

To enhance the local-regional tumor control achieved by conventional EBRT and chemotherapy, specialized radiation therapy techniques that increase the dose of radiation to the desired tumor volume have been used in an attempt to improve local tumor control without increasing normal tissue morbidity. These include iodine 125 implants or intraoperative electrons as a boost dose in combination with EBRT and chemotherapy. A lower incidence of local failure in most series and improved median survival in some have been reported with these techniques when compared with conventional EBRT ( [Table 33.4-10](#)),<sup>299,306,307,308</sup> and <sup>309</sup> but it is uncertain whether the differences are due to superior treatment or to case selection.

**TABLE 33.4-10.** External-Beam and Intraoperative Radiation Therapy for Locally Advanced Unresectable Pancreatic Cancer

In the Massachusetts General Hospital<sup>308</sup> and Mayo Clinic studies<sup>308</sup> combining EBRT and IOERT for locally advanced pancreatic cancer, local tumor control was improved; however, the median survival was only approximately 12 months, and the 2-year survival rate remained approximately 20%. Most patients developed liver metastases, peritoneal seeding, or both. Although slight gains in survival may be achieved by improving local tumor control, the high incidence of distant metastases precludes significant improvements in long-term survival duration with IOERT.

#### NEW AGENTS COMBINED WITH RADIATION THERAPY

Because of the high incidence of hepatic and peritoneal metastases and the poor results with standard chemotherapy, current and future research efforts include evaluation of EBRT with new radiosensitizing agents (paclitaxel and gemcitabine). Interest in these agents is based on both their systemic cytotoxic effects and their radiosensitizing properties. In radiobiologic models, paclitaxel results in enhanced radiosensitization through tumor reoxygenation after apoptotic clearance of paclitaxel-damaged cells. In a phase I trial at Brown University<sup>303</sup> evaluating paclitaxel and 50 Gy of EBRT for patients with unresectable pancreatic and gastric cancers, the maximum tolerated dose of weekly paclitaxel with conventional irradiation was 50 mg/m<sup>2</sup>. The response rate was 31% among 13 evaluable pancreatic cancer patients. In the Brown University phase II study,<sup>310</sup> which administered 50 Gy of EBRT with 50 mg/m<sup>2</sup>/week of paclitaxel, 6 (33%) of 18 evaluable pancreatic cancer patients have had a partial response; stable disease has been observed in seven patients (39%); only one patient (6%) has had local tumor progression after completion of treatment; and four (22%) have developed distant metastases. These data have led to the initiation of an RTOG phase II study evaluating paclitaxel with EBRT for patients with unresectable pancreatic cancer.

Gemcitabine also has been the focus of an investigation in patients with advanced pancreatic cancer. Burris and colleagues<sup>223</sup> randomized 160 previously untreated patients with advanced and metastatic pancreatic cancer to receive either gemcitabine or 5-FU. Patients who received gemcitabine had a statistically improved median survival, 1-year survival rate, and clinical benefit compared to patients who received 5-FU. In radiobiologic models, gemcitabine also has been observed to be a potent radiosensitizer, likely because it depletes intracellular deoxynucleoside triphosphates. At present, numerous investigators are pursuing phase I and II studies combining EBRT with gemcitabine. Investigators from Wake Forest University and the University of North Carolina have reported the results of a phase I trial<sup>230</sup> of twice-weekly gemcitabine and 50.4 Gy of concurrent upper abdominal EBRT in 19 patients with unresectable pancreatic cancer. In this study, the maximum tolerated dose of gemcitabine was 40 mg/m<sup>2</sup>. At this dose level, gemcitabine was well tolerated. Of eight patients with a minimum follow-up of 12 months, three remain alive, and one of the three has no evidence of disease progression. On the basis of these data, a phase II Cancer and Leukemia Group B study of EBRT and twice-weekly gemcitabine is currently accruing patients with locally advanced pancreatic cancer. At the Massachusetts General Hospital, Dana-Farber Cancer Institute, and Brigham and Women's Hospital, a phase I/II study (unpublished) is under way examining preoperative EBRT (50.4 Gy) to the pancreas with continuous-infusion 5-FU and weekly gemcitabine for locally advanced pancreatic cancer. If no evidence of distant metastases is found at the time of restaging after completion of chemoradiation, patients proceed to laparotomy and IOERT to the primary tumor.

#### RADIATION THERAPY TECHNIQUES

For patients undergoing surgery, clips should be placed to mark the extent of the lesion for postoperative EBRT. Used sparingly (e.g., a single small vascular clip placed in each location to mark superior, inferior, lateral, and medial margins), small clips produce only minimal interference on CT scans. Titanium clips produce less CT interference but sometimes cannot be located on lateral simulation x-ray films because of their lesser density. During simulation and treatment, the patient should be supine. An initial set of anteroposterior and cross-table lateral x-ray films is obtained after injection of renal contrast medium to identify operative clips and renal position relative to the field center. Additional films can be obtained with contrast medium in the stomach and duodenal loop.

Radiation therapy for locally advanced pancreatic cancer generally involves multiple-field, fractionated, external-beam techniques with high-energy photons to deliver 45 to 54 Gy in 1.8-Gy fractions to unresected or residual tumor (as defined by CT and clips) and to at-risk nodal areas. For lesions in the head of the pancreas, major at-risk lymph node groups include the pancreaticoduodenal, porta hepatis, celiac, and suprapancreatic nodes. The suprapancreatic lymph node group is included with the body of the pancreas in the radiation field to encompass a 3- to 5-cm margin beyond gross disease; however, more than two-thirds of the left kidney is excluded from the anteroposterior-posteroanterior field because at least 50% of the right kidney needs to be included in this field to treat the entire pancreatic head and duodenum. The entire duodenal loop with a margin of grossly uninvolved tissue is included because pancreatic head lesions may invade the medial wall of the duodenum and place the entire circumference at risk.

For pancreatic body or tail lesions, at least 50% of the left kidney may need to be included in the radiation field to achieve adequate margins and to include lymph node groups at risk (i.e., lateral suprapancreatic and splenic hilum nodes). Because inclusion of the entire duodenal loop is not indicated with body or tail lesions, at least two-thirds of the right kidney can be preserved; with tailored blocks, it is usually possible to do this and still cover the pancreaticoduodenal and porta hepatis nodes adequately.

For pancreatic head lesions, the superior field extent is at the middle or upper portion of the T11 vertebral body to achieve adequate margins along the celiac vessels (T12-L1). The superior field extent is occasionally more superior for pancreatic body lesions to obtain an adequate margin around the primary lesion.

For the lateral fields, the anterior field margin is 1.5 to 2.0 cm beyond gross disease. The posterior margin is at least 1.5 cm behind the anterior portion of the vertebral body to allow adequate margins around paraaortic nodes, which are at risk for posterior tumor extension of head or body lesions. The dose to the lateral fields is usually limited to 18 to 20 Gy because a moderate volume of kidney or liver may be in the fields.

After resection, anteroposterior-posteroanterior and lateral fields are designed on the basis of preresection CT tumor volumes, operative clip placement, and postoperative CT lymph node volumes. The only border that can be reduced is the anterior border of the lateral fields, because the primary tumor has been resected. This border is determined by vascular or nodal boundaries (porta hepatis, superior mesenteric, and celiac arteries) as demonstrated on CT.

Three-dimensional conformal therapy is currently being investigated in patients with pancreatic cancer. [Figure 33.4-5](#) illustrates a multifield technique and composite isodose distribution for a patient with an unresectable pancreatic head cancer. Preliminary studies indicate that five or six conformal fields can be designed to improve dose-volume characteristics over those achieved with conventional four-field treatment designs, but the posterior wall of the stomach and the medial wall of the duodenum cannot be excluded from the high-dose volume.<sup>311</sup>

**FIGURE 33.4-5.** A multifield radiation technique **(A)** and composite isodose distributions **(B)** for a patient with an unresectable adenocarcinoma of the pancreatic head.

## TREATMENT DECISIONS: LOCALLY ADVANCED, NONMETASTATIC DISEASE

Patients with clear evidence of encasement of the celiac axis or SMA or occlusion of the SMPV confluence on contrast-enhanced helical CT do not require laparotomy to confirm that the tumor is unresectable; cytologic confirmation of malignancy can be achieved with EUS- or CT-guided FNA. This fundamental advance in the pretreatment diagnosis of pancreatic tumors can improve the quality of patient survival and reduce health care costs by avoiding the morbidity and prolonged recovery associated with palliative pancreatic cancer surgery. Published data have suggested an increased survival duration for patients treated with chemoradiation, but this benefit is limited largely to patients with higher performance status. In selected patients, aggressive treatment programs consisting of EBRT and chemotherapy may result in a median survival of approximately 12 months and a 2-year survival rate of 20%, although long-term survivors are rare. A program of chemoradiation is justified in fully ambulatory patients with locally advanced disease who have minimal symptoms. Systemic therapy with gemcitabine also represents a reasonable alternative in these patients. For patients with poor performance status, chemoradiation is probably not indicated. Current pharmacologic and interventional techniques for pain control, including percutaneous injection of alcohol into the celiac plexus, have proven highly successful in patients with pancreatic cancer.<sup>312</sup> Furthermore, adequate pain control improves performance status and quality of life, which may translate into increased length of life.<sup>313</sup> The limited therapeutic options available for patients with locally advanced disease and the modest impact of current treatments on survival rates provide the rationale for the entry of these patients into trials examining novel systemic agents.

## TREATMENT OF METASTATIC AND RECURRENT DISEASE

The early emergence of metastatic disease in patients with exocrine pancreatic cancer suggests that systemic therapy (chemotherapy) should play a major role in the management of this disease. However, only marginal success has been achieved in identifying effective systemic therapies for pancreatic cancer. Most studies of single-agent or combination chemotherapy in patients with advanced adenocarcinoma of the pancreas have documented low response rates and little reproducible impact on patient survival or quality of life. Response rates as high as 15% to 30% occasionally seen in pilot studies of novel agents or combinations have generally been difficult to reproduce in larger trials, suggesting that patient selection often accounts for apparent differences between study results. The inherent difficulty in accurately applying bidimensional measurements to local pancreatic masses and the problem of interobserver variations in the measurement of metastatic disease may also contribute to the poor reproducibility of clinical trial findings in patients with locally advanced or metastatic pancreatic cancer.<sup>314,315</sup>

Because of the large volume of published material on this disease, we have chosen to present the results of important new studies and approaches to therapy; comprehensive reviews of the results of chemotherapy for pancreatic cancer are available,<sup>316,317,318,319</sup> and a previous edition of this text provides a comprehensive review of past chemotherapy trials.<sup>321</sup>

### SINGLE-AGENT CHEMOTHERAPY

The thymidylate synthase inhibitor 5-FU remains the most extensively evaluated chemotherapeutic agent for pancreatic cancer. In 212 cases collected from the literature in the pre-CT era, the response rate to 5-FU was 28%.<sup>322</sup> However, despite numerous trials, the optimal dose and schedule of 5-FU have not been clearly defined. Two of the most commonly used schedules are continuous infusion of 1000 mg/m<sup>2</sup>/d for 5 days or bolus infusion of 400 to 500 mg/m<sup>2</sup>/d for 5 days.<sup>318,323,324</sup> A highly potent and specific thymidylate synthase inhibitor, Tomudex, has been evaluated in patients with advanced pancreatic cancer. However, despite its potent inhibition of thymidylate synthase and other biochemical advantages over 5-FU, clinical trial results have been disappointing, with only 2 of 42 patients achieving an objective response.<sup>325</sup> Additional regimens based on protracted infusions of 5-FU continue to be explored but have not demonstrated any major effect on the outcome of the disease.<sup>326,327</sup> The new oral 5-FU prodrugs (capecitabine, uracil-tegafur, and S-1) have not yet been comprehensively tested in pancreatic cancer, but given the limited impact of intravenous 5-FU on this disease, expectations for these agents are low.

Most of the cytotoxic chemotherapeutic agents studied during the 1990s have demonstrated little objective evidence of significant activity against advanced pancreatic cancer (Table 33.4-11).<sup>222,328,329,330,331,332,333,334,335,336,338</sup> and <sup>339</sup> Inactive drugs that have undergone evaluation during this period include iproplatin,<sup>328</sup> trimetrexate,<sup>329</sup> edatrexate,<sup>330</sup> fazarabine,<sup>331</sup> diaziquone,<sup>332</sup> mitoguazone,<sup>332</sup> and amonafide.<sup>333</sup> Ifosfamide, evaluated in the 1980s, showed initial promise, with six partial responses in 29 patients with advanced disease.<sup>340</sup> A subsequent phase II trial that used ifosfamide as a continuous infusion with mesna yielded three partial responses, one complete response, and six minor responses in 25 evaluable patients.<sup>341</sup> However, a follow-up study did not confirm these favorable results.<sup>342</sup>

TABLE 33.4-11. Single-Agent Chemotherapy Trials in Patients with Advanced Pancreatic Cancer

More recently, the semisynthetic taxanes paclitaxel and docetaxel have been studied in patients with locally advanced and metastatic pancreatic cancer. *In vitro*, docetaxel demonstrated significant activity against human pancreatic cancer cell lines.<sup>343</sup> In a subsequent clinical trial, Rougier and coworkers<sup>334</sup> at the Institut Gustave-Roussy reported five objective responses (29%) in 17 patients with hepatic metastases. However, toxic effects were substantial and included grade 3 or 4 neutropenia in all patients and severe edema in 13%. In three patients, the edema was so severe that therapy had to be discontinued. Three confirmatory phase II trials failed to confirm the initial response findings.<sup>335,344,345</sup> Similarly, paclitaxel, even when administered using an aggressive schedule with granulocyte colony-stimulating factor, had only minimal efficacy against advanced pancreatic cancer.<sup>315</sup>

Novel analogues of the topoisomerase I inhibitor camptothecin also have undergone evaluation in patients with advanced pancreatic cancer. Topotecan, administered once daily for 5 days or using a 21-day continuous infusion schedule, was ineffective.<sup>337,338,346,347</sup> Irinotecan (CPT-11) was evaluated in 34 patients by the EORTC Early Clinical Trials group.<sup>339</sup> Irinotecan was administered intravenously over 30 minutes at a dose of 350 mg/m<sup>2</sup> every 3 weeks; objective partial responses were documented in only three patients, with a median survival for the entire group of 5 months.

Gemcitabine is a deoxycytidine analogue with structural and metabolic similarities to cytarabine.<sup>348</sup> As a prodrug, gemcitabine must be phosphorylated to its active metabolites gemcitabine diphosphate and gemcitabine triphosphate (dFdCTP). In both preclinical and clinical testing, gemcitabine demonstrated activity in solid tumors greater than that of cytarabine.<sup>349</sup> These observations can be potentially explained by the following properties of gemcitabine: (1) It is three to four times more lipophilic than cytarabine, resulting in greater membrane permeability and cellular uptake; (2) it has higher affinity for deoxycytidine kinase; and (3) the intracellular retention of dFdCTP is long.<sup>350</sup> In the initial multicenter trial,<sup>222</sup> objective responses to gemcitabine were documented in only 5 (11%) of 44 patients with advanced pancreatic cancer, but the investigators noted frequent subjective symptomatic benefits, often in the absence of an objective tumor response. Based on these observations, two subsequent trials of gemcitabine in patients with advanced pancreatic cancer have been completed. In one randomized trial,<sup>223</sup> gemcitabine was compared to 5-FU in previously untreated patients. Patients treated with gemcitabine had a median survival of 5.65 months, compared to 4.41 months ( $P = .0025$ ) in those treated with 5-FU. Twenty-four percent of patients treated with gemcitabine were alive at 9 months, compared to 6% of patients treated with 5-FU. In addition, more clinically meaningful effects on disease-related symptoms (pain control, performance status, weight gain) were seen with gemcitabine (23.8% of patients) than with 5-FU (4.8% of patients). Similar systemic effects and demonstrable disease responses were documented in patients who were treated with gemcitabine after experiencing disease progression while receiving 5-FU.<sup>351</sup> These results have helped gemcitabine to become the accepted first-line therapy for patients with

advanced pancreatic adenocarcinoma in the United States, although this approach is not necessarily shared worldwide. <sup>352</sup>

During the early phase II trials of weekly gemcitabine in chemotherapy-naive patients, it became clear that much higher doses could be safely administered (using 30-minute bolus infusions) than were tolerated in patients who had received multiple prior chemotherapies. However, previous cellular pharmacologic studies of this agent suggested that simply increasing the dose administered over 30 minutes may not increase cytotoxicity or improve gemcitabine's therapeutic index. During the early clinical experience in patients with solid tumors, dFdCTP levels were measured in peripheral blood mononuclear cells and showed that the rate of gemcitabine phosphorylation, like that of cytarabine, was subject to saturation kinetics. <sup>221,353</sup> The concentration of dFdCTP in the circulating mononuclear cells increased in proportion to the gemcitabine dose between 35 and 250 mg/m<sup>2</sup>, but further increments in cellular dFdCTP were not observed at higher doses (350 to 1000 mg/m<sup>2</sup>); instead, the plasma gemcitabine concentrations rose to more than 20 nmol/L, suggesting saturation of gemcitabine 5'-phosphate accumulation. The rate of dFdCTP accumulation and the peak cellular concentration were highest at a dose rate of 350 mg/m<sup>2</sup> per 30 minutes (approximately 10 mg/m<sup>2</sup>/min), during which steady-state gemcitabine levels of 15 to 20 nmol/L were achieved in plasma. <sup>353</sup> Similar results were found in a pilot trial of gemcitabine in leukemia patients in which dFdCTP levels were measured in circulating malignant cells. <sup>354</sup> A more comprehensive phase I trial <sup>355</sup> in leukemia patients showed that a gemcitabine dose rate of 10 mg/m<sup>2</sup>/min achieved a mean steady-state gemcitabine level of 26.5 nmol/L and was sufficient to maximize the rate of dFdCTP accumulation in circulating leukemic cells.

The most commonly applied approach to dose intensification in phase II studies of gemcitabine was to maintain the weekly schedule and increase the dose administered over 30 minutes. <sup>356</sup> However, because the plasma levels of gemcitabine achieved using this approach are well above 20 nmol/L, this strategy is not likely to increase intracellular levels of the active metabolite dFdCTP or improve efficacy. The pharmacodynamic relationships documented through the studies just described suggest that increasing the infusion time while holding the dose rate constant increases intracellular levels of the active metabolites gemcitabine diphosphate and dFdCTP and thus achieves the goal of dose intensification. To establish the feasibility of this approach, a phase I study <sup>357,358</sup> of gemcitabine was conducted in patients with advanced solid tumors whereby dose escalation was achieved by increasing the duration of the weekly gemcitabine infusions while maintaining the dose rate at 10 mg/m<sup>2</sup>/min. A subsequent randomized phase II trial <sup>232</sup> in patients with metastatic pancreatic cancer suggested that short infusions (10 mg/m<sup>2</sup>/min) of gemcitabine may be more effective than the standard 30-minute bolus technique.

Given gemcitabine's manageable toxicity profile and favorable intracellular pharmacology, gemcitabine-based combinations are also under active evaluation. <sup>359,360</sup> Early trials have combined gemcitabine with 5-FU, <sup>361,362</sup> cisplatin, <sup>363,364</sup> docetaxel, <sup>365,366</sup> and <sup>367</sup> paclitaxel, <sup>368</sup> epirubicin, <sup>369</sup> and marimastat <sup>370</sup> (Table 33.4-12).

Study	Agents	Objective Response/Total Patients (%)	Median Survival (mo)	Clinical Benefit (%)
Carino et al. <sup>361</sup> (199)	Gen/5FU	1/4 (4)	7	31
Hidajet et al. <sup>362</sup> (199)	Gen/5FU	1/25 (4)	7.1	38
Brennan et al. <sup>363</sup> (199)	Gen/cisplatin	1/4 (1)	8.3	30
Colucci et al. <sup>364</sup> (199)	Gen/cisplatin	18/22 (81)	3.8	38
Scheithauer et al. <sup>365</sup> (199)	Gen/epidoxin	14/42 (33)	7.3	41

5FU, 5-fluorouracil; Gen, gemcitabine; NA, not available.  
 Includes improvement in performance ratio and pain intensity and weight gain.

**TABLE 33.4-12.** Gemcitabine -Based Combination Chemotherapy Trials in Patients with Advanced Pancreatic Cancer

Despite the encouraging results with gemcitabine and gemcitabine-based combinations, the median survival for patients with metastatic disease continues to be less than 6 months, with very few patients achieving long-term disease stabilization. Although two trials have supported the superiority of chemotherapy over supportive care, <sup>371,372</sup> some of the effects attributed to chemotherapy may not be substantially different from what can be achieved with aggressive supportive care alone. The study of novel chemotherapeutic agents based on the evolving understanding of the pathobiology of pancreatic cancer must continue.

### MODULATION OF 5-FLUOROURACIL

Interest remains in the possibility of increasing the activity and therapeutic index of 5-FU by the use of biochemical modulators. N-(Phosphonoacetyl)- L-aspartate disodium (PALA) depletes uridine nucleotide pools by inhibiting aspartate transcarbamoylase, favoring incorporation of 5-FU nucleotide metabolites into RNA and thereby potentiating the antitumor activity of 5-FU. Administering methotrexate before PALA and 5-FU results in increased formation of fluorouridine monophosphate. A study by Morrell et al. <sup>373</sup> using a weekly schedule of PALA at a dose of 250 mg/m<sup>2</sup> followed 24 hours later by a 24-hour continuous infusion of 5-FU (2600 mg/m<sup>2</sup>) in patients with advanced pancreatic cancer was associated with severe toxicity, including one death, and only one response. A similar study demonstrated less toxicity but also no benefit from the use of PALA plus 5-FU compared with 5-FU alone. <sup>374</sup> The addition of methotrexate or 6-methylmercaptopurine riboside also provided no benefit over 5-FU alone. <sup>375,376</sup>

Regimens that rely on the modulation of 5-FU and prolong inhibition of thymidylate synthase have demonstrated efficacy against colon cancer but have shown little activity against pancreatic cancer. Prospective clinical trials in patients with advanced pancreatic cancer have evaluated high-dose leucovorin (500 mg/m<sup>2</sup>), administered daily or as a continuous infusion for 6 days, in combination with 5-FU. <sup>377,378</sup> The daily dose of 5-FU ranged from 375 mg/m<sup>2</sup> to 600 mg/m<sup>2</sup>. Objective response rates averaged less than 10%, and toxicity was often significant. The substitution of 5-methyltetrahydrofolate for leucovorin also failed to demonstrate clinically meaningful biochemical modulation of 5-FU. <sup>379</sup> Thus, despite some evidence to the contrary, <sup>371,380</sup> the current consensus is that the addition of leucovorin to 5-FU provides no therapeutic advantage over single-agent 5-FU in advanced pancreatic cancer.

Another potential modulator of 5-FU is interferon- $\alpha$ , with or without leucovorin. <sup>381,382,383</sup> and <sup>384</sup> Scheithauer et al. <sup>385</sup> combined 5-FU (20 mg/kg on day 3) with interferon- $\alpha$  (10  $\times$  10<sup>6</sup> U/d for 3 days) and leucovorin (200 mg on day 3). The observed response rate (4 of 32) and median duration of survival (5.5 months) were no different than with 5-FU alone. Gattani et al. <sup>386</sup> used three potential biomodulators—cisplatin, leucovorin, and methotrexate—in an effort to enhance the cytotoxicity of 5-FU. Six responses were seen in 24 patients with advanced pancreatic cancer, but mucositis occurred in more than one-half of the study population. Thus, the results from clinical trials to date have not demonstrated any reproducible benefit of 5-FU modulation in patients with pancreatic cancer.

### HORMONAL THERAPY

Johnson and Corbishley <sup>387</sup> were the first to note that pancreatic tumors contain sex steroid hormone receptors, stimulating interest in a hormonal approach to the management of pancreatic cancer. This interest continues as investigators refine their understanding of the hormonally controlled signal transduction pathways that control cellular proliferation. <sup>388,389</sup> and <sup>390</sup> Early research in this area demonstrated that serum testosterone concentrations were lower in both men and women with pancreatic cancer than in patients with other cancers or healthy controls. <sup>391,392</sup> and <sup>393</sup> Laboratory evidence that exocrine pancreatic cancers are sensitive to gastrointestinal hormones, sex steroids, and growth factors led to the use of hormonal manipulation in patients with pancreatic cancer. <sup>394,395,396</sup> and <sup>397</sup> Cyproterone acetate, an antiandrogen, inhibited the growth of human pancreatic xenografts in nude mice, <sup>398</sup> and a luteinizing hormone-releasing hormone (LHRH) analogue, D-trp-6-LHRH, induced regression of nitrosamine-induced pancreatic cancers in hamsters. <sup>399</sup> When this analogue was combined with RC-160, an experimental somatostatin analogue, the same growth inhibition was observed. <sup>400</sup> Another somatostatin analogue, SMS-201-995, also demonstrated *in vivo* inhibition of human adenocarcinoma cell lines. <sup>401</sup> These laboratory observations stimulated clinical trials evaluating LHRH agonists, growth factor inhibitors (octreotide), <sup>402,403</sup> and <sup>404</sup> tamoxifen, and more recently, flutamide <sup>405,406</sup> in patients with advanced pancreatic cancer. Consistent with the cytostatic effect of hormonal therapy, objective responses were not seen; median survival duration ranged from 3 to 8 months. <sup>405,407,408,409,410,411,412,413,414,415,416,417</sup> and <sup>418</sup> The potential cytostatic effects of tamoxifen continue to be studied in the laboratory. <sup>419</sup>

Several uncontrolled clinical studies have suggested improved survival in patients with pancreatic cancer treated with tamoxifen, <sup>407,408,420,421</sup> yet other studies have not

confirm this observation.<sup>414,415</sup> and <sup>416</sup> A case-control study involving 80 patients did suggest a survival advantage for patients treated with tamoxifen.<sup>409</sup> However, in a prospective, randomized, double-blind trial, pancreatic cancer patients receiving tamoxifen had a median survival of 115 days compared to 122 days for the placebo-treated patients; 8% of patients were alive at 1 year in both groups.<sup>415</sup> A small trial reported by Crowson et al.<sup>410</sup> using CT to evaluate tumor response also demonstrated no benefit with tamoxifen. Studies with octreotide,<sup>417</sup> steroids, and LHRH agonists,<sup>411,422</sup> as well as combinations of these agents,<sup>403,412,413</sup> have not shown an increase in survival for patients with pancreatic cancer. Likewise, a pilot study of MK329, a cholecystokinin antagonist, in 18 patients with pancreatic cancer demonstrated no antitumor activity.<sup>423</sup> Nevertheless, despite the lack of a clear effect of currently available hormonal therapies on exocrine pancreatic carcinoma, research in this area continues.

## COMBINATION CHEMOTHERAPY

In general, combination chemotherapy has not been a successful approach to the management of pancreatic cancer. However, the results of prior studies of combination chemotherapy are presented here for historical purposes.

### **5-Fluorouracil , Doxorubicin (Adriamycin), and Mitomycin C Regimen**

The combination of 5-FU, doxorubicin (Adriamycin), and mitomycin C (FAM) for metastatic pancreatic adenocarcinoma was first described by Smith et al.<sup>424</sup> in 1980, based on previous work demonstrating a 13% partial response rate with doxorubicin in previously untreated patients.<sup>425</sup> Twenty-seven of 39 patients had measurable disease; ten (37%) of these achieved a partial response.<sup>424</sup> These ten patients had a median survival of 12 months, compared with 3.5 months in nonresponders. Bitran et al.<sup>426</sup> reported similar results. An earlier report of streptozocin, mitomycin C, and 5-FU (SMF) for advanced pancreatic cancer suggested a response rate of 43%, although many patients experienced severe gastrointestinal and renal toxicity.<sup>427</sup> Therefore, several cooperative groups compared FAM and SMF. The Cancer and Leukemia Group B studied 184 patients and found response rates of 14% for FAM and 4% for SMF (not significantly different), both of which were much lower than suggested by previous reports.<sup>428</sup> Comparison of FAM to two schedules of SMF,<sup>429</sup> to 5-FU alone, and to 5-FU and doxorubicin<sup>430</sup> confirmed these low response rates. More recently, FAM was combined with aminoglutethimide without benefit.<sup>431</sup> Despite these negative trials, a randomized study of a modified FAM regimen compared to no treatment demonstrated an improved median survival for FAM-treated patients.<sup>432</sup> However, this was a small study involving only 44 patients, and the pancreatic cancer was pathologically confirmed in only 31. Based on the results to date, the use of FAM chemotherapy in the management of advanced pancreatic cancer cannot be recommended.

### **Mallinson Regimen**

In 1980, Mallinson et al.<sup>433</sup> first reported on a regimen of induction therapy with 5-FU, cyclophosphamide, methotrexate, and vincristine followed by maintenance treatment with 5-FU and mitomycin C for advanced pancreatic cancer. A median survival of 44 weeks was reported for patients who received therapy, compared with 9 weeks for patients offered only supportive care. However, a phase III trial comparing the Mallinson regimen to 5-FU alone and to 5-FU, doxorubicin, and cisplatin was unable to confirm these results; the median survival was only 4.5 months in patients who received the Mallinson regimen.<sup>434</sup>

### **Cisplatin -Containing Regimens**

After a trial that showed significant activity of cisplatin administered at a dose of 100 mg/m<sup>2</sup> every 4 weeks,<sup>435</sup> cisplatin was combined with continuous-infusion 5-FU. However, poor results have been seen with low-dose schedules,<sup>436</sup> and toxic effects have been seen in a high percentage of patients.<sup>437</sup> Somewhat better results have been observed with higher doses of cisplatin (100 mg/m<sup>2</sup>) combined with 5-FU (1000 mg/m<sup>2</sup>/d) administered by continuous infusion. In a study of 40 pancreatic cancer patients,<sup>438</sup> 13 of whom were previously treated and 36 of whom had metastatic disease, one complete and nine partial remissions (response rate, 26.5%) were documented; the median survival rate was 7 months. This high-dose regimen was associated with one treatment-related death and the occurrence of grade 4 granulocytopenia in 27% of patients. The most recent report of cisplatin and 5-FU comes from Japan.<sup>439</sup> These investigators used a lower dose of both agents (5-FU, 500 mg/m<sup>2</sup>/d; cisplatin, 80 mg/m<sup>2</sup>) based on phase I studies in their country. In 37 previously untreated patients with pancreatic adenocarcinoma, the response rate was only 8%.

### **Other Combinations**

A combination regimen of 5-FU, leucovorin, mitomycin C, and dipyridamole produced 12 responses in 16 patients with locally advanced pancreatic cancer.<sup>440</sup> Five of these were objective complete responses documented by CT and tumor marker measurements. At the time of this report, median survival had not yet been reached but was projected to be greater than 1 year. Five patients had received EBRT, but this was not believed to have affected overall survival. In a subsequent report from the same group, this regimen achieved an overall response rate of 39% in patients with locally advanced pancreatic cancer, with six patients achieving sufficient improvement in their tumor status on CT scans to justify surgical exploration.<sup>301</sup>

Based on laboratory data suggesting synergy of this drug combination, Dougherty et al.<sup>441</sup> reported on a phase I/II study of cisplatin, high-dose cytarabine, and caffeine (CAC) in 28 patients with advanced pancreatic cancer. A partial response was documented in 7 of 18 evaluable patients. This finding prompted a phase III study by Kelsen et al.<sup>442</sup> comparing CAC to SMF. Eighty-two patients were randomized, and 90% were evaluable; objective responses were seen in two patients who received CAC and four patients who received SMF.

The question of the benefit gained by multiagent chemotherapy compared with single-agent therapy also has been examined. The Southwest Oncology Group performed a series of phase II trials comparing single-agent chemotherapy with combination chemotherapy (5-FU, doxorubicin, mitomycin C, and streptozocin).<sup>332</sup> The single agents studied included mitoguanine, dihydroxyanthracenedione, and diaziquone. Eighty-two patients received single-agent therapy, and 71 received combination chemotherapy; the median survival durations were 3.4 and 4.8 months, respectively, indicating no significant benefit from combination chemotherapy.

In sum, these results confirm the ineffectiveness of conventional combination chemotherapy and support clinical studies evaluating novel single agents in previously untreated patients with advanced pancreatic cancer.

## REGIONAL CHEMOTHERAPY

The high incidence of liver metastases and local tumor recurrence in the pancreatic bed has prompted investigation of regional chemotherapy. Regional approaches to chemotherapy for pancreatic cancer have included infusion of the SMA or celiac axis,<sup>443,444</sup> combined intraarterial and SMV infusion,<sup>445,446</sup> and isolated perfusion with extracorporeal chemofiltration.<sup>447,448</sup> One report includes a phase II study from the Puget Sound Oncology Consortium of combined intraarterial cisplatin, intravenous infusional 5-FU, and EBRT in 16 patients with locally advanced pancreatic adenocarcinoma.<sup>443</sup> No treatment-related deaths occurred, five patients achieved a minor response, and the median survival was 9 months. The authors thus concluded that this regimen was not superior to more standard chemoradiation regimens.

Maurer et al.<sup>444</sup> treated 12 patients with locally advanced, recurrent, or metastatic pancreatic cancer with intraarterial chemotherapy (mitoxantrone, folinic acid, 5-FU, and cisplatin). Only one patient achieved a partial response, and the median survival was 6 months. However, an improvement in tumor-related pain was achieved in 9 of 11 evaluable patients.

Researchers at Tulane University combined intraarterial chemotherapy (mitomycin C, 5-FU, and mitoxantrone) with hemofiltration.<sup>449</sup> They reported two complete responses and ten partial responses in 32 patients with advanced pancreatic cancer. Although these results demonstrate the feasibility of the regional chemotherapy approach to pancreatic cancer, future pilot studies aimed at achieving local control of disease in the pancreas or at decreasing the growth or development of liver metastases will require more sophisticated therapeutic agents to achieve meaningful anticancer effects.

Regional chemotherapy infusion may be more applicable to patients who have undergone pancreaticoduodenectomy and in whom liver metastases are the dominant site of disease recurrence. Ishikawa and colleagues<sup>445</sup> treated 21 patients with continuous-infusion 5-FU (125 mg/d) delivered through the hepatic artery and portal vein for the first 4 to 5 weeks after pancreaticoduodenectomy. No chemotherapy-related complications were reported; one patient died of surgery-related complications. Survival in the 20 evaluable patients was superior to that of historical controls, and liver metastases were the cause of death in only 8% of patients at 3

years of follow-up. Updated results from Ishikawa et al.<sup>446</sup> with 27 patients who received postoperative adjuvant intraarterial and portal venous 5-FU demonstrated a 5-year survival rate of 39%; this high survival rate was thought to be secondary to a marked decrease in hepatic metastases. Reported experiences from both Lygidakis and Stringaris<sup>450</sup> (intraarterial immunochemotherapy) and Beger et al.<sup>451</sup> (intraarterial chemotherapy) support the potential benefit of adjuvant intraarterial therapy after pancreaticoduodenectomy. These results come from highly talented and very experienced physicians; similar results will be difficult to produce outside of specialty centers because of the complexity of treatment delivery. However, the concept of postoperative, adjuvant, liver-directed regional therapy will likely receive greater attention because of improved local tumor control with contemporary forms of chemoradiation and surgery.

## NEW APPROACHES TO SYSTEMIC DISEASE

Despite advances in the understanding of the molecular biology of pancreatic cancer, the systemic treatment of metastatic disease remains unsatisfactory. Chemotherapy and the administration of biologically active molecules, such as tumor necrosis factor<sup>452,453</sup> or interferons,<sup>381,453</sup> have not resulted in significant improvements in response rates or patient survival. The study of novel chemotherapeutic agents based on the evolving understanding of the molecular biology of pancreatic cancer must receive the highest priority.

A number of general areas of clinical investigation may yield favorable results. These include interruption or modulation of known growth factors and signal transduction pathways involved with cell growth, invasion, and angiogenesis. Some of the systemic agents undergoing clinical investigation are described in this section, with an emphasis on therapies that are intended to inhibit specific signals required for cell growth and metastasis.

### Farnesyl Transferase Inhibition

Because the *ras* oncogene is mutated and thereby constitutively activated in the majority of pancreatic cancers, inhibition of *ras* signaling has been postulated as a possible target for therapy. A particularly attractive approach under active development is the inhibition of *ras* protein function through interruption of essential posttranslational processing (farnesylation) necessary to localize *ras* proteins to the cytoplasmic side of the plasma membrane. This effort involved the discovery and synthesis of specific small molecules that inhibit the protein farnesyl transferase.<sup>454,455 and 456</sup> The functional consequence of this inhibitory effect is that the *ras* oncoprotein cannot localize to the cell membrane and is rendered inactive. A number of these small molecules are under investigation and include drugs that are administered orally and intravenously. Phase I and II trials of these agents are under way.<sup>457</sup>

Other approaches are also under investigation. The monoterpene limonene and its more potent metabolite perillyl alcohol decrease farnesylated *ras* levels, probably through a different mechanism than lovastatin (which acts via hepatic hydroxymethylglutaryl coenzyme A reductase inhibition, thereby lowering plasma levels of farnesyl pyrophosphate).<sup>458</sup> Orally administered perillyl alcohol demonstrated significant *in vivo* activity against pancreatic cancer in a Syrian golden hamster model.<sup>459</sup> A phase I clinical trial of orally administered perillyl alcohol has been reported.<sup>460</sup> Perillyl alcohol also holds promise as a potential chemopreventive agent for pancreatic cancer.<sup>461</sup>

### Somatostatin Analogues

Overexpression of the somatostatin receptor occurs in both ductal adenocarcinomas and neuroendocrine tumors. Physiologically, somatostatin is an antitrophic hormone that inhibits the trophic effects of cholecystokinin and other factors. Binding the somatostatin receptor with the octapeptide somatostatin analogue octreotide has been demonstrated to inhibit cell growth *in vitro*. Initial animal studies were encouraging, but early clinical trials have proved disappointing.<sup>462,463 and 464</sup> Two large multicenter phase III clinical trials have been conducted comparing a long-acting octreotide analogue with a placebo in the treatment of advanced pancreatic cancer. In one trial,<sup>417</sup> patients received either a placebo or a long-acting octreotide analogue (SMS-201-995 pa LAR; octreotide pamoate LAR) alone. No objective responses were observed, and the median survival times for patients receiving the octreotide analogue or the placebo were equivalent (16 weeks). In the other trial,<sup>418</sup> all patients received 5-FU infusions with either an octreotide analogue (SMS-201-995 pa LAR) or a placebo. The addition of the octreotide analogue to 5-FU provided no advantage in terms of objective response or survival.

A novel variation of this approach used an octapeptide analogue of somatostatin containing methotrexate attached to the  $\alpha$ -amino group of D-phenylalanine in position 1 of the octapeptide. Subsequent experiments with this agent against the MIA PaCa-2 human pancreatic cancer cell line in nude mice demonstrated significant inhibition of tumor growth.<sup>465</sup> Further preclinical trials investigating the efficacy of such an approach continue.

Another strategy being explored is binding somatostatin analogues, such as octreotide, with radioisotopes, specifically yttrium 90, to selectively deliver therapeutic doses of radiation.<sup>466</sup>

### Receptor Tyrosine Kinase Inhibition

**TRASTUZUMAB (HERCEPTIN).** Binding the HER2/*neu* oncoprotein with specific antibodies leads to growth-inhibitory signaling and promotes apoptosis. Trastuzumab (Herceptin) is a humanized monoclonal antibody developed in mice that specifically binds the HER-2 receptor. Preclinical studies have shown that Herceptin leads to growth inhibition in cell lines that overexpress *HER2/neu*. Clinical trials in patients with metastatic breast cancer whose tumors overexpress *HER2/neu* have demonstrated that Herceptin has activity as a single agent, with objective response rates of 11% to 26%.<sup>467,468</sup> Preclinical studies also have suggested synergy between Herceptin and cytotoxic agents.<sup>469</sup> In a clinical trial,<sup>470</sup> response rates and survival were both improved in women receiving Herceptin and chemotherapy compared to chemotherapy alone for metastatic breast cancer (all patients had tumors that overexpressed *HER2/neu*.) Side effects were generally mild, but it should be noted that, when Herceptin was delivered in combination with an anthracycline, class III or IV heart failure (by New York Heart Association criteria) was observed in 19% of patients, compared to only 3% of patients receiving anthracycline-based chemotherapy without herceptin.<sup>470</sup>

In pancreatic cancer, 30% to 40% of human tumors overexpress *HER2/neu*; however, the role of Herceptin has not yet been defined. A phase II trial is now under way to assess the combination of Herceptin and gemcitabine in patients with advanced pancreatic cancer.

**EPIDERMAL GROWTH FACTOR RECEPTOR MONOCLONAL ANTIBODY (C225).** Antibodies to the epidermal growth factor receptor have been shown to compete with the growth stimulatory ligands for binding to this receptor. Binding with specific antibodies leads to growth inhibition and in some cases to apoptosis. A humanized monoclonal antibody to epidermal growth factor receptor (C225) has demonstrated potent competitive binding to the receptor, leading to growth inhibition. *In vitro* studies suggest an additive effect of C225 with cytotoxic agents.<sup>471</sup> Data from laboratories at the M. D. Anderson Cancer Center suggest a synergistic interaction in animal models of metastasis when gemcitabine and C225 are combined.<sup>472</sup> The exact mechanisms of this synergy are being investigated, including effects on growth inhibition, apoptotic cell death, and angiogenesis. Clinical trials are under way with C225 in head and neck cancer patients; a clinical trial studying the toxicity and efficacy of gemcitabine combined with C225 is planned for patients with advanced pancreatic cancer.

### Matrix Metalloproteinase Inhibitors

Matrix metalloproteinase inhibitors (MMPi) occur as both endogenous factors that tightly regulate the activity of proteases in the extracellular milieu and as exogenous synthetic molecules. The two primary endogenous inhibitors are tissue metalloproteinase inhibitors 1 and 2. Both are fairly large proteins (28 kD and 21 kD, respectively) and unlikely to be clinically relevant because of their poor pharmacologic properties.<sup>473</sup>

A number of synthetic MMPi have been developed, including batimastat, marimastat, and BAY 12-9566. Marimastat is an orally bioavailable agent that has been studied clinically in patients with advanced prostate cancer, colorectal cancer, ovarian cancer, and pancreatic cancer. Interestingly, the dose-limiting toxicity is often musculoskeletal pain with arthralgias and myalgias.<sup>474</sup> BAY 12-9566 is another orally bioavailable MMPi. Both marimastat and BAY 12-9566 are under investigation in multicenter phase III trials. In one randomized trial, marimastat is being compared with gemcitabine as a treatment for advanced pancreatic cancer; the results from this trial will be available soon. Marimastat is also being investigated in a randomized, double-blind, placebo-controlled trial designed to evaluate whether this agent can delay or prevent the onset of metastatic disease after pancreaticoduodenectomy in patients undergoing surgery with curative intent. In yet another clinical trial, patients with advanced pancreatic cancer are being randomized to receive gemcitabine with marimastat or gemcitabine alone; the primary end point of this trial is survival (data unpublished).

## Antiangiogenic Agents

Tumor vascularity is an important requirement for tumor growth beyond a few millimeters, and it is now accepted that specific endogenous angiogenic factors exist that allow for endothelial cell growth and migration into tumor nodules. One such factor is VEGF, which is up-regulated in pancreatic cancer. Strategies have been developed to inhibit the effects of VEGF, including monoclonal antibodies to VEGF. In addition, a specific inhibitor to the receptor tyrosine kinase for VEGF has been discovered (SU5416).<sup>475</sup> Phase I and early phase II clinical trials of SU5416 are currently under way.

Another antiangiogenic agent being studied is TNP-470, an analogue of fumagillin. Fumagillin is derived from the fungus *Aspergillus fumigatus fresenius* and was found to inhibit angiogenesis in an *in vitro* angiogenesis model. Pharmacokinetic studies of TNP-470 have demonstrated that it has a half-life of only 1 hour, suggesting that prolonged or frequent infusions of the agent may be required for activity.<sup>476</sup> Nevertheless, as a single agent, TNP-470 produced a complete response in one patient with metastatic cervical cancer, with other study subjects achieving disease stabilization.<sup>477</sup>

Two other antiangiogenic molecules that have been isolated from tumor-bearing animals are angiostatin, which is a peptide fragment of plasminogen, and endostatin, a fragment from collagenase XVIII.<sup>478</sup> Both angiostatin and endostatin have shown significant antitumor activity in animal models, and angiostatin has induced tumor dormancy in mice.<sup>479,480</sup> Endostatin entered clinical trials in the latter part of 1999.

## Gene Therapy

Given the large number of somatic mutations in pancreatic cancer, gene therapy represents a potentially powerful approach to this disease. Generally, gene therapy for pancreatic cancer includes approaches designed to replace the function of inactivated tumor suppressor genes such as *p53*, *p16*, and *SMAD4/DPC4*. Correcting loss of functional cellular changes is more challenging than inhibiting overexpressed proteins or a mutated oncogene. However, *in vitro* reintroduction of genetic information into cells has been shown to be an effective way to alter cellular growth, induce apoptosis, and sensitize pancreatic cancer cells to chemotherapy and radiation.<sup>481,482</sup> and <sup>483</sup> Other approaches use genetic strategies to inhibit dominant oncogene function. The high frequency with which K-*ras* is altered in exocrine pancreatic cancer and its central function in signal transduction suggest that inhibiting production of the K-*ras* protein could lead to significant growth-inhibitory effects. This strategy has been used successfully in lung adenocarcinoma cells using retroviral constructs coding for K-*ras* antisense RNA.<sup>484</sup> In addition, evolving ribozyme technologies offer the possibility of improved inhibition compared with traditional antisense approaches.<sup>485</sup> A particularly interesting gene-therapy approach uses an oncolytic adenovirus that is genetically modified to replicate only in *p53*-deficient cells.<sup>486</sup> Direct injection of this oncolytic virus has been shown to be feasible.<sup>487</sup> The challenge in gene therapy for pancreatic cancer will be to develop delivery strategies that are capable of targeting both the local and metastatic components of this neoplasm.

## TREATMENT DECISIONS: METASTATIC DISEASE

The complex pathophysiologic abnormalities accompanying metastatic pancreatic cancer often make specific treatment decisions extremely difficult. Many patients present to the medical oncologist or surgeon with profound debilitation, severe pain, and extensive metastatic disease. For these patients, chemotherapy is unlikely to result in significant improvements in quality of life or survival, and the toxic effects of chemotherapy may create additional complications. Management with supportive care or nontoxic hormonal approaches may be the optimal strategies for these patients.

For patients with metastatic pancreatic cancer who present with a good performance status, systemic chemotherapy is appropriate. In view of the limited impact of the currently available agents on survival, continued enrollment of patients in phase II trials of new agents or combinations is essential. In the absence of access to a phase II trial, treatment with gemcitabine appears to be the standard in the United States. However, it must be recognized that the primary impact of gemcitabine is on quality of life; therefore, continued evaluation of novel agents, especially those targeted against specific molecular events important in the pathogenesis of pancreatic cancer, is crucial. With the expansion of our understanding of the molecular and biochemical basis of pancreatic cancer, we are entering an era in which treatments may be tailored to interact with specific molecular and biochemical targets thought to be important in the development or maintenance of neoplasia.

## INTRODUCTION

Primary hepatobiliary malignancies are the most common of solid-organ cancers, and include hepatocellular carcinomas (HCCs), cholangiocarcinomas, and gallbladder cancers. As a group, these tumors represent both major diagnostic and therapeutic challenges. Though surgery can be potentially curative for these tumors, until recently, most cases of hepatobiliary cancers were discovered at a stage far too advanced for complete excision. These tumors also are highly resistant to chemotherapy, limiting options for palliative treatment. However, the last two decades have seen great advances in the diagnosis of and therapy for these tumors. Advances in imaging have allowed for earlier detection and more accurate staging of disease. The safety of surgical therapy has improved and, as a consequence of increased understanding of the biology of these diseases, favorable short- and long-term results are increasingly achieved by extensive but rational resection. Palliative measures such as radiotherapy and ablative therapy have extended the limits of tumor eradication and treatment. In this chapter, a discussion of the current therapy for these hepatobiliary tumors will be presented, emphasizing the recent major advances as well as the most important areas of ongoing and future studies.

## HEPATOCELLULAR CARCINOMA

HCC is the most common solid-organ tumor worldwide, being responsible for more than 1 million deaths annually. The difficulties in treating HCC and the high mortality associated with it are attributable to a number of factors. First, this cancer usually is associated with cirrhosis, which is not only a cause of morbidity but also limits treatment options for the cancer. Second, HCC is usually asymptomatic at early stages and has a great propensity for intravascular or intrabiliary extension, even when the primary tumor is small. As a result, the carcinoma is usually at an advanced stage when discovered. This tumor is, therefore, usually beyond curative therapy at presentation and, indeed, often beyond any useful therapy.

## EPIDEMIOLOGY AND ETIOLOGY

At least 1 million new cases of HCC occur yearly.<sup>1</sup> The incidence of HCC increases with age and is four to eight times more common in men than in women.<sup>2</sup> This cancer is clearly associated with chronic liver injury and, therefore, geographic distribution of HCC closely mirrors that of viral hepatitis ( [Table 33.5-1](#)). Countries with a high incidence of hepatitis B virus (HBV) infection—namely Taiwan, Korea, Thailand, Hong Kong, Singapore, Malaysia, China, and countries of tropical Africa—have the highest incidence of HCC.<sup>3,4</sup> and <sup>5</sup> Areas in which hepatitis C virus (HCV) infections are endemic, such as Japan and Italy, also experience an increased rate of HCC.<sup>3,6,7,8,9</sup> and <sup>10</sup> In these areas, incidence varies from a high of 150 per 100,000 in Taiwan<sup>3</sup> to 28 per 100,000 in Singapore.<sup>4</sup> Comparatively, in low-incidence areas such as Australia, North America, and Europe, HCC occurs in only 1 to 3 per 100,000 population. In high-incidence areas, HCC also occurs in younger individuals as compared to its occurrence in low incidence areas. In Mozambique, one of the areas of highest incidence of HCC, 50% of patients with the tumor are younger than 30 years. In fact, the incidence of HCC among men aged 25 to 34 years is more than 500-fold that of the same age group in Western countries.<sup>11</sup>

INFECTIONS
Hepatitis B virus
Hepatitis C virus
CHOLELITHIASIS
Alcohol
Autoimmune hepatitis
Primary biliary cirrhosis
Cryptosporidiosis
ENVIRONMENT
Aflatoxin
Aluminum

Thioamides
METABOLIC DISEASES
Beta-mannosidosis
α <sub>1</sub> -Antitrypsin deficiency
Wilson's disease
Porphyria cutanea tarda
Type 1 and 2 glycerol storage disease
Cofactor deficiency
Cystic fibrosis
HEREDITARY DISORDERS
Familial cholelithiasis

TABLE 33.5-1. Conditions Predisposing to or Associated with Development of Hepatocellular Carcinoma

This etiologic association between HBV infection and HCC is well established. In a landmark study examining HBV infection and HCC, Beasley et al.<sup>12</sup> followed 22,707 male subjects in Taiwan, 15.2% of whom were HBV chronic carriers, as exhibited by detection of hepatitis B surface antigen (HB<sub>s</sub>Ag) in the serum. Of the 116 cases of HCC that occurred during a mean follow-up period of 7 years, 113 occurred in patients positive for HB<sub>s</sub>Ag. This study demonstrated that HCC was related not

simply to a history of HBV infection but to the chronic carrier states and that the relative risk of developing HCC was 200-fold greater in individuals with evidence of HBV infection than in noninfected individuals.<sup>12</sup>

Epidemiologic evidence has also clearly linked HCV infection with HCC. Antibodies to HCV have been found in as many as 76% of patients with HCC in Japan, Italy, and Spain<sup>13</sup> and in 36% in the United States.<sup>14</sup> In contrast to HBV-associated HCC, however, HCC rarely occurs in HCV carriers before the development of cirrhosis. In addition, the incidence of HCC in cirrhotic carriers of HCV is estimated to be as high as 5% per year, as compared to 0.5% per year for HBV carriers.<sup>15</sup>

Chemical carcinogens also have been linked to primary liver cancers. Chemicals such as nitrites, hydrocarbons, solvents, organochlorine pesticides, primary metals, and polychlorinated biphenyls have been implicated in the development of HCC.<sup>16</sup> Colloidal thorium dioxide (Thorotrast), which emits high level a, b, and g radiation and was used as an angiographic agent in the 1930s, has been linked to angiosarcoma, cholangiocarcinoma, and HCC.<sup>1</sup>

Of all the chemicals linked to development of HCC, the most important is ethanol. Alcohol abuse has been linked to the development of not only HCC but also carcinomas in the larynx, mouth, and esophagus. Ethanol is thought to produce HCC through development of hepatic cirrhosis or as a cocarcinogen with other agents such as HBV, HCV, hepatotoxins, and tobacco,<sup>17,18,19,20,21</sup> and <sup>22</sup> rather than through direct effect on the hepatocytes.

Aflatoxins produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus* have also been linked to HCC. These are fungi that grow on grains, peanuts, and other food products and are the most common cause of food spoilage in the tropics. These fungi produce aflatoxins designated as B<sub>1</sub>, B<sub>2</sub>, G<sub>1</sub>, and G<sub>2</sub>. Aflatoxin B<sub>1</sub> is the most hepatotoxic, and chronic exposure to these mycotoxins leads to development of HCC.<sup>23</sup>

Some congenital conditions also lead to development of HCC. Genetic diseases such as hemochromatosis, Wilson's disease, hereditary tyrosinemia, type 1 glycogen storage disease, hepatic porphyria of both intermittent and cutanea tarda types, familial polyposis coli, ataxia telangiectasia, familial cholestatic cirrhosis, biliary atresia, congenital hepatic fibrosis, neurofibromatosis, situs inversus, fetal alcohol syndrome, a-antitrypsin deficiency, and the Budd-Chiari syndrome<sup>11</sup> have all been linked to a higher incidence of HCC. Ultimately, though, the unifying etiology of HCC may be chronic injury and inflammation.

## PATHOLOGIC FEATURES

HCC has been graded as well differentiated, moderately well differentiated, and poorly differentiated. The well-differentiated variety may be difficult to distinguish from a regenerating nodule on fine-needle biopsy. No firm correlation of grade to prognosis has been established. HCC can be classified generally into three different growth patterns, and these growth patterns have a much greater influence than does histologic grade on resectability and, therefore, greater influence on long-term outcome. The hanging type of tumor is attached to the normal liver by a small vascular stalk, even if the tumor is large. This type is easily excised with little loss in functional parenchyma. The pushing type generally is well demarcated and often encapsulated by a fibrous capsule. This type of tumor displaces normal vasculature rather than infiltrates and invades the major vessels. It is often resectable, even when tumor bulk is substantial. Finally, the infiltrative variety has a very indistinct tumor-liver interface and tends to exhibit a much greater degree of vascular infiltration and invasion, even when the tumor is small. Excising the infiltrative variety often is complicated by positive margins. The practical nature of this gross pathologic classification is reinforced by the distinctive radiologic appearance of these three different growth patterns on imaging.

The most important pathologic issue is the distinct appearance and clinical behavior of the fibrolamellar variant of HCC. The contrast in clinical behavior is summarized in [Table 33.5-2](#). On gross and radiologic inspection, fibrolamellar HCC is generally well demarcated and often encapsulated, with a central fibrotic area. It is a variant that generally occurs in young patients who lack underlying cirrhosis. a-Fetoprotein (AFP), which is commonly elevated in the usual case of HCC, is not elevated in fibrolamellar HCC. Other serum markers that often are elevated in fibrolamellar HCC include neurotensin<sup>24</sup> and vitamin B<sub>12</sub> binding protein. The fibrolamellar variant of HCC is associated with a prolonged survival as compared with typical HCC, likely owing to the well-demarcated nature of the tumor and the greater range in treatment options for patients without underlying cirrhosis.<sup>25</sup>

Characteristic	HCC	Fibrolamellar HCC
Male:female ratio	4:1-8:1	1:1
Median age	55	25
Tumor	Invasive	Well circumscribed
Resectability	<25%	50-75%
Cirrhosis	90%	5%
AFP+	80%	5%
HepB+	65%	5%

AFP+, a-fetoprotein-positive; HCC, hepatocellular carcinoma; HepB+, hepatitis B-positive.

**TABLE 33.5-2.** Comparison of Standard Hepatocellular Carcinoma with the Fibrolamellar Variant

HCC can also appear with mixed or combined features of HCC and cholangiocarcinoma. The two components of this tumor may be separate, adjacent to each other, or intimately mixed.<sup>1,26</sup> Biliary differentiation in HCC is associated with a poor prognosis, because such tumors are more rapidly growing and less vascular and, therefore, are more resistant to embolic therapy.<sup>27</sup> In the clear-cell variant of HCC, the cells have an abundant, pale, finely granular or vacuolated cytoplasm as a result of abundant glycogen, fat, or water. The prognostic importance of finding the clear-cell variant has been debated, but this subtype may be associated with a better prognosis.<sup>28,29</sup>

## CLINICAL PRESENTATION

Even though it is generally a slow-growing tumor, the majority of HCCs present at an advanced stage, when most are beyond curative treatment. Because the liver is relatively hidden behind the right costal cartilages, tumors must reach substantial size before they are palpable. Furthermore, the large functional reserve of the liver masks any small impairment produced by local parenchymal disturbances. Therefore, small tumors are most often asymptomatic and are usually discovered during screening programs<sup>30,31</sup> and <sup>32</sup> or incidentally during imaging performed for other abdominal conditions.

Most cases of HCC are detected only when tumors are large, at a stage when local symptoms are common. Patients usually complain of a dull, right upper quadrant ache, sometimes referred to the shoulder. Hepatomegaly is a frequent accompanying finding. The liver edge is hard and irregular, due both to tumor and the usual accompanying cirrhosis. A vascular bruit can be heard in approximately 25% of cases.<sup>33</sup> General symptoms of malignancy, including anorexia, nausea, lethargy, and weight loss, are common. The most common clinical presentation is the triad of right upper quadrant pain, mass, and weight loss.<sup>34,35</sup> and <sup>36</sup> Central necrosis of large tumors can also lead to fever, and HCC can present as pyrexia of unknown origin. For most patients, the presentation of HCC will also be the first presentation of the underlying cirrhosis. In one study, although 90% of patients were eventually found to have cirrhosis, fewer than 10% were thought, at first evaluation for HCC, to have chronic liver disease on the basis of history and clinical examination.<sup>35</sup>

Hepatic decompensation is another common presentation of HCC, with patients seeking medical attention owing to typical symptoms of liver failure such as ascites, jaundice, or encephalopathy. This decompensation of liver function is most often attributable to bulk replacement of functional parenchyma in a patient with previously compensated cirrhosis. HCC has a great propensity for vascular invasion and intravascular growth. Therefore, hepatic failure may also be due to portal vein occlusion secondary to intravascular tumor thrombus.<sup>37,38</sup> and <sup>39</sup> A much rarer cause of liver failure is Budd-Chiari syndrome, resulting from direct invasion and occlusion of the hepatic vein and inferior vena cava by tumor and tumor thrombus.

Gastrointestinal bleeding often complicates the clinical course of patients with HCC and, in 10% of patients, is the presenting finding.<sup>35</sup> In approximately one-half of these cases, bleeding is from esophageal varices,<sup>39</sup> which can result from portal hypertension due to cirrhosis alone or with an added contribution of intraportal

thrombus. Patients with gastrointestinal bleeding from esophageal varices have an extraordinarily poor prognosis, with a median survival measurable in weeks.<sup>38</sup> The particularly poor prognosis of variceal bleeding complicating HCC is due to the common finding of intraportal thrombus, which further increases the portal pressure and makes control of bleeding varices more difficult. In fact, in one study, nearly one-fourth of patients with HCC died from massive variceal hemorrhage.<sup>37</sup> Gastrointestinal bleeding can occur from other causes as well, such as benign peptic ulcer or direct invasion of the gastrointestinal tract by tumor.<sup>39</sup>

The most dramatic presentation of HCC is tumor rupture, which is the initial presentation in 2% to 5% of patients with HCC.<sup>40,41,42,43,44</sup> and <sup>45</sup> Patients present with acute abdominal pain and swelling and are found to have, in addition to swelling, guarding, rebound tenderness, and ileus. Patients also commonly have signs of hemodynamic instability or overt hypovolemic shock. Diagnosis is confirmed by findings of either tumor mass or peritoneal blood through imaging, laparotomy, or paracentesis.<sup>44,46,47</sup>

Jaundice as a presenting symptom of HCC occurs in up to one-half of all patients. The most common cause of the jaundice is hepatic parenchymal insufficiency.<sup>34,48,49</sup> and <sup>50</sup> On rare occasions (<10% of jaundiced patients), jaundice associated with HCC results from biliary obstruction.<sup>34,51,52,53,54,55</sup> and <sup>56</sup> The biliary obstruction can occur from intraluminal tumor, from hemobilia, or from extraluminal bile duct obstruction. In the clinical evaluation of jaundice in a patient with HCC, it is enormously important to distinguish hepatocellular failure from obstruction. The former usually indicates that the patient is beyond any therapeutic benefit, whereas the latter can be treated, often with good palliation and even potential cure.<sup>53,54,57,58,59,60</sup> and <sup>61</sup>

Rarely (<5% of cases), HCC can present with paraneoplastic syndromes owing to hormonal or immune effects of the tumors.<sup>62</sup> The most important of these syndromes are hypoglycemia, erythrocytosis, hypercalcemia, and hypercholesterolemia. Porphyria cutanea tarda, virilization and feminization syndromes, carcinoid syndrome, hypertrophic osteoarthropathy, hyperthyroidism, and osteoporosis can also occur.<sup>63,64</sup> and <sup>65</sup>

## DIAGNOSTIC INVESTIGATIONS

For patients suspected of suffering from HCC, the aims of diagnostic investigations are (1) verification of diagnosis, (2) determination of extent of disease, (3) determination of functional liver reserve, and (4) assessment of biologic determinants that affect long-term prognosis.

### *Verification of Diagnosis*

Diagnosis of HCC can usually be positively established noninvasively by a combination of history, physical assessment, imaging, and blood tests. There is little diagnostic doubt in a patient with a liver mass consistent with an HCC visible on computed tomography (CT) or magnetic resonance imaging (MRI) and a serum AFP of more than 500 ng/dL. This combination is diagnostic, and treatment can be instituted without tissue diagnosis. The presence of cirrhosis or hepatitis infection, as documented by presence of HB<sub>s</sub>Ag or HCV virus in the blood, is further confirmation.

In the patient with a space-occupying lesion on ultrasonography (US) or CT and a nondiagnostic AFP level, the role of a percutaneous needle biopsy often is debated. There is no doubt that needle biopsy is diagnostic for HCC. However, complications are also not infrequent. Hemorrhage or tumor rupture can occur. Furthermore, there is also a small but finite risk of tumor spillage and seeding of the needle biopsy tract.<sup>66</sup> In cases of potentially resectable HCC, where the diagnostic certainty is high, we would proceed to surgical exploration without tumor biopsy. Indeed, in this clinical scenario, the histologic appearance of the nonneoplastic liver may have a greater impact on surgical planning. If advanced cirrhosis will preclude safe resection, we often perform a biopsy the portion of the liver that does not contain tumor, for histologic evaluation.

In patients with a nondiagnostic AFP level who are not surgical candidates and, therefore, are not candidates for curative therapy, tumor biopsy is performed if the patients are candidates for palliative therapy. In that case, fine-needle aspiration for cytologic evaluation is usually performed in preference to core-needle biopsy for histology, as comparative studies indicate that smear cytology yielded a much higher percentage of correct diagnoses as compared to microhistology (86% vs. 66%).<sup>67</sup> Patients who are not candidates for palliative therapy do not need a definitive diagnosis, and biopsy is discouraged.

### *Determination of Extent of Disease*

The two issues to be resolved by the extent-of-disease evaluation are whether the disease is isolated to the liver and whether distribution of tumor in the liver is amenable to surgical excision. The most common sites of metastases of HCC include lung, peritoneum, adrenal gland, and bone. Hence, chest radiography is mandatory. Cross-sectional imaging, such as CT or MRI, of the abdomen should be scrutinized for peritoneal and adrenal sites of disease. Many centers consider bone scans mandatory prior to liver resection. Certainly, in patients with pain attributable to bony metastases, a bone scan should be performed. A finding of extrahepatic disease changes the prognosis of the patients greatly, as such a finding precludes the possibility of hepatectomy as curative therapy.

The extent of liver involvement usually is determined by CT scanning. This diagnostic imaging modality is widely available and relatively inexpensive. In interpreting any cross-sectional imaging modality for the patient with HCC, the number and distribution of liver tumors must be determined, as well as the degree of vascular invasion. In this regard, triple-phase (non-contrast-enhanced, arterial phase, and portal phase) CT images should be obtained. HCCs are generally highly vascular tumors, and tumors on images with contrast enhancement may become isodense with the surrounding liver. Tumors sometimes are visible only during the non-contrast-enhanced phase. Because HCC has a great propensity for vascular invasion and extension, tumor thrombus in the portal vein, hepatic vein, or vena cava is not unusual. Scans should therefore be scrutinized for evidence of such invasion, as therapy and prognosis can be altered significantly by such findings. If such invasion is suspected but not proven by CT, Doppler US or MRI is indicated.

At some centers, hepatic angiography is standard.<sup>68,69</sup> Some have even advocated routine use of iodized oil (Lipiodol) injected angiographically to delineate hepatic extent of disease further.<sup>70</sup> This lipid is preferentially retained in HCC because of the particle size. These angiographic methods are highly sensitive for the presence of tumor. Nonetheless, with current helical CT or MRI, there is only minor incremental yield. We rely on angiography only when we suspect small tumors not visible by conventional cross-sectional imaging, such as for a patient with small amounts of disease seen on CT who has a very high AFP level.

### *Assessment of the Patient's General Condition and Hepatic Functional Reserve*

In the evaluation of patients for possible hepatectomy, cardiopulmonary assessment should be conducted as for any major procedure. Patients older than 65 years or patients with a history or symptoms consistent with cardiopulmonary disease should be referred for formal medical preoperative evaluation.

Assessment of baseline liver function and assessment of complications of cirrhosis are paramount in the process of determining the optimal treatment option for each patient. Recovery from liver resection is reliant on the capacity of the liver to regenerate. The cirrhotic liver often has a reduced capacity for regeneration. In addition, cirrhosis and portal hypertension often are associated with derangements in hepatic production of coagulation factors and with thrombocytopenia, which explains the increased risk of liver failure and bleeding after resection for HCC. Indeed, the complication rate after ablative therapies is increased proportionate to the degree of liver dysfunction.<sup>71,72</sup> Consequently, many clinical and laboratory methods have been devised for determining the level of risk for various therapies.

**SERUM LIVER FUNCTION TESTS AND CLINICAL ASSESSMENT.** Various liver function tests, alone or in combination, have been touted as useful for predicting risks of liver resection and other treatments for HCC. Various single serum measures of liver function have been suggested to be useful predictors of perioperative outcome, including serum bilirubin<sup>73</sup> and serum alanine aminotransferase.<sup>74</sup> A doubling of bilirubin has been suggested as a contraindication for liver resection.<sup>73</sup> Other investigators have deemed a platelet count of fewer than 50,000 or a prolonged prothrombin time (>4 seconds over control) as a relative contraindication for hepatic resection.<sup>75</sup> Most investigators, however, have not relied on a single parameter but rather have used a combination of clinical and biochemical parameters to gauge safety of hepatectomy and other treatments. In this regard, the most clinically useful system is the Pugh-Child's classification, which is a point-scoring system for evaluation of liver function based on the levels of serum bilirubin, coagulation profile, serum albumin, presence or absence of ascites and encephalopathy, and nutritional status ([Table 33.5-3](#)).<sup>76,77</sup> Functionally well-compensated cirrhosis is classified as Pugh-Child's classification grade A; decompensating cirrhosis is grade B; and decompensated cirrhosis is grade C. Generally, partial hepatectomy is offered only to patients who are Pugh-Child's grade A and to the most favorable grade B patients.<sup>78</sup> In general, Pugh-Child's grade C patients are offered only supportive care, as even nonsurgical ablative methods, such as embolization, are associated with procedure-related mortality in one-third of patients.<sup>71</sup>

Measurement	1 Point	2 Points	3 Points
Bilirubin (mg/dL)	1-1.9	2-2.9	>2.9
Prothrombin time pro-longation (sec)	1-3	4-6	>6
Albumin (g/dL)	>3.5	2.8-3.4	<2.8
Ascites	None	Mild	Moderate to severe
Encephalopathy	None	Grade 1 or 2	Grade 3 or 4

Note: Pugh-Child's grade A, 5-6 points; B, 7-9 points; C, 10-15 points.

**TABLE 33.5-3.** Pugh's Modification of Child's Grading of Cirrhosis

**DYNAMIC TESTS.** Many sophisticated dynamic measures of liver function have also been used in attempts to quantitate hepatic function. Investigators have attempted to use elimination of certain dyes that are exclusively cleared by the liver, such as bromsulphophthalein or indocyanine green, as measures of hepatic function. Galactose clearance or [<sup>14</sup>C]aminopyrine clearance has also been used to evaluate the specific metabolic capacity of the liver. Of these, the most commonly used evaluative modalities in clinical practice are indocyanine green retention at 15 minutes <sup>79</sup> and the [<sup>14</sup>C]aminopyrine breath test, <sup>80</sup> though controversy still exists concerning their usefulness. <sup>81</sup> We do not use these tests on a routine basis in our care of the patient with HCC but have found the clinical Pugh-Child's classification sufficiently discriminatory for selecting patients for therapies.

**PORTAL PRESSURES AND BLOOD FLOW.** Another relatively simple test that may be predictive of perioperative outcome is the hepatic venous wedge pressure. By passing a venous catheter through the vena cava into the hepatic vein, the hepatic venous pressure can be directly ascertained. By balloon occlusion of the hepatic vein, the hepatic venous wedge pressure, which is a reflection of the portal pressure, can be determined. These measurements have been touted as useful in segregating Pugh-Child's grade B patients who may have favorable results from resection from those likely to experience major complications. <sup>82</sup>

### POTENTIALLY CURATIVE TREATMENTS

Therapies for HCC can be separated into resection, ablation, radiotherapy, systemic chemotherapy or immunotherapy, and supportive care ( [Table 33.5-4](#)). Resectional therapy represents the only potentially curative option.

POTENTIALLY CURATIVE OPTIONS	
Resectional therapies	
Total hepatectomy with orthotopic liver transplantation	
PALLIATIVE TREATMENTS	
Regional therapies	
Ablative therapies: cryoablation, radiofrequency ablation	
Palliative resections

**TABLE 33.5-4.** Treatment Options for Hepatocellular Carcinoma

### Partial Hepatectomy

Partial hepatectomy represents the most common procedure for treatment of HCC performed with curative intent. The liver is normally a very resilient organ with remarkable regenerative capacity. In a noncirrhotic liver, routine recovery can be expected even after resection of more than two-thirds of the functional parenchyma. <sup>83</sup> In the United States, nearly one-half the patients with HCC will have no associated cirrhosis. <sup>84</sup> For patients with no cirrhosis, operative mortality at most major centers is generally less than 5%, and very extensive procedures are justified by the low risk and the potential for long-term survival and cure. Resection is associated with a 5-year survival in more than 30% of patients. <sup>85,86,87,88</sup> and <sup>89</sup> For a patient without cirrhosis, partial hepatectomy is a relatively safe procedure and is the treatment of choice for eradication of HCC ( [Table 33.5-5](#)).

**TABLE 33.5-5.** Operative Mortality as Related to Liver Cirrhosis

Worldwide, however, most cases of HCC are associated with cirrhosis, which greatly increases the risk for partial hepatectomy (see [Table 33.5-5](#)). This increase in risk is due in part to intraoperative factors. These patients will usually have rigid and hard parenchyma and established varices that are difficult to manipulate and are prone to bleeding. In addition, such patients will have thrombocytopenia and coagulation defects that further exacerbate the risk of hemorrhage. Postoperatively, the liver may not regenerate, resulting in liver failure. Furthermore, postoperative exaggeration of portal hypertension may lead to ascites and variceal bleeds. It is understandable, therefore, that resection is associated with increased morbidity and mortality in these patients. Even for a cirrhotic patient with well-compensated liver function, we are reluctant to remove more than 20% to 25% of the functional parenchyma. <sup>81,89,90,91</sup> and <sup>92</sup> Until recently, even at centers with a low mortality for partial hepatectomy in the noncirrhotic population, partial hepatectomy for patients with cirrhosis was associated with a 10% mortality or higher (see [Table 33.5-5](#)). <sup>85,86,93,94</sup> and <sup>95</sup> This explains the nihilistic view adopted by some for this disease, as well as the interest in treating this disease by total hepatectomy and liver transplantation. Nevertheless, even now, cirrhotic patients who survive the operation have a 5-year survival of approximately 30% ( [Table 33.5-6](#)). <sup>85,86,87,88</sup> and <sup>89,93,94</sup> and <sup>95</sup> Over the last decade, a number of series have demonstrated increasing safety of partial hepatectomy in cirrhotic patients (see [Table 33.5-5](#)). The mortality at most major centers treating HCC has been reduced to the 5% level, owing to improvements in patient selection, perioperative support, and surgical technique. <sup>84,96,97</sup> and <sup>98</sup>

significant activity against small HCCs, but problems with dosimetry have limited its use for patients with bulky unresectable disease. In a prospective, randomized study, Lau et al.<sup>124</sup> compared 21 patients who received 50 mCi of transarterial <sup>131</sup>I-Lipiodol within 6 weeks of liver resection for HCC with 22 patients receiving no adjuvant therapy. The 3-year survival rates for the treated group and the control group were 85% and 46%, respectively. These results await multicenter studies to confirm with bigger numbers not only the long-term cancer results but also the feasibility of using such radioembolization methods in diverse centers.

### Total Hepatectomy and Liver Transplantation

From a theoretic standpoint, total hepatectomy and liver transplantation is the most attractive treatment for HCC. This treatment allows for removal of the liver cancer with the widest margin possible. It also allows for removal of diseased parenchyma that may contain microscopic metastatic disease as well as parenchyma that may be predisposed to formation of second primary tumors. A number of studies have attempted to define the biologic parameters predicting good long-term outcome after liver transplantation. The best results are seen in patients with fibrolamellar histology and in patients with small incidental tumors found unexpectedly within the explanted liver. Characteristics associated with poor long-term outcome include advanced stage, the presence of a margin involved by tumor, large tumors, multiple tumors, microscopic or macroscopic vascular invasion, and bilobar disease.<sup>125,126</sup> Patients with tumors smaller than 5 cm have a mean survival of 55 months, whereas those with tumors larger than 5 cm have a mean survival of only 24 months.<sup>127,128</sup> Therefore, most transplantation centers will not consider patients with tumors larger than 5 cm for transplantation. Currently, at most centers, only patients with fewer than three tumors, all smaller than 5 cm, and with no main portal vein or vena caval involvement are considered for liver transplantation.

In clinical practice, however, biology of the cancer is not the most important determinant of the usefulness of transplantation. Liver transplantation is associated with substantial morbidity and mortality (Table 33.5-7). Series from the 1980s and early 1990s often report mortality rates as high as 10% to 20%.<sup>129</sup> Though some recent series have reported much-improved perioperative mortality (see Table 33.5-7),<sup>130,131</sup> and <sup>132</sup> the morbidity is still substantial. In patients with liver dysfunction in either the Pugh-Child's grade B or C categories, however, total hepatectomy with liver transplantation represents the only potentially curative option.

TABLE 33.5-7. Results of Liver Transplantation for Hepatocellular Carcinoma

The greatest obstacle is the limited availability of livers for transplantation. Even in the United States, where active public campaigns have resulted in comparatively high rates of organ donations for transplantation, only 3000 to 4000 livers are available each year. This would explain the limited numbers of livers used in transplantation for treatment of liver cancers. Only approximately 100 transplantations are performed each year for this indication (Fig. 33.5-1). In countries in the Far East, where organ donation goes against social and religious beliefs, the shortage of donated organs is even greater. Living-relative liver transplants offer a potential source of organs for such use.<sup>133,134</sup> However, the morbidity associated with donation of a lobe of liver is substantial, and mortality is not only a theoretic but a documented actual complication. For patients with cancer, the likelihood of recurrence brings into question the ethics of endangering a donor's life.

FIGURE 33.5-1. Number of liver transplantations performed each year in the United States for cancer. Use of liver transplantation for this indication is greatly limited by the shortage of organs. (Data from UNOS.)

In addition, the costs of liver transplantation are substantial. Certainly, it is much more cost-effective to use available livers for the treatment of benign diseases. In many parts of the world, however, the high costs completely rule out transplantation for any indication. Because of these obstacles, liver transplantation is not likely to make an important impact on the worldwide treatment of cancer in the near future.

Comparing results of partial hepatectomy with results of liver transplantation for HCC has been difficult, primarily because patients with very distinct clinical characteristics are usually selected for each treatment. Patients selected for partial hepatectomy generally have good liver function and may have enormous tumors. Patients selected for transplantation almost always have small tumors but may have advanced liver failure. In the past, the reported 1-, 3-, and 5-year survival rates of liver transplantation for HCC were 40% to 82%, 16% to 71%, and 19.6% to 36%, respectively, rates that were highly comparable to those achieved with partial hepatectomy (see Table 33.5-7). This indicated not so much that these two techniques were equivalent as that the right patients were being selected for each treatment.

Recently, two series of studies have encouraged a renewed comparison of these two treatment options. In a series from the transplantation literature, operative mortality appears to have been dramatically reduced to a current low of less than 5%.<sup>126,130,131</sup> and <sup>132</sup> With such low operative mortality, Mazzafarro et al.<sup>131</sup> are reporting 3-year survival after transplantation of 85% for small HCC. This has fueled enthusiasm for liver transplantation in this clinical setting. At the same time, a number of articles examining partial hepatectomy for HCC have been published that include sufficient data in the subset of patients with small tumors to allow comparison.<sup>84,135</sup> It appears that partial hepatectomy for patients with small tumors also results in very favorable outcomes. For a patient with a tumor that is less than 5 cm in diameter, the 5-year survival can be expected to be 45% to 57%.<sup>84,135,136</sup> In fact, disease-free survival can be expected in 44% of patients (Fig. 33.5-2).<sup>84</sup> These results are comparable to the best results for liver transplantation. Therefore, given the organ shortage and costs of liver transplantation, partial hepatectomy should still be regarded as the curative treatment of choice. For patients without cirrhosis or with Pugh-Child's grade A cirrhosis, partial hepatectomy should be considered first. Total hepatectomy with transplantation may be necessary in this group if removal of tumor requires extensive resection of nonneoplastic liver. For patients with severe liver dysfunction, total hepatectomy and transplantation is a better option and may be the only viable option.

**FIGURE 33.5-2.** Survival (solid line) and disease-free survival (dotted line) after resection of (A) small (<5 cm) or (B) large (>10 cm) hepatocellular carcinoma. Results of resection for these small tumors are highly favorable and comparable to liver transplantation. (From ref. 84, with permission.)

Because the incidence of recurrence of HCC after liver transplantation is high, many investigators have attempted to improve long-term results by use of adjuvant therapies. Cherqui et al.<sup>137</sup> used an adjuvant regimen combining neoadjuvant chemoembolization and radiotherapy with posttransplantation chemotherapy. Stone et al.<sup>138</sup> used a regimen of aggressive neoadjuvant, intraoperative, and postoperative chemotherapy. Farmer et al.<sup>139</sup> used an adjuvant chemotherapeutic regimen combining 5-FU, cisplatin, and doxorubicin. These are all small studies based on a sound understanding of HCC and represent promising approaches. All use neoadjuvant therapy because patients often spend a considerable amount of time awaiting availability of a liver for transplantation. However, given the small number of transplantations performed yearly for HCC, the role, timing, and regimens to be used are far from decided.

### PALLIATIVE TREATMENT MODALITIES

Most patients presenting with HCC will have disease that is not treatable by partial hepatectomy. Even if the disease is confined to the liver, the likelihood of treatment with total hepatectomy and transplantation is low for reasons outlined in the preceding section, [Total Hepatectomy and Liver Transplantation](#). Nevertheless, if the disease is confined completely or largely to the liver, local tumor ablative therapies can be performed and result in good local control of disease. The ablative methods with the longest track record include ethanol injection, embolization, and cryotherapy. These will be discussed with specific emphasis on technical limitations, morbidity, and their likely role in patient clinical management. Other more investigative modalities, such as radiotherapy, radiofrequency ablation, and laser heat ablation, also are discussed.

#### Systemic Therapies

When a patient has widely disseminated disease, only systemic therapies make sense. However, the results of chemotherapeutic therapy or other systemic therapies for HCC have been dismal.

**SYSTEMIC CHEMOTHERAPY.** Numerous chemotherapeutic regimens have been tested for use against HCC ([Table 33.5-8](#)). HCC is, however, highly resistant to chemotherapy, owing to multiple factors: Tissue analysis has revealed that HCC harbors high levels of dehydropyrimidine dehydrogenase (DPD), and it is known that cells high in DPD are generally resistant to 5-FU.<sup>140</sup> In addition, HCC exhibits overexpression of the MDR1 (multidrug resistance) gene<sup>141,142</sup> and the gene product P-glycoprotein.<sup>141</sup> This would explain the modest effects of 5-FU on HCC. In an Eastern Cooperative Oncology Group (ECOG) study of eniluracil (a DPD inhibitor) and 5-FU, 5 of 35 patients with HCC developed stable disease but no responses.

Ref	No.	Chemotherapy	Partial Response (%)	Median Survival (mo)
143	30	Doxorubicin, 5-FU + IFN	10 (33)	4 (20)
144	1	5-FU	0	3 (30)

169	10	Doxorubicin + 5-FU + IFN	5 (50)	4 (40)
170	10	Doxorubicin + 5-FU + IFN	5 (50)	4 (40)

**TABLE 33.5-8.** Systemic Chemotherapy for Hepatocellular Carcinoma

Doxorubicin is the most popular drug studied, though published data from 13 studies indicate that administration of this drug either alone or in combinations results in less than a 20% response and a median survival of less than 4 months.<sup>143,144</sup> Response to either single agent or multiagent systemic chemotherapy occurs in only 10% to 20% of patients (see [Table 33.5-8](#)). Furthermore, even the objective responses are short-lasting. In a systemic review<sup>145</sup> and metaanalysis<sup>146</sup> of the published randomized studies on HCC, neither doxorubicin nor any chemotherapeutic agent used singly or in combination has been shown to have any survival benefit for HCC patients. It is generally acknowledged that systemic chemotherapy has minimal impact on survival of patients with this disease. At our institution, systemic chemotherapy is offered mostly in the context of clinical trials. Moreover, most patients with unresectable disease are jaundiced or have a poor performance status because of extensive liver disease, making use of chemotherapeutic drugs virtually impossible.

**HEPATIC ARTERIAL INFUSION.** Because the results with systemic chemotherapy are far from optimal, regional delivery of chemotherapy has been attempted. Such regional approaches rely on the dual nutrient blood supply of the liver, portal vein, and hepatic artery. Hepatic tumors, however, derive their blood supply mainly from the hepatic artery.<sup>147,148</sup> Infusion of chemotherapy directly into the hepatic artery may allow increased effective dose at the tumor with fewer systemic side effects.

Hepatic arterial infusion (HAI) chemotherapy can be accomplished through a percutaneously placed angiographic catheter, through an implantable arterial port inserted at open operation and connected to an external infusion pump, or using self-contained subcutaneous infusion pumps implanted at surgery. Drugs with high liver extraction rates and short plasma half-lives are particularly well suited for HAI chemotherapy.<sup>149</sup> The fluoropyrimidines [5-FU and 5-fluorodeoxyuridine (5-FUDR)], cisplatin, doxorubicin, and 4'-epidoxorubicin are chemotherapeutic agents that have been tested in this mode of delivery.

Most data for treatment of HCC by HAI chemotherapy are gleaned from various phase II clinical trials ([Table 33.5-9](#)). Intraarterial doxorubicin seems to be more active than intravenous treatment.<sup>150,151</sup> The highest response rates have been obtained with the drug FUDR. This drug has a high hepatic extraction ratio and short serum half-life, making it ideal for regional therapy. Warren et al.<sup>152</sup> reported a response rate of 60% in 15 patients. Atiq et al.<sup>153</sup> reported a 50% response rate in ten patients using an HAI regimen of mitomycin C, FUDR, and subcutaneous IFN. Makela and Kairaluoma<sup>154</sup> reported a 48% response rate with HAI mitomycin, with a median survival of 14 months. HAI of cisplatin has produced responses between 20% and 40%. In a small study comparing HAI of doxorubicin with systemic administration of doxorubicin, the response rate was greatly increased with HAI.<sup>155</sup>

**TABLE 33.5-9.** Hepatic Arterial Chemotherapy for Hepatocellular Carcinoma and Other Hepatobiliary Tumors

Though these results are encouraging, this route of chemotherapy is unlikely to make a great impact on the treatment of HCC. Significant toxicity, including cholangitis and bone marrow suppression, can still be encountered. Furthermore, the studies with the most encouraging results used surgically implanted infusion pumps or ports. Most patients with unresectable disease are not in sufficiently fit condition for surgery and pump implantation, as any operation in patients with underlying cirrhosis of the liver carries significant morbidity.

**SYSTEMIC IMMUNOTHERAPY.** Most studies of immunotherapy for HCC have involved the use of IFN-a or IFN-b. In a randomized controlled trial, high-dose IFN-a (18 to 50 mU/m<sup>2</sup> three times weekly) was found to be superior to doxorubicin in inducing more tumor regression (10% partial response), less toxicity, and fewer fatalities.<sup>156</sup> The same group also compared high-dose IFN-a (50 mU/m<sup>2</sup> three times weekly) to supportive treatment and found better survival and tumor regression for the patients treated with IFN. However, the median survival was only 14.5 weeks for patients so treated.<sup>157</sup> In another study comparing IFN-b with the chemotherapeutic agent menogaril, a slightly longer 1-year but shorter 2-year survival was found for the patients treated with IFN-b.<sup>158</sup> These modest results certainly do not support the use of IFN as a single agent. Furthermore, all these studies used relatively high doses of IFN, and therefore toxicities requiring dose reduction were not uncommon.

Most current studies of immunotherapies, therefore, involve use of lower doses of IFN in combination with chemotherapeutic agents. The most promising combination is a regimen of cisplatin, doxorubicin, 5-FU, and IFN-a. Using this combination, Leung and Lau<sup>112</sup> achieved a partial response rate of 26% in 50 patients with unresectable HCC. Six of these patients experienced sufficient regression of tumor to allow subsequent surgical resection. Two of these six patients had a complete response as confirmed by pathologic analysis. This regimen incites significant toxicity, as demonstrated by a 4% treatment-related mortality.<sup>112</sup> Future randomized multicenter trials must be performed to define completely the clinical role for this regimen.

**SYSTEMIC HORMONAL THERAPY.** HCC has long been observed to be more common in men. Subsequently, it was noted that these tumors also express receptors for estrogens and androgens.<sup>159</sup> Therefore, hormonal manipulation has been the basis of a number of trials directed at HCC. Of the antiestrogen compounds, tamoxifen has undergone the most extensive testing. This drug inhibits growth of HCC *in vitro*. The mechanisms of action against HCC, however, may not be related to its antiestrogen effects. Hepatocellular tumors express a high level of the MDR gene product P glycoprotein.<sup>160</sup> Tamoxifen is a potential MDR-reversing agent.<sup>161</sup> Overall, results of clinical trials using tamoxifen have been mixed. Three small, randomized studies comparing tamoxifen to no treatment or placebo showed that tamoxifen significantly prolonged survival.<sup>162,163</sup> and <sup>164</sup> A large study involving 120 patients showed no benefit of tamoxifen over placebo in terms of tumor progression or survival.<sup>165,166</sup> Another recent randomized study of 496 patients with HCC showed no difference in survival in patients receiving tamoxifen or no tamoxifen.<sup>167</sup> Tamoxifen is not believed to be clinically useful as a single agent.

A number of trials have also attempted to combine tamoxifen with other therapeutic agents. There were encouraging results in phase II trials. In 33 patients with HCC who were receiving tamoxifen and etoposide (VP-16), 8 (24%) had a partial response, with a median survival of 8 months in the responders.<sup>168</sup> Combining epirubicin and VP-16 produced a 36% response rate in 36 patients.<sup>169</sup> However, a randomized study of 59 patients with inoperable HCC showed no difference in response rates or survival between patients who received doxorubicin and those who received doxorubicin plus tamoxifen.<sup>170</sup> Further larger-scale randomized trials are required to define tamoxifen's exact role in the management of HCC in combination with chemotherapeutic agents.

Antiandrogenic treatment has also been attempted using agents such as ketoconazole and cyproterone acetate. The experience is, however, still too preliminary to permit firm conclusions.<sup>171</sup> Overall, hormonal manipulation in the treatment of HCC has a good theoretic basis but has not yet been upheld by clinical data.

### **Ablative Therapies**

**PERCUTANEOUS ETHANOL INJECTION.** Percutaneous ethanol injection (PEI) was first advocated by Sugiura<sup>171a</sup> in 1983 for ablation of liver tumors. Tumor cells are killed by a combination of cellular dehydration, coagulative necrosis, and vascular thrombosis. Direct injections can be easily performed during open surgery or laparoscopy or percutaneously using ultrasound guidance. This ablative procedure is most often performed percutaneously and is very effective and safe for treating small HCCs. Ethanol injections are usually very well tolerated by patients, side effects being primarily pain, fever, and a transient rise in liver enzymes. Though other side effects, including bleeding, tumor rupture, needle tract tumor implantation,<sup>172</sup> and death, can occur, these are uncommon complications. HCC is well suited for such injections also because these tumors are most often soft and lie in a hard, cirrhotic liver. The injected alcohol tends to diffuse well within the soft tumors for good coverage of the cancerous tissues.

Because of technical limitations, only tumors smaller than 3 cm are generally treatable by PEI.<sup>173</sup> In addition, most clinicians are unwilling to treat more than three tumors by this method. Tumors at the dome of the liver are difficult to treat because of overlying lung and the risk of pneumothorax. Patients with ascites are poor candidates for such injections, as the risk of bleeding is higher in these patients because the abdominal wall is not directly against the liver and cannot act to tamponade the sites of injection.

When tumors are within the limits for injection, results are very good. Nonrandomized studies have demonstrated a 3-year survival rate of 55% to 77% after PEI.<sup>172,174,175</sup> and <sup>176</sup> In one large phase II trial that included 210 patients, the 5-year survival was found to be 33%.<sup>177</sup> These treatments are unlikely to be curative, however. Patients should be followed up closely by imaging, and repeated treatments should be given when appropriate.

In a nonrandomized case study comparing liver resection (n = 33) with PEI (n = 30) in the treatment of small (<4-cm) HCCs, the recurrence rate was higher with PEI, but 1- and 4-year survival rates were similar for both treatment modalities.<sup>175</sup> Two randomized, controlled trials have been performed, one comparing PEI to no treatment<sup>178</sup> and the other comparing PEI plus transarterial chemotherapy to transarterial chemotherapy alone.<sup>179</sup> No definitive differences were found, but this may be due to small sample size.<sup>146</sup>

Currently, we use PEI as the ablative method of choice for small (<3 cm) HCCs of limited number (<3) in Pugh-Child's grade A or B cirrhotics in whom resection is not possible. The procedure is well tolerated and the risks minimal. Patients are followed up closely, and treatments are repeated when viable tumor is again demonstrated. Larger trials comparing this technique with supportive care and other ablative techniques are sorely needed for patients with unresectable small tumors. In addition, for patients with resectable small tumors, a comparative study of resection versus PEI is important. The greatest limitation to PEI, however, is that few patients in the Western world present with tumors of sufficiently small size for such treatments.

Tumor ablation can also be accomplished by injection of other agents. Agents so tested have included acetic acid, hot saline, glass microspheres containing <sup>90</sup>Y, and various chemotherapeutic drugs.<sup>180</sup> Partial and complete destruction of tumors has been documented with each of these. However, an advantage of any of these agents over ethanol has not been demonstrated to date. Ethanol is so well tolerated and the procedure so simple, particularly as compared to injections of radioactive isotopes, that until results from future comparative trials demonstrate a better alternative, PEI remains the treatment of choice for small, locally limited HCC.

**CRYOSURGERY.** Repeated freezing and thawing of tissues also produces tissue destruction. Recent technologic advancements have allowed for design and mass marketing of vacuum-sealed probes that are cooled by liquid nitrogen or argon. These probes can be introduced into tumors, and freezing can be performed under

ultrasound guidance until the ice ball is more than 2 cm beyond the tumor margin. The tumor then is thawed and frozen again to produce effective cryoablation. The major advantage of this method over ethanol injection is the relatively larger size of tumor that can be treated effectively by cryoablation. Using probes of a diameter of 2 to 3 mm, a 5- to 6-cm ice ball can be produced. By placing multiple probes in proximity to one another, ice balls of up to 10 cm can be produced.

The major disadvantage is the need for general anesthesia and laparoscopy or laparotomy. Furthermore, not only is freezing of tumors near major vascular channels difficult because of the risks of bleeding, but complete freezing is virtually impossible because warm blood circulates in the vessels.

A number of series have been published that clearly demonstrate the safety of such an ablative approach in experienced hands.<sup>181,182</sup> Recently, as smaller and smaller cryoprobe have become available, some investigators have also attempted to perform the cryoablation percutaneously. Whether this will represent an advance is not yet known. Certainly, comparative studies of cryoablation to nonsurgical ablative methods such as ethanol injection or embolization are needed.<sup>174,183,184</sup>

In our practice, we are prepared to perform cryoablation whenever an operation is performed to attempt resection. If a tumor is found to be unresectable at the time of surgery, and the patient has already incurred the risks of anesthesia and laparotomy, we will proceed with cryoablation if it is technically feasible. We will also perform cryoablation for patients with clearly unresectable cancers in whom nonsurgical forms of ablative therapy fail.

**RADIOFREQUENCY ABLATION.** An ablation technique that is becoming increasingly popular is radiofrequency ablation (RFA). In this ablative modality, heat as generated by a radiofrequency electrode is used to kill tumors. The radiofrequency electrode is passed under radiologic guidance into the tumor of interest and tumor is ablated by thermal energy. The major advantage of RFA results from the small diameter of the electrodes, which allows routine percutaneous and laparoscopic ablation.<sup>185,186</sup> and <sup>187</sup> RFA equipment is also much less expensive than is cryotherapy equipment and is more portable and easier to maintain. However, RFA is limited by the small size of tumors that can be completely ablated by current radiofrequency instruments. As heat is generated within the tumor, charring of tissues occurs, decreasing the conduction of heat. The result is that tumors of only 3-cm diameter or smaller can currently be ablated reliably. In addition, in contrast to cryoablation, wherein the ice ball appears unequivocally as a homogeneous, hypoechoic lesion on US, the RFA lesion is much more difficult to follow radiographically.

The published experience to date on use of RFA is meager.<sup>186,188</sup> It is already clear, however, that patients tolerate RFA well. The tumors treatable by RFA are currently being treated by PEI. RFA carries a theoretically lower risk of bleeding, as the needle track can be coagulated during withdrawal of the radiofrequency electrode. PEI however, is simpler, less expensive, and has a longer track record. A direct trial comparing these two techniques is essential. For now, PEI represents the standard ablative modality for unresectable, small HCC, though RFA is a promising investigational treatment for this same population.

**HEPATIC ARTERIAL EMBOLIZATION.** The liver has a dual nutrient blood supply consisting of the hepatic artery and the portal vein. Under normal conditions, the hepatic parenchyma derives most of its nutrients from the portal vein, and complete occlusion of the hepatic artery does not render the liver ischemic. In contrast, hepatic tumors derive most of their nutrients from the hepatic artery. To induce ischemia and death of unresectable tumors, surgical hepatic arterial ligation was at one time the treatment of choice but has largely been abandoned for two main reasons. First, long-term clinical efficacy is poor, probably owing to the rapid development of collateral vessels after ligation of the main vessels.<sup>189</sup> Second, in patients with cirrhosis and portal hypertension, a high percentage of nutrient blood supplying functional noncancerous parenchyma is derived from the hepatic artery. Ligation of the main hepatic artery therefore was associated with a high procedure-related mortality, as high as 13%. Hence, this procedure has largely been abandoned as a treatment mode for HCC in the cirrhotic patient.<sup>118,190</sup>

Percutaneous selective TAE is a much safer method for treating liver tumors when vascular interruption is desired and has largely replaced surgical arterial ligation. In this method, a catheter is introduced through a percutaneous femoral approach and is threaded under fluoroscopic guidance to the hepatic artery. The branch feeding each tumor can then be cannulated selectively and occluded with degradable or nondegradable particles, coils, or oils. Such selective embolization maintains patency of the main hepatic arteries, thus sparing normal functional liver parenchyma. In addition, it allows repeated treatments through the same arteries. Possible adverse effects include pain, fever, nausea, and transient increase in liver enzymes.<sup>191</sup> Hepatic insufficiency and infected necrotic tumor are rare complications but may be a cause of treatment-related mortality. The risk of complications is clearly related to the degree of hepatic dysfunction. Treatment-related mortality is as high as 30% in patients with Pugh-Child's grade C hepatic function.<sup>71</sup> Therefore, embolization generally is performed only for patients with Pugh-Child's grade A or B liver function. In addition, patients with portal vein occlusion tolerate arterial interruption very poorly, and presence of tumor thrombus in the main portal vein is considered a relative contraindication to embolization.

There is no doubt that such embolization produces objective responses in approximately one-half the patients ( [Table 33.5-10](#) ).<sup>192,193,194,195</sup> and <sup>196</sup> For patients with painful, unresectable tumors, embolization is effective therapy. It can also be life-saving therapy for patients with ruptured HCC.<sup>197</sup> Documenting the benefits of embolization in other settings has been more difficult. Randomized studies comparing TAE to chemotherapy<sup>198</sup> or to supportive care<sup>199,200</sup> and <sup>201</sup> have been unable to document an improvement in survival. However, most studies are plagued by difficulties and flaws, including small sample size. More important, treatment in these studies has usually involved embolization of the main hepatic arteries rather than the safer and more effective selective embolization performed at major centers.

**TABLE 33.5-10.** Embolization and Chemoembolization for Hepatocellular Carcinoma

To improve on the efficacy of embolization, investigators have attempted to soak the embolization particles, such as Gelfoam, with chemotherapeutic agents prior to delivery by chemoembolization. In two randomized studies of chemoembolization versus embolization alone, however, there were no differences in survival.<sup>202,203</sup>

In other attempts to improve the results of TAE, investigators have used Lipiodol or ethiodized oil (Ethiodol). Each of these agents is a lymphangiogram dye derived from poppy seed oil that selectively wedges within HCC when administered via the hepatic artery.<sup>204,205</sup> Embolization of tumors using these oils was originally developed to enhance visualization of HCC. It then was discovered that these oils can be used to deliver and concentrate chemotherapeutic agents at sites of tumor. By mixing hydrophilic drugs with Lipiodol, an emulsion is produced that can be administered intraarterially to produce Lipiodol chemoembolization.

Phase I and II studies and small phase III studies have demonstrated a significant tumor response rate after such treatment. Treatment with doxorubicin and Lipiodol produced responses in 10 of 18 patients with small HCCs (<4 cm) and in 5 of 49 patients with large tumors.<sup>206</sup> Yoshikawa et al.<sup>207</sup> randomized 19 patients to receive Lipiodol-epirubicin and compared them with 17 patients who received epirubicin alone through the hepatic artery. Lipiodol-epirubicin gave a higher tumor response rate as compared with epirubicin alone (42% vs. 12%, respectively).

Larger, randomized trials have been unable to substantiate a survival benefit for such Lipiodol chemoembolizations, however. Madden et al.<sup>208</sup> randomized 136 HCC patients to receive intraarterial Lipiodol-epirubicin versus supportive care and found no survival benefit. Instead, there was an increased morbidity for the treatment arm. A randomized study comparing treatment using Lipiodol plus Adriamycin to Lipiodol alone showed a trend toward a better response at 1 and 2 years with the combination of Lipiodol and Adriamycin, but the difference was not statistically significant.<sup>202</sup>

A further modification of this same theme involved the intraarterial administration of hydrophilic drugs mixed with Lipiodol in an emulsion, followed by temporary or

permanent occlusion of the hepatic artery by embolization using a Gelfoam pellet, Ivalon particles, or starch particles. Okuda et al. <sup>194</sup> treated 52 patients with HCC using HAI 5-FU plus cisplatin followed by particle embolization and Lipiodol injections. They reported a response rate of 71% and a 5-year survival of 46%. <sup>194</sup> In another study comparing particle embolization with epirubicin and Lipiodol versus chemotherapy alone in 38 patients, the 1- and 2-year survivals were 73 and 35 versus 43 and 0 in the two groups, respectively. <sup>207</sup> A randomized study comparing intraarterial Lipiodol-cisplatin and Gelfoam embolization to supportive care showed no improvement in survival among the treated group, though this is likely attributable to the high incidence of liver failure in the treated patients. <sup>200</sup> Another randomized study comparing treatment with Lipiodol-cisplatin plus Gelfoam embolization to Lipiodol and Gelfoam in patients with HCC showed a worse outcome in the group using cisplatin. <sup>203</sup> The case for chemoembolization with or without Lipiodol administration is, therefore, far from proven. Because of the small size of individual studies, metaanalyses of the published randomized studies have been performed <sup>146</sup> but have failed to show any clear benefit of transarterial chemoembolization over no treatment.

Particle embolization clearly produces responses in the majority of tumors. At times, the response can be very dramatic, resulting in impressive relief of symptoms. Hence, these treatments may be useful in a patient with ruptured tumors or tumors that are symptomatic in pain or paraneoplastic syndromes. In addition, it is our bias (though not yet supported by randomized trials) that, for the subset of patients with good liver function, tumors of less than 10 cm in diameter, less than 50% liver replacement by tumors, and no portal vein thrombus, selective embolization may be beneficial. It is in this favorable subset of patients that future clinical trials should be directed, examining the utility of embolization. We believe that current data do not support the use of chemoembolization or Lipiodol mixtures but rather indicate that these complex mixtures may merely add cost and complications without improving efficacy. At present, we prefer to use simple particle embolization for treatment of symptomatic or favorable tumors. It is likely that effective palliative therapy will be a combination of local therapy by embolization and an as-yet unidentified systemic treatment.

### Radiotherapy

Initial attempts to use whole liver radiation in the treatment of primary hepatobiliary cancer were unsuccessful. <sup>209,210</sup> For instance, in the series by El-Domeiri et al. <sup>209</sup> and Phillips and Murikami, <sup>210</sup> only 1 of 31 patients with unresectable disease who underwent radiation survived more than 1 year. The most important reason for this lack of success is the low tolerance of the liver to whole organ radiation. Indeed, the radiation tolerance of the whole liver in patients with primary HCC may tend to be lower than in those with metastatic cancer to the liver, as many patients with primary disease have some degree of underlying cirrhosis.

Attempts have been made to increase the effectiveness of whole liver irradiation in the treatment of patients with unresectable hepatoma by the addition of intravenous chemotherapy <sup>211,212</sup> and <sup>131</sup>I antiferritin monoclonal antibody therapy. <sup>213,214</sup> Radiation Therapy Oncology Group (RTOG) trial RTOG 83-19 was a randomized trial assessing the benefit of adding <sup>131</sup>I antiferritin monoclonal antibody therapy to doxorubicin and 5-FU for patients who had received initial treatment with doxorubicin plus 5-FU and whole liver irradiation (21 Gy in seven fractions). <sup>214</sup> RTOG 88-23 measured the benefit of combining antibody with hepatic artery cisplatin for patients who had received induction treatment with whole liver irradiation (21 Gy in seven fractions) and intravenous cisplatin. The conclusions from these and other studies <sup>215</sup> are that <sup>131</sup>I antiferritin increased toxicity without benefit and that hepatic arterial cisplatin may be superior to either intravenous <sup>211</sup> or hepatic arterial <sup>212</sup> doxorubicin and 5-FU when combined with irradiation. The finding that hepatic arterial cisplatin and radiation can produce an objective response rate of 43% and a median survival of 7.5 months in a relatively large group of patients <sup>76</sup> suggests that these combinations have some activity. <sup>215</sup>

In contrast to the relative ineffectiveness of whole liver irradiation (when used alone), focal liver irradiation can produce regression of primary hepatobiliary cancers (Fig. 33.5-3). At least four techniques have been assessed: <sup>90</sup>Y microspheres, <sup>131</sup>I-labeled ethiodized oil, and external-beam radiotherapy with either protons or photons. In <sup>90</sup>Y therapy, <sup>89</sup>Y oxide is incorporated into a stable glass matrix. When bombarded with neutrons, <sup>89</sup>Y is converted to <sup>90</sup>Y, a pure beta emitter with a half-life of 64.5 hours and average electron energy of 2.23 MeV, which produces an electron range of approximately 2.5 cm. The microspheres have been infused into the hepatic artery as a form of regional therapy for well-vascularized tumors, producing objective response rates ranging from 0% to 25% <sup>109,216,117</sup> and <sup>218</sup> (for review, see Ho et al. <sup>219</sup>). Note that <sup>90</sup>Y doses (50 to 150 Gy) cannot be compared directly to the more familiar external-beam doses, as the former are calculated by assuming full decay with all radiation homogeneously deposited within the liver. More important, low dose-rate irradiation (<0.2 Gy/h) delivered by <sup>90</sup>Y has far less effect than the same physical dose delivered by standard external-beam treatment (>2 Gy/min). A better understanding of the dosimetry of this technique <sup>220</sup> as well as of the technical factors (such as pulmonary shunting, which can lead to radiation pneumonitis, <sup>221</sup> or variant arterial supply to the stomach, which can produce gastric ulcers) is required before the application of microspheres can become routine. <sup>90</sup>Y microspheres are not available for clinical use in the United States currently.

**FIGURE 33.5-3.** Treatment of hepatocellular carcinoma (HCC) by conformal radiation. The large HCC in the right lobe of the liver (A) has had a dramatic response (B) to such treatment.

Another method of delivering focal liver irradiation involves hepatic arterial administration of <sup>131</sup>I ethiodized oil. Ethiodized oil has been used extensively for chemoembolization for HCC (discussed earlier in the section [Hepatic Arterial Embolization](#)); in this approach it is formulated with radioactive iodine in an attempt to deliver localized irradiation using the beta (electron) component of the <sup>131</sup>I emissions. <sup>222,223</sup> Randomized trials led by French investigators compared <sup>131</sup>I-labeled ethiodized oil to chemoembolization <sup>224</sup> and <sup>131</sup>I-labeled ethiodized oil to supportive care for patients with portal vein thrombosis. <sup>225</sup> In the former study, 129 patients were randomized to receive either 60 mCi of <sup>131</sup>I-labeled ethiodized oil or chemoembolization with cisplatin (70 mg). There was no difference in overall survival between the two groups (median survival, approximately 40 weeks), but the toxicity of the ethiodized oil arm was significantly less. In the latter study, 27 patients were randomized to receive either 60 mCi of <sup>131</sup>I-labeled ethiodized oil or control treatment (such as tamoxifen). The ethiodized oil group showed a statistically significantly greater median survival (approximately 6 months as compared to 2 months). Although these findings suggest that <sup>131</sup>I-labeled ethiodized oil has activity in HCC, this small study does not permit a firm conclusion to be drawn. Furthermore, as is the case for <sup>90</sup>Y, little is known about the tumor and normal tissue dosimetry. <sup>131</sup>I-labeled ethiodized oil is not available for use in the United States.

Traditional external-beam photon techniques, either alone <sup>226</sup> or in combination with chemoembolization, <sup>227</sup> have produced objective responses in patients with unresectable HCC. However, standard photon techniques often require the treatment of large volumes of normal liver. In contrast, three-dimensional conformal radiotherapy (3D-CRT) planning using beams not confined to the axial plane can substantially reduce irradiation of normal liver. <sup>228,229</sup> Phase I and II trials for patients using 3D conformal external-beam irradiation combined with hepatic arterial FUDR have demonstrated that high-dose focal irradiation can produce a 60% response rate (see Fig. 33.5-3). <sup>230,231</sup> Recent results support the hypothesis that the dose delivered is an important prognostic factor in both local control and survival for patients with primary hepatobiliary cancers. In this study, dose is prescribed (to a maximum of 90 Gy) according to the fraction of normal liver that is spared, based on a normal tissue complication probability (NTCP) model. Patients who can receive more than 70 Gy have a median survival in excess of 17 months, which approaches that achieved by surgical resection. In a multivariate analysis, dose is a prognostic factor independent of tumor size. <sup>232</sup>

Although 3D techniques permit parts of the liver to be treated with doses of radiation far higher than the entire liver can tolerate, it is possible that both higher doses and larger volumes than have been used in the current studies could be used safely. A first step in defining these limits is to develop an NTCP model to describe the dependence of liver tolerance on the combination of dose and volume. A number of theoretic models (all of which require knowledge of the 3D dose distribution) have been proposed to estimate the volume dependence of normal tissue tolerance. <sup>233,234</sup> Initial investigations have suggested that it will be possible to derive a quantitative model to predict radiation-induced liver disease. <sup>235</sup> More recently, an NTCP model with parameters calculated from patient data has been used

prospectively to prescribe a dose that would subject each patient to a predetermined complication risk. Twenty-one patients have completed treatment on such a protocol. The mean dose delivered was  $56.6 \pm 2.3$  Gy (range: 40.5 to 81 Gy). One of 21 patients developed radiation-induced liver disease. The observed complication rate of 4.8% (95% confidence interval, 0% to 23.8%) did not differ significantly from the predicted 8.8% NTCP (based on dose delivered). These results suggest that an NTCP model can be used prospectively to deliver safely far higher doses of radiation to patients with intrahepatic cancer than were possible using previous approaches.<sup>236</sup> The widespread adoption of 3D conformal planning systems should permit these concepts to be tested in multiinstitutional trials.

Another method of delivering highly conformal radiation is with protons. Investigators at the Proton Medical Research Center in Japan have demonstrated response rates similar to those just reported using 3D-CRT.<sup>237,238</sup> Interestingly, high-dose focal irradiation using either photons<sup>239</sup> or protons<sup>240</sup> can produce hypertrophy in the nonirradiated liver, resembling the effect of partial hepatectomy.

In summary, whole liver irradiation alone has little efficacy in the treatment of HCC. The addition of hepatic arterial cisplatin may increase the efficacy somewhat. High-dose focal irradiation, especially using external-beam photons or protons, can produce objective responses in the majority of patients, although the relative merit of these techniques as compared to other nonsurgical approaches described in this chapter has not been assessed in randomized trials.

## SCREENING FOR HEPATOCELLULAR CARCINOMA

Patients found to have small (<5-cm) HCC have a much better prognosis than do those presenting with larger tumors. The size of a tumor is a significant risk factor for intrahepatic and extrahepatic spread.<sup>241,242</sup> and <sup>243</sup> The frequency of intrahepatic metastases rose by almost one-third between HCCs smaller and larger than 5 cm (60% to 90%), and the rate of portal vein tumor thrombosis almost doubled (40% to 75%).<sup>242,243</sup> Many more treatment options are also available for patients with small tumors. Tumors smaller than 3 cm can be treated by PEI, RFA, resection, or transplantation, whereas tumors smaller than 5 cm can be treated by cryoablation, resection, or transplantation. Hence, smaller tumors are not only biologically more favorable but are technically more easily treated. Because symptomatic tumors are usually large, widely disseminated, and beyond therapeutic option, the rationale for screening patients at risk for HCC is clear.

Whole population screening, even in areas where HBV is endemic, is almost certainly not a financially viable option. In epidemiologic studies, it is apparent that the incidence of HCC in HB<sub>s</sub>Ag-positive patients is approximately 0.5% annually.<sup>244</sup> Therefore, the yield for screening programs is low. Hepatitis occurs mainly in developing countries, where the cost of any population screening program will also be too prohibitive.

In the presence of HCV, however, the risk of HCC in a patient with established cirrhosis is estimated to be as high as 5% per year.<sup>15</sup> Also, HCV occurs more often in industrialized nations. Hence, it is much more justifiable and likely that screening programs will be developed for detection of HCC in patients with cirrhosis due to HCV infection.

As a clinician striving to deliver optimal care for individual patients, screening high-risk patients for HCC is justifiable. Patients with established cirrhosis or chronic HCV infection are clearly important candidates for screening. Patients with chronic HBV infection should also be considered for screening. Furthermore, only patients with Pugh-Child's grade A or B liver functional status should be screened, as patients with Pugh-Child's grade C disease will generally be too sick for therapeutic interventions and early detection of HCC will only cause anxiety and detrimentally affect the patient's likelihood for liver transplantation. Screening protocols are largely based on the biases of each major center. Some have advocated frequent testing, including ultrasound examination every 3 months<sup>245</sup> and serum AFP testing once every 2 months.<sup>246</sup> Because HCC is slow-growing, however, with a documented median doubling time of 4 to 5 months for small HCCs,<sup>245</sup> we advocate AFP and liver function tests every 3 months and liver imaging every 6 months.

## OTHER PRIMARY TUMORS OF THE LIVER

### HEPATOBLASTOMA

Hepatoblastoma affects approximately 1 in 100,000 children and is the most common primary malignant liver tumor in children.<sup>247,248</sup> It is usually diagnosed before the age of 3 years, with a 2:1 male predominance. Patients usually present with abdominal swelling<sup>247,248</sup> and elevated serum AFP (>75% of patients).<sup>249</sup> CT scans will reveal a vascular mass that often (50%) is speckled with calcifications.<sup>249</sup> The Children's Cancer Study Group staging system is shown in [Table 33.5-11](#).<sup>250</sup> Overall long-term survival varies between 15% and 37%.<sup>249,251,252</sup> and <sup>253</sup> Poor prognosis is associated with unresectable tumors and tumors demonstrating aneuploidy and anaplastic characteristics.<sup>251,254,255</sup>

Group I	Complete resection of tumor by wedge, lobectomy, or extended lobectomy as initial treatment
Group IIA	Tumor rendered completely resectable by initial irradiation and chemotherapy
Group IIB	Residual tumor confined to one lobe
Group IIIA	Tumor involving both lobes of the liver
Group IIIB	Regional lymph node involvement with tumor
Group IV	Distant metastases of tumor regardless of the extent of liver involvement

**TABLE 33.5-11.** Children's Cancer Study Group Staging for Hepatoblastoma

Complete resection is possible in 50% to 65% of children with hepatoblastoma and is associated with cure rates between 30% and 70%.<sup>247,248</sup> Unlike adult primary liver tumors, chemotherapy may produce response in a significant number of patients with hepatoblastomas. Preoperative chemotherapy has been used with some success in converting unresectable tumors to resectable lesions.<sup>256,257</sup> Adjuvant chemotherapy has also been used after resection of hepatoblastoma.<sup>250</sup> Evans et al.<sup>250</sup> reported that 20% of 24 patients with hepatoblastoma were relapse-free 8 to 42 months after surgical resection coupled with adjuvant vincristine, doxorubicin, 5-FU, and cyclophosphamide.

Radiotherapy has been used in the treatment of unresectable hepatoblastomas, but its utility is far from proven.<sup>256,258</sup> Orthotopic liver transplantation should be considered in children with unresectable hepatoblastoma if the tumor does not become resectable after preoperative chemotherapy. Penn<sup>259</sup> reported on 18 patients undergoing liver transplantation for unresectable hepatoblastoma. Though tumors recurred in six patients, five have survived disease-free for more than 2 years, with actuarial survival rates of approximately 50%.

### ANGIOSARCOMA

Angiosarcomas are malignant mesenchymal tumors of the liver that are also referred to as *hemangiosarcomas*. Only approximately 25 cases occur in the United States each year.<sup>260</sup> Peak incidence is in the sixth and seventh decades, with a predominance in men (85%).<sup>261</sup> Abdominal pain, abdominal swelling (usually due to liver enlargement), liver failure, nausea, anorexia, vomiting, and jaundice are seen. These malignant tumors have been associated with exposure to thorostrast, arsenic, or vinyl chloride.

Angiosarcomas are aggressive neoplasms. Partial hepatectomy can result in long-term survival, but most patients present with advanced tumors that cannot be treated by excision. Distant metastases are found at initial presentation in one-half of patients. Most patients die within 6 months of diagnosis. Even with surgical excision, few patients survive more than 1 to 3 years after complete resection because of metastatic disease. Results of radiotherapy and chemotherapy or both have been disappointing.<sup>261</sup> The results of orthotopic liver transplantation for treatment of angiosarcoma have also been poor. Penn et al. reported development of tumor

recurrences in 9 of 14 transplant patients with tumors classified as either angiosarcomas or epithelioid tissue sarcomas. The 2-year survival rate was 15%, and no patient survived more than 28 months postoperatively.<sup>259</sup>

The liver can occasionally be the primary site for rhabdomyosarcoma,<sup>262</sup> though this is more common in children than in adults. Hepatic metastases from a gastrointestinal or uterine primary tumor must be ruled out before the diagnosis of primary leiomyosarcoma of the liver can be made. Surgical resection is the treatment of choice for these primary hepatic sarcomas.<sup>262</sup> Unresectable disease carries an unfavorable prognosis.

Undifferentiated sarcomas of the liver are very rare and usually occur in children between the ages of 6 and 15 years.<sup>263,264</sup> Most undifferentiated sarcomas of the liver are found at an advanced stage, when surgical resection is not possible. The patient with such a tumor rapidly succumbs to the sarcoma, as such tumors usually are not responsive to radiotherapy or chemotherapy.<sup>263</sup>

## EPITHELIOID HEMANGIOENDOTHELIOMA

Epithelioid hemangioma is another malignant soft tissue tumor of endothelial cell origin.<sup>260,262,265</sup> Factor VII staining differentiates hemangioendothelioma from other nonvascular tumors. Infantile hemangioendothelioma, which is benign, is unlikely; the adult variety is malignant and highly aggressive. Average age at presentation is 50 years, and the usual presenting signs and symptoms consist generally of nonspecific complaints, including pain, and an abdominal mass. In contrast to angiosarcoma, there is a female predominance (63% of patients).<sup>262</sup> Epithelioid hemangioendothelioma has also been related to vinyl chloride exposure in some patients.<sup>265</sup>

Weiss and Enzinger<sup>260</sup> recommended radical surgery, if possible. However, these tumors are almost always diffuse and multifocal and, therefore, are unlikely to be cured by partial hepatectomy. If hemangioendothelioma is suspected, a percutaneous biopsy is performed for diagnosis. Frozen-section analysis is not usually helpful at open surgery because special stains are required for diagnosis of this tumor. Patients with hemangioendotheliomas should be considered for total hepatectomy and liver transplantation. Penn<sup>259</sup> reported a series of 21 patients who underwent orthotopic liver transplantation for treatment of epithelioid hemangioendotheliomas; 7 of 21 patients experienced tumor recurrence. The actuarial survival rate was 82% at 2 years and 43% at 5 years.

## CHOLANGIOCARCINOMA

Cancers of the bile ducts are rare tumors, with only approximately 4000 cases presenting in the United States annually. Because of the proximity of the bile duct to the liver, the pancreas, and major vascular structures, surgical excision of these tumors usually requires a major hepatic or pancreatic resection or both. Major vascular reconstructions may also be necessary. The technical demands of such resections and the lack of effective alternative therapies for cholangiocarcinomas explain the nihilistic attitude that generally surrounds this disease. Advances in imaging over the last two decades now allow for earlier diagnosis of bile duct cancer and better surgical planning. Recent improvements in operative technique have substantially improved the outlook of patients presenting with this cancer.

### EPIDEMIOLOGY AND ETIOLOGY

Cholangiocarcinoma is an uncommon cancer, with an incidence of 1 to 2 cases per 100,000 population in the United States<sup>266</sup> and constituting approximately 2% of all reported cancers.<sup>267</sup> It is a disease of the elderly, with the majority of such lesions occurring in patients older than 65 years and the peak incidence occurring in the eighth decade of life.<sup>266</sup> Untreated, bile duct cancers are rapidly fatal diseases, and the majority of patients will die within 6 months to a year of diagnosis. Death usually results from liver failure or biliary sepsis.<sup>267,268,269</sup> and <sup>270</sup> Long-term survival is highly dependent on the effectiveness of surgical therapy. Indeed, it has been shown that tumor location within the biliary tree has no impact on survival, provided that complete resection is achieved.<sup>271</sup> Nonetheless, it is more likely that distal bile duct cancer will be resected with curative intent, which explains the relatively more favorable prognosis of distal tumors.

A number of conditions are associated with an increased incidence of cholangiocarcinomas, including PSC, choledochal cysts or Caroli's disease, and pyogenic cholangiohepatitis and other hepatic infections. In addition, environmental agents may influence the incidence of cholangiocarcinomas.

#### *Primary Sclerosing Cholangitis*

In Western nations, the disease most often associated with development of cholangiocarcinoma is primary sclerosing cholangitis (PSC). This is an autoimmune disease characterized by inflammation of the periductal tissues and, at advanced stages, is characterized by multifocal strictures of the intrahepatic and extrahepatic bile ducts.<sup>272,273</sup> and <sup>274</sup> The majority (70% to 80%) of patients with PSC also have associated inflammatory bowel disease in the form of ulcerative colitis.<sup>272</sup> In a longitudinal study of patients with PSC, 8% of patients developed clinically apparent cholangiocarcinoma over a 5-year period.<sup>272</sup> This explains the high incidence (30% to 40%) of occult cholangiocarcinoma found in autopsy or explant specimens from patients with PSC.<sup>272,273</sup> and <sup>274</sup> Cholangiocarcinomas presenting in patients with PSC are often multifocal and not amenable to treatment by partial hepatectomy. Liver transplantation is often the only treatment possible for these patients, not only because of multifocal cancer but also because of the baseline hepatic insufficiency from the underlying inflammatory disease.

#### *Choledochal Cysts or Caroli's Disease*

The increased risk of cholangiocarcinoma in patients with congenital cystic disease of the biliary tree is well recognized.<sup>275,276</sup> The reason for the malignant transformation is thought to be related to chronic inflammation and bacterial contamination within the cystic areas.<sup>276,277,278</sup> and <sup>279</sup> Early excision of the choledochal cyst significantly reduces the risk of cancer.<sup>276,277</sup> Fifteen to twenty percent of adult patients with unexcised choledochal cysts or cysts previously treated with bypass will be found to have a cholangiocarcinoma.<sup>276,277</sup>

#### *Pyogenic Cholangiohepatitis and Other Hepatic Infections*

In the Orient, chronic infections of the liver can predispose to development of cholangiocarcinoma. Pyogenic cholangiohepatitis or Oriental cholangiohepatitis results from chronic portal bacteremia and portal phlebitis, which gives rise to intrahepatic pigment stone formation. This hepatolithiasis leads to recurrent episodes of cholangitis and stricture formation.<sup>280,281,282</sup> and <sup>283</sup> Those patients who do not succumb to sepsis will have approximately a 10% chance of developing cholangiocarcinoma.<sup>281,282</sup> and <sup>283</sup> In Southeast Asia, biliary parasites (*Clonorchis sinensis*, *Opisthorchis viverrini*) are also associated with an increased risk of cholangiocarcinoma.<sup>273</sup> In areas where these parasites are endemic, the incidence of cholangiocarcinoma is as high as 87 per 100,000.<sup>284</sup>

#### *Influence of Environmental Agents*

Several radionuclides and chemical carcinogens, including thorium, radon, nitrosamines, dioxin, and asbestos, have also been implicated in the development of cholangiocarcinomas.

## PATHOLOGY AND CLASSIFICATION

Cholangiocarcinoma can arise anywhere within the biliary tree. Approximately 10% of cholangiocarcinoma cases arise within the intrahepatic bile ducts.<sup>285,286,287,288</sup> and <sup>289</sup> These usually present as hepatic masses that are thought at first to be HCCs or metastatic tumor of unknown origin. The extrahepatic variety is more common and can occur along the entire length of the bile duct from the confluence of the hepatic ducts to the ampulla. Some have classified these extrahepatic tumors into proximal (hilar), middle, and distal bile duct tumors. Nakeeb et al.<sup>290</sup> proposed a more practical division of cholangiocarcinomas into intrahepatic, perihilar, and distal subgroups, thus eliminating the midduct group. Those lesions that are proximal to the cystic duct–common duct junction usually require a liver resection for extirpation. These represent approximately 40% to 60% of cases of cholangiocarcinoma and include the hilar cholangiocarcinomas or Klatskin tumors.<sup>270,290,291,292,293,294,295</sup> and <sup>296</sup> Those tumors distal to the cystic duct usually require pancreatectomy for treatment. Fewer than 10% of patients will present with multifocal or diffuse involvement of the biliary tree.<sup>297</sup>

Cholangiocarcinomas are characterized by early invasion of adjacent organs.<sup>298</sup> Nodal metastases are also common and occur in up to one-third of cases.<sup>270,299</sup> In

addition to lymphatic involvement, these tumors are also characterized by neural, perineural, and subepithelial extension. <sup>298</sup>

Cholangiocarcinomas can be separated into three distinct macroscopic subtypes: sclerosing, nodular, and papillary. <sup>298</sup> Most are *sclerosing* tumors, which are very firm and are seen as annular thickening of the bile duct, often with diffuse infiltration and fibrosis of the periductal tissues. *Nodular* tumors are firm tumors that project into the lumen of the duct. Frequently, features of both sclerosing and nodular tumors are found, and the tumor is described as *nodular-sclerosing*. *Papillary* tumors are soft and friable and often demonstrate little transmural invasion. These tumors have a more favorable prognosis than do the others, <sup>273</sup> are more common in the distal bile duct, and account for approximately 10% of all cholangiocarcinomas. <sup>298</sup>

The overwhelming majority (>90%) of cholangiocarcinomas are adenocarcinomas, often well differentiated and mucin-producing. <sup>266,298,300</sup> Rarely, malignant obstruction of the bile duct may be due to other cell types, such as carcinoid tumors, arising primarily in the biliary tree or to tumors metastatic to the biliary tree. <sup>301,302</sup> and <sup>303</sup>

## DISTAL BILE DUCT CANCERS

Distal bile duct cancers are rare cancers that usually are reported as part of a series of periampullary tumors or as a series describing all bile duct cancers. Distal bile duct tumors represent approximately 20% to 30% of all cholangiocarcinomas or 5% to 10% of all periampullary tumors. <sup>290,293,294,304</sup> Approximately 2000 new cases of distal bile duct cancer are diagnosed in the United States each year. <sup>293</sup> They are almost always adenocarcinomas. The papillary variety is also more common in this location than in other parts of the bile duct. <sup>292</sup>

### Clinical Presentation and Diagnosis

On the practical level, patients with distal bile duct cancers usually present with jaundice and a mass at the head of the pancreas. Except in the case of the papillary variety of this cancer, patients are brought to the operating room with the diagnosis of periampullary cancer, and it is in the final pathologic analysis that the anatomic site of origin of the tumor becomes clear. The importance of distinguishing distal bile duct cancer from the other periampullary tumors is in the prognostic implications, as distal bile duct cancer has a much more favorable outcome than does the more common adenocarcinoma of the pancreas.

Jaundice is the presenting symptom in up to 90% of patients with distal bile duct cancer. Abdominal pain, weight loss, fever, or pruritus are also common symptoms, though these occur in one-third of cases or fewer. <sup>290,293</sup> If the patient reports that the jaundice is intermittent, a papillary bile duct cancer should be suspected. Most often, however, the symptoms and signs will be indistinguishable from adenocarcinoma of the pancreatic head or other periampullary malignancies.

US will demonstrate a dilated extrahepatic and intrahepatic biliary tree. Cross-sectional imaging by CT scanning will usually then demonstrate a mass in the region of the head of the pancreas. Endoscopic retrograde cholangiopancreatography (ERCP) may be diagnostic if it demonstrates an obstruction in the bile duct that does not involve the pancreatic duct. Most often, however, ERCP will demonstrate distal biliary obstruction without diagnostic information on the cell origin of the malignancy. In fact, we tend not to perform ERCP if the patient is a surgical candidate, preferring to operate on the patient without direct biliary manipulation, as this decreases the risk of biliary sepsis. <sup>305</sup>

If surgical resection is planned, a preoperative tissue diagnosis of cancer is not necessary and often is not possible. Endoscopic brush biopsy has a low sensitivity, making a negative result virtually useless. <sup>306</sup> Performing a percutaneous needle biopsy is difficult because of the small size of these tumors. Therefore, preoperative diagnosis is usually based on clinical impression. In patients with a stricture of the distal bile duct and a clinical presentation consistent with cholangiocarcinoma, cross-sectional imaging studies are scrutinized for signs of unresectable cancer. In this regard, a contrast-enhanced helical CT scan with overlapping 5-mm sections through the area of the pancreas is the most useful. This test allows for evaluation for vascular involvement or metastatic disease. Magnetic resonance cholangiopancreatography (MRCP) may also be used for evaluation of these periampullary tumors. <sup>307</sup>

If the tumor is judged unresectable by radiologic criteria, it is usually of sufficient size for diagnosis by percutaneous needle biopsy. Biliary obstruction then can also be treated by endoscopic stenting or, if necessary, through percutaneous transhepatic stenting to avoid surgery.

### Treatment Options

Complete resection is the only effective and potentially curative therapy for cancers of the lower bile duct. <sup>271,290,292,293</sup> and <sup>294,304</sup> Resection usually requires a pancreaticoduodenectomy. <sup>293,304</sup> In comparison to pancreatic cancer, distal bile duct cancer is more often amenable to resection and patients less often have microscopic disease at the resection margin and less frequently demonstrate spread of tumor to adjacent lymph nodes. <sup>290,293,294</sup> Completeness of resection, presence of lymphatic metastases, <sup>293,304</sup> and tumor differentiation <sup>290</sup> are the prognostic factors that most strongly influence long-term outcome. Fong et al. <sup>293</sup> found that lymph node status was the only independent predictor of long-term survival in patients who have undergone resection, with positive nodes conferring a 6.7 times greater likelihood of recurrence and death.

The results of resection for distal bile duct cancer as compared to the other periampullary tumors are demonstrated in [Figure 33.5-4](#). The results are similar to those for duodenal cancer, more favorable than those for adenocarcinoma of the pancreas, <sup>293,304</sup> and less favorable than those for neuroendocrine or ampullary tumors. Five-year survival rates of up to 40% have been reported after complete resection ( [Table 33.5-12](#)). It has long been assumed that survival after resection of distal bile duct tumors is more favorable than after resection of hilar cholangiocarcinomas, <sup>292</sup> but this commonly held belief has been refuted by data. Though it is true that resectability rates are higher for distal bile duct cancers and the likelihood of achieving a negative margin during resection is greater, the survival rates of the various bile duct tumors, if adjusted for stage and completeness of resection, appear to be comparable. <sup>271</sup>

**TABLE 33.5-12.** Survival after Resection of Distal Cholangiocarcinoma

Because of the rarity of distal cholangiocarcinoma, no prospective data are available to guide the use of adjuvant therapy after resection.<sup>290</sup> We tend not to use adjuvant therapy if resection margins are clear of tumor, though many other practitioners use regimens of chemoradiation originally developed for adenocarcinoma of the pancreas.

In patients with nonresectable cancers, palliation for biliary obstruction can be achieved with a surgical bypass or biliary endoprosthesis. Endoprosthesis for distal biliary obstruction are usually placed endoscopically and provide more durable palliation than does an endoprosthesis placed for hilar obstruction.<sup>277</sup> Surgical bypasses also provide excellent relief of jaundice and can be achieved with an acceptably low morbidity and mortality. In our practice, patients found to have unresectable disease at laparotomy are subjected to surgical bypasses, as they will already have incurred the risk of anesthesia and laparotomy. Furthermore, patients expected to survive longer than 6 months are also considered for surgical bypass.<sup>308</sup> All other patients are treated with biliary endoprosthesis.

Chemotherapy or radiotherapy or both have offered generally poor results as palliative treatment for unresectable cases. Survival beyond 1 year is uncommon in patients subjected to palliative therapies.<sup>290,292,293,304</sup>

### PROXIMAL OR HILAR CHOLANGIOCARCINOMA

Proximal or hilar cholangiocarcinomas were first described by Altemeier<sup>341</sup> in 1957 and subsequently by Klatskin<sup>309</sup> in 1965. Of the hepatobiliary tumors, these cholangiocarcinomas represent the greatest diagnostic and therapeutic challenge because of the vast number of vital structures that can be involved by even a small hilar cholangiocarcinoma. Proximal or hilar cholangiocarcinomas require the most extensive of liver resections and vascular reconstruction for extirpation.

#### *Clinical Presentation and Diagnosis*

**CLINICAL FINDINGS.** Most patients with cholangiocarcinoma come to medical attention because of jaundice or abnormal liver function tests. Other associated symptoms are nonspecific. Abdominal pain or discomfort, anorexia, weight loss, and pruritus are the most common symptoms but are seen in only approximately one-third of patients. Fever usually is seen only after biliary manipulation.<sup>273,274,283,290,310,311</sup> In some patients, pruritus precedes jaundice by some weeks, and this symptom should prompt an evaluation, especially if associated with abnormal liver function tests. Intermittent jaundice may be seen with papillary tumors and is usually due to intermittent detachment of pieces of friable tumors from the right or left hepatic duct that pass into and occlude the common hepatic duct. The serum bilirubin level is usually greater than 10 mg/dL and averages 18 mg/dL, whereas bilirubin levels of 2 to 4 mg/dL are the norm in patients with obstruction from choledocholithiasis.<sup>312</sup> Malignancy should be strongly suspected in patients with deep, painless jaundice who present with no fever or other signs of infection.

On physical examination, jaundice is usually obvious. Patients with pruritus may have multiple excoriations of the skin. Proximal biliary obstruction is usually associated with a decompressed and nonpalpable gallbladder. Thus, a palpable gallbladder would suggest a more distal obstruction or gallbladder cancer. Signs of portal hypertension are rare but would be an ominous indication of advanced vascular involvement or the alternative diagnosis of cirrhosis and HCC.

Medical history and family history should be scrutinized for conditions such as PSC or Oriental cholangiohepatitis that may predispose to cholangiocarcinoma. Many tumors express carcinoembryonic antigen (CEA) and the carbohydrate antigen CA 19-9. The diagnostic value of these serum markers is, however, debated.<sup>273</sup> It has been suggested that CEA levels in hepatic bile may help to distinguish between benign and malignant strictures in patients with premalignant conditions.<sup>313</sup> Diagnosis of cholangiocarcinoma is usually made radiologically.

**RADIOGRAPHIC EVALUATION.** Radiologic imaging is central to the diagnosis and treatment planning for patients with cholangiocarcinomas. The importance of imaging studies results from the difficulties in obtaining a positive tissue diagnosis by biopsy, particularly when the tumors are small and in the potentially curable stages. Relying on the results of percutaneous needle biopsy or biliary brush cytology is dangerous, as the results of these tests are often misleading and one may miss the opportunity to resect an early cancer.<sup>314,315</sup> Therefore, the preoperative and, often, operative diagnoses are based mainly on the history and radiologic appearance of the tumors.

The differential diagnosis must include gallbladder carcinoma, Mirizzi syndrome, idiopathic benign focal stenosis (malignant masquerade), or sclerosing cholangitis. Unless there is a large intraluminal mass in the gallbladder, distinguishing gallbladder carcinoma from hilar cholangiocarcinoma can be difficult. Mirizzi syndrome is caused by a large gallstone impacted in the neck of the gallbladder, resulting in biliary obstruction from periductal inflammation.<sup>316,317</sup> and <sup>318</sup> Benign focal strictures (malignant masquerade) can also occur at the hepatic duct confluence but are uncommon.<sup>319,320,321</sup> and <sup>322</sup>

Beyond diagnosis, the radiologic evaluation is aimed at determining resectability, as surgical resection is the most effective and only potentially curative therapy. Imaging may locate occult distant metastases and thereby spare patients from nontherapeutic surgery. In defining the degree of invasion of adjacent organs and vasculature, imaging is also essential for planning the surgical procedure and directing major vascular reconstructions when necessary.

Most patients will present to the surgeon having already been subjected to a sonogram and CT. US is usually the first investigation performed because it is noninvasive, readily available, and provides important diagnostic information regarding the jaundiced patient. Generally, intrahepatic biliary dilatation will be seen without evidence of extrahepatic bile duct abnormality and without evidence of stones. In experienced hands, the tumor will often be clearly defined by US, as will information important for planning of surgery such as delineation of the biliary extent of disease, vascular involvement, presence of lymph node metastases in the porta hepatis, and presence of noncontiguous liver metastases. US not only may demonstrate the level of biliary ductal obstruction but can also provide information regarding tumor extension within the bile duct and in the periductal tissues.<sup>323,324</sup> and <sup>325</sup> In centers specializing in treatment of cholangiocarcinomas, a good Doppler US may indeed provide diagnostic information equivalent to that provided by a combination of angiography and CT and is highly accurate in predicting resectability.<sup>325,326</sup> However, US is more operator-dependent than is most cross-sectional imaging. Therefore, in most circumstances, other cross-sectional imaging is necessary.

Most patients will present to a tertiary care center having already been imaged by CT. CT remains an important study for evaluating patients and is less dependent than US on the skills of the operator. Important information regarding level of biliary obstruction, vascular involvement, and presence of nodal or noncontiguous metastases can be assessed. One of the most important findings to be gleaned from a CT scan, however, is the presence of hepatic lobar atrophy, which is usually indicative of portal venous occlusion.<sup>327</sup>

In years past, most patients also were subjected to direct angiography and cholangiography. Angiography allows for determination of arterial or portal venous vascular encasement. Cholangiography demonstrates the location of the tumor and the biliary extent of disease. Recently, however, MRCP has emerged as a noninvasive substitute for direct cholangiography.<sup>328,329,330</sup> and <sup>331</sup> MRCP not only may identify the tumor and the level of biliary obstruction but also may reveal obstructed and isolated ducts not appreciated at endoscopic or percutaneous study. Magnetic resonance angiography (MRA) or CT angiography has become a substitute for direct angiography. Today, the need to perform invasive tests is moot. When direct cholangiography is needed, percutaneous transhepatic cholangiography (PTC) is preferred over ERCP because it is more likely to provide the details of the intrahepatic biliary tree necessary for surgical planning.

For patients presenting with proximal cholangiocarcinomas, a Doppler US, helical CT, and chest radiograph may suffice as preoperative radiologic evaluation. In patients in whom further delineation of biliary or vascular involvement may be necessary, MRCP and MRA are the next tests of choice. This noninvasive approach prevents biliary instrumentation and bacteremia and the associated increased perioperative morbidity.<sup>305,332</sup> When necessary, direct cholangiography or angiography is used.

#### **Staging**

The most commonly used staging systems are the modified Bismuth-Corlette and the American Joint Committee on Cancer (AJCC) TNM (tumor, node, metastasis) staging system. The former classifies patients based on the extent of biliary duct involvement by tumor,<sup>333</sup> whereas the latter is based largely on pathologic criteria

(Table 33.5-13). These staging systems do not distinguish between extensive unilateral disease and bilateral disease because, before surgical resections became commonplace, such distinctions had little value. Thus, a patient with tumor extension into third-order biliary ducts on one side of the liver accompanied by ipsilateral portal vein occlusion will be classified as having very advanced disease, though this patient may now be treatable with potentially curative resection as disease is confined to one side.

TUMOR (T)			
T0	Carcinoma in situ		
T1	Tumor invades subepithelial connective tissue or fibromuscular layer		
T2	Tumor invades periductumular connective tissue		
T3	Tumor invades adjacent organs (liver, pancreas, duodenum, gallbladder, colon, stomach)		
NODE (N)			
N0	No regional lymph node metastases		
N1	Metastasis to lymph nodes within the hepatoduodenal ligament (cystic duct, periductal, and/or other lymph nodes)		
N2	Metastasis to periductal, periductumular, periportal, colic, superior mesenteric, and/or posterior gastroepiploic lymph nodes		
METASTASIS (M)			
M0	No distant metastasis		
M1	Distant metastasis		
STAGE GROUPING			
Stage 0	T0	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3 or T2	N1 or N2	M0
Stage IVA	T3	Any N	M0
Stage IVB	Any T	Any N	M1

TABLE 33.5-13. American Joint Committee on Cancer TNM Staging System for Proximal (Hilar) Cholangiocarcinoma and Cancer of the Extrahepatic Bile Ducts

We recently proposed a staging system, using preoperative imaging and taking into account the extent of biliary ductal involvement, vascular involvement, and lobar atrophy, that may be more applicable than the other systems, given modern surgical therapies (Table 33.5-14).<sup>270</sup> In the era of effective surgical therapy for cholangiocarcinomas, this staging system is a better predictor of resectability and outcome than is the AJCC classification.

T Stage	Biliary Involvement	Ipsilateral Portal Vein Involvement	Non Portal Vein Involvement
T1	Hilar and/or right or left hepatic duct	No	No
T2	Hilar and/or right or left hepatic duct	Yes	No
T3	Hilar and/or right or left hepatic duct	Yes/No	No
T4	Secondary biliary radicles bilaterally	Yes/No	Yes/No

(Data from ref. 270.)

TABLE 33.5-14. Proposed Staging System for Proximal (Hilar) Cholangiocarcinoma in the Era of Effective Surgical Therapy

### Treatment with Curative Intent

The only curative option is complete surgical excision of the cholangiocarcinoma. Until the last decade, such surgical resections were rarely accomplished, because complete excision usually requires a major liver resection, biliary resection and reconstruction and, often, a major vascular resection and reconstruction.<sup>270,334,335</sup> As advances in diagnostic imaging have been made, earlier detection of cholangiocarcinoma and improved operative planning are possible. As surgical techniques have evolved to make major hepatectomies routine, increasing numbers of resections have been accomplished. The results generated over the last decades has firmly established resection as safe and effective treatment and have helped to define patient selection and operative conduct.

**RESECTION.** It has become clear over the last three decades that curative treatment of tumors involving the upper third of the bile duct very much depends on aggressive surgical excision. Until as recently as one decade ago, surgical treatment of hilar cholangiocarcinomas was associated with a mortality as high as 30%.<sup>333,336,337,338,339</sup> and <sup>340</sup> Before the 1990s, most surgical series were small, operative mortalities were high, and only a handful of 5-year survivors were reported.<sup>578,579,580,581,582</sup> and <sup>583</sup> That this entire disease was regarded with pessimism was understandable.<sup>309,341,342</sup> It is not surprising, therefore, that until recently, the surgical therapy for proximal biliary malignancies consisted mainly of biliary-enteric bypass as palliation for jaundice and cholangitis. Results reported over the last decade, however, have indicated a major improvement in safety of these operations such that resections of hilar tumors can be accomplished (even when liver resections are required) with a mortality of less than 10% (Table 33.5-15).<sup>271,333,337,343</sup> Increasingly large series have been reported that have firmly documented the curative potential of such major resections (see Table 33.5-15). Given that unresected disease is uniformly fatal, usually within 6 to 12 months, surgical resection has become the treatment of choice when possible.

Author, Year <sup>a</sup>	No. of Cases	No. Resected	Mortality (%)	Survival

TABLE 33.5-15. Results of Resection for Proximal (Hilar) Cholangiocarcinoma after 1990

The goals of surgical management for cholangiocarcinomas are eradication of tumor and establishment of adequate biliary drainage. For tumors of the hepatic ducts and the biliary confluence, symptoms often appear late in the course of disease when the lesion has already involved adjacent structures, including the portal vein or adjacent hepatic parenchyma. Complete resection, therefore, usually requires not only biliary resection but also major liver resection and, often, major vascular and biliary reconstruction.

Discussion of the fine details of resections for hilar cholangiocarcinomas is beyond the scope of this chapter. The reader is referred to standard texts of surgical techniques for detailed technical discussions.<sup>126,344,345</sup> Nonetheless, some major points and principles warrant emphasis.

Laparoscopic evaluation should be considered before a formal laparotomy is performed. Metastatic disease is common in patients with hilar cholangiocarcinoma. One-half or more of the patients will have metastatic disease found at surgery.<sup>270,343,346,347</sup> Recent studies suggest that staging laparoscopy combined with laparoscopic US may be useful in hepatobiliary malignancies to find such metastatic disease and thereby prevent unnecessary laparotomies.<sup>318</sup> In our recent series, 50% of unresectable cases were identified as such by laparoscopy.<sup>347</sup> Of the causes of unresectability, laparoscopy was best at identifying peritoneal metastases and

noncontiguous liver metastases and was poor at identifying vascular invasion and nodal metastases.<sup>347</sup> Hence, we would recommend a laparoscopic evaluation immediately before laparotomy. We also recommend that the examination concentrate on peritoneal and liver disease and not persevere on the biliary or nodal extent of disease in the porta hepatis because of low yield and risk of violation and spread of tumor.

Laparotomy then commences with a thorough exploration of the abdomen. The lymph nodes in the porta hepatis and celiac and retropancreatic area are carefully assessed. If there is spread to celiac or retropancreatic nodes, the chance of long-term survival is sufficiently low that resection is ill-advised. Though a segmental bile duct resection and biliary reconstruction are possible in some patients, most require partial hepatectomy to achieve complete tumor clearance. The extent of liver resection should be tailored to achieve tumor clearance. Some patients with small tumors and low bifurcation of the hepatic ducts may be treatable with a central liver resection. Most patients will, however, require either a lobectomy or a trisegmentectomy for resection of tumor. A subset of patients will also require excision of the caudate lobe (segment 1) to clear tumor completely.<sup>348,349</sup>

The factors most influential in predicting recurrence are a margin-positive resection,<sup>350</sup> node-positive tumor,<sup>351</sup> and vascular involvement by tumor. Of these, the only factor over which the surgeon can routinely have influence is the surgical margin. There is now substantial evidence that partial hepatectomy is usually required to achieve a surgical margin clear of tumor. Bile duct excision and partial hepatectomy, often with *en bloc* caudate lobectomy,<sup>352</sup> are frequently necessary to achieve negative margins. Indeed, several recent studies show a parallel between the number of patients undergoing partial hepatectomy and the number of patients with negative margins (Fig. 33.5-5A).<sup>270,339,353,354</sup> and <sup>355</sup> Furthermore, there is a direct correlation between negative margins and long-term survival (see Fig. 33.5-5B). Clearance of tumor is essential for potential cure.<sup>270</sup>

**FIGURE 33.5-5. A:** Relationship of percentage of liver resection to percentage of margin-negative cases for proximal (hilar) cholangiocarcinomas. Willingness to resect liver is essential for complete excision of cholangiocarcinomas and for achieving negative surgical margins. **B:** Relationship of percentage of margin-negative cases to percentage of 5-year survivors for proximal (hilar) cholangiocarcinomas. Achieving a negative margin is essential for favorable long-term outcome.

In the era when surgeons were unwilling to perform major liver resections to clear tumor, only the smallest of hilar cholangiocarcinomas could be resected. Given that extensive liver resections are now routine at many major centers, extensive unilobar disease is commonly resected with curative intent. In a recent study, of the 30 patients subjected to resections of cholangiocarcinoma, including 25 (83%) with negative histologic margins, 15 patients had tumor involvement of secondary biliary radicals, 11 had unilateral lobar liver atrophy, and 8 had encasement or occlusion of a major portal vein branch.<sup>270</sup> In the past, these findings would have been considered technically insurmountable.

The entire extrahepatic bile duct should be removed, as this assists in resection of the lymphatic tissues in the porta hepatis. Lymphatic metastases are common,<sup>270</sup> and a complete portal lymphadenectomy is essential. Biliary continuity is then reestablished using a jejunal reconstruction.<sup>356,357</sup> Portal vein invasion by tumor does not rule out resection, long-term survival, or potential cure,<sup>270</sup> provided that the portal vein involvement is unilobar and on the side of the dominant biliary involvement. Bilateral portal venous involvement or unilobar invasion contralateral to extensive biliary invasion usually denotes unresectable disease and, consequently, poor prognosis.

Recent results of resection have shown great improvement over previous results. Median survival is longer than 24 months.<sup>271,333,337</sup> Five-year survival is accomplished in nearly 30% of patients (see Table 33.5-15). Such long-term survival can be achieved with an acceptable operative mortality.<sup>187,270,271,295,313,316,339,352,353,354</sup> and <sup>355,358,359,360,361</sup> and <sup>362</sup> For those surviving the operative procedure, surgical resection provides not only improved survival but also improved quality of survival.<sup>363</sup>

**ADJUVANT THERAPY.** To date, no chemotherapeutic regimen has consistently shown activity in cholangiocarcinoma.<sup>364</sup> Although chemotherapy based on 5-FU often is offered to patients with nonresectable disease, the likelihood of response is less than 10% (see later in [Chemotherapy and Immunotherapy](#)). There is certainly no proven role for adjuvant chemotherapy in the treatment of cholangiocarcinoma.

The role of radiotherapy in the treatment of resected extrahepatic bile duct cancer is controversial. Given the poor prognosis of patients who have undergone a complete resection (median survival range, 1.5 to 2.0 years) and the fact that many resections leave microscopically positive margins, many practitioners have advocated postoperative irradiation with or without systemic chemotherapy (Table 33.5-16). External-beam doses in the range of 45 to 60 Gy (with the latter doses for positive margins) are usually administered. In addition to external-beam radiation, boost doses can be administered using intraluminal brachytherapy (ILB). In this approach, a wire or string of radioactive seeds (typically <sup>192</sup>Ir) is introduced into the bile duct, which delivers 20 to 30 Gy at a 0.5- to 1.0-cm depth. Traditionally, this has been performed using low dose-rate radiation (<1 Gy/h); more recently, high dose-rate radiation (approximately 2 Gy/min) has been administered.<sup>365</sup> The advantage of ILB is the potential to deliver a high dose of radiation to the duct itself with minimal damage to surrounding liver.<sup>366,367</sup> The disadvantage is that disease more than 1 cm from the duct tends to be underdosed. In addition, ILB may be associated with an increased risk of infection.

Study	Surgery	Radiotherapy			Median Survival (yr)
		Dose	No. of Patients	Chemotherapy	
Hep <sup>271</sup>	Prep (includes positive margin)	40-60 Gy (E.B. 0-30 Gy)	34	None	26
	None		17	None	26
Ureg <sup>371</sup>	Prep (includes positive margin)	45 Gy (median)	23	Orally 5-FU	34 <sup>a</sup>
	None		30	None	24
Kamada <sup>370</sup>	Prep (includes positive margin)	50 Gy (total)	41	None	34
	None		33	None	24
Kamada <sup>370</sup>	Prep	45 Gy + 20 Gy ILB (median)	9	SFU by infusion	22
	None		11	SFU by infusion	22

**TABLE 33.5-16. Results of Adjuvant Radiotherapy in Patients with Resected Cholangiocarcinoma**

In two separate reports from Johns Hopkins, no benefit of adjuvant external-beam and intraluminal radiotherapy was demonstrated.<sup>343,368</sup> In contrast, Kamada et al.<sup>369</sup> suggested that radiation may improve survival in patients with histologically positive hepatic duct margins. Additionally, in a small series of patients (five with hilar cholangiocarcinoma) from Louisville, resectability was reportedly greater in patients given neoadjuvant radiotherapy prior to exploration.<sup>370</sup> In a series of 23 patients with cholangiocarcinoma, Uregio et al.<sup>371</sup> used a chemoradiation regimen for adjuvant therapy, consisting of postoperative irradiation, 5-FU, leucovorin, and IFN. The 5-year survival was 53%.<sup>371</sup> These results certainly encourage further study of radiotherapy with or without chemosensitization in the adjuvant treatment of

cholangiocarcinoma. Given the small size of the studies and lack of randomized trials, the utility of radiotherapy, and particularly ILB, is far from proven. In our practice, adjuvant therapy is generally used only if there is a positive margin or in the setting of metastases to lymph nodes. Other patients are not offered adjuvant therapy.

**LIVER TRANSPLANTATION.** Orthotopic liver transplantation has been attempted for unresectable hilar tumors. Klemprauer et al. <sup>372</sup> reported 4 long-term survivors of 32 patients submitted to transplantation for hilar cholangiocarcinoma. Comparable results were reported by Iwatsuki et al. <sup>373</sup> These results do not justify the use of precious organs when many patients with benign disease are dying awaiting liver transplantation. Therefore, most centers do not currently perform liver transplantation for cholangiocarcinoma.

**Palliative Treatments**

Patients with hilar cholangiocarcinoma most often die from liver failure due to tumor progression or from sepsis due to biliary infection. If resection is not feasible, then palliative treatment must be directed first and foremost at preventing or relieving biliary infection. Secondly, palliative antitumor treatments such as radiotherapy or chemotherapy should be considered, though neither of these modalities has been clearly proven to prolong survival significantly.

**BILIARY DRAINAGE.** The important concept in the prevention of biliary sepsis is the understanding that jaundice alone is not necessarily an indication for biliary decompression. Unlike biliary obstruction in the lower bile duct, where a single stent usually effectively relieves the biliary obstruction, biliary obstruction near the hilus is much more difficult to relieve. Even with a small tumor, a single stent likely will drain only one-half of the liver. When the tumors are large and involve second- or third-order bile ducts, many stents may be required to provide effective biliary decompression; it is also possible that effective biliary decompression cannot be achieved in such cases. Biliary manipulation of any kind may therefore introduce bacteria into the biliary tree and cause sepsis that may not subsequently be fixable.

Good indication for biliary drainage must exist before attempts are made. Our current indications for biliary decompression in inoperable patients are intractable pruritus, cholangitis, the need for access for intraluminal radiotherapy, or the need for drainage for administration of chemotherapeutic agents. When none of these indications exists, the patient is probably better served by avoiding biliary manipulation. Supportive care alone is probably the best approach, particularly for elderly patients with significant comorbid conditions.

Unfortunately, most patients present to a tertiary care center already having undergone manipulation of the biliary tree. Most of these patients, therefore, have bacteremia and, possibly, overt sepsis, and drainage of the biliary tree is an essential part of the therapy to prevent immediate life-threatening complications.

Biliary drainage can be accomplished nonsurgically or surgically. Nonsurgical drainage is preferred if the patient has significant comorbid conditions or if the tumor as evaluated by preoperative imaging is clearly not resectable for cure. Though biliary decompression can theoretically be accomplished either by percutaneous transhepatic puncture or by endoscopic stent placement, hilar tumors are notoriously difficult to traverse with the endoscopic technique. Moreover, the failure rates and incidence of subsequent cholangitis are high. <sup>374</sup> Thus, most patients with unresectable hilar tumors are not candidates for endoscopic biliary drainage. Percutaneous transhepatic biliary drainage and subsequent placement of a self-expandable metallic endoprosthesis (Wallstent, Boston Scientific, Boston, MA) is the palliative procedure of choice for these patients. However, as mentioned, satisfactory results are more difficult to achieve in patients with hilar tumors than in those with distal biliary obstruction. <sup>277,375,376</sup> Frequently, hilar tumors isolate the liver into multiple obstructed biliary units, and two or more stents must be placed for adequate drainage. <sup>377</sup> Portal venous involvement and consequent hepatic lobar atrophy may also complicate drainage procedures, as drainage through an atrophic lobe usually does not relieve jaundice. Furthermore, a stent placed for a hilar obstruction is associated with a substantially higher rate of occlusion than that placed in the distal duct. <sup>277,378</sup> Therefore, most patients will require multiple manipulations of their stents placed for hilar obstruction. <sup>277,377,378,779,380,381</sup> and <sup>382</sup> These difficulties also explain the high periprocedural mortality in this patient population: 14% at 30 days. <sup>380</sup>

Biliary enteric bypass is a surgical alternative to percutaneous placement of an endobiliary prosthesis. Certainly, patients whose tumors are found to be unresectable at operation should be considered for such bypasses, <sup>270</sup> because they will have already incurred the morbidity of laparotomy. Patients with small, unresectable, but well-localized disease are particularly good candidates for biliary enteric bypass, as this allows access to the biliary tree for ILB. <sup>383</sup> Typically, segment III bypass is used. <sup>384</sup> Relief of jaundice will be achieved if at least one-third of the functioning hepatic parenchyma is adequately drained. Additional percutaneous stenting to reestablish biliary continuity of the two sides of the liver is required if the bypass is to an atrophic or a small lobe or if infection has occurred in the contralateral lobe of liver. <sup>385</sup> In our recent report of 55 consecutive bypasses in patients with malignant hilar obstruction, segment III bypass yielded a 1-year bypass patency of 80%, and there were no perioperative deaths. <sup>384</sup>

**CHEMOTHERAPY AND IMMUNOTHERAPY.** Many different chemotherapeutic regimens have been investigated in small uncontrolled studies, with generally poor results (Table 33.5-17). A study by the European Organization for Research and Treatment of Cancer testing mitomycin C on patients with gallbladder and biliary carcinomas showed a response rate of 10% (3 of 30). The group also compared oral 5-FU to 5-FU with either streptozotocin or MeCCNU in patients with gallbladder or biliary duct cancer and demonstrated a similarly low response rate of 9%, with no differences in the types of drugs used. <sup>386</sup> Some of the newer drugs have also not demonstrated significant efficacy as single-agent therapy. Paclitaxel demonstrated no activity in 15 patients with biliary carcinoma, <sup>387</sup> and a phase II study of docetaxel likewise demonstrated no activity. <sup>388</sup>

**TABLE 33.5-17.** Results of Chemotherapy for Biliary Tract Tumors (Cholangiocarcinomas or Gallbladder Cancers)

Combinations of various chemotherapeutic agents have been tested, with mixed and conflicting results. Patt et al. <sup>389</sup> used 5-FU and IFN as combined therapy for patients with cholangiocarcinoma. Of 32 patients, 11 (34%) had a partial response, with a median time to disease progression of 9.5 months and a median survival of 12 months. <sup>389</sup> However, another phase II study analyzing the effect of 5-FU combined with IFN- $\alpha_{2c}$  and paclitaxel failed to show any benefit. <sup>390</sup> In one study combining 5-FU, mitomycin, and doxorubicin, 31% of patients responded, <sup>391</sup> whereas in another trial, there were no responses among 18 patients. <sup>392</sup> The combination of 5-FU, cisplatin, and epirubicin produced a 33% response rate in 15 patients with biliary tract carcinoma in an Italian study, <sup>393</sup> and 5-FU, leucovorin, and carboplatin produced a 21% response rate among 14 patients. <sup>394</sup> Rougier et al., <sup>395</sup> using continuous-infusion 5-FU and cisplatin, produced a 33% response rate in 18 patients. Gemcitabine <sup>396</sup> and 5-FU plus gemcitabine <sup>397</sup> have also been tested and, in one study involving 14 patients, 42% responded. <sup>397</sup> At present, either 5-FU and cisplatin or 5-FU and gemcitabine must be considered the regimens of greatest promise in the palliative treatment of unresectable cholangiocarcinoma. We tend to use the latter combination because of its lower toxicity as compared to the former.

The blood supply to the biliary tree is derived primarily from the hepatic artery. Therefore, attempts have been directed at delivering chemotherapeutic treatment via hepatic arterial infusion to patients with cholangiocarcinoma. In one study of 11 patients (4 with cholangiocarcinomas and 7 with gallbladder cancers), hepatic infusion of 5-FU and mitomycin produced 7 responses but a median duration of response of only 3 months and a median survival of 12.5 months. <sup>398</sup> Reed et al. <sup>399</sup> reported seven significant regressions in nine patients with biliary carcinoma treated with intraarterial FUDR. This approach is far from proven and, at present, operative intervention to implant an arterial infusion pump for delivery of regional chemotherapy should be performed only in the investigational setting.

Tamoxifen is a potential MDR-reversing agent<sup>161</sup> and has been shown to inhibit human cholangiocarcinoma cell lines.<sup>400</sup> No clinical data exist, however, to indicate whether this may be a reasonable therapeutic modality for patients with unresectable cholangiocarcinomas.

**PALLIATIVE RADIOTHERAPY.** External-beam irradiation with or without ILB has also been used for palliation of patients with unresectable perihilar bile duct cancer. External-beam irradiation is usually delivered to a dose of 5000 to 6000 cGy. ILB most often uses <sup>192</sup>Ir (2000 cGy) delivered percutaneously. Several authors have demonstrated the feasibility of radiotherapy in small, nonrandomized trials.<sup>343,383,401,402,403 and 404</sup> However, to date, no study has clearly demonstrated efficacy for this modality. In a group of 12 patients treated with a combination of endoluminal and external-beam radiotherapy, the median survival was 15 months. Though episodes of cholangitis and intermittent jaundice were relatively common, the incidence of serious complications was low, and there were no treatment-related deaths.<sup>383</sup> Cameron et al.<sup>343</sup> reported improved survival in irradiated patients as compared to a group of patients who were not irradiated; however, the median survival in both groups was less than 1 year. Others have reported no benefit of radiotherapy in this setting and question its routine use, given the increased incidence of complications and the greater time spent in hospital.<sup>401</sup> Certainly, radiotherapy has not been shown to produce improved survival as compared with biliary decompression in randomized, controlled trials. Though anecdotal reports of long-term survivors after external-beam radiotherapy show that some individuals may benefit from such treatment, such potential benefit must be weighed against the possible complications, such as duodenal or bile duct stenosis and duodenitis.

Evidence in the literature supports using fluoropyrimidines as radiosensitizers, and chemoradiotherapy is used as standard therapy for a number of other tumor types. For bile duct cancers in particular, however, evidence supporting the use of chemoradiotherapy is sparse. In a study conducted by the Eastern Cooperative Oncology Group, 16 patients with pancreatic carcinoma and 9 with bile duct cancers were treated with a combination of 5-FU (200 mg/m<sup>2</sup>/d) and concurrent radiotherapy (59.4 Gy). The entire group had a median survival time of 11.9 months. Unfortunately, 15 of the 25 patients had clinical or radiographic evidence of progression of disease at the site of the primary tumor, which was in the radiotherapy port.<sup>405</sup> Moreover, median survival for the patients with locally advanced, unresectable disease that was treated with radiotherapy with or without systemic chemotherapy tends to be less than 1 year.<sup>273,370,371,401,406,407 and 408</sup> Our current practice is to use combined interstitial irradiation and external-beam irradiation in patients with very limited, locally unresectable disease, when there are no indications of distant spread. Multicenter, randomized trials are in order for this subpopulation. Radiotherapy is clearly inappropriate in patients with widespread disease.

## PERIPHERAL CHOLANGIOCARCINOMA

Peripheral or intrahepatic cholangiocarcinoma is another rare disease, accounting for 1000 to 2000 cases per year in the United States.<sup>409</sup> Clinical presentation is similar to that for HCC, with the most common symptoms being right upper quadrant pain, epigastric pain, and weight loss.<sup>287,409</sup> Jaundice occurs in only 24% of patients with peripheral cholangiocarcinoma as compared with 71% of patients with hilar or Klatskin tumors.<sup>409</sup> Because the tumor is usually asymptomatic in its early stages, most patients have advanced disease at presentation. On cross-sectional imaging by CT or MRI, the peripheral cholangiocarcinoma usually is confused with HCC or metastatic tumor from an unknown primary source. Unlike HCC, AFP levels will be normal. A search for alternative primary cancers that may have produced a liver metastases will not be fruitful. A solitary lesion not associated with the gallbladder in a patient with no cirrhosis and no other primary cancer and with a normal serum AFP should raise suspicion of a peripheral cholangiocarcinoma. However, intrahepatic metastases and tumor growth along the biliary tract frequently occur. When multiple tumors are found, it is even more difficult to distinguish these tumors from metastatic disease originating from a distant site.

Lymph node involvement is more common with peripheral cholangiocarcinoma with hilar bile duct tumors. In a series of 65 peripheral and 27 hilar cholangiocarcinomas, Nakajima et al.<sup>410</sup> found lymph node involvement in 86% of peripheral tumors as compared with 33% of hilar tumors. Intrahepatic and systemic metastases were found in 68% and 71%, respectively. The TNM staging of intrahepatic or peripheral cholangiocarcinoma is the same as that for HCC.

Conventional surgical resection, when possible, is the treatment of choice. In a series of 42 patients with peripheral cholangiocarcinoma, Altaee et al.<sup>336</sup> reported that survival was indistinguishable from that of 70 patients with hilar cholangiocarcinomas. The median survival was 12 months, and no patient survived more than 42 months. Others have reported more favorable results. Chen et al.<sup>409</sup> reported on 20 patients with peripheral cholangiocarcinoma undergoing surgery over a 10-year period who had a median survival of 21 months. Four patients lived more than 3 years, and one patient was alive 5 years after resection. In our own report of 32 cases of resected peripheral cholangiocarcinoma, median survival was 59 months, with an actuarial 5-year survival of 42%. Vascular invasion and intrahepatic satellite lesions were predictors of worse survival ( $P < .05$ ).<sup>287</sup>

The few data available concerning results of liver transplantation for this disease have not been encouraging. Penn<sup>259</sup> reported a 17% actuarial 5-year survival rate for 109 intrahepatic and extrahepatic cholangiocarcinoma patients who received liver transplants at various centers throughout the world. In this series also, there was no significant difference between the recurrence rates of hilar and peripheral tumors.

Data for chemotherapy or radiotherapy in treating this disease is even more sketchy. Stillwagon et al.<sup>411</sup> reported a 5% complete response and 46% partial response for the treatment of peripheral cholangiocarcinoma with a regimen of initial whole liver irradiation to 2100 cGy in seven fractions and doxorubicin, cisplatin, and <sup>131</sup>I anti-CEA antibody.<sup>411</sup> Although the median survival was 14 months from diagnosis and 10 months from treatment, no patient survived more than 2 years from the start of therapy.

## TUMORS OF THE GALLBLADDER

Alfred Blalock recommended in 1924 that “. . . in malignancy of the gallbladder when a diagnosis can be made without exploration, no operation should be performed, inasmuch as it only shortens the patient's life.”<sup>412</sup> This nihilistic view of gallbladder cancer is understandable because this rapidly growing tumor has a propensity for early dissemination by direct invasion of liver, by lymphatic spread, by hematogenous spread, and by production of peritoneal “drop” metastases. In addition, because of the proximity of the liver and major vasculature, extensive hepatic resections often are required to eradicate local disease. Until recently, therefore, most cases in which patients were cured of gallbladder cancer occurred “accidentally” when early-stage disease was completely excised by simple cholecystectomy for suspected stone disease. With improving safety of liver resections and biliary reconstructions, major resections are increasingly performed for gallbladder cancer and have demonstrated a curative potential even for advanced disease. Given that gallbladder cancer treated by any method other than complete excision is associated with a median survival of less than 6 months, surgery, when possible, is standard treatment.

## EPIDEMIOLOGY AND ETIOLOGY

Gallbladder cancer is a relatively rare disease in the United States, with an incidence of approximately 1.2 cases per 100,000 population per year.<sup>266</sup> Even though this would still make gallbladder cancer the most common biliary tract malignancy in this country and the fifth most common gastrointestinal malignancy, only 2000 to 3000 cases occur in the United States annually. Certain geographic regions and racial or ethnic groups demonstrate a much higher incidence, which can be 25 times higher than the national figure.<sup>413</sup> The highest incidences are reported in Chileans, northeastern Europeans, Israelis, American Indians, and Americans of Mexican origin. In fact, gallbladder cancer is the main cause of death from cancer among women in Chile.<sup>414</sup> Within the United States and the United Kingdom, urban areas show higher incidences than rural regions.<sup>413,415</sup> This cancer affects women two to six times more often than it does men.<sup>416,417</sup> The incidence steadily increases with age, reaching its maximum in the seventh decade of life.<sup>418</sup>

The epidemiology of gallbladder cancer is similar to the epidemiology of gallbladder stones,<sup>415</sup> though there is still no general agreement as to whether this represents cause and effect or common risk factors. Seventy-five to ninety-eight percent of all patients with carcinoma of the gallbladder have cholelithiasis.<sup>419</sup> Gallbladder cancer is usually associated with cholesterol-type gallstones. Other risk factors include the presence of an anomalous pancreaticobiliary duct junction,<sup>420</sup> chronic typhoid infection,<sup>421</sup> and inflammatory bowel disease.<sup>422</sup> Calcification of the gallbladder (porcelain gallbladder), signifying long-standing inflammation, is associated with gallbladder cancer in 10% to 25% of cases.<sup>423</sup> These conditions suggest that chronic inflammation may play an important role in the development of gallbladder cancer. Though reports of family clusters of gallbladder cancer exist in the literature,<sup>424</sup> congenital predisposition is not believed to play a major role in the development of this cancer.

Exposure to a number of chemicals has been suggested to play a role in carcinogenesis in the gallbladder, including methyldopa,<sup>425</sup> oral contraceptives,<sup>426</sup> isoniazid,<sup>427</sup> and chemicals used in the rubber industry.<sup>428</sup> None of these associations have been definitively proven, however. It may be that chronic inflammation acts as a promoter for some other carcinogenic exposure. This is suggested by the studies of Kowalewski and Todd,<sup>429</sup> in which carcinoma of the gallbladder was induced in 68% of hamsters in whom cholesterol pellets were inserted into the gallbladder and the carcinogen dimethylnitrosamine was administered, as compared to only 6%

of control hamsters who received the carcinogen only.

## **PATHOLOGIC FEATURES**

In general, gallbladder cancers can be categorized by growth pattern into infiltrative, nodular, papillary, or combined forms. <sup>430</sup> Most common are the infiltrative and combined nodular-infiltrative forms. The infiltrative tumors cause thickening and induration of the gallbladder wall, sometimes extending to involve the entire gallbladder. These infiltrative tumors often are difficult to distinguish from a chronically inflamed but benign gallbladder. Because the spread of tumor is often along the subserosal plane, which, incidentally, is the plane of dissection during cholecystectomy for gallstone disease, it is not uncommon for tumor to go unrecognized and for tumor to be disseminated by cholecystectomy.

Nodular types of gallbladder cancer are more distinctive and can show early invasion through the gallbladder wall into the liver or neighboring structures. Despite this invasiveness, nodular disease may be easier to control surgically than the infiltrative form, wherein the margins are less defined.

Papillary carcinomas exhibit a polypoid appearance. This variety has a much better prognosis than the other types owing to its relatively low invasiveness. A papillary tumor may be sufficiently large to fill the entire lumen of the gallbladder and still show minimal invasion of the gallbladder wall.

Most gallbladder cancers (99%) are of epithelial cell origin <sup>431</sup> and can be separated histologically into adenocarcinoma, squamous, adenosquamous, <sup>432</sup> and oat cell <sup>433</sup> subtypes. Most are adenocarcinomas. Rarely, tumors can be of mesenchymal cell origin and result in embryonal rhabdomyosarcoma, leiomyosarcoma, malignant fibrous histiocytoma, angiosarcoma, and Kaposi's sarcoma. Even more rarely, carcinosarcoma, carcinoid, lymphoma, and melanoma can occur at this site. In addition, the gallbladder can be involved with metastatic cancers. While classification is academically interesting, the only primary histologic type having clear prognostic significance is the papillary adenocarcinoma, for which the outlook is comparatively favorable. <sup>266</sup> Grading of tumors is also performed and may have prognostic significance. <sup>433</sup> However, it is extent of dissemination and resectability that has the greatest influence on outcome.

## **PATTERN OF SPREAD AND STAGING**

Gallbladder cancer generally disseminates by all four routes of tumor spread: direct adjacent organ invasion, lymphatic spread, hematogenous spread, and peritoneal drop metastases. The gallbladder is attached to the undersurface of the liver along segments IVb and V. The organ has a thin wall, a narrow lamina propria, and only a single muscle layer. Direct invasion of the liver is therefore common. In addition, the infundibulum and the cystic duct abut the common bile duct and are in proximity of the major vasculature of the porta hepatis. Tumors of the infundibulum or the cystic duct may occlude the hepatic arteries, portal veins, and bile ducts, making tumor unresectable at an early stage or dictating an extensive resection and vascular reconstruction. Whereas tumors of the fundus may be resected by a limited liver resection, tumors of the infundibulum most often will require a major liver resection for extirpation.

Once gallbladder cancer penetrates the thin muscle layer, it has access to major lymphatic and vascular channels. Lymph node metastases and hematogenous metastases are therefore common. An autopsy study revealed a 94% incidence of lymphatic metastasis and 65% incidence of hematogenous dissemination. <sup>434</sup> In general, lymphatic spread of tumor descends around the bile duct and involves cystic and pericholedochal nodes first and subsequently descends to portacaval and celiac nodes. Further spread will lead tumor to nodes in the retropancreatic, interaortocaval, and superior mesenteric artery lymph nodes. Therefore, it is essential that full mobilization of the duodenum and head of the pancreas be performed for full evaluation of the extent of lymphatic spread of disease. Though autopsy studies demonstrate as high a rate of distant metastases as 32% in lung and 5% in brain, <sup>435</sup> such spread is clinically apparent only late in the disease. Metastasis to the lung is rare, however, in the absence of advanced locoregional disease.

Gallbladder cancer has a great propensity for peritoneal spread and for seeding incisions and laparoscopic port sites. <sup>436,437</sup> At postmortem examination, Perpetuo et al. <sup>435</sup> reported that 60% of gallbladder cancer patients had peritoneal spread. This reflects a predilection for transserosal tumor both to shed and to implant and grow. In addition, a large proportion of patients present after previous cholecystectomy for presumed gallstone disease, when violation of tumor is likely.

Multiple staging systems have been advocated for the classification of gallbladder cancer. The most popular systems are listed in [Table 33.5-18](#). Most useful are the modified Nevin system <sup>438,439</sup> and the AJCC–Union Internationale Contre le Cancer TNM staging system. <sup>440</sup> The Japanese Biliary Surgical Society system <sup>441</sup> is included because of the extensive literature on gallbladder cancer originating in Japan. Understanding the Japanese system is essential for interpreting this literature.

Stage	TNM System	Modified Nevin System	Japanese Biliary Surgical Society System	Perpetuo Site Staging System
I	Mucosal or muscular invasion (T1/T2)	In situ carcinoma	Confined to gallbladder capsule	Mucosal or muscular invasion
II	Transmural invasion (T3)	Mucosal or muscular invasion	N1 lymph nodes, minimal liver or bile duct invasion	Transmural invasion
III	Liver invasion <2 cm, lymph node metastases (T4/N1)	Transmural direct liver invasion	N2 lymph nodes, nodal liver or bile duct invasion	A liver invasion <2 cm (T4/N1) B liver invasion >2 cm (T4/N2)
IV	A liver invasion >2 cm (T4/N2, T4/N3) B distant metastases (T4/N3, T4/N4)	Lymph node metastases	Distant metastases	A N1 disease (T4/N3) B distant metastases (T4/N4)
V	—	Distant metastases	—	—

T0: none; n0: no; n1:1; n2:2; n3:3; n4:4

**TABLE 33.5-18.** Summary of Most Commonly Used Staging Systems for Gallbladder Cancer

Nevin et al. <sup>439</sup> originally classified patients into five stages, based primarily on the thickness of invasion, and combined patients with direct liver extension or distant metastasis into stage V. This staging system was later modified by Donohue et al. <sup>438</sup> such that tumors with contiguous liver invasion were reclassified as stage 3 and noncontiguous liver involvement as stage 5. Stage 4 continued to include lymph node metastasis. The disadvantage of this system is that it does not differentiate between tumors that invade through muscle without invading the liver and tumors with minimal (<2 cm) or extensive (>2 cm) invasion of the liver, factors that seem to have significant prognostic significance.

In the TNM staging system, T1 tumors are those involving only the mucosa or muscle layer. T2 tumors involve perimuscular connective tissue. T3 tumors extend beyond the serosa but involve less than 2 cm of liver. T4 tumors invade beyond 2 cm of liver. T1 or T2 tumors with no lymph node metastases are stage I and II, respectively. T3 of N1 (perihilar) nodal involvement is classified as stage III. T4 tumors with no lymph node or distant metastasis constitute stage IVA, while distant nodal or other metastases are classified as stage IVB. We agree with Donohue et al. <sup>438</sup> that direct liver invasion is less ominous than nodal metastases, which in turn are less ominous than distant metastases. Included in [Table 33.5-18](#) is a proposed revision of the TNM staging system that we believe more closely segregates patients according to biologic features of the disease.

## **CLINICAL PRESENTATION**

Distinguishing the clinical presentation of gallbladder cancer from gallstone disease is usually difficult. Pain is the most common symptom, occurring in 60% to 95% of cases. Symptoms are often mistaken for biliary colic or chronic cholecystitis. Jaundice occurs in one-fourth to one-half of patients and usually denotes far-advanced disease <sup>442,443</sup> or an infundibular tumor. Gallbladder cancer can also cause obstructive jaundice by direct invasion of the common hepatic duct or by compression and involvement of the common hepatic duct by pericholedochal lymph nodes. A high correlation between Mirizzi syndrome and gallbladder cancer exists. <sup>444</sup> Anorexia, weight loss, and anemia are other nonspecific symptoms that often accompany this cancer. Obstruction of the cystic duct or the neck of the gallbladder may lead to hydrops of the gallbladder, which manifests as a mass in the right upper quadrant. A firm, fixed mass, however, would be an ominous sign and usually denotes extensive local invasion. In a review from Thorbjarnarson and Glenn, <sup>443</sup> the presence of a right upper quadrant mass in association with gallbladder cancer reflected unresectability in 23 of 25 patients.

Laboratory examination usually reveals nonspecific liver function abnormalities. Increased alkaline phosphatase or bilirubin levels are found commonly in cases of

advanced tumors. CEA and CA 19-9 are tumor markers that may be useful in the diagnosis and treatment of this cancer. A CEA level greater than 4 ng/mL is 93% specific for the diagnosis of gallbladder cancer, as compared to controls undergoing cholecystectomy or upper abdominal surgery for benign conditions, though it is only 50% sensitive.<sup>445</sup> Serum CA 19-9 levels greater than 20 units/mL have a 79.4% sensitivity and 79.2% specificity.<sup>446</sup> These markers may be useful when radiologic imaging is ambiguous or indeterminate.

## RADIOLOGIC EVALUATION

Before the routine use of CT and US, the preoperative diagnosis rate for gallbladder carcinoma was generally less than 10%, which, in part, explains the dismal outcomes of surgical therapy in the era prior to sophisticated cross-sectional imaging, as many patients with incurable disease were subjected to exploration. With the routine use of CT scanning and real-time US in the 1980s, preoperative diagnosis was achieved in 75% to 88% of patients.<sup>447</sup> Beyond diagnosis, the goals of imaging also include accurate staging. The goal of imaging is to determine extent of liver invasion, invasion of other adjacent organs, vascular involvement, extent of biliary involvement, presence of nodal metastases, and presence of peritoneal metastases.

Because the majority of patients will present with symptoms suggestive of biliary colic or chronic cholecystitis, the diagnostic workup will usually begin with abdominal US. Discontinuous gallbladder mucosa, echogenic mucosa, submucosal echolucency, or a mass greater than 1 cm should arouse suspicion of gallbladder cancer.<sup>448</sup> The finding most convincing of a gallbladder malignancy is an inhomogeneous mass replacing all or part of the gallbladder.<sup>449,450</sup> The index of suspicion should be high for elderly patients, patients with atypical symptoms, and patients with suspicious laboratory findings such as anemia, hypoalbuminemia, and abnormal liver function tests. US can also delineate the degree of biliary involvement and can define the presence of arterial or portal venous involvement by tumor. In experienced hands, US will provide diagnostic information equivalent to that provided by much more expensive cross-sectional imaging.

CT scanning is usually the next imaging examination performed because of its wide availability, low cost, low risk, and high yield. On CT, gallbladder cancer can appear as a mass almost filling the gallbladder lumen in 42% of cases, a polypoid mass in 26%, and diffuse wall thickening in 6% of gallbladder cancer patients.<sup>451</sup> CT is better than US in demonstrating liver atrophy, which usually is indicative of ipsilateral portal vein involvement by tumor. CT is also better at detecting lymphadenopathy,<sup>452</sup> particularly for retropancreatic nodal disease, which would rule out the potential for cure, though only 38% of pathologically positive nodes were identified preoperatively by CT scan.<sup>452</sup>

In years past, jaundice or radiologic signs of biliary obstruction would lead to direct cholangiography via ERCP or PTC. Indeed, direct cholangiography may provide a diagnosis. A long stricture at the mid-common bile duct is more likely to be a gallbladder cancer than any other malignancy. Direct cholangiography also allows brush sampling of the area of tumor invasion for diagnosis by cytology. Such cholangiography, however, carries the risk of introducing bacteria into an obstructed biliary tree and may cause infection and sepsis.<sup>332</sup> In addition, the presence of a biliary catheter or stent may produce sufficient inflammation to obscure margins between tumor and normal ductal epithelium. This may, in turn, compromise surgical resection.

Angiography was another common test for assessing vascular invasion when the mass encroached on the porta hepatis, but this invasive method of examination carries finite risks. Cholangiography and angiography remain important tests in certain settings, but Doppler US, magnetic resonance cholangiography, and MRA have largely replaced these invasive procedures in the majority of cases.<sup>307,453</sup>

Magnetic resonance procedures have long been accepted as invaluable for characterizing hepatic tumors. Such procedures may also identify and characterize lymph node metastases with greater precision than can other cross-sectional imaging techniques.<sup>454</sup> With recent advances in hardware and software, the extent of biliary involvement can now be determined through MRCP.<sup>455</sup> MRA allows for assessment of vascular invasion to determine resectability and can demonstrate anomalous anatomic findings to assist in surgical planning.

If a patient presents with a clinical picture and ultrasound scans suspicious for gallbladder cancer, a CT scan of the abdomen and a chest radiograph usually are obtained. Findings of pulmonary metastases, peritoneal metastases, vascular or biliary involvement not amenable to reconstruction, discontinuous liver metastases, or distant nodal disease indicate unresectability. Tissue confirmation of diagnosis can be obtained by needle biopsy, and the patient can be sent for alternative therapy.

Barring signs of unresectability, medically fit and nonjaundiced patients may proceed directly to surgical exploration. For those with jaundice or equivocal CT findings, MRCP represents the next least invasive test that may have utility. In patients with medical contraindications to immediate surgery, particularly those with renal insufficiency or sepsis, a PTC should be performed to delineate extent of biliary involvement and to treat the jaundice. At times, arteriography is still needed to demonstrate clearly unresectable vascular involvement. On rare occasions, the gallbladder cancer can erode into the transverse colon and produce a colonic fistula as a source of sepsis. In patients in whom this condition is suspected, a colonoscopy should be performed and full bowel preparation should be undertaken prior to surgical exploration.

## ROLE FOR NEEDLE BIOPSY

Generally, needle biopsy is contraindicated if a patient is thought to have a resectable gallbladder cancer. This cancer has a great propensity to spread in needle tracts, a laparoscopic port site, surgical wounds, and the peritoneal cavity.<sup>456,457</sup> Therefore, needle biopsy is not indicated if surgical exploration is otherwise appropriate. However, if radiologic studies demonstrate an unresectable tumor, percutaneous fine-needle aspiration cytology is highly accurate<sup>458</sup> and may avoid an unnecessary laparotomy in many patients. If the tumor is clearly unresectable and the patient is jaundiced, direct cholangiography allows for placement of stents to relieve jaundice and allows diagnosis to be established by either bile cytology or brush biopsy.<sup>458,459 and 460</sup> Yield can be expected in 50% to 75% of cases, and the false-positive rate is less than 1%.

## TREATMENT

### Surgical Management

Much controversy exists as to the extent of surgery required for treatment of gallbladder cancer. Recommendations have ranged from simple cholecystectomy to ultraaggressive resections consisting of combined major liver resection and pancreaticoduodenectomy.<sup>461</sup> This controversy exists because, until recently, the operations required for complete resection of cancer were associated with prohibitive morbidity and mortality.<sup>462,463</sup> The majority of patients undergoing treatment for gallbladder cancer are in their seventh or eighth decade of life and may be at increased risk for radical surgery as a consequence of concomitant medical problems. The major morbidity after resection for gallbladder cancer has ranged from 5% to 54% and mortality from 0% to 21% (Table 33.5-19). In a multiinstitutional review of 1686 gallbladder cancer resections from Japan, a comparison of morbidity by procedure was made.<sup>463</sup> The review reports 12.8% morbidity for cholecystectomy, 21.9% for extended cholecystectomy, and 48.3% for hepatic lobectomy. The mortality rates were 2.9%, 2.3%, and 17.9%, respectively.<sup>463</sup> The morbidity and mortality rates of major liver resections have decreased in recent reports, even in the aged population.<sup>464,465</sup> Most recent series report a mortality rate of 5% or less even with extensive liver resections. With these improvements in perioperative outcome, radical resections are increasingly accepted.

Author	Year	No. of Cases	Procedure	Morbidity (%)	Mortality (%)

ERCP, endoscopic retrograde cholangiopancreatography.  
 Note: Extended procedures include common bile duct resection and liver resection.

**TABLE 33.5-19.** Morbidity and Mortality of Resection for Gallbladder Cancer

Controversy concerning the extent of resection is also based on the dismal results of treatment in decades past. Until the last decade, the results of treatment for gallbladder cancer in general, including surgical treatment, were dismal. Piehler and Crichlow<sup>466</sup> reviewed 5836 cases in the world's literature from 1960 to 1978. The overall 5-year survival rate was consistently less than 5%, with a median survival of 5 to 8 months. Even for the 25% who were treated by resections with curative intent, only 16.5% survived 5 years. In fact, the only long-term survivors were among the group in which the tumor was small enough not to be recognized at the time of cholecystectomy. Perpetuo et al.<sup>435</sup> reviewed a 36-year experience with gallbladder cancer from the M. D. Anderson Cancer Center and reported a 5-year survival rate of less than 5% and median survival of 5.2 months. Cubertafond et al.<sup>467</sup> recently reported the results of a French Surgical Association survey of 724 carcinomas of the gallbladder. These investigators reported a median survival of 3 months, a 5-year survival rate of 5%, and a 1-year survival rate of 14%. They observed no differences among the various surgical procedures adopted and concluded that no progress had been made in the treatment of gallbladder cancer. A review of gallbladder cancer from Australia revealed a 12% 5-year survival rate, with all survivors having stage I or II disease. The median survival for patients with stage III or IV disease was only 46 days.<sup>468</sup> These miserable results sowed the seeds of nihilism that surrounded this disease in the past.

Over the last decade, many reports have demonstrated the utility of aggressive therapy. As a result, a more reasoned approach based on the biology of the disease is now advocated. The following recommendations are based on the goal of complete resection of tumor. To achieve this goal, surgery must remove the cancerous gallbladder, remove any adjacent organ invaded by tumor, remove involved lymph glands, and provide biliary continuity if resection of the bile duct is necessary. Surgical strategy is best directed by the suspected T stage of disease.

**T1 DISEASE.** Patients with T1 stage tumor (tumor confined within the mucosa or muscular layers of the gallbladder) most often present after the gallbladder has already been removed by simple cholecystectomy for presumed gallstone disease. Ample literature reports that patients with T1 tumors may be cured by simple cholecystectomy alone. The 5-year survival rate is expected to be 85% to 100% ([Table 33.5-20](#)).<sup>469,470,471</sup> and <sup>472</sup> Therefore, when patients present after simple cholecystectomy, the pathologic findings are reviewed to ensure that margins are negative. Particular attention is paid to the cystic duct margin. If all margins are negative, no other therapy is undertaken. If the cystic duct margin is positive, patients should be subjected to a common bile duct excision and biliary reconstruction.

**TABLE 33.5-20.** Survival after Resection of Stage I Gallbladder Cancers

Alternatively, the early-stage tumor may be discovered radiographically by a vigilant radiologist. If a T1 cancerous lesion is suspected, an open simple cholecystectomy should be performed and the diagnosis and stage confirmed immediately by frozen-section pathology. If a benign lesion or a T1 tumor is confirmed, simple cholecystectomy is all that is necessary. If deeper invasion is found, further resection according to stage should be performed, as outlined next.

**T2 DISEASE.** T2 tumors remain subserosal but have invaded through the muscular layer. It would at first seem logical that a simple cholecystectomy may be adequate for T2 tumors. However, there are two good reasons for performing more extensive resection. First, the plane that is generally taken between the liver and gallbladder is subserosal and may violate T2 tumors along the liver interphase. In the review by Yamaguchi and Tsuneyoshi,<sup>470</sup> 25 patients had tumor extending into the subserosal layer and 11 of these had positive microscopic margins after simple cholecystectomy. Second, T2 tumors are associated with a high incidence of regional nodal metastases ([Table 33.5-21](#)). Therefore, the most reasonable primary operation for T2 gallbladder cancer is the radical cholecystectomy that was first advocated by Thorbjarnarson and Glenn.<sup>443</sup> This includes a wedge resection of the gallbladder bed and regional lymphadenectomy of the hepatoduodenal ligament. Except for the thinnest of patients, total nodal clearance in the porta hepatis is difficult without removal of the common bile duct. In addition, adequate lymph node dissection of the porta hepatis has a good chance of devascularizing the common bile duct, and subsequent benign stricture is a possible late consequence. For both reasons, we prefer to resect the common bile duct as part of the clearance of lymphatic tissue in this region. A hepaticojejunostomy using a Roux-en-Y loop of jejunum is the preferred method of reestablishing biliary continuity.

Stage	Definition	Total No. of Cases	Peritoneal Metastases (%)	Nodal Metastases (%)
T2	Submucosal invasion	9	12	50
T3	Full-thickness invasion through gallbladder wall with <2-cm extension into liver	16	43	50
T4	More than 2-cm extension into liver	16	68	66

**TABLE 33.5-21.** Incidence of Nodal and Peritoneal Metastases from Gallbladder Cancer According to T Stage of Disease

A large number of patients will present for definitive therapy after simple cholecystectomy. Good evidence supports a repeat exploration for a more definitive resection. Data from many series have demonstrated that simple cholecystectomy results in 30% to 40% 5-year survival, while radical cholecystectomy or a more extensive liver resection results in a 5-year survival of 80% to 90% ([Table 33.5-22](#)). This could be explained by the possibility of residual tumor in the gallbladder bed or the 30% to 50% chance of regional lymph node involvement in cases of T2 gallbladder cancer.<sup>469,473</sup> In an article by Shirai et al.,<sup>471</sup> the 5-year survival rate after radical re-resection for stage II tumors was 90%, as compared to 40% 5-year survival for simple cholecystectomy alone. In a study comparing 20 patients treated by radical re-resection for T2 tumors with 18 patients treated by simple cholecystectomy, de Aretxabala<sup>472</sup> demonstrated a 50% improved 5-year survival rate for the more aggressive approach (70% vs. 20%).

**T3 AND T4 CANCERS.** The greatest controversy in surgical management of gallbladder cancer lies in the treatment of advanced tumors. The debate centers on whether radical surgery is ever justified for such advanced disease, given the perceived poor long-term prognosis. The literature from the last decade has provided much support for an aggressive approach by confirming a possibility for long-term survival after resection of locally advanced disease ( [Table 33.5-23](#)). Onoyama et al.<sup>441</sup> recently reported a 63.6% 5-year survival for patients with Japanese Biliary Surgical Society stage II disease and a 44.4% 5-year survival for stage III disease after extended cholecystectomy (these stages combined represent AJCC stage III). Similarly, Nakamura et al.<sup>418</sup> reported 13 radical resections for tumors of Nevin's stage V, with 54% alive at 1 year and 15% (two patients) alive for longer than 7 years.<sup>474</sup> Similar results were recently reported from the Memorial Sloan-Kettering Cancer Center, where a 67% 5-year survival was achieved for patients with completely resected stage III disease and a 33% 5-year survival was noted for patients with completely resected stage IV tumors.<sup>473</sup> It is clear from these results that an aggressive approach to locally advanced disease is justified.

**TABLE 33.5-23.** Survival after Extended Resection of Stage III and IV Gallbladder Cancers

**POSITIVE RETROPERITONEAL NODES.** Metastases to cystic, portal, and portacaval lymph nodes may be curable by regional lymphadenectomy. Onoyama et al.<sup>441</sup> reported a 5-year survival rate of 60% for patients having metastatic disease to N1 nodes. Shirai et al.<sup>474</sup> reported a 45% 5-year survival for patients with positive regional nodes, documenting nine patients surviving for more than 5 years after radical resection. Such findings support radical lymphadenectomy for gallbladder cancer.

Some researchers have advocated even more radical lymphadenectomies. The next nodal area for extension of tumor includes the retropancreatic and aortocaval nodes, which explains the recommendation of some investigators to perform a pancreaticoduodenectomy for patients with suspicious retropancreatic nodes.<sup>461,475</sup> It is assumed that nodal clearance is improved with pancreaticoduodenectomy. One multicenter series of 150 hepatopancreaticoduodenectomies for gallbladder cancer reported a 54% morbidity and 15.3% mortality rate.<sup>463</sup> Most other series report higher mortality rates. Such high morbidity and mortality of combined hepatectomy and pancreaticoduodenectomy is not justified by the long-term outcome. Long-term survival is extremely rare, even after such radical resection, when N2 nodes contain metastatic disease.

**RE-RESECTION AFTER LAPAROSCOPIC CHOLECYSTECTOMY.** A significant number of gallbladder cancers will present for definitive therapy after prior cholecystectomy. This is particularly common for early-stage tumors, which account for most cancers diagnosed at pathologic analysis. For patients treated initially with open cholecystectomy, data clearly indicate that a radical re-resection is justified for tumors with a depth of penetration equal to or greater than T2.<sup>471</sup> As would be expected, however, prognosis for patients subjected to two operations is less favorable than for patients treated with a single procedure. Gall et al.<sup>476</sup> reported a median survival of 42 months for patients undergoing a curative resection at the first operation as compared to 13 months for those requiring two operations.

Laparoscopic cholecystectomy has given birth to an entirely new clinical entity since 1989—namely, laparoscopically discovered gallbladder cancer. To date, few data have addressed the utility of radical re-resection after gallbladder cancer has been discovered laparoscopically. We recently reported a series of 42 gallbladder cancers discovered at laparoscopy.<sup>436</sup> One patient with T1 gallbladder cancer was advised that his laparoscopic cholecystectomy was a definitive procedure, and no additional therapy was undertaken. All other patients underwent extent-of-disease evaluation and re-resection as appropriate. Of the 41 patients with T2, T3, or T4 disease, 5 were not offered further surgery because disease was determined on imaging to be unresectable. The remaining 36 patients were subjected to surgical exploration, which revealed that an additional 17 patients had unresectable disease. The survival of the 19 re-resected patients was significantly different from that of the patients whose disease was found to be unresectable. Only 3 of these 19 patients subjected to re-resection have died, and the median survival has not been reached, whereas 14 of the 17 patients whose disease was deemed unresectable have died, with a median survival of 4 months. These data would indicate that such reexploration and re-resection are justified and useful.

Gallbladder cancer has a great potential for peritoneal dissemination. This propensity for abdominal seeding is further enhanced by laparoscopic exploration. Data indicate that the incidence of peritoneal metastases is higher now than that reported in the prelaparoscopy age.<sup>475</sup> During reexploration, therefore, care must be taken to perform a full abdominal inspection to rule out peritoneal disease.

Special consideration should also be extended for the laparoscopic port sites: A number of studies have demonstrated the propensity of tumor to recur in the laparoscopic port sites.<sup>437,456,477,478,479,480</sup> and 483 It has become our standard practice to excise laparoscopic port sites at reexploration. Whether such excision of port sites is useful will be proven only by future follow-up, but it is known that the procedure adds little morbidity.

### **Chemotherapy, Radiotherapy, and Adjuvant Therapy**

In general, chemotherapy and radiotherapy have offered poor results in the treatment of gallbladder cancer. A European Organization for Research and Treatment of Cancer cooperative study examined bolus mitomycin C in advanced gallbladder and biliary tree carcinoma, with no significant activity identified.<sup>484</sup> Other regimens based on 5-FU, Adriamycin, or nitrosoureas alone and in combination for gallbladder cancer result in only minimal responses.<sup>435</sup> In a study that treated 30 patients with advanced gallbladder carcinoma with 5-FU, leucovorin, and hydroxyurea, 9 had a partial response. However, the median duration of response was only 6.5 months, and the median survival was only 8 months.<sup>485</sup> Regional therapy has recently been examined using intraarterial mitomycin C for gallbladder cancer. A 48% overall response rate and a prolongation of median survival from 5 months to 14 months as compared to historic controls was reported.<sup>486</sup> However, a regional approach is rarely indicated, since the major reasons for unresectability usually are disseminated disease and extensive involvement of the porta hepatis.

The results for radiotherapy have also been poor, because the mode of spread of gallbladder cancer does not lend itself well to radiotherapy. Although Houry et al.<sup>487</sup> suggest that radiotherapy may increase survival after no resection or palliative resection of gallbladder carcinoma, the suggested benefit is small, with a median

survival of only 6 to 8 months. However, because it does appear to be well tolerated, radiotherapy with or without chemosensitization is the most common palliative modality used.

Because of the rarity of this disease in general and the rarity of completely resected gallbladder cancers, it is not surprising that there are no prospective, randomized studies examining the utility of adjuvant therapy. Nonetheless, as part of many retrospective studies, the issue of adjuvant therapy has been addressed. Chao and Greager<sup>488</sup> compared 15 patients who received some form of chemotherapy or radiotherapy (or both) after resection for gallbladder cancer to 7 patients who did not receive any adjuvant therapy and found no significant difference in outcome. Oswalt and Cruz<sup>489</sup> reported a median survival of 20 weeks in 13 patients treated with adjuvant chemotherapy, as compared to 8 weeks in patients treated with surgery alone. Morrow et al.<sup>490</sup> from the University of Minnesota reported a median survival of 4.5 months for those receiving adjuvant chemotherapy or radiotherapy versus 3 months for those treated with surgery alone. With such small sample sizes and the generally dismal results in these series, it is difficult to draw firm conclusions from these data.

Definitive data for adjuvant radiotherapy also are lacking, but the existing data are a bit more encouraging than are those for chemotherapy. <sup>491</sup> Todoroki et al.<sup>492</sup> examined intraoperative radiotherapy after complete resection for stage IV gallbladder cancer and reported a 10% 3-year survival for patients receiving intraoperative radiotherapy versus 0% for surgery alone. Hanna and Rider<sup>493</sup> reviewed results for 51 patients with gallbladder cancer and found survival to be significantly longer in patients receiving postoperative radiotherapy as compared with those who underwent only surgery. In another retrospective study, the median survival of patients receiving postoperative irradiation was 63 months, as compared with 29 months for patients undergoing surgery alone.<sup>494</sup> Though the data are encouraging, firm support for such adjuvant therapy awaits confirmation by prospective trials. Nevertheless, given the high incidence of local recurrence of gallbladder carcinoma and the low morbidity of radiotherapy, it is not unreasonable to recommend some form of radiotherapy, particularly for patients with advanced-stage disease.

### Other Palliative Management

Palliative management for gallbladder cancer usually is directed at relief of jaundice, treatment of sepsis, and palliation for pain and bowel obstruction. Decisions on palliative treatment should take into account the short survival of patients with nonresectable gallbladder cancer. The median survival for patients presenting with unresectable disease is generally 2 to 4 months, with a 1-year survival rate of less than 5%.<sup>413,442</sup> All palliative treatments should, therefore, be kept as simple as possible, given the aggressive nature of this disease. For jaundiced patients, for example, procedures to achieve relief of jaundice should be attempted only if patients are symptomatic (itching or experiencing biliary sepsis) or require a normal bilirubin level for chemotherapy. This is because any attempt to relieve the jaundice can result in introduction of bacteria into the biliary tree, which subsequently becomes a source of biliary sepsis. If the patient is experiencing pruritus or biliary sepsis, percutaneous drainage of the biliary tree is preferred. Surgical bypass often is difficult because of advanced disease in the porta hepatis. Even though a segment III bypass is possible<sup>495</sup> and can be performed at the time of laparotomy for attempted resection, it is unreasonable to perform exploratory surgery on patients with the sole goal of achieving biliary bypass. Kapoor et al.<sup>496</sup> report a 12% 30-day mortality rate for segment III bypasses. In addition, subjecting a patient with an anticipated 4-month survival to a palliative procedure that requires a 1- to 2-month recovery period is unwise. In the event of a preoperative diagnosis of advanced, unresectable gallbladder cancer in the jaundiced patient, a noninvasive radiologic approach to biliary drainage is justified. This disease is rapidly progressive, and so it is preferable to avoid the morbidity and recovery time of a laparotomy and surgical bypass.

### GALLBLADDER POLYPS

A section on gallbladder cancer must include a discussion of gallbladder polyps, as polyps are found in up to 5% of patients in the general population.<sup>497,498</sup> The majority of polyps are benign and can be classified as epithelial tumors (adenoma), mesenchymal tumors (fibroma, lipoma, hemangioma), or pseudotumors (cholesterol polyps, inflammatory polyps, and adenomyoma). Most polyps are cholesterol polyps,<sup>499</sup> which histologically are submucosal deposits of lipid-laden macrophages. Of the various types of polyps, the only type believed to be precancerous is the adenoma.<sup>500</sup>

Distinguishing benign from malignant or premalignant lesions is essential in the patient presenting with a polyp. US is the most practical test for evaluating polypoid lesions of the gallbladder and has a sensitivity of 90.1% and a specificity of 93.9% in making the diagnosis.<sup>501</sup> In general, malignant lesions were significantly more likely to be found in patients older than 50 years and more likely to be present as a solitary lesion, to be sessile in character, and to measure greater than 1.0 cm in diameter. Conversely, cholesterol polyps, which account for more than 90% of benign lesions, are more likely to occur as multiple lesions (more than three), to be small, and to retain an intact mucosa. Because of the poor prognosis of gallbladder cancer and the low morbidity of a cholecystectomy, most investigators recommend open cholecystectomy for any solitary polyp greater than 1.0 cm. Some investigators have advocated an even more aggressive approach. Shinkai et al.<sup>499</sup> recommend cholecystectomy for patients with fewer than three polyps, regardless of size.

Figure 33.5-6 is our recommended algorithm for the treatment of gallbladder polyps. It is based on the recommendations of Boulton and Adams<sup>498</sup> and on the findings in longitudinal follow-up studies in which small (<1-cm) gallbladder polyps were followed by imaging, demonstrating a low rate of subsequent diagnosis of cancer.<sup>502</sup> For symptomatic polyps, cholecystectomy should be performed. For patients with gallbladder polyps and other conditions that warrant cholecystectomy (e.g., cholelithiasis), cholecystectomy should be performed. Likewise, for patients with characteristics suspicious for cancer—namely, a lesion larger than 1 cm, fewer than three lesions, and eroded mucosa—cholecystectomy should be performed. Other patients should be followed by US every 6 months, and any suspicious findings should prompt cholecystectomy.

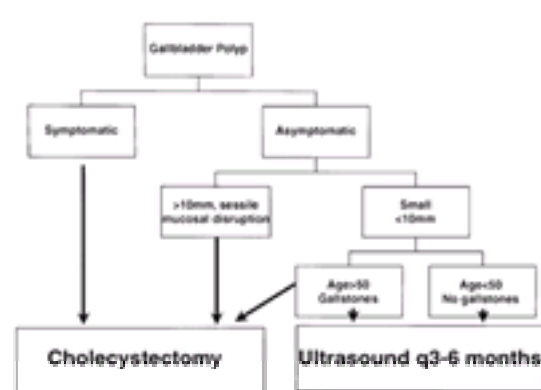

FIGURE 33.5-6. Algorithm for treatment of gallbladder polyps. (Modified from ref. 498.)

#### HISTORY

The first small bowel tumor, a perforated duodenal carcinoma, was described by Hamberger in 1746.<sup>1</sup> The first small bowel leiomyoma was described by Foerster in 1858,<sup>2</sup> and the first small bowel leiomyosarcoma was described by Wesener in 1883.<sup>3</sup> An early review of malignant small bowel tumors was published by Leichtenstern in 1876,<sup>4</sup> and Heurtaux published a review of benign small bowel tumors in 1899.<sup>5</sup> Many of the earlier reviews were weighted heavily by the autopsy incidence of tumors. Most of the current information we have about the presentation, diagnosis, management, and outcome of bowel tumors is derived either from small single-center series or larger collective reviews.

#### INCIDENCE

Small bowel tumors, both benign and malignant, are exceedingly unusual. It has been estimated that small bowel tumors constitute fewer than 10% of all gastrointestinal tumors,<sup>6</sup> although the incidence varies significantly depending on whether autopsy data are included. Approximately 64% of all small bowel tumors are malignant. These account for 0.1% to 0.3% of all malignancies.<sup>7,8</sup> and<sup>9</sup> Some 2100 to 2400 new cases of small bowel malignancies occur each year in the United States,<sup>10,11</sup> approximately 0.4 to 1 case per 100,000 population,<sup>12,13</sup> and<sup>14</sup> with a slight male predominance.<sup>15,16,17,18,19</sup> and<sup>20</sup> Fewer than 1000 deaths are due to primary malignant small bowel tumors annually in the United States, which is approximately 0.5 deaths per 100,000 population.<sup>21</sup> By contrast, approximately 36% of small bowel tumors are benign, with roughly equal gender incidence.

In a review of the Surveillance, Epidemiology, and End Results program registries from 1973 to 1982, Weiss and Yang<sup>14</sup> showed the incidence of malignant small bowel tumors to be low in patients younger than 30 years of age, with a steady increase in incidence with age for adenocarcinoma, carcinoid, and lymphoma. The incidence of sarcoma levels off after the seventh decade.<sup>14</sup>

#### ETIOLOGY

##### CHARACTERISTICS OF THE SMALL BOWEL

The small bowel constitutes approximately 75% of the length of the gastrointestinal tract and provides 90% of the absorptive surface. Despite this predominance in length and surface area, however, it appears to be resistant to the development of malignancy. Small bowel malignancies account for only 1% to 3% of all gastrointestinal malignancies,<sup>7,10,11,12</sup> and<sup>13,22,23</sup> and they are estimated at 36 to 60 times less frequent than malignancies of the colon.<sup>9,15,24,25</sup> and<sup>26</sup> A number of hypotheses have been formulated to explain this finding. Transit through the small bowel is relatively rapid compared with the colon, resulting in less contact of the mucosa with potential carcinogens. Any potential carcinogens would be diluted by the large volume of secretions, which create liquid small bowel contents. This liquid in turn may be less mechanically irritating to the small bowel mucosa than solid stool would be to the colonic mucosa. The small bowel contains a small, metabolically inactive bacterial population, one that may not be capable of transforming potential procarcinogens to their active component.<sup>9</sup> The contribution of the alkaline pH to the resistance of small bowel neoplasms is unknown. The proximal small bowel contains a number of microsomal enzyme systems known to detoxify carcinogens, particularly benzopyrene hydroxylase.<sup>27,28</sup> Finally, high numbers of lymphocytes and B cells secrete immunoglobulin A in the distal ileum, which may contribute to a local immunosurveillance system that prevents the development of malignancies. Evidence in support of this supposition is derived from immunocompromised patients, either those with acquired immunodeficiency syndrome or those on chronic immunosuppression, who seem more prone to the development of malignancies, both lymphoma and Kaposi's sarcoma, in the distal small bowel.

The small intestine does appear to be susceptible to carcinogens. It is of interest that, as is shown later, adenocarcinomas in the small intestine occur proximally, in much the same distribution as azoxymethane-induced adenocarcinoma in rats.<sup>29,30</sup> This distribution of small bowel adenocarcinomas also correlates with the length of contact of the small bowel mucosa with pancreaticobiliary secretions, implicating bile as a possible carcinogen.<sup>31</sup> Diversion of the bile in animals has been shown to decrease the incidence of experimentally induced small bowel malignancy.<sup>32</sup>

Chow and colleagues<sup>33</sup> looked at risk factors in 430 patients with small bowel cancer, who they compared with 921 case-control patients dying of other causes. They found that weekly or more frequent consumption of red meat and monthly or more frequent consumption of salt-cured smoked foods was associated with a two- to threefold increase in risk. Tobacco use and alcohol consumption were not associated with increased risk of small bowel cancer in the study.<sup>33</sup> Lowenfels and Sonni<sup>34</sup> showed an excellent correlation between dietary fat intake and the incidence of small bowel carcinoma in various countries around the world. Pollard<sup>34a</sup> showed that the incidence of methylazoxymethanol acetate-induced intestinal carcinoma in rats could be markedly reduced by dietary restriction, further implicating oral intake as a possible promoter of intestinal malignancy.

Other factors that predispose patients to development of large bowel adenocarcinoma may also play a role in the development of small bowel adenocarcinoma. Neugut and Santos<sup>16</sup> looked at the incidence of second cancers among 2581 cases of small bowel malignancy from a Surveillance, Epidemiology, and End Results program cohort collected from 1973 to 1988. They found an increased probability of subsequent colorectal carcinoma after small bowel carcinoma (relative risk, 3.6 to 5.0) and an increased risk of small bowel carcinoma after colorectal carcinoma (relative risk, 7.1 to 9.0).

##### PREMALIGNANT LESIONS

A number of small bowel lesions are thought to predispose patients to the development of small bowel malignancy. The adenoma-carcinoma sequence has been well described.<sup>29,35</sup> Perzin and Bridge<sup>36</sup> observed that 25% of primary small bowel carcinomas demonstrated adenomatous epithelium in the same lesion. This finding has particular significance in patients with familial adenomatous polyposis, in whom polyps of the upper gastrointestinal tract are being recognized with increasing frequency.<sup>37,38,39,40,41</sup> and<sup>42</sup>

Patients with chronic Crohn's disease are at increased risk for the development of small bowel carcinoma.<sup>43,44,45</sup> and<sup>46</sup> These patients usually exhibit malignancy by the appearance of dysplasia.<sup>47,48</sup> However, distinguishing clinically between distal small bowel malignancy and Crohn's disease without histologic confirmation can be exceedingly difficult.<sup>49,50,51,52</sup> and<sup>53</sup>

Patients with adult celiac disease (nontropical sprue), particularly those who are unresponsive to dietary gluten withdrawal, are also at significantly increased risk for

development of small bowel malignancy, particularly lymphoma, although adenocarcinomas also have been reported. [54,55,56](#) and [57](#)

Patients with Peutz-Jeghers syndrome have been reported to develop primary carcinoma of the gastrointestinal tract. [58,59,60](#) and [61](#) The primary polyp of Peutz-Jeghers is a hamartoma, and the *in situ* transformation of a hamartomatous polyp to adenocarcinoma has not been clearly demonstrated. Because these patients often have an adenomatous component in their primarily hyperplastic and hamartomatous polyps, the development of malignancy more likely represents malignant evolution of that adenomatous component rather than transformation of the other hamartomatous elements. [60,61](#)

Patients with von Recklinghausen's neurofibromatosis also have been reported to have gastrointestinal involvement, both benign and malignant. [62,63,64](#) and [65](#) Although most of these small bowel tumors are benign neurofibromas and leiomyomas, malignant tumors of nerve tissue origin have been reported. [66](#) Case reports of a proximal small bowel adenocarcinoma and carcinoid tumor occurring in association with neurofibromatosis have also appeared. [67,68](#)

## ANATOMY

Grossly, the small bowel extends from the pylorus to the iliosacral valve. It is estimated to measure 625 cm in length but may vary from 300 to 850 cm. [69](#) The duodenum, measuring approximately 25 cm, forms a C loop; the first portion extends 5 cm horizontally from the pylorus before turning inferiorly into the second portion. The second, or descending, portion of the duodenum is approximately 10 cm long, just anterior to the hilus of the right kidney. Typically, the ampulla of Vater, through which pancreaticobiliary secretions pass into the small bowel, is found midway down the descending second portion of the duodenum medially. The third portion of the duodenum travels transversely in close relationship to the uncinate process of the pancreas, anterior to the ureter, inferior vena cava, vertebral column, and aorta. This leads to the fourth portion of the duodenum, which measures approximately 2.5 cm in diameter, ascends to join with the proximal jejunum, and is suspended on the right cross of the diaphragm by the ligament of Treitz at the level of the second lumbar vertebra.

The jejunum, comprising the proximal 250 cm of the small bowel distal to the duodenum, and the ileum, the remaining 350 cm of small bowel, are supported on a fan-shaped mesentery that measures approximately 15 cm in length. More distally, this mesentery becomes progressively longer, with arterial blood supply, venous and lymphatic drainage, and small bowel innervation traversing between its two leaves. Grossly, the duodenum tends to be the largest in diameter and the ileum the smallest.

The arterial blood supply for the duodenum is derived from the gastroduodenal branch of the hepatic artery as well as the inferior pancreaticoduodenal branch of the superior mesenteric artery. The blood supply for the remaining small bowel is derived from intestinal branches of this superior mesenteric artery. Venous return from the entire small intestine is into the portal vein. Lymphatic drainage of the duodenum is to peripancreatic nodes. The remainder of the small bowel drains into the abundant lymph nodes through channels that parallel the course of the mesenteric blood vessels. Autonomic innervation of the small bowel is by means of the celiac and superior mesenteric plexus. Sensory fibers are responsive to distention but not to other painful stimuli.

Microscopically, the intestine is a hollow muscular tube composed of four layers: serosa, muscularis, submucosa, and mucosa. The muscular layer consists of an outer longitudinal layer and an inner circular layer. Immediately beneath the mucosa is the lamina propria. The absorptive surface of the intestine is increased manifold by the presence of dense glandular villi covered by an epithelium of mucus-secreting goblet cells and absorptive cells, secretory Paneth's cells, and rare argentaffin cells. Mucus-secreting Brunner's glands are found in the duodenum but not in the distal small bowel. The myenteric plexus of Auerbach is located between the two muscular layers of the intestine; Meissner's plexus is located in the small bowel submucosa. Lymphatic tissue is found in the lamina propria of the submucosa; this tissue increases as one progresses distally, becoming quite abundant in the distal ileum, where it is seen as Peyer's patches.

## PATHOLOGY

More than 35 histologic variants of small bowel neoplasms have been described. For practical purposes, they can be subdivided as benign and malignant and further classified according to their cell of origin ([Table 33.6-1](#)). Thirty-six percent of all small bowel tumors are benign.

Cell of Origin	Benign	Malignant
Epithelium	Adenoma	Adenocarcinoma
Connective tissue	Fibroma	Fibrosarcoma
Smooth muscle	Leiomyoma	Leiomyosarcoma
Fat	Lipoma	Liposarcoma
Vascular endothelium	Hemangioma	Angiosarcoma
Lymphatics	Lymphangioma	Lymphangiosarcoma
Lymphoid tissue	Pseudolymphoma	Lymphoma
Nerve	Neurofibroma	Neurofibrosarcoma
Argentaffin cell	—	GAN tumor
Mixed	Hamartoma	—

GAN, giant axonal neuropathy.  
(Modified from Siedler WF. Cancer of the small intestine. In: DeVita VT Jr, Hellman S, Rosenberg SA, eds. *Cancer: principles and practice of oncology*, 3rd ed. Philadelphia, JB Lippincott, 1989:678, with permission.)

**TABLE 33.6-1.** Pathology of Primary Small Bowel Tumors by Cell of Origin

A number of authors have commented on the inordinately high incidence of second primary malignant tumors in patients with primary small bowel malignancy. [16,18](#) The reason for this high incidence is not clear, although many have linked it to a defect in the individual patient's immune surveillance system. The clinical implications of these observations are clear. Any patient who has had a primary small bowel malignancy should be watched closely for the development of a second malignant tumor.

## PRESENTATION

Although no specific symptom complex is diagnostic of small bowel tumors, either benign or malignant, a few generalizations can be made. Presentation depends on the location of the tumor and its growth pattern. Malignant lesions are more often symptomatic than are benign lesions, and for a shorter duration. [15,70,71,72,73,74,75](#) and [76](#) Furthermore, in large part because of the nonspecific nature of the symptoms, the delay between the onset of symptoms and the final diagnosis is often significant, averaging 6 to 8 months. [71,77,78,79](#) and [80](#) The average age at presentation of patients with small bowel tumors is the seventh decade and is slightly younger for patients with malignant tumors than for patients with benign tumors. [15](#)

Although fewer than 50% of patients with benign small bowel tumors develop symptoms, [15](#) more than 90% of patients with malignant tumors of the small bowel have symptoms before diagnosis. [11,24,81,82](#) These symptoms can be subdivided into four general categories: mass, obstruction, bleeding, and perforation.

In patients with benign tumors, pain from obstruction is the most common symptom, occurring in 42% to 70% of cases. Bleeding, usually chronic, is seen in 20% to 53% of patients. [15,79,83](#) The most common cause of adult intussusception is a benign small bowel tumor. A palpable mass or perforation is rare.

In patients with malignant tumors, the most common symptoms are pain (not always associated with obstruction) in 32% to 86% and weight loss in 32% to 67% of cases. [15,70,79,83](#) Bleeding occurs somewhat less frequently than in patients with benign small bowel tumors. [25](#) Perforation, usually localized, is seen in roughly 10% of patients, usually those with lymphomas or sarcomas. A mass that may represent dilated bowel proximal to an obstructing tumor is palpable in fewer than 25% of patients with malignant small bowel tumors.

## DIAGNOSIS

The diagnosis of small bowel tumors is rarely made preoperatively. In fact, the diagnosis of small bowel malignancy is frequently delayed, not necessarily because of delay in presentation to the physician. Maglinte and colleagues, [80](#) in a review of 77 patients with small bowel malignancy, reported the average delay between onset

of symptoms and presentation to the physician as 1 month, whereas the average interval from seeing the physician to final diagnosis was 7.8 months.

With the exception of an elevated 5-hydroxyindole acetic acid level in the presence of carcinoid syndrome, all the presenting signs and symptoms of small bowel tumors are nonspecific. Laboratory examination may reveal a mild anemia in the presence of chronic blood loss. Hyperbilirubinemia may be seen in the presence of periampullary duodenal tumors. Mild to moderate elevations of liver function tests may be seen in the presence of hepatic metastases, occasionally associated with an elevation in carcinoembryonic antigen.

Radiologic studies may be more suggestive of the diagnosis. Plain abdominal films that reveal signs of partial or complete bowel obstruction in the absence of prior laparotomy are suggestive of primary small bowel neoplasm, although nonspecific as to the diagnosis. Upper gastrointestinal series with small bowel follow-through is abnormal in 53% to 83% of patients and delineates small bowel tumor in 30% to 44% of patients.<sup>84,85</sup> A number of investigators have suggested that this diagnostic accuracy can be improved to in excess of 90% using enteroclysis, with particular attention to the distensibility of the small bowel.<sup>85,86</sup> and <sup>87</sup> Barium enema can be useful in the diagnosis of small bowel disease, particularly lymphoma, in which thickening of the distal ileum can be seen on refluxing contrast material into the distal small bowel. This finding, however, is nonspecific and can be identical to the appearance of regional ileitis. Hyams and associates<sup>48</sup> suggested that a rectal biopsy revealing granulomatous disease can reliably distinguish between inflammatory and neoplastic changes in the terminal ileum.

Computed tomography (CT) is thought to be somewhat more accurate in detecting small bowel tumors.<sup>88,89,90,91,92</sup> and <sup>93</sup> In a review of 35 patients with small bowel tumors, Laurent and colleagues<sup>89</sup> found the CT scan to be abnormal in 97%, predicting tumor in 80%. CT was predictive of the tumor histology 69% of the time and of the tumor stage in 61% of patients. Of 18 malignant tumors, the CT predicted extramural invasion and liver metastases correctly 75% of the time; CT was accurate in predicting regional lymph node status only 25% of the time. Laurent and colleagues described characteristic CT findings for the following<sup>89</sup>:

Adenocarcinoma: partially obstructing concentric narrowing in the proximal small bowel, best detected with tumors more than 3 cm in diameter

Lymphoma: thickened distal small bowel, best seen with tumors larger than 2 cm

Leiomyosarcoma: eccentric tumor of the mid- or distal small bowel, with malignancy suggested by the presence of necrosis, ulceration, and size greater than 5 cm

Carcinoid: homogeneous mesenteric mass, often associated with stranding of the mesentery

Lipoma: small homogeneous fat density; small bowel or mesenteric nodule

Dudiak and coworkers,<sup>91</sup> in a review of 63 patients with small bowel tumors, found that CT was able to detect a tumor in 73% of patients and to correctly predict the diagnosis in 43%. Radiologic criteria similar to those of Laurent and associates were described.<sup>91</sup>

Other investigators have focused on small bowel thickness as measured by CT scanning to predict enteric disease.<sup>88,93</sup> However, although small bowel wall thickness is predictive of disease, it is not predictive of malignancy.

Angiography is rarely helpful in the diagnosis of small bowel tumors. Angiograms may be distinctly abnormal in vascular smooth muscle tumors of the small bowel<sup>84</sup> and may help to define the source of occult but active upper gastrointestinal bleeding in patients with a small bowel hemangioma. Alfidi and colleagues<sup>94</sup> reported angiography as being helpful in patients with small bowel arteriovenous malformations, identifying lesions in nine patients after negative laparotomy. In addition, angiography may on occasion demonstrate occlusion of the peripheral branches of the mesenteric circulation that is responsible for a syndrome of mesenteric ischemia seen occasionally in the carcinoid syndrome.

Nuclear medicine scans using technetium-labeled red blood cells may be helpful, again to delineate an occult source of chronic gastrointestinal blood loss in the presence of a normal colonic and upper gastrointestinal endoscopy. It can be difficult to localize the site of bleeding with this test, however, and Oliver and coworkers<sup>95</sup> suggested that if technetium-labeled red blood cell scanning is used, the sensitivity of the examination improves if more frequent images are obtained.

With more sophisticated instrumentation, endoscopy is being more frequently used in the investigation of small bowel disease. Clearly, upper gastrointestinal endoscopy with total duodenoscopy is the mainstay for detection, diagnosis and, occasionally, treatment of more proximal neoplasms. Interest has been renewed in perioral enteroscopy.<sup>96</sup> With new instrumentation, and some experience, total small bowel enteroscopy can be achieved. Enteroscopy can be helpful in diagnosing both focal lesions<sup>97</sup> and more diffuse lesions, such as Mediterranean lymphoma.<sup>98</sup> It may be most useful in localizing the source of occult nongastric, noncolonic gastrointestinal bleeding.<sup>99</sup> Lida and associates<sup>100</sup> described the use of intraoperative enteroscopy to increase the detection of polyps in familial adenomatous polyposis syndrome. In addition, intraoperative enteroscopy with trans-illumination of the bowel wall has been useful in patients with identified arteriovenous malformations that cannot be otherwise localized at the time of operation.<sup>96,101</sup>

Colonoscopy with retrograde ileoscopy has been described as useful in the diagnosis of primary lymphoma of the ileum.<sup>102</sup> In experienced hands, the small bowel can be visualized by retrograde ileoscopy in up to 30% of patients.<sup>83</sup>

## MANAGEMENT

### BENIGN TUMORS OF THE SMALL BOWEL

The distribution of benign small bowel tumors by diagnosis and anatomic location is shown in [Table 33.6-2](#). Most common are leiomyomas, followed by adenomas, lipomas, vascular lesions, and fibrous lesions.

Tumor	Duodenum	Jejunum	Ileum	Total
Leiomyoma	24	64	67	155 (37%)
Polyp/adenoma	34	17	17	68 (39%)
Lipoma	11	13	30	54 (15%)
Hemangioma	1	11	25	37 (10%)
Fibroma	4	7	12	23 (6%)
Other	27	9	13	49 (13%)
Total	100 (27%)	115 (32%)	145 (40%)	360 (100%)

**TABLE 33.6-2.** Distribution of Benign Tumors of the Small Bowel by Site in 13 Series

#### Leiomyomas

Leiomyomas of the small bowel account for 20% to 40% of all benign small bowel tumors and are the most common small bowel tumor according to a review by Wilson and associates.<sup>103</sup> These tumors may grow within or outside the bowel lumen, and the growth pattern determines the presenting symptoms. Perforation is unusual. It can be difficult to distinguish benign from malignant smooth muscle tumors of the gastrointestinal tract intraoperatively, even with histologic evaluation by frozen section. According to the comprehensive review by Skandalakis and Gray,<sup>104</sup> malignancy in lesions less than 4 cm in diameter is distinctly unusual. Histologic criteria of malignancy include necrosis, nuclear pleomorphism, and frequent mitotic activity. Surgical management of small bowel leiomyomas includes adequate

segmental resection with grossly negative serosal margins. Because lymph node metastases are unusual, even for malignant leiomyosarcomas of the small bowel, extensive mesenteric lymphadenectomy is not required.

Small bowel polyps can be divided into three broad categories based on principles of management: villous adenomas of the duodenum, adenomas of the distal small bowel, and Peutz-Jeghers hamartomas.

**VILLOUS ADENOMAS OF THE DUODENUM.** Although villous adenomas of the duodenum are unusual, the duodenum is the most common small bowel location for these lesions. Their most common presenting sign is obstructive jaundice, and diagnosis is straightforward with upper gastrointestinal endoscopy. Most lesions are located in the second portion of the duodenum, usually on the medial wall, surrounding the ampulla of Vater. They are being increasingly recognized as a component of the familial adenomatous polyposis syndrome.<sup>37,38,39,40,41</sup> and <sup>42</sup> A number of reports of villous tumors of the duodenum have appeared since the late 1980s. These tumors have a high propensity for malignant degeneration, averaging 45%. Risk factors associated with malignancy include size greater than 5 cm,<sup>105</sup> age over 50 years,<sup>106</sup> and more distally situated polyps.<sup>106</sup> This propensity toward malignant degeneration, together with their location around the ampulla of Vater, combine to make management decisions difficult. Although a number of experts have advocated local excision for benign lesions,<sup>107,108</sup> one cannot always be certain of the benign nature of a tumor before complete histologic examination. Furthermore, local recurrence rates of 17% to 75% have been reported after local excision of these tumors,<sup>109,110,111,112</sup> and <sup>113</sup> occasionally with malignant degeneration. Certainly, close ongoing endoscopic surveillance is mandatory after local excision of these lesions. Lesions in the third and fourth portion of the duodenum should be managed with wedge or sleeve resection. Lesions in the first or second portion of the duodenum should be managed with pancreaticoduodenectomy, particularly if any question remains about the diagnosis.

Survival after complete excision is excellent in patients with both benign villous adenomas and carcinoma *in situ*. Patients with invasive carcinoma fare comparably to those with periampullary adenocarcinoma.

**SMALL BOWEL ADENOMAS.** Adenomas in the remainder of the small intestine are distinctly unusual. These tend to be distributed more proximally, and case reports of malignant degeneration have appeared.<sup>114</sup> These tumors should be managed with segmental resection.

**PEUTZ-JEGHERS HAMARTOMAS.** Peutz-Jeghers hamartomas are always multifocal and occur primarily in the small intestine.<sup>115,116</sup> Symptoms of low-grade obstruction with chronic recurrent intussusception usually become apparent in the second decade of life and frequently warrant repeated surgical intervention.

Appropriate surgical management of these tumors includes enterotomy and polypectomy. If bowel resection is required, an absolute minimum length of bowel should be sacrificed, because this is a chronic problem, and frequent reoperation can be anticipated. It is important to verify the status of both the stomach and colon before laparotomy, because intraoperative palpation of these structures can be notoriously unreliable. Furthermore, gastrointestinal malignancy occurs in these patients with increased frequency, probably because of malignant generation of adenomatous polyps.

### Other Benign Lesions

Angiomas of the small bowel are less common and may be multifocal. They are usually discrete and well circumscribed, presenting most often as occult gastrointestinal bleeding. Management consists of segmental resection of the small bowel.<sup>103,117,118</sup>

Lipomas of the small intestine are distinctly unusual. Patients usually present with symptoms of abdominal pain consistent with partial bowel obstruction.<sup>119</sup> The difficulty in managing these lesions is that they may involve the small bowel diffusely.<sup>120</sup> Surgical management involves resection of the symptomatic segment of bowel.

Brunner's gland hamartomas are extremely rare, with fewer than 100 reports in the world literature. Symptoms at presentation depend on the size of the tumor and range from a lack of symptoms to chronic upper gastrointestinal bleeding and duodenal or biliary obstruction. Because these are submucosal tumors, preoperative diagnosis is rarely possible. Treatment involves either endoscopic removal of pedunculated lesions or surgical resection of larger lesions.<sup>121,122</sup> and <sup>123</sup>

Upper digestive tract involvement has been estimated to occur in 2% to 25% of patients with systemic neurofibromatosis (von Recklinghausen's disease).<sup>63</sup> This range may well represent an underestimate, because much of the involvement is asymptomatic and detected only on postmortem examination. Typically, the involvement is characterized by submucosal neurofibromas, originating in the submucosal nerve plexus. Duodenal paragangliomas have been reported to occur in association with von Recklinghausen's disease.<sup>64,65</sup> Although these lesions are generally considered benign, Inai and colleagues<sup>66</sup> reported a case of duodenal paraganglioma with regional lymph node metastases.

Inflammatory polyps may occur at any point within the small bowel, from the duodenum through the ileum, and occasionally are reported in association with preexisting Crohn's disease.<sup>124,125,126</sup> and <sup>127</sup> These are uniformly benign lesions arising from the submucosa, are usually solitary, and present with symptoms of obstruction. Management consists of polypectomy or segmental small bowel resection.

## MALIGNANT TUMORS OF THE SMALL BOWEL

The distribution of malignant small bowel tumors by anatomic location and diagnosis is shown in [Table 33.6-3](#).

Tumor	Duodenum	Jejunum	Ileum	Total
Adenocarcinoma	634	454	301	1389 (44%)
Carcinoid	60	92	781	933 (29%)
Lymphoma	34	183	276	493 (15%)
Sarcoma	61	139	148	348 (11%)
Total	789 (25%)	868 (26%)	1506 (47%)	3163 (100%)

**TABLE 33.6-3.** Distribution of Malignant Tumors of the Small Bowel by Site in 27 Series

### Adenocarcinoma

Adenocarcinomas constitute 25% of all small bowel tumors and 39% of all malignant small bowel tumors. These tumors are distributed proximally in the small bowel, with nearly 80% located in the duodenum or jejunum. For purposes of analyzing mode of presentation, diagnosis, management, and outcome, these tumors can be separated into two categories: those of the duodenum and those of the jejunum and ileum.

**DUODENUM.** Approximately 45% of all adenocarcinomas of the small bowel arise within the duodenum. In general, approximately 15% of these are in the first portion of the duodenum, 40% are in the second portion of the duodenum, and 45% are in the distal duodenum,<sup>128,129,130,131,132</sup> and <sup>133</sup> a distribution pattern that parallels the relative lengths of each portion. The median age of these patients is 60 years. Symptoms relate primarily to the size and site of the tumor. The most common symptom is upper abdominal pain related to partial duodenal obstruction.<sup>129,132</sup> Series that include periampullary tumors also report an incidence of biliary obstruction.<sup>130</sup> Anemia with Hemocult-positive stools is frequent, although frank upper gastrointestinal hemorrhage is unusual.<sup>132</sup>

Diagnosis is usually suspected from an upper gastrointestinal series. Hypotonic duodenography may improve the accuracy of this test. <sup>134</sup> Histologic confirmation can be obtained preoperatively in most patients by upper gastrointestinal endoscopy with total duodenoscopy.

As can be seen from [Table 33.6-4](#), most patients who present with duodenal carcinoma undergo exploration; in these patients, resectability rates tend to be high. In general, patients with tumors of the first and second portions of the duodenum require pancreaticoduodenectomy; patients with tumors of the third and fourth portions of the duodenum often can undergo complete resection with segmental duodenectomy and primary anastomosis. Because 22% to 71% of patients with duodenal adenocarcinoma have positive nodes at presentation <sup>129,130,131,132</sup> and <sup>133,135</sup> and a finite 5-year survival rate is seen in the presence of regional nodal involvement, <sup>129,135</sup> curative resection of duodenal carcinomas should always include a systemic regional lymphadenectomy regardless of the primary tumor location.

Author	Year	Tumor	Explor.	Operative Mortality Rate* (%)	Resect†	5-Y Survival Rate (%)
Adler et al. <sup>53</sup>	1980	36	40 (75%)	24	40 (100%)	30
Adler and associates <sup>53</sup>	1980	12	12 (100%)	26	4 (33%)	30

\*Mortality rate as a percentage of those explored.  
†Resected as a percentage of those explored.

**TABLE 33.6-4.** Duodenal Adenocarcinoma

A number of authors have commented on the steady decrease in operative mortality after pancreaticoduodenectomy; this procedure can now be performed with an operative mortality rate of less than 5%. <sup>132,135,136</sup> and <sup>137</sup> Outcome in duodenal carcinoma patients is determined by resectability, lymph node involvement and, in some series, histologic grade. <sup>129,130,131,132</sup> and <sup>133</sup> No clear-cut evidence has established that pancreaticoduodenectomy results in superior survival to that with segmental resection when the latter is technically feasible. <sup>136,138</sup>

The role of postoperative adjuvant therapy has not been clearly defined in this group of patients. In patients with advanced unresectable disease, it may be that palliative radiation therapy can be of some benefit in controlling chronic blood loss. Because these tumors clinically appear to behave more like gastric cancer than pancreatic cancer, <sup>135</sup> participation in an investigational chemotherapy program with a 5-fluorouracil (5-FU)-based regimen may be warranted.

**JEJUNUM AND ILEUM.** Tumors of the jejunum and ileum account for the remaining 55% of small bowel adenocarcinoma. As can be seen in [Table 33.6-5](#), much of the information about these tumors is derived from small series collected over a number of years. The report by Adler and associates <sup>53</sup> is a collected series based on several large tumor registries. In general, most reports are from institutions that see fewer than one patient with small bowel adenocarcinoma per year.

**TABLE 33.6-5.** Survival of Patients with Adenocarcinoma of the Small Intestine

These patients present with signs or symptoms of obstruction in 50% to 74%, or occult gastrointestinal bleeding in 33% to 64%. <sup>30,53,139</sup> Although adenocarcinoma of the small bowel may be suspected based on a small bowel follow-through series or CT scan, neither examination is specific, and the diagnosis is frequently not made until laparotomy. <sup>30</sup>

At the time of operation, 77% to 100% of distal small bowel adenocarcinomas are resectable, <sup>30,128,139</sup> although regional lymph node metastases are frequent. <sup>128,140,141</sup> The principles of surgical resection include attainment of negative surgical margins and wide resection of the corresponding mesentery of the involved segment of small bowel.

Survival in these patients is generally poor, with most series reporting only 20% to 30% of patients alive at 5 years (see [Table 33.6-5](#)). Prognostic factors in these patients include depth of tumor penetration and the presence of nodal or systemic metastases. Histologic grade of the tumor also has been shown to be predictive of outcome. <sup>128</sup> Survival rates of 45% to 70% have been reported in patients with negative nodes after curative resection; these rates fall to 12% to 14% in patients with positive nodes. <sup>53,128</sup> Radiation therapy is difficult in these patients given the mobile nature of the small bowel mesentery and the inability to localize the target field. Because these tumors are rare, any meaningful comment on the impact of chemotherapy in their management is difficult. Jigyasu and associates <sup>142</sup> reported one partial response in 14 patients treated with 5-FU-based combination chemotherapy accrued over 30 years.

### Carcinoid Tumors

Carcinoid tumors represent 29% of all small bowel malignancies and 19% of all small bowel tumors; they are second only to adenocarcinoma in frequency. The small bowel is the second most common site of carcinoid tumors after the appendix. Ninety percent of all small bowel carcinoids arise in the ileum. These tumors are often silent, with many series including otherwise asymptomatic tumors discovered incidentally, either at laparotomy or autopsy. When present, the most common presenting symptom is vague, nonspecific abdominal pain. <sup>143,144</sup> and <sup>145</sup> This pain may be due to a number of causes. Frequently, an intense desmoplastic fibrous reaction occurs around the primary tumor, with shortening of the small bowel mesentery, which is thought to be induced in some way by the biochemical products of the tumor. This reaction induces foreshortening of the mesentery with kinking of the bowel and either ileus or partial bowel obstruction. Partial bowel obstruction may also occur from the tumor itself, although this appears less often. In addition, a syndrome of chronic mesenteric ischemia has been described in these patients, associated with a mesenteric angiopathy described as *elastic vascular sclerosis*. <sup>146</sup> On angiography, this condition is manifest by occlusion of the peripheral small vessels of the mesenteric arcade.

Although only 10% to 17% of patients with small bowel carcinoid present with carcinoid syndrome, <sup>147,148</sup> up to 67% develop features of the syndrome at some point during the course of the disease. <sup>149</sup> Symptoms include flushing of the head, neck, and upper chest in 84% to 94% of patients and a watery secretory diarrhea in 70% to 86% of patients; both symptoms are present in 58% of patients. Right-sided valvular heart disease is present in 37% to 50% of patients, and bronchial asthma is manifest in 17% to 23% of patients. <sup>147,149,148,149,150</sup> and <sup>151</sup> These symptoms are often prompted by emotion, alcohol intake, or the ingestion of tyramine-containing foods, such as blue cheese or chocolate. <sup>150</sup> Virtually all patients with evidence of carcinoid syndrome have bulky liver metastases and elevated urinary 5-hydroxyindole

acetic acid levels.

In the absence of the classic carcinoid syndrome, preoperative diagnosis of these tumors is unusual. Radiologic findings, even with small bowel follow-through studies, are inconclusive, revealing only an ileus-like or partial obstruction picture. CT scanning may reveal a mass infiltrating the mesentery with or without liver metastases, but this finding is nonspecific.<sup>152</sup> Mesenteric angiography may reveal occlusion of the peripheral mesenteric vessels, but this finding is unusual.

At laparotomy, carcinoid tumors appear as firm, tan, submucosal nodules, usually in the distal small bowel. Invariably, symptomatic tumors are larger than those found incidentally or at autopsy.<sup>144</sup> The frequency of metastatic disease to regional lymph nodes and liver is directly related to the size of the tumor. Nodal metastases are unusual with tumors less than 1 cm in diameter but are present in 33% to 67% of tumors 1 to 3 cm in size and in 75% to 90% of tumors larger than 3 cm.<sup>143,147,150,153,154</sup> and <sup>155</sup> The majority of patients presenting with symptomatic carcinoids of the small intestine have metastatic disease at the time of operation.

Approximately 30% of small bowel carcinoids are multiple,<sup>143,144</sup> and <sup>145,148,151,153</sup> mandating a careful search of the remainder of the small bowel for other primary lesions before definitive surgical management.

Surgical management of the primary tumor includes wide resection of all visible disease, together with complete resection of the supporting mesentery. Although the likelihood of regional lymph node metastases is known to increase with tumor size, metastases have been reported in carcinoids smaller than 1 cm.<sup>147,156</sup>

Management of carcinoid tumors metastatic to liver is aimed primarily at controlling the symptoms of the carcinoid syndrome. Prolonged remission of symptoms has been observed with resection of bulk liver metastases, even if incomplete.<sup>147,154,157,158</sup> For unresectable disease, short-term remission of symptoms has been observed with hepatic dearterialization.<sup>147,158</sup> Hepatic arterial infusion chemotherapy has been attempted without convincing reports of success.<sup>149,154</sup>

Medical management of the symptoms of carcinoid syndrome has included a long list of drugs, all with limited success. The most effective drug in controlling these symptoms is the long-acting somatostatin analogue SMS-201. Given as a subcutaneous injection, this drug controls symptoms in nearly all patients.<sup>150</sup>

Systemic chemotherapy has been disappointing in carcinoid syndrome. Active agents include 5-FU, streptozotocin, mitomycin C, cyclophosphamide, methotrexate, interferon- $\alpha$ , and doxorubicin (Adriamycin). The most active single agents are 5-FU and doxorubicin, and the most effective combination regimens are methotrexate with cyclophosphamide, 5-FU with streptozotocin, and streptozotocin with doxorubicin.<sup>147</sup> Although response rates of 30% to 55% are reported, none of these drugs, either alone or in combination, has clearly demonstrated any impact on the generally indolent natural history of carcinoid tumors.

The prognosis in patients with carcinoid tumors of the small intestine is generally better than that for adenocarcinoma and depends on a number of factors, including tumor size, depth of invasion, presence of lymph node, and liver metastases.<sup>143,144</sup> and <sup>145,147,159</sup> Other factors identified as prognostically significant by univariate analysis are lack of symptoms, complete resectability,<sup>143</sup> and histologic growth pattern.<sup>160</sup> In advanced disease, two groups have looked at the association of DNA ploidy and prognosis, with both finding a trend toward better prognosis in patients with solely diploid tumors.<sup>161,162</sup> In general, however, this tumor can be characterized as one of indolent growth. In the absence of metastatic disease, complete resection of localized carcinoid tumors results in a 75% to 94% 5-year survival rate.<sup>150,159</sup> With regional lymph node involvement, 5-year survival rates of 45% to 90% have been reported.<sup>145,147,149,154,159</sup> Five-year survival rates of 19% to 54% have been reported in the presence of liver metastases.<sup>145,147,149,150</sup> and <sup>151,159</sup>

## Lymphoma

Lymphoma may involve the gastrointestinal tract either primarily or as a manifestation of extensively disseminated systemic disease. Primary small bowel lymphoma constitutes 1% to 4% of all gastrointestinal malignancies and, in a review of series, 15% of all small bowel malignancies (see [Table 33.6-3](#)). The gastrointestinal tract is the most frequent site of extranodal lymphoma, the stomach being the most frequent site, followed by the small bowel and colon, respectively.<sup>163</sup> Within the small bowel, the incidence of lymphoma increases as one progresses distally, the most frequent site being the ileum. The incidence parallels the relative amount of lymphatic tissue in the wall of the small bowel at these locations.

The incidence of primary intestinal lymphoma in the United States nearly doubled in the period from 1985 to 1990.<sup>164</sup> Factors implicated in this increase include the increasing number of immunocompromised patients (acquired immunodeficiency syndrome patients, transplantation recipients) and the increasing number of immigrants from Third World countries.

For the diagnosis of primary small bowel lymphoma, one must satisfy the criteria specified by Dawson and coworkers<sup>165</sup>: (1) There must be no peripheral or mediastinal lymphadenopathy, (2) the peripheral blood smear must display a normal white blood cell count and differential, and (3) tumor involvement must be predominantly in the gastrointestinal tract.

Most authors think that there should be no evidence of liver or spleen involvement.<sup>166,167</sup> Antecedent conditions reported to be associated with the development of primary small bowel lymphoma include nontropical sprue and Crohn's disease.<sup>56,138,166</sup>

Patients with gastrointestinal lymphoma have been traditionally staged using a modification of the Ann Arbor staging system.<sup>168</sup> Because this was not a staging system originally designed for lymphomas of the gastrointestinal tract, Blackledge and colleagues<sup>169</sup> described a staging system to incorporate the prognostic significance of perforation ([Table 33.6-6](#)). Another clinically relevant modification of the Ann Arbor staging system, by Mussoff and Schmidt-Vollmer,<sup>164</sup> recognizes the prognostic significance of regional (stage II<sub>1</sub>E), as opposed to extraregional (stage II<sub>2</sub>E), lymph node involvement.

Stage	Description
<b>ANN ARBOR STAGING SYSTEM</b>	
I	Involvement of a single nodal group or single nodal site (IE)
II	Involvement of more than one nodal group on the same side of the diaphragm or involvement of a single extranodal site with one or more nodal groups on the same side of the diaphragm (IIE)
III	Involvement of nodes on both sides of the diaphragm, with or without involvement of extranodal sites (IIE), spleen (IIS), or both (IIIES)
IV	Diffuse involvement of viscera or bone marrow
<b>BLACKLEDGE STAGING SYSTEM</b>	
I	Tumor confined to the gastrointestinal tract
II	Tumor with local mesenteric nodal involvement
III	Tumor with perforation
IV	Tumor with distant (paraortic and beyond) nodal involvement
V	Tumor with visceral or bone marrow involvement

**TABLE 33.6-6.** Staging Systems for Small Bowel Lymphoma

Five clinically distinct subtypes of primary small intestinal lymphoma have been described: the adult Western type; the pediatric type; the immunoproliferative small intestinal disease, or Mediterranean, type; enteropathy-associated T-cell lymphoma; and Hodgkin's lymphoma.<sup>164</sup>

The most common lymphoma of the small intestine, the Western type, occurs primarily in adults at a median age of 54 to 61 years and has a distinct male predominance.<sup>170,171</sup> and <sup>172</sup> These lesions are usually focal and are found in the distal small bowel. The most common presenting symptom is abdominal pain related to partial bowel obstruction. The most common physical finding is a mass. Anemia occurs in approximately 20% of these patients, and approximately 10% of patients present with perforation.<sup>138,170,172,173</sup> and <sup>174</sup>

The diagnosis of Western-type lymphoma is often made only at laparotomy. Radiologic findings suggestive of this diagnosis include a diffuse segment of thickened distal small bowel on follow-through examination. This finding can often be even better demonstrated by CT scan. However, radiologically, the diagnosis is easily

confused with other segmental disease of the distal small intestine, such as Crohn's disease.<sup>175</sup>

Several systems have been described to classify the pathology of small bowel lymphomas. Using the Rappaport system, approximately 60% of non-Hodgkin's lymphomas are diffuse histiocytic (40% diffuse large cell and 20% immunoblastic), 25% are lymphocytic, and the remainder are of mixed type. The more recently described Kiel system uses both morphology and cell surface markers to classify lymphomas. Although histologic staging systems remain in evolution, the grade of the lymphoma remains most predictive of outcome. Most small bowel lymphomas are intermediate or high grade.<sup>166,171,176,177</sup>

Management of these patients usually entails surgical exploration with resection of the affected segment of small bowel together with its subjacent mesentery. Fifty percent to 78% of patients who present with this type of lymphoma undergo complete surgical resection.<sup>30,138,170,171</sup>

The role of adjuvant therapy in patients who undergo complete resection is debated. Most authors agree that any patient with evidence of incompletely resected disease or regional nodal metastases can benefit from systemic chemotherapy.<sup>170</sup> Some believe that adjuvant chemotherapy is warranted after complete resection of all high-grade lymphomas, even if they are stage IE.<sup>178,179</sup> Auger and Allan<sup>171</sup> reported on 16 patients undergoing complete surgical resection of intestinal lymphomas. The median survival in patients who underwent complete resection with chemotherapy was 34 months, compared with 14 months in patients who underwent complete surgical resection without adjuvant chemotherapy.<sup>171</sup> These 16 patients were not broken down by the presence or absence of nodal metastases, and as such, the issue of adjuvant chemotherapy remains unresolved in patients with lymphoma localized to the bowel.

Adjuvant radiation therapy had been advocated by some investigators,<sup>138,170</sup> although the permanent long-term side effects of abdominal radiation therapy, together with the efficacy of contemporary combination chemotherapy, make this option less attractive.<sup>178</sup>

Most of the larger more recent series report 5-year survival rates in excess of 50% with aggressive multimodality therapy. Prognostic factors include tumor grade, stage at presentation, complete response to therapy, complete resectability, histologic subtype, and the use of multimodality therapy.<sup>163,166,170,171,175,177,178,180</sup> Patients with B-cell lymphomas tend to have better median survival than those with T-cell lymphomas.<sup>57,181</sup> In contrast to the indolent course of patients with carcinoid tumors, most deaths in patients with small bowel lymphoma occur within 2 years of diagnosis.<sup>173,182,183</sup>

The second major type of lymphoma is childhood lymphoma. This disease typically occurs in patients younger than 15 years of age and presents with symptoms of pain and physical findings of a mass in the right lower quadrant, often with associated intussusception. Histologically, nearly one-half of these lymphomas resemble a Burkitt's-type lymphoma.<sup>184</sup> These patients often require resection before systemic therapy, because perforation while on treatment is not uncommon. The prognosis for these children is improving in the era of combined-modality therapy, with a survival rate of 76% reported by Fleming and colleagues<sup>184</sup>; all deaths in this series occurred within 10 months of diagnosis. Outcome depends on stage at presentation and resectability.<sup>166,185,186</sup>

A third clinically distinct type of intestinal lymphoma is immunoproliferative small intestinal disease, or Mediterranean lymphoma. This is the most common lymphoma encountered in Middle Eastern and African populations, occurring with equal gender predilection in young adults, with a median age of 30.<sup>183,185,186</sup> Typically, these patients present with the triad of pain, malabsorption (manifest by weight loss and diarrhea), and nail clubbing.<sup>185</sup> Approximately 50% of these patients present with a mass. Mediterranean lymphoma generally involves the entire small bowel and is manifested histologically by villous atrophy and an intense lymphoplasmacytoid infiltrate in the lamina propria of the small bowel. As such, diagnosis can often be made by peroral jejunal biopsy. Surgery is reserved for cases in which the diagnosis is unclear or for complications such as obstruction or perforation. Grossly, the bowel appears to be involved by a diffuse thickening with some nodularity. Lymph nodes are involved in 85% of patients. As a biologic curiosity, approximately 30% of patients with Mediterranean lymphoma have free a heavy-chain protein in their serum and jejunal fluid. This finding, however, is neither specific nor diagnostic in this disease.

Treatment of patients with Mediterranean lymphoma consists primarily of systemic chemotherapy, although reports of whole abdominal radiation therapy have appeared.<sup>178</sup> The use of tetracycline in the management of this lymphoma supports the role of an infectious etiology.<sup>187,188</sup> Prognosis is variable, with Al-Bahrani and associates<sup>185</sup> reporting a 23% 5-year survival rate; El Saghir and colleagues<sup>187</sup> reported an overall 5-year survival rate of 58% after aggressive therapy.

Enteropathy-associated T-cell lymphoma is an unusual variant of intestinal lymphoma, most often seen in the Middle East and often associated with an antecedent history of malabsorption or frank celiac disease. The malignancy is believed to arise from unrestricted proliferation of T-cell clones from the reactive T-cell population in the enteropathic bowel.<sup>189</sup> It is usually disseminated at presentation and is often associated with significant malnutrition. Prognosis is generally poor despite multiagent chemotherapy.<sup>57</sup>

Primary Hodgkin's lymphoma of the small bowel is extremely unusual, accounting for fewer than 3% of all small bowel lymphomas.<sup>166,176</sup> In many cases, this diagnosis may represent impingement of mesenteric lymphadenopathy on the small bowel rather than primary visceral involvement.<sup>190</sup> Management consists of diagnostic and palliative surgery followed by definitive systemic chemotherapy.

### **Sarcoma**

Sarcomas of the small intestine are extremely unusual, constituting only approximately 9% of all small bowel tumors and 14% of all small bowel malignancies (see [Table 33.6-2](#)). Most are of smooth muscle origin (leiomyosarcomas and leiomyoblastomas), although case reports of other histologies have appeared. More recent reports have grouped these tumors under the category of gastrointestinal stromal tumors, from which another variant, gastrointestinal autonomic nerve tumors, can be distinguished based on immunohistochemistry and electron microscopy.<sup>191,192</sup> From a clinical and prognostic viewpoint, however, these tumors can be discussed together.

Sarcomas of the small intestine can present with a number of symptoms, depending on their growth pattern. Endoenteric lesions can present as either bleeding or obstruction. Exoenteric lesions can present as an abdominal mass or perforation before any sense of obstruction is evident. Although the diagnosis may be suggested by upper gastrointestinal series with small bowel follow-through or enteroclysis, with or without abdominal CT scan, it is rarely made with certainty preoperatively. These tumors also tend to be highly vascular, with a plethora of tumor vessels seen with arteriography. Intraoperatively, these tumors have a variety of appearances, but they are usually appreciated as firm, encapsulated masses that arise in relation to the bowel. It is difficult both clinically and by frozen-section examination to distinguish a small leiomyosarcoma from its benign counterpart, the leiomyoma.

The principles of surgical management include wide resection of the primary tumor, including any adjacent structures that may be invaded. Duodenal tumors often require pancreaticoduodenectomy if the medial wall of the second portion of the duodenum is involved. Smaller leiomyosarcomas of the duodenum may be treated with wedge or sleeve resection. For sarcomas of the jejunum and ileum, the involved segment of intestine is resected together with its supporting mesentery. Deliberate or extended lymphadenectomy is unnecessary, because these tumors involve regional lymph nodes in fewer than 15% of cases.<sup>104</sup>

The overall 5-year survival rate for patients with small bowel sarcoma is approximately 20% and depends on tumor size, histologic grade, local invasiveness, and resectability.<sup>193,194,195,196,197,198,199</sup> and <sup>200</sup> In a review of patients at Memorial Sloan-Kettering Cancer Center, all of nine patients with high-grade sarcomas of the small bowel had experienced recurrences, whereas none of four patients with low-grade sarcomas had recurrences.<sup>201</sup>

Peritoneal and liver metastases are the most common causes of treatment failure. No evidence suggests that adjuvant chemotherapy or radiation therapy after complete resection diminishes the risk of subsequent recurrence.

Standard treatment of symptomatic metastatic disease usually involves doxorubicin-based combination chemotherapy, with or without high-dose ifosfamide. Although response rates of up to 40% have been reported with these regimens, no convincing impact on the survival of patients with advanced metastatic gastrointestinal sarcoma has been demonstrated.

### **Metastatic Disease**

The small bowel is not infrequently involved by metastatic disease. The most common tumor metastasizing to the gastrointestinal tract is melanoma, with 60% of patients who die of melanoma having autopsy evidence of metastatic disease involving the gastrointestinal tract.<sup>202</sup> Other extraabdominal tumors known to

metastasize to the small intestine include those of the lung,<sup>203,204</sup> breast,<sup>205,206</sup> cervix,<sup>207,208</sup> and kidney.<sup>209,210</sup> Case reports of small bowel metastases from other tumors, including tumors of the thyroid,<sup>211</sup> Merkel cell carcinoma,<sup>212</sup> and hepatoma,<sup>213</sup> have appeared. Intraabdominal tumors that may involve the small bowel by transperitoneal spread include colorectal carcinoma, ovarian carcinoma, gastric carcinoma, pancreatic carcinoma, and transitional cell carcinoma of the genitourinary system. The small bowel may also be involved by direct extension from any intraabdominal malignancy.

Symptoms of small bowel metastases most commonly include bleeding and obstruction; rarely, perforation is seen. Although surgical treatment of patients with local small bowel invasion can often be performed with curative intent, it is almost always palliative in patients with hematogenous or peritoneal metastases. Identification of an obstructing metastatic lesion is usually possible, although these lesions are rarely solitary. Identification of a bleeding metastasis among multiple small bowel lesions can be difficult.

The outcome in patients undergoing small bowel resection for metastatic melanoma has been summarized by a number of authors. Median survival rates of 4.5 to 8.5 months have been reported, with few, if any, long-term survivors.<sup>202,214,215,216</sup> and<sup>217</sup> Caputy and colleagues<sup>215</sup> were able to identify small bowel involvement as an independent adverse prognostic indicator in patients with melanoma metastatic to the gastrointestinal tract. Branum and Seigler<sup>216</sup> found a mean survival of 31 months in patients who underwent complete resection, compared with 10 months in patients who underwent noncurative procedures, which is more likely a reflection of the extent of tumor rather than the impact of therapy. Ricaniadis and colleagues<sup>218</sup> reported a 28% 5-year survival rate in 12 patients with no other site of metastatic melanoma who underwent complete surgical resection; these patients were selected from a group of 68 patients with involvement of the gastrointestinal tract by recurrent melanoma.

## INTRODUCTION

Colorectal cancer represents a major public health problem, especially in developed countries. As such, it has attracted the efforts of researchers from a wide variety of disciplines, including epidemiologists, molecular biologists, nutritionists, gastroenterologists, prevention experts, surgeons, radiation therapists, nurses, medical oncologists, and outcomes researchers. This chapter section and [Chapter 33.8](#) present some of the exciting information that has been generated about this common malignancy.

## ANATOMY

## GROSS ANATOMY

The large bowel is divided into the colon and the rectum. Segments of both may be intraperitoneal or extraperitoneal. The treatment and pattern of recurrence of colon and rectal cancer are affected by the location of the tumor in these organs and its relationship to the peritoneal cavity and surrounding structures. Treatment failures in large bowel tumors involving extraperitoneal segments often occur because of a locoregional recurrence.<sup>1</sup> This is especially true of rectal cancers, which usually have no serosal covering and are surrounded by fat, bone, nerves, blood vessels, and viscera within the confines of the pelvis. The colon has segments that are largely intraperitoneal, and the relationship of certain aspects of the colon to the retroperitoneum and its structures are important factors in tumor spread. The cecum, transverse colon, and sigmoid loop are the intraperitoneal portions of the colon. The ascending colon, descending colon, splenic and hepatic flexures, and beginning and end of the sigmoid colon have their posterior surface in the retroperitoneum.

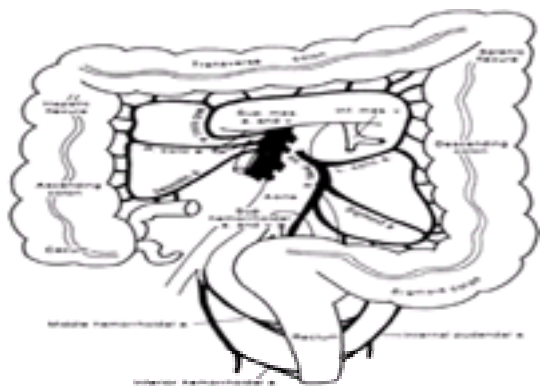

The large bowel is immediately recognized by its large diameter, haustra, and presence of appendices epiploicae and tenia coli. The tenia consist of condensations of longitudinal muscle fibers starting near the base of the appendix and continuing throughout the abdominal colon to form a continuous longitudinal muscle coat in the upper rectum. Haustra are outpouchings of bowel wall separated by folds that give a classic appearance on radiography or barium enema.

The first part of the colon is the cecum, with the appendix lying at the lower pole. The ascending colon lies on the right aspect of the retroperitoneum and extends up to the hepatic flexure. The hepatic flexure lies near the gallbladder fossa and porta hepatis and overlies the lower portion of the right kidney and the duodenum. The transverse colon is variable in its length. The splenic flexure lies just beneath the left diaphragm and abuts the hilum of the spleen and tail of the pancreas. The descending colon lies along the left retroperitoneum and terminates in the sigmoid colon. The descending colon is of variable length. The sigmoid colon is the narrowest portion of the large bowel, and it terminates at its junction with the upper rectum just below the sacral promontory.

## VASCULAR SUPPLY

In general, the artery and vein supplying and draining each segment of the colon accompany each other in the mesocolon. The mesocolon contains vessels, lymph nodes, nerves, and lymphatic trunks. The marginal artery and vein form an arcade along the mesocolic side of the colon. The presence of collateral circulation allows performance of mesenteric resection to the level of the principal nodes found at the origin of the major vessels supplying segments of the colon.

The superior mesenteric artery (SMA) and the inferior mesenteric artery (IMA) contribute to the arterial supply of the colon ( Fig. 33.7-1).<sup>2</sup> Shortly after its origin, the SMA divides into the middle colic artery and the trunk of the SMA. The middle colic artery immediately forms two to three large arcades in the transverse mesocolon. The SMA ileocolic arterial branches then extend from the SMA. The right colic artery arises as a separate branch from the SMA in 10.7% of cases.<sup>3</sup> The ileocolic artery gives off a right colic artery to the upper ascending colon and forms an anastomosis with branches from the middle colic artery. The ileal branch of the ileocolic artery gives off branches to the distal small bowel and cecum, whereas the colic branch supplies the ascending colon. An anastomosis occurs between the distal SMA and the ileal branch of the ileocolic artery at the junction of the terminal ileum and cecum.

**FIGURE 33.7-1.** Anatomic segments and vascular supply to the colon and rectum. a, artery; Inf, inferior; Int, internal; L, left; mes, mesenteric; R, right; Sup, superior; v, vein. (From Jones T, Shepard WC, *A manual of surgical anatomy*. Philadelphia: WB Saunders, 1945, with permission.)

The arterial supply to the left side of the colon comes from the IMA, which arises from the aorta. The IMA gives off the left colic artery. It also gives off three to four sigmoidal arteries. The anastomosis between the vessels of the middle colic artery and those of the left colic artery occurs at the splenic flexure. This vessel parallels the course of the colon between the middle colic artery and the branches of the IMA. This is critical in surgical reconstruction of the left colon and rectum.

The venous drainage of the colon parallels that of the arterial supply. The drainage of the superior and inferior mesenteric veins is to the portal vein. This enhances the production of liver metastases. The venous drainage of the lower rectum is also into the vena cava and, therefore, rectal cancers are more likely to produce isolated pulmonary metastases than are cancers at other large bowel sites.

## LYMPHATIC DRAINAGE

Curative surgical resection and staging of large bowel cancer requires resection of the lymph nodes that drain the primary tumor site. The relationship between the blood vessels supplying the affected segment of colon and the draining lymphatics determines the extent of bowel resection to be done.

Lymphatic drainage of the large bowel follows its arterial supply in the mesocolon ( Fig. 33.7-2). Invasive carcinoma of the large bowel is identified by spread beyond the muscularis mucosa into the submucosa, where it gains access to lymphatic channels through open junctions formed by the destruction of lymphatic endothelial cells.<sup>4</sup> The efferent lymphatic channels pass from the submucosa to the intramuscular and subserosal plexus of the bowel to the first tier of lymph nodes lying adjacent to the large intestine and known as *epicolic nodes*. *Paracolic nodes* lie on the marginal vessels along the mesenteric side of the colon and are frequently involved in metastases. *Intermediate nodes* are found along the major arterial branches of the SMA and IMA in the mesocolon. The *principal nodes* are found around the origin of these vessels from the aorta, and they drain into retroperitoneal nodes.

**FIGURE 33.7-2.** For tumors that lie between two pedicles, lymphatic flow may drain in either or both directions. From a study of cleared specimens, it was possible to determine the preferential route by the location of lymphatic metastases. The numbers signify the percentage of metastasizing carcinomas in the indicated locations that have demonstrated positive nodes along a given vascular route. For example, node-positive tumors lying between the ileocolic and right colic arcades metastasize along the ileocolic pedicle in 100% of cases and along the right colon in 12% of cases. (From Hertzler FP, Slanetz CA, Patterns and significance of lymphatic spread from cancer of the colon and rectum. In: Weiss L, Gilbert HA, Ballon SC, eds, *Lymphatic system metastasis*. Boston: GK Hall, 1980:283, with

permission.)

## EPIDEMIOLOGY

Colorectal cancers rank third in frequency in men and second in women. Male incidence rates, adjusted for age and race, appear greater than female rates for both proximal and distal cancers [odds ratio (OR), 1.32 for proximal cancers and 1.68 for distal cancers, respectively]. The mortality rate is similar in men and women, the ratio being 1.05:1.00. Colorectal cancer is the fourth leading cause of cancer mortality because it has a better prognosis than more common cancers. A 5-year survival rate of 61% is reported by the U.S. Surveillance, Epidemiology, and End Results program,<sup>6,7</sup> as compared with a 5-year survival rate of 41% to 42% in European and Indian registries.<sup>5</sup> Slightly lower survival rates of 32% and 38% are reported in China and developing countries, respectively. The lowest estimated survival rate (30%) is in Eastern Europe.

The incidence of colorectal cancer is higher in developed countries than in developing countries.<sup>7</sup> Fewer than one-third of these cancers occur in developing countries. The incidence rates vary tenfold. The lifetime risk of developing colorectal cancer in developed countries appears to be 4.6% in men and 3.2% in women. Incidence rates are relatively low in Africa and Asia, except in Japan, which now has an incidence rate similar to that in Europe. Sharp increases in incidence have been seen in Eastern Europe and Japan.<sup>8</sup> The geographic differences in colorectal cancer incidence appear to be attributable to differences in exposures that are essentially dietary and environmentally imposed on a background of genetically determined susceptibility. Immigration from a low-incidence to a high-incidence environment will increase a person's risk.<sup>11</sup> This has been most evident among immigrants to the United States from Japan.

Decreases in the incidence of colon and rectal cancers in the United States began in the mid-1980s and continue today. African American men have the highest incidence rates of colon and rectal cancer among U.S. racial and ethnic groups. Differences in subsite distribution between African Americans and whites have been noted.<sup>9</sup> African Americans have the highest mortality rates for colon and rectal cancer among ethnic and racial groups. Studies have postulated that these differences are not due to biologic aggressiveness of the tumors but rather to access to care.<sup>10</sup> U.S. colorectal cancer mortality and incidence rates continue to decline, with age-adjusted rates dropping to 16.8 and 42.7 per 100,000 population, respectively, in 1996.<sup>11</sup> An analysis of data from population studies that included the National Cancer Institute's Surveillance, Epidemiology, and End Results program reports that changes in the use of endoscopic polypectomy, dietary factors, energy intake, physical activity, serum cholesterol, cigarette smoking, and obesity contributed to this fall in incidence after 1986.<sup>12</sup>

Recent epidemiologic studies have suggested that the anatomic distribution of colorectal cancer may have undergone a distal to proximal shift over several decades. The U.S. National Cancer Database has reported that cecal and ascending colon tumors increased in incidence from 33.9% to 36.1%, tumors of the transverse colon increased from 15.8% to 17.2%, and tumors of the sigmoid colon decreased from 36.0% to 33.4%. These changes occurred between 1986 and 1992.<sup>13</sup> Reports suggest that the apparent distal to proximal shift may be a result of preventive measures and improved diagnostic techniques used in developed, high-incidence countries but that these have not had an impact in less developed nations.<sup>14</sup> In an analysis of improvements in survival over time by anatomic subsites of colon cancer, it was found that 5-year survival rates improved significantly for patients with left colon and transverse colon cancers, owing to advances in treatment and diagnostic techniques, whereas survival rates from right colon cancer did not improve.<sup>15</sup>

## ETIOLOGY

The essential element of the etiology of colorectal cancer is a process of genetic change in the epithelial cells of the colonic mucosa.<sup>16</sup> These changes are discussed more fully in the [Chapter 33.1](#) that address the molecular biology of this disease.

Epidemiologic factors have provided initial evidence about the specific factors that initiate the process of carcinogenesis in the large bowel mucosa.<sup>17</sup> Chief among the factors that can initiate colorectal cancer development are a predisposition to mutagen effects, fecal mutagens, meat intake, bile acids, altered vitamin and mineral intake, and fecal pH.

### PREDISPOSITION TO MUTAGEN EFFECTS

There is an interaction between mutagen exposure and genetic constitution. Metabolic pathways may be altered by polymorphisms in genes responsible for detoxifying mutagens.<sup>18</sup> Protection from the effects of mutagen-induced DNA damage is achieved by a range of detoxification enzymes. Examples are reduced glutathione S-transferase (GSH transferase), DT-diaphorase, and N-acetyltransferase.<sup>19</sup>

Differences among individuals can account for susceptibility to mutagens from the diet. An example is a polymorphism in N-acetyltransferase, an enzyme that catalyzes the formation of mutagenic products from heterocyclic amines, which can play a role in colorectal cancer development.<sup>20</sup> Heterocyclic amines are substances formed in cooked meats. Differences in N-acetyltransferase activity classify individuals as slow or fast acetylators. Risk for colorectal cancer development increases with the level of red meat consumption in fast acetylators but not in slow acetylators.<sup>21</sup>

Individuals with risk factors for colorectal cancer have significantly lower levels of GSH transferase activity in their blood lymphocytes.<sup>22</sup> Strategies to enhance the expression of detoxifying enzymes are available.<sup>23</sup>

### FECAL MUTAGENS

Mutagenic compounds such as fecapentaenes, 3-ketosteroids, and heterocyclic amines in the stool may be produced by the interaction of digestion and food products.<sup>24</sup> These compounds produce reactive molecules that may form bulky adducts to DNA. One of the chief influences of diet is the production of fecal mutagens by certain diets. Changes in the fecal microflora indicate that changes in diet may alter mutagenic activity by altering extracellular superoxide formation.<sup>25</sup> For instance, a change in a lactovegetarian diet to a diet with increased fiber intake caused a dilution of mitogenic activity within the stool.<sup>26</sup> Other factors may moderate the effects of fecal mutagens. Intake of antioxidants reduces the mutagenicity of compounds in the stool. Changes in intestinal transit time owing to fiber intake affects the exposure of the mucosa to mutagens.

In addition to mutagenic compounds such as fecapentaenes, the presence of other products of digestion such as 3-ketosteroids, which are products of cholesterol metabolism, may act as tumor promoters or initiators.

### MEAT INTAKE

Armstrong and Doll (1975) described the high correlation of meat intake and mortality from colorectal cancer. Among the risk factors are the intake of red meats and the compounds that result from cooking meats at high temperatures.<sup>27</sup> In a study of meat preparation, it was observed that the association between red meat and colorectal cancer could be due to heterocyclic amines present in cooked meat.<sup>28</sup> This mechanism has been implicated in the high incidence of colorectal cancer in New Zealand.<sup>29</sup> The method of red meat preparation and frequency of intake can be correlated with the prevalence of distal colorectal adenomas. Subjects who ate browned, fried red meat more than once per week had an OR of 2.2 for distal colorectal adenomas, as compared with those who ate lightly browned red meat one time or less per week.<sup>30</sup> In Western countries, fried meat is the main source of exposure to heterocyclic amines. Nurses who consumed the highest ratio of red meat to white meat had a higher relative risk (RR) of colon cancer (OR 2.49,  $P < .001$ ).<sup>31</sup>

### BILE ACIDS

Normal bile acids that are related to the digestion of fat can induce intestinal mucosal hyperproliferation, which acts as a marker for neoplasia risk.<sup>32</sup> The presence of bile acids correlates with fat consumption, which is a known risk factor for colorectal cancer.<sup>33</sup> Bile acids have been shown to activate AP-1, a transcription factor associated with the promotion of neoplastic transformation in colonic cells.<sup>34</sup> They are also able to induce apoptosis, and variations in the epithelial apoptotic response to bile acids may correlate with risk.<sup>35</sup> Cholecystectomy can result in high levels of bile acids in the cecum and ascending colon and appears to increase the

frequency of right-sided carcinoma. In a retrospective study of colorectal cancer patients, it was found that levels of the secondary bile acid deoxycholic acid were higher than normal and that the ratio between deoxycholic acid and cholic acid may be an indicator of risk. <sup>36</sup>

## VITAMIN AND MINERAL INTAKE

Calcium can alter colonic mucosal proliferation by binding fatty acids and bile acids in the stool, resulting in insoluble complexes that are less likely to affect the mucosa. It can also decrease proliferation of the mucosa directly. <sup>37</sup> These effects of calcium may be site-specific within the colon. <sup>38</sup> In a large study of U.S. health professionals, the risk reduction from high calcium intake appeared modest after adjusting for confounding variables. <sup>39</sup> Two case-control studies suggest that any protective effect of calcium may occur only at low levels of fat intake. <sup>40</sup> The National Polyp Prevention Trial indicated that supplemental calcium intake reduced adenoma formation by 19%. <sup>41</sup> A similar effect has been seen in patients with hereditary nonpolyposis colon cancer (HNPCC) syndrome. <sup>38</sup>

In case-control studies, the use of multivitamins has been shown to reduce the risk of adenoma formation in high-risk patients. <sup>42</sup> In an update of the Nurses' Health Study, Giovannucci et al. <sup>43</sup> found a reduced risk of colon cancer [OR, 0.25; confidence interval (CI), 0.13 to 0.51] after 15 years of use of folate-containing multivitamins. The contribution of dietary folate appeared to be modest.

That folate is a potentially protective agent has been demonstrated also by other studies. Experimental tumor studies have shown that folate depletion increases the risk of tumor formation and that it also reduces methyl group availability for DNA methylation. Individuals with different forms of the 5,10-methylenetetrahydrofolate reductase gene may demonstrate different risks for colorectal cancer, which may account for differences in the effectiveness of folate supplementation on colorectal cancer risk. <sup>48</sup> Administration of a folate agent may interact with alcohol consumption as a risk factor because demands for folate are raised by alcohol consumption. <sup>49</sup> Low folate intake has been implicated in increased colorectal cancer risk, especially when combined with alcohol and a low-protein diet. <sup>50</sup>

Populations with increased vitamin D intake have been noted to be at reduced risk for colon carcinoma. <sup>44</sup> The effects of dihydroxyvitamin D<sub>3</sub> on differentiation are mediated through protein kinase C and its activation by dihydroxyvitamin D<sub>3</sub>. Total vitamin D intake was inversely related to colorectal cancer incidence in the Nurses' Health Study (RR, 0.33; CI, 0.16 to 0.70). <sup>45</sup>

A reduced risk of colon cancer is associated with the use of vitamin C. <sup>46</sup> Antioxidants such as vitamin E have been given in conjunction with vitamins C and A in studies indicating some protection against colorectal cancer risks. <sup>47</sup>

There is a weak association between high iron exposure and colorectal polyps (OR, 1.5; CI, 1.0 to 2.3). <sup>51</sup> Low levels of selenium correlated with the presence of adenomas, whereas increased levels were associated with reduced risk of adenomas (OR, 0.58; CI, 0.31 to 1.08). <sup>52</sup> Intervention trials have found a beneficial effect of selenium supplementation. <sup>53</sup>

## FECAL PH

Another aspect of the interaction between the intestinal milieu and the genome of the intestinal mucosa is the fact that alkaline environments in the stool support higher concentrations of free bile acids and other potential carcinogens. <sup>54</sup> This pH may affect the solubility of bile acid and carcinogens and make them more damaging to the DNA of the intestinal mucosal cells. Epidemiologic studies show that higher rates of colon carcinoma are found in subjects with a higher stool pH. <sup>55</sup>

## PRIMARY PREVENTION

*Primary prevention* of colorectal carcinoma is defined as the identification and eradication of etiologic factors responsible for this disease. Dietary factors, energy intake, nonsteroidal antiinflammatory drug (NSAID) use, and such lifestyle factors as hormone use in women, tobacco and alcohol use, parity, and exercise, will be discussed. These issues are addressed extensively in [Chapter 22](#), [Chapter 23.1](#), [Chapter 23.2](#), [Chapter 23.3](#), [Chapter 23.4](#), [Chapter 23.5](#), [Chapter 23.6](#), and [Chapter 23.7](#).

## DIETARY FACTORS

### Fiber

The term *fiber* refers to a diverse group of complex carbohydrates. Numerous epidemiologic studies suggest that fiber exerts a protective effect, whereas other epidemiologic studies report no protective activity of fiber in relation to colorectal carcinoma. <sup>56</sup> High fiber intake may be associated with other dietary habits that also decrease cancer risk. <sup>57</sup>

Certain types of fiber appear to be more effective than others in reducing the risk of carcinogenesis. Cellulose and bran are specific examples of fibers that have demonstrated increased effectiveness. <sup>58</sup> In an epidemiologic study of 16,448 health professionals, a trend toward a reduced risk of distal colorectal adenomas from fruit fiber ingestion but not from cereals or vegetables was seen. When data from this study were adjusted for incidents of polyp development, the risk reduction associated with soluble fiber intake was stronger (RR, 0.27; CI, 0.11 to 0.66). <sup>59</sup> Fiber may not reduce rectal cancer risk as much as it reduces colon cancer risk. <sup>59</sup> Intervention trials involving fiber are appealing because of fiber's ready availability and low cost. <sup>60</sup> However, the effect of fiber may not be independent of meat intake. <sup>31</sup> A recent long-term analysis of this issue failed to demonstrate a significant reduction in risk for colorectal cancer or adenomas (OR, 0.95; CI, 0.73 to 1.25) attributable to dietary fiber. <sup>56</sup>

### Dietary Fat

Epidemiologic data suggest a direct relationship between total fat intake and increased cancer risk in the colon and rectum, and migrant studies show that changes toward a low-fat, low-fiber Western diet result in a rise in colorectal cancer incidence. <sup>61</sup> Type of dietary fat may be important in the risk for colorectal cancer, as studies appear to link animal fat and red meat to colon cancer risk but do not support an association between colon cancer and vegetable fat. <sup>31</sup> However, fish oils may have protective effects. <sup>62</sup> Elevated levels of serum triglycerides have been associated with a higher risk of adenomatous polyps (OR, 1.5). <sup>63</sup> Interestingly, lower cholesterol levels have been demonstrated in patients in whom colorectal cancer is diagnosed. <sup>64</sup>

## ALCOHOL AND TOBACCO INTAKE

Daily alcohol intake has been associated with a twofold increase in colon carcinoma. <sup>65</sup> A more moderate risk is likely when a number of studies are considered. <sup>66</sup> Genetic polymorphisms in metabolic pathways may modify this risk. In addition, current and past smoking habits are independent factors that increase risk. Among Japanese men and women, it was found that long-term smoking conveyed a 1.6 to 4.54 RR for adenoma formation. <sup>67</sup>

## HORMONE REPLACEMENT IN WOMEN

In a review of 59,002 postmenopausal participants in the Nurses' Health Study, self-reported data were used to study the relationship between postmenopausal hormone therapy and colorectal carcinomas and adenomas. <sup>68</sup> Current use of postmenopausal hormones was associated with decreased risk of colorectal cancer (RR, 0.65; CI, 0.50 to 0.83). The protective effect of hormonal replacement disappeared within 5 years after hormone use was discontinued. Similar protective effects were noted in a Minnesota study. <sup>69,70</sup> In the Nurses' Health Study, oral contraceptive use has been implicated in reducing the risk of colorectal cancer development by 40% (OR, 0.60; CI, 0.40 to 0.89). <sup>71</sup> A higher parity was found to increase risk in those women with a family history of colorectal cancer. <sup>72</sup>

## ENERGY INTAKE, PHYSICAL ACTIVITY, AND OBESITY

Multiple studies have correlated factors such as energy intake, physical activity, and other lifestyle factors with colorectal cancer risk. <sup>73</sup> In animal models, restricted energy intake has reduced the development of colonic tumors. <sup>74</sup> The interaction between obesity and reduced physical activity was demonstrated by an alteration in

intestinal prostaglandin activity, which can correlate with colon cancer risk.<sup>75</sup> The Nurses' Health Study showed an inverse relationship between physical activity and adenomas. In this same study, obesity was associated with an increased risk.<sup>76</sup> A similar protective effect from physical activity in men was noted in a population-based cohort study conducted in Norway.<sup>77</sup>

Excessive weight and abdominal obesity were found to be risk indicators in men and women.<sup>78</sup> An exploration of the relationship among obesity, energy intake, and insulin as a growth factor indicated an increased risk of colorectal cancer in the face of a high fasting glucose level, high insulin levels, and obesity.<sup>79,80</sup> Epidemiologic studies in the United States and Italy have shown a similar association between diabetes mellitus and colorectal cancer risk.<sup>81</sup>

## NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Experimental, epidemiologic, and intervention trails address the role of aspirin and NSAIDs in colorectal cancer biology.<sup>82</sup> Human and experimental animal colon tumors contain increased amounts of prostaglandin E<sub>2</sub>, and this compound is thought to participate in colon cancer carcinogenesis.<sup>83</sup> Formation of prostaglandins requires the action of cyclooxygenase (COX), which exists in two isoforms. COX-2 appears to be responsible for increased prostaglandin E<sub>2</sub> in response to growth factors in human and animal colonic tumors.<sup>84</sup> COX-2 inhibition, therefore, may play a role in colon cancer prevention.

Aspirin, a relatively nonspecific COX-2 inhibitor, has been associated with lower-than-expected rates of colorectal adenomas and carcinomas in epidemiologic studies.<sup>85,86</sup> and<sup>87</sup> However, in a large aspirin intervention trial involving more than 22,000 U.S. male physicians, a secondary analysis did not confirm a reduced incidence of colorectal cancer.<sup>88</sup>

In a Wisconsin study, regular NSAID use conferred a lower risk of a colorectal cancer diagnosis than did nonuse (OR, 0.65; CI, 0.40 to 1.03).<sup>89</sup> Importantly, the risk reduction was greater for those using nonaspirin compounds (OR, 0.43; 95% CI, 0.20 to 0.89) as compared with users of aspirin compounds (OR, 0.79; CI, 0.46 to 1.36). The NSAID sulindac has been studied in the setting of familial adenomatous polyposis (FAP), where it achieved a 56% reduction in polyps.<sup>90</sup> The long-term use of nonselective COX inhibitors can be associated with increased toxicity.<sup>91</sup> Use of more selective COX-2 inhibitors may be beneficial in preventing toxicity with long-term use while maintaining the agents' preventive effects.<sup>92</sup>

## SECONDARY PREVENTION

Secondary prevention focuses on the identification of high-risk populations and interventions that can prevent the development of colorectal carcinoma. It involves identifying those persons at increased risk of death from colorectal cancer owing to the presence of premalignant lesions or early cancers. Examples of secondary prevention strategies are screening for adenomas, treatment of adenomatous polyps by endoscopic polypectomy, or excision of the large bowel in FAP. High-risk states can be identified by an individual's age, genetic makeup, and predisposing diseases such as previous cancer or inflammatory bowel disease. In addition, previous medical treatments can have an impact on a patient's risk ([Table 33.7-1](#)). In nearly three-fourths of colorectal cancer cases, no predisposing factors will be identifiable.<sup>93</sup>

Average risk
Age ≥50 y
Increased risk
Adenomatous polyposis syndromes
Familial adenomatous polyposis
Attenuated familial adenomatous polyposis
13097K mutation
Hamartomatous polyposis syndromes
Peutz-Jeghers syndrome
Juvenile adenomatous polyposis
Hereditary nonpolyposis colon cancer
Family history of polyps or colorectal cancer
Inflammatory bowel disease
Chronic ulcerative colitis
Chronic granulomatous colitis
Medical history
Colorectal carcinoma
Colorectal polyps
Pelvic irradiation
Noncancer surgery (cholecystectomy and ureterostomy)

**TABLE 33.7-1.** Risk Factors for Colorectal Cancer

## CLINICAL RISK FACTOR: AGE

Age is the most relevant factor affecting colorectal cancer risk in most general populations ([Fig. 33.7-3](#)). The peak onset of colorectal cancer in the United States is at age 65 years. People older than 40 years are the largest increased-risk group. Fewer than 10% of cancers of the colorectum occur in people younger than 40 years. The increase in incidence occurs into the eighth decade of life, when a decline begins. The most common risk factor for polyp development is age greater than 50 years.<sup>94</sup>

**FIGURE 33.7-3.** Cumulative incidence of colorectal cancer by age in the general population (*open circle*), hereditary nonpolyposis colon cancer population (*open square*), and familial adenomatous polyposis population (*closed circle*).

## GENETIC RISK FACTORS

### FAMILIAL POLYPOSIS SYNDROMES

FAP syndromes are a group of syndromes characterized by the early onset of multiple polyps and a virtually 100% risk of colorectal cancer development.<sup>95</sup> FAP represents but a small percentage of the overall number of colorectal cancer cases. Its importance as a model for sporadic colorectal cancer development far outweighs its importance as a problem in public health.<sup>96</sup> It affects from 1 in 8000 to 1 in 10,000 persons. These syndromes have autosomal dominant inheritance with high but variable penetrance. The phenotype may vary by mutation site.<sup>97</sup> Synchronous cancers are common in FAP patients.

There is an association between FAP and periampullary, thyroid, and specific cancers or nonneoplastic growth such as osteomas, sebaceous cysts, and gastric fundic gland polyps. It is important to realize that 10% to 20% of the cases are *de novo* mutations with no apparent family history. After the colorectal cancer risk has

been controlled by surgery, other neoplasms such as periampullary tumors are prominent causes of death among people with FAP.<sup>98</sup>

A subset of polyposis patients have Gardner's syndrome, which is characterized by colonic adenomatous polyposis associated with the presence of mesenteric or abdominal wall desmoid tumors, lipomas, and fibromas.<sup>99</sup> The presence of a mesenteric desmoid tumor is a cause of great morbidity in these patients. Other diseases included under the category of polyposis syndromes are Turcot's syndrome and Oldfield's syndrome. Hamilton<sup>96a</sup> has described the presence of two germline defects in Turcot's syndrome that are seen with both polyposis and HNPCC syndromes. There can often be considerable overlap between these adenomatous polyposis syndromes, and they are best characterized on the basis of their common genetic abnormality in the adenomatosis polyposis coli (*APC*) gene.

The basic genetic defect in FAP is a mutation in the *APC* gene. The genetic locus for the *APC* gene has been identified at 5q21.<sup>100</sup> The most common abnormality is an alteration in the genetic sequence resulting in the generation of a stop codon, which in turn results in the production of a truncated nonfunctional protein.<sup>101</sup> This is the basis for a commonly used screening procedure in which the truncated protein is synthesized *in vitro* and is identified. Since the introduction of genetic testing into the medical armamentarium, it is important that patients have access to appropriate genetic counseling and proper interpretation of test results.<sup>102</sup>

### HEREDITARY NONPOLYPOSIS COLON CANCER

The HNPCC syndrome is inherited as an autosomal dominant trait with high penetrance. Its phenotypic features are early-onset colorectal cancer (mean age, 46 years), multiple (synchronous or metachronous) colorectal cancers (35%), and colorectal cancers usually (but not always) located in the proximal colon.<sup>103</sup> There is an associated early onset of adenocarcinoma of the colon, ovary, pancreas, breast, bile duct, endometrium, stomach, genitourinary tract, and small bowel.<sup>104</sup> In addition, sebaceous gland adenomas and carcinomas are seen in the Muir-Torre syndrome, a variant of HNPCC.<sup>105</sup> A high rate of colorectal cancer is seen in first-degree relatives of patients with HNPCC.<sup>106</sup> Approximately 1% to 6% of colorectal cancers fit the criteria for HNPCC.<sup>107</sup>

The phenomenon of microsatellite instability is present in the tumor of patients (90%) with HNPCC and in 12% to 15% of sporadic colorectal cancer cases. The genes responsible for this are *hMSH2*, *hMLH1*, *PMS1*, *PMS2*, and *hMSH6*.<sup>108</sup> Germline mutations in these genetic loci produce the DNA mismatch repair phenomenon, causing the development of colorectal cancer in patients with HNPCC. Though the results of genetic testing depend on criteria used for instituting testing, the overall mutation detection rate appears to be greater than 50% in suspected cases.<sup>109</sup>

HNPCC cancers are more likely to be signet-ring cancers and poorly differentiated, with extensive inflammatory infiltrates.<sup>110,111</sup> There may be a more rapid time course for the development of cancers in this syndrome.<sup>107</sup> The adenomas tend to have a villous component and to be more dysplastic than in sporadic cases.<sup>112</sup> In general, on a stage-for-stage basis, survival for colorectal cancer patients with HNPCC is better than for patients with sporadic cases.<sup>104</sup>

The Amsterdam criteria, developed in 1991, are helpful in identifying and categorizing patients with a familial history of colorectal cancer.<sup>113</sup> The initial Amsterdam criteria—Criteria I—require first that at least three relatives have colorectal cancer. In addition, one of the three relatives must be a first-degree relative of the other two; the colorectal cancer must involve at least two successive generations; at least one family member who developed colorectal cancer must be younger than 50 years; and FAP must be excluded and tumors must be verified by pathologic examination.<sup>113</sup> These criteria may underestimate the true incidence of HNPCC as pedigree analysis is uninformative for some families.<sup>110</sup> Because the initial Amsterdam criteria were established to be specific and to define criteria for HNPCC recognition strictly, families with more subtle histories or extracolonic cancers may be missed. Therefore, newer criteria were established to address these concerns.<sup>112</sup>

---

There should be at least three relatives with an HNPCC-associated cancer (CRC, endometrium, small bowel, ureter, or renal pelvis).  
One affected relative should be a first-degree relative of the other two.  
At least two successive generations should be affected.  
At least one relative should receive diagnosis before age 50 years.  
Familial adenomatous polyposis should be excluded.  
Tumors should be verified by pathologic examination.

---

CRC, colorectal carcinoma; HNPCC, hereditary nonpolyposis colon cancer.

---

**TABLE 33.7-2.** Amsterdam II Criteria

Amsterdam Criteria II (Table 33.7-2) include consideration of extracolonic tumors and eliminate the requirement that one of the index cancers be a colorectal cancer. The HNPCC cancers accepted are colorectal, endometrial, small bowel, ureteral, or renal pelvic. This less exclusionary set of criteria will reduce the number of families in which colorectal cancer is suspected but that fail to receive genetic counseling and mutation analysis. Counseling is critical for appropriate management.<sup>114</sup>

Aaltonen et al.<sup>115</sup> examined the feasibility of screening for HNPCC mutations in patients with colorectal carcinoma. They prospectively screened tumor specimens from patients with colorectal adenocarcinomas for microsatellite instability. DNA from the normal tissues of patients with tumors demonstrating replication errors was screened for germline mutations in the mismatched repair genes *MLH1* and *MSH2*. Sixteen percent of patients with replication errors had detectable germline mutations. All the patients in whom germline mutations were detected had a family history of colorectal cancer or were younger than 50 years. In patients with replication errors, further testing should be carried out for germline mutations in known DNA mismatch repair genes.

Because successful strategies for identifying patients suspected of harboring HNPCC have been terminated, the Bethesda guidelines for testing colorectal tumors for microsatellite instability have been developed (Table 33.7-3). These guidelines are expected to apply to 15% to 20% of colorectal cancer patients in the United States.

---

1. Individuals with cancer in families that meet the Amsterdam Criteria  
2. Individuals with two HNPCC-related cancers, including synchronous and metachronous colorectal cancer or associated extracolonic cancers  
3. Individuals with colorectal cancer and a first-degree relative with colorectal cancer or HNPCC-related extracolonic cancer (or both) or a colorectal adenoma (one of the cancers diagnosed at age <46 y and the adenoma diagnosed at age <40 y)  
4. Individuals with colorectal cancer or endometrial cancer diagnosed at age <45 y  
5. Individuals with right-sided colorectal cancer with an undifferentiated pattern (solid, cribriform) on histopathology in whom diagnosis is made at age <45 y  
6. Individuals with signet-ring type colorectal cancer diagnosed at age <45 y  
7. Individuals with adenomas diagnosed at age <40 y

---

HNPCC, hereditary nonpolyposis colon cancer.

**TABLE 33.7-3.** Bethesda Guidelines for Testing Colorectal Tumors for Microsatellite Instability

### INHERITED COLORECTAL CANCER IN ASHKENAZI JEWS

Israeli Jews of European birth have the highest colorectal cancer incidence of any Israeli ethnic group. There are reports of a missense mutation (I 1307 K) in the *APC*

gene found in 6% of unselected Ashkenazi Jews and 28% of this population who have a family history of colorectal cancer. Colorectal cancer is found in 13% of those with polyps.<sup>116,117</sup> This condition lacks the florid polyposis seen in FAP. These polymorphisms of the *APC* gene create a hypermutable region of the *APC* gene that causes a predisposition to colorectal cancer.<sup>118</sup> There do not appear to be any differences in clinical presentation or family history between carriers of the mutation and noncarriers, so genetic testing in this population may be required to identify high-risk individuals for screening. This mutation appears to be unique to Ashkenazi Jews.<sup>116</sup>

## ATTENUATED FAMILIAL ADENOMATOUS POLYPOSIS SYNDROME

Attenuated FAP syndrome is characterized by the development of flat adenomas that are precursor lesions to carcinoma.<sup>67</sup> Genetic linkage studies identify abnormalities on chromosome 5Q, and this may be a variant of FAP, with the mutation being more proximal or distal in the gene than common mutations with classic FAP. In patients with attenuated FAP syndrome, disease onset is later than usual for FAP, neoplasms appear in the proximal colon, and oligopolyposis is present.<sup>97</sup> Because these characteristics commonly are associated with HNPCC, making the clinical diagnosis is difficult.

### *Peutz-Jeghers Syndrome*

Peutz-Jeghers syndrome is an autosomal dominant inherited condition in which hamartomatous polyps can occur throughout the gastrointestinal (GI) tract. The polyps are nonneoplastic and have a characteristic branching muscular framework. Melanin pigmentation surrounding the lips is associated with this syndrome. There is an estimated frequency of associated GI cancer of 2% to 3%. Although these patients may develop a variety of cancers throughout life, their polyps should be managed symptomatically. Prophylactic colectomy is not recommended. Germline mutations in a chromosome 19 gene have been found in Peutz-Jeghers syndrome families. This gene may act as a tumor suppressor gene.<sup>119</sup> Inactivating mutations in the responsible gene act on a protein kinase.<sup>119</sup>

### *Juvenile Polyposis*

In juvenile polyposis, multiple hamartomatous polyps occur in the colorectum, although they may also be found in the small bowel and stomach. Jass et al.<sup>120</sup> defined this syndrome as the presence of more than five juvenile polyps, which differs from the solitary juvenile polyp seen in children. These investigators found colorectal cancer in 18 of 80 cases.<sup>120</sup> Neoplasia can occur in the index polyps or in a separate adenoma. Colonoscopic control of polyps appears appropriate, whereas colectomy may be used for large numbers of polyps, symptomatic polyps, or cancers.<sup>121</sup>

A subset of patients with juvenile polyposis has been identified to carry germline mutations in the *SMAD4* gene,<sup>122</sup> which causes a defect in growth factor control. The risk of colorectal cancer has been estimated at 38%. There is a 21% risk of upper GI cancers.<sup>123</sup>

## FAMILY HISTORY OF COLON CARCINOMA OR POLYPS

Even among populations that do not exhibit any of the well-characterized familial cancer syndromes, there is an increased risk among those who have first-degree relatives with colorectal cancer. This group accounts for most of the increased risk population (15% to 20% of patients).<sup>125</sup> An autosomal dominant mode of inheritance has been suggested. Depending on the age at onset of the cancer and the number of relatives involved, lifetime risk can increase from 1.8- to 8-fold.<sup>125</sup> It appears that the age-adjusted risk for those with one affected first-degree relative is approximately 1.72 (CI, 1.34 to 2.19).<sup>126</sup> For those with two or more affected first-degree relatives, the risk is 2.75 (CI, 1.34 to 5.63). The age at onset of the colorectal cancer in the affected relative is an important factor: Risk can be increased 5.37-fold (CI, 1.98 to 14.6) in those who have an affected first-degree relative whose colorectal cancer occurred at less than 45 years of age.<sup>127</sup> When the age at onset is 60 years or older, there is little increased risk, beyond that of having an affected first-degree relative.<sup>126</sup> People with first-degree relatives having colorectal cancer have an 8% risk of developing large adenomas, and colonoscopy appears to be the most appropriate screening technique for these lesions.<sup>128</sup>

In the review of data from participants in the National Polyp Study who had a newly diagnosed adenomatous polyp, information was gathered on the history of colorectal cancer in their parents and siblings.<sup>129</sup> The RR of colorectal cancer was 1.78 for parents and siblings of patients with adenomas as compared with controls. The RR for colorectal cancer in siblings of patients in whom adenomas were diagnosed before 60 years of age was 2.59 (CI, 1.46 to 4.58). When this group was compared with the siblings of patients 60 years of age or older at the time of diagnosis, a decrease in the risk for colorectal cancer was associated with an increase in age at the time of diagnosis of the adenoma. First-degree relatives of patients with adenomatous polyps are at increased risk for developing colorectal cancer, particularly when an adenoma is diagnosed before the age of 60 or, in the case of siblings, when a parent has had colorectal cancer. The subsequent familial risk of colon cancer is independent of the size and histologic features of the polyp.

## PREDISPOSING MEDICAL CONDITIONS

### INFLAMMATORY BOWEL DISEASE

There is an increased colorectal cancer risk in patients with inflammatory bowel disease.<sup>131</sup> Specifically, patients with ulcerative colitis demonstrate a high risk of colorectal cancer that is related to the duration and extent of disease and dysplasia.<sup>132</sup> The risk of colorectal cancer in people with ulcerative colitis is estimated to be 5% or 10% at 20 years after diagnosis of ulcerative colitis and 12% to 20% at 30 years.<sup>133</sup> This justifies the intensive surveillance that is carried out in patients with long-standing disease, especially those who demonstrate pancolitis. Synchronous cancers are seen in 10% to 20% of cases.<sup>134</sup>

Genetic alterations associated with inflammatory bowel disease suggest that there are accumulated genetic defects similar to those of sporadic carcinomas.<sup>135</sup> The pattern of progressive genetic abnormalities has been confirmed by analysis of p53 abnormalities found in both active colitis and dysplasia. The RR for patients with proctitis alone is 1.7 (CI, 4.6 to 7.0); patients with left-sided colitis have an RR of 2.8 (CI, 1.6 to 4.4); and a 14.8-fold RR (the highest risk of colorectal cancer) is seen in those suffering from pancolitis (CI, 11.4 to 18.9). The mean age at onset of cancer has been found to be 48 years. The value of assessment of cancer risk based totally on the presence of dysplasia has been questioned.<sup>136</sup> Ulcerative colitis patients operated on for colorectal cancer may not have a preoperative diagnosis of dysplasia. Other researchers have found that screening for high-grade dysplasia is a useful marker of the risk of coexistent cancer mandating colectomy.

### GRANULOMATOUS COLITIS

Crohn's disease can affect the ileocolic area or may be limited to portions of the colon. In the absence of colonic involvement, there is no increased risk of colorectal cancer. The RR for ileocolic involvement was 3.2 and, for colonic involvement, was 5.6. The RR for those with colonic involvement in whom diagnosis was made before age 30 was 20.9.<sup>137</sup> In addition to being at increased risk for large bowel cancer, all patients with Crohn's disease also have an increased risk of small bowel carcinomas.<sup>138</sup> In studies of specimens of intestinal adenocarcinoma complicating Crohn's disease, an early age at onset for adenocarcinomas (49 years) was noted.<sup>138</sup> The carcinomas are associated with the site of the Crohn's disease. Seventy-three percent of the intestinal cancers in patients with Crohn's disease are found in the colon or rectum. Most carcinomas were found to be poorly differentiated. Dysplasia was found adjacent to carcinoma in 87% of the cases. Mucinous adenocarcinomas accounted for one-third of the carcinomas affecting Crohn's disease.<sup>139</sup>

## HISTORY OF COLORECTAL CARCINOMA OR POLYPS

The incidence of metachronous colorectal cancer often is reported to be between 0.5% and 3%.<sup>140</sup> In an analysis that takes into account the number of patients remaining at each time point during follow-up, the incidence at 18 years was 6.3%.<sup>141</sup> In this study of 5476 patients, it was also demonstrated that metachronous colorectal cancers were diagnosed at earlier stages than were index lesions. Metachronous tumors occur four times more often in patients with HNPCC.<sup>142</sup> An Italian study of patients with multiple tumors of the large bowel demonstrated that the interval between first and second malignancies was 8.7 years. The recommendations for colonoscopic follow-up and complete colonic evaluation at the time of colorectal cancer diagnosis are based on these risks.

A personal history of colonic polyps is important in the risk assessment of patients for colon carcinoma. The presence of adenomatous polyps within the colon carries a risk of carcinoma in the index polyp as well as for additional sites within the colon. The risk of carcinoma in the individual polyp is related to the size and the histology of the polyp. Tubular adenomas are less likely to carry a risk of carcinoma as compared with villous polyps. In general, approximately half of the polyps larger than 2 cm will harbor a carcinoma. The greater the number of adenomas, the more likely it is that a cancer will develop. If these multiple polyps harbor

advanced characteristics, the incidence of colon cancer development increases six-fold (OR, 6.6; CI, 3.3 to 11.8).<sup>143</sup>

In studies of patients with colon polyps identified on flexible sigmoidoscopy, it was found that at complete colonoscopy, 20% had advanced lesions such as adenomas greater than 1 cm with a villous component, severe dysplasia, or invasive cancer.<sup>144</sup> The risk of proximal colonic neoplasia was increased with sessile lesions in the distal colorectum.<sup>145</sup> In a multicenter, prospective study of colonoscopic findings in patients with proximal colon cancer, 116 patients were found to have cancer proximal to the splenic flexure, and 34% had neoplasia distal to the splenic flexure.<sup>145</sup> Most average-risk patients with proximal colon cancer will have normal results on flexible sigmoidoscopy.

After the removal of rectal or sigmoid polyps with villous or tubulovillous histology or size greater than 1 cm, the rate of colon cancer incidence was increased threefold over the general population (OR, 3.6; CI, 2.4 to 5.0).<sup>143</sup> The cumulative incidence of colon cancer appears to be approximately 4% at 5 years and 14% at 10 years in patients with an untreated rectosigmoid polyp. Sixty-six percent of these cancers are in the index polyp, and 34% are at other sites.<sup>146</sup> These findings help to demonstrate the effectiveness of polypectomy in preventing colon cancer.<sup>147</sup>

## PELVIC IRRADIATION

The data implicating irradiation as a cause of colorectal cancer are controversial.<sup>148</sup> Such reports imply that patients are followed up for extremely long periods, because the interval between pelvic irradiation and the onset of a radiation therapy–induced GI tract malignancy appears to be 15 to 28 years.<sup>149</sup> The radiation doses and techniques may have an impact on the overall incidence of GI tract cancers induced by pelvic radiation therapy. Second cancers are increased in patients with previous malignancies. The risk of colorectal cancer in this population is small and should not alter plans for curative treatment for pelvic malignancies.

## NONCANCER SURGERY

Some studies suggest that cholecystectomy increases the incidence of colorectal cancer. The etiology for the relationship between cholecystectomy and colorectal carcinoma is controversial.<sup>150</sup> In a study conducted in the United Kingdom, a metaanalysis of 35 studies was conducted.<sup>151</sup> The OR for a positive association between cholecystectomy and colorectal cancer was found to be only 1.11 (95% CI, 1.02 to 1.21). For women, the OR was 1.14 (95% CI, 1.01 to 1.28) and, for right-sided cancers, the ratio was 1.86 (95% CI, 1.31 to 2.65). It appeared from this that any additional risk was quite small. Data from case-control studies have shown an increased risk for proximal colon cancers after cholecystectomy. However, there was no indication that there was an increased risk for distal colorectal cancer.<sup>152</sup> The risk of colorectal cancer after cholecystectomy cannot be separated from the presence of cholelithiasis as a possible marker for dietary changes that affect colorectal cancer risk.<sup>153</sup> The risks associated with ureterosigmoidostomy may be related to the presence of mutagens within the stool or urine. An additional factor is that patients subjected to such operations may have confounding factors such as previous pelvic irradiation.

## SCREENING

Screening involves testing asymptomatic individuals to assess the likelihood that they may have colorectal cancer or precursors. For a screening technique to be practical, it must be a risk-based approach to the assessment of asymptomatic patients. Colorectal cancer lends itself to screening because of the long period between the development of early mucosal abnormalities and the development of invasive carcinoma.<sup>143,144,145</sup> and <sup>146</sup> Adenomatous polyps are the well-described precursor lesions of invasive colorectal cancer and can be effectively managed by endoscopic intervention.<sup>147</sup> In the general population, the risk of development of a colorectal adenoma is approximately 19%, and it is estimated that 2% to 5% of these sporadic polyps will develop into an invasive carcinoma.<sup>154</sup>

Screening tests are available that detect early curable disease and are well-established aspects of medical practice.<sup>155</sup> The screening techniques do not involve excessive risk.<sup>156</sup> The benefits of early diagnosis are improvements in treatment effectiveness and survival.

## SCREENING OF HIGH-RISK GROUPS

### *Familial Adenomatous Polyposis*

Once an average-risk person reaches the fourth decade of life, his or her risk of developing colorectal cancer increases almost 100%. Screening is not an effective management tool. On establishment of a diagnosis of FAP, patients should be considered for colectomy to reduce the risk of colorectal cancer development. In cases in which there is a remaining rectal stump that has been cleared of polyps, the patient should undergo annual screening to assess for polyp development and the need for proctectomy or fulguration of polyps. The usual recommendation is to start annual screening for FAP during early adolescence. If no polyps are found after age 24, the screening schedule can be modified to every 2 years until age 34, then every 3 years until age 44, when screening reverts to that of an average-risk individual. Molecular testing for genetic mutations is appropriate in screening at-risk family members when the mutation is known.

### *Hereditary Nonpolyposis Colon Cancer*

Patients affected by HNPCC have cancers that develop from adenomatous polyps that are commonly proximal to the splenic flexure. The risk of colorectal cancer in HNPCC patients begins to increase by age 20 and is very high by age 45.<sup>157</sup> The risk for colorectal cancer by age 60 is estimated to be 57% to 80%.<sup>158</sup> Colonoscopy is the preferred method of surveillance because it allows complete examination of the colon. Its yields are high in HNPCC because of the high risk of cancer. Metachronous cancers are common in people who have an intact colon after an initial cancer; the annual rate of metachronous colorectal cancer appears to be 2.1% to 1.7%.

There is a concern of rapid *de novo* development of carcinomas from flat lesions that may be inapparent during endoscopy. Therefore, intervals between screening for HNPCC patients should probably be shorter than for average-risk persons. Because of a higher 5-year survival of colorectal cancer in many patients with HNPCC as compared to patients with sporadic colorectal cancer, it may be even more beneficial to screen these patients than average-risk patients. The Cancer Genetic Studies Consortium reviewed the literature on cancer surveillance and risk reduction for individuals with HNPCC and concluded that the efficacy of cancer surveillance in reducing risk in these individuals is unknown. However, on the basis of observational studies, the Consortium recommended colonoscopy every 1 to 3 years starting at age 25 for individuals known to have HNPCC-associated mutations.

Jarvinen et al.<sup>159</sup> described the effects of screening on colorectal cancer rates in families with HNPCC. They evaluated the effectiveness of long-term screening in 22 families with HNPCC. The incidence of colorectal cancer and colorectal cancer mortality between those who were screened at 3-year intervals by colonoscopy or barium enema sigmoidoscopy and those who did not undergo screening were compared. Colorectal cancer occurred in 4.5% of the screened subjects and 11.9% of the unscreened group. No deaths due to colorectal cancer occurred in the screened group, as compared with colorectal cancer death in 5 of the 14 cases in the control group.<sup>159</sup> This provides strong evidence that increased screenings reduce the colorectal cancer death rate in members of families with a history of HNPCC.

Syngal et al.<sup>160</sup> conducted a decision analysis study of the benefits of colonoscopic surveillance and subsequent colectomy on mortality and quality of life for patients with HNPCC mutations. They assessed risk for colorectal cancer in the study to be 31.5% by 40 years, 54.5% by 50 years, 63% by 60 years, and 87.5% by 75 years of age. The cumulative lifetime risk for colorectal cancer was 88.2%. The risk of metachronous colorectal cancer was estimated at 45% in those not undergoing a prophylactic total colectomy. Endoscopic surveillance would reduce lifetime risk by 52%. Mortality from endoscopic surveillance was estimated to be approximately 0.02%. These investigators found a life expectancy benefit of 2.1 years associated with prophylactic colectomy as compared with surveillance.<sup>160</sup> However, when estimates of health-related quality of life were incorporated into the analysis, surveillance became the preferred cancer prevention mode.

In a study using data from the International Collaborative Group on HNPCC, rectal cancers were found to have developed in 11% of patients at a median of 158 months from the time of their abdominal colectomy.<sup>161</sup> Adenomas were found to have developed in the rectal mucosa in five of eight of the patients who developed rectal carcinoma and hence were deemed a marker of risk. The risk of developing rectal cancer was estimated to be 3% for every 3 years after abdominal colectomy for the first 12 years of follow-up. The authors recommended endoscopic surveillance of the rectum after abdominal colectomy. Lin et al. (1998) estimated that rectal cancer was more common in *MSH2* kindreds.

### *Family History of Colorectal Cancer or Adenomatous Polyps*

Specialty organizations recommend that people with first-degree relatives who have had colorectal cancer or adenomatous polyps should be screened on a schedule similar to that for average-risk persons but beginning at age 40 instead of 50.<sup>157</sup> Individuals who have a relative with early-onset disease should begin surveillance 3 to 10 years prior to the age of onset in the index individual. Owing to the overlap between patients who have been affected by an HNPCC mutation and an otherwise genetically undefined familial colorectal cancer risk, it is prudent to consider complete examination of the colon in these patients as opposed to flexible sigmoidoscopy.<sup>162</sup>

### **Personal History of Colorectal Cancer or Adenomatous Polyps**

Patients who have had a previous colorectal cancer are at increased risk for polyp formation and development of second primary cancers. It is recommended that patients in whom a colorectal cancer has been resected undergo complete examination of the colon within 1 year after resection. This surveillance schedule is similar to that recommended for patients with a previous polypectomy. If the results of this examination are otherwise normal, then the patient can undergo evaluation in 3 years, with subsequent examinations dependent on the findings at that initial examination. Any subsequent cancers often are preceded by polyps, in the same adenoma-to-carcinoma sequence seen in sporadic colorectal cancer. Because of the effectiveness of polypectomy, the follow-up procedure should be colonoscopy.<sup>162</sup>

Patients who have undergone previous removal of an adenomatous polyp should undergo colonoscopy during follow-up. The rate of metachronous adenoma formation is 3.3% over 3 years.<sup>147</sup> The Polyp Prevention Study did not demonstrate any increase in risk of developing advanced polyps when subsequent screening was deferred for 3 years.<sup>163</sup> No direct evidence supports a recommendation for the cessation of screening.<sup>164</sup>

### **Inflammatory Bowel Disease**

Because the rate of colorectal cancer development in patients with inflammatory bowel disease is related to dysplasia and duration and extent of disease, surveillance colonoscopy is an important consideration in the management of these patients.<sup>165</sup> Colonoscopic surveillance should begin annually after 8 years of disease in patients with pancolitis or after 15 years of disease in those with colitis involving the left side of the colon.<sup>166</sup> Random biopsy should be performed to detect dysplasia, which is a marker for the presence of colorectal cancer.<sup>167</sup> However, there is no direct evidence that this practice is more effective than colectomy performed on the basis of extent and duration of disease.

## **SCREENING OF AVERAGE-RISK GROUPS: THE GENERAL POPULATION**

Subjects who are healthy and have an average risk of colon cancer represent the largest population appropriate for screening. There is a relatively high risk of colorectal cancer in the United States, and the screening can be targeted to older individuals in whom colorectal cancer is much more common. For average-risk groups, the screening techniques consist primarily of digital rectal examination, fecal occult blood testing, and endoscopic examination. It is hoped that less invasive but sensitive tests such as virtual colonoscopy may be useful in screening in the future.<sup>168</sup>

Any discussion of screening techniques must be analyzed in terms of the effectiveness and cost of such programs for asymptomatic individuals. These considerations and evolving clinical practice have generated recommendations that asymptomatic patients with no family history of colorectal cancer begin screening at 50 years of age with digital rectal examination and fecal occult blood assessment annually and flexible sigmoidoscopy every 5 years.<sup>157</sup> Alternative approaches may be total colonoscopy every 10 years or a double-contrast barium enema every 5 to 10 years.<sup>169</sup>

### **Digital Rectal Examination**

The digital rectal examination is part of the routine physical examination. Approximately 5% to 10% of colorectal cancers may be palpable.

### **Fecal Occult Blood Testing**

Fecal occult blood testing relies on the presence of blood in the stool to indicate a neoplastic lesion in the large bowel. Testing for the presence of fecal occult blood using guaiac-impregnated paper slides is a relatively low-cost examination that is based on the ability of heme to catalyze a reaction involving the oxidation of guaiac in the presence of hydrogen peroxide, which produces a blue stain.<sup>170</sup> Other techniques rely on the detection of hemoglobin by its conversion to porphyrin or the detection of human hemoglobin by immunochemical approaches.

The advantages of this test are ease, low cost, and low risk to the patient. The use of this test has been criticized, however, for its relatively low ability to predict the presence or absence of disease, leading to missed lesions (owing to poor sensitivity) and unnecessary invasive workups in patients without colorectal neoplasia. Nonetheless, studies have demonstrated a decline in mortality from colorectal cancer in patients screened annually with fecal occult blood testing as compared with control groups. This improvement is attributable to the fact that cancers detected by fecal occult blood testing were at an earlier stage of disease at diagnosis, resulting in a decrease in the proportion of patients who had metastatic disease at the time of cancer discovery. These findings support the use of this method of cancer screening.<sup>171</sup>

Not all rectal cancers bleed and not all blood in the GI tract is due to cancer. Some cancers may bleed intermittently. False negative fecal occult blood test results have been reported in 20% to 30% of patients with known colorectal cancers.<sup>172</sup> The ability to detect polyps in the colon and rectum by testing for fecal occult blood is even less successful.<sup>172</sup> Yearly testing for fecal occult blood has been recommended, because randomized trials show that yearly testing is more effective than testing every 2 years.

Fecal occult blood testing provides only a suspicion of colorectal cancer or polyps. The consequences of a positive test are that the patient requires a complete colon examination, usually in the form of a barium enema and sigmoidoscopy or colonoscopy.<sup>173</sup> The costs and effectiveness of fecal occult blood testing as a screening modality must be evaluated in the context of these additional tests resulting from a positive examination. Elements of an ordinary diet, including red meat and certain vegetables that may have peroxidase activity, can cause false-positive reactions in guaiac-based tests. The use of salicylates and vitamin C can cause either false-positive or false-negative examinations, respectively.<sup>174</sup> Because of these factors, the best results for fecal occult blood testing in screening for colorectal cancer are from studies that use rehydrated tests on two samples from each of three consecutive stools in individuals who were adhering to a restricted diet and who were abstaining from compounds that could alter test results. Fecal occult blood testing is limited by the fact that the testing is aimed mainly at detecting cancer, owing to the low incidence of bleeding in small adenomatous polyps. An additional drawback of such testing is that the false-positive rate commits large groups of patients to undergoing the cost and inconvenience of testing with colonoscopy or barium enema when no colorectal pathologic process is present.<sup>175</sup>

In a randomized trial of 46,551 asymptomatic people between the ages of 50 and 80 years, fecal occult blood testing was studied. Patients were evaluated with colonoscopy after fecal occult blood tests proved positive. The 13-year cumulative mortality rate per 1000 from colorectal cancer was 5.88% in the annually screened group, 8.33% in the biannually screened group, and 8.83% in the control group.<sup>86</sup> A randomized, controlled trial was performed in England with patients aged 45 to 74 years who were offered either fecal occult blood testing every 2 years or routine medical management. Again, colonoscopy was used to evaluate positive tests, which resulted in a 15% reduction in mortality in the screened group.<sup>172</sup> Some practitioners have expressed concern that the improvement in mortality seen in these studies could be related to chance selection for colonoscopy and its effects.<sup>176</sup>

### **Flexible Sigmoidoscopy**

Flexible sigmoidoscopy can be used to evaluate the region from the anal verge to approximately 60 cm of the distal large intestine. This can allow detection of up to one-half to two-thirds of colorectal adenomas and cancers.<sup>177</sup> Because distal adenomas and cancers are an indicator of more proximal neoplasia, a patient with findings of neoplastic polyp on flexible sigmoidoscopy should undergo complete colonic examination.

Flexible sigmoidoscopy screening programs can be expected to detect neoplasms in the distal colon and rectum in up to 8% of asymptomatic persons older than 40 years. Reductions in sigmoid and rectal cancer risk with rigid proctosigmoidoscopy of 70% were seen in a case-control study.<sup>178,179</sup> It has been proposed that once-only sigmoidoscopy would be a cost-effective method of screening and subsequently assigning patients to low- or high-risk groups.<sup>180</sup> Its use is a recommended

part of screening for low- and average-risk patients older than 50 years in the United States. <sup>157</sup>

## DIAGNOSIS

### WORKUP OF A SYMPTOMATIC PATIENT

The diagnosis of colorectal cancer can be made either by the workup of a symptomatic patient or by discovery of cancer by screening in an asymptomatic patient. Most Americans are not currently screened for colorectal cancer. In a survey of the general population, it was found that only approximately 17.3% of people aged 50 years or older had undergone fecal occult blood testing in the previous year and that only 9.4% had undergone sigmoidoscopy in the previous 3 years. The majority of patients will be found to have colorectal cancer on investigation of symptoms or signs.

Patients who present with symptoms are not appropriate candidates for a screening examination (i.e., less than a total colonic examination). Those in whom symptoms are compatible with the diagnosis of colorectal cancer, such as those with rectal bleeding, iron-deficiency anemia, obstruction, or alteration in bowel habits, should undergo total colonic examination. Colonoscopy will allow biopsy of colonic masses as well as removal of polyps; however, a mass in the colon should not be managed conservatively, even in the case of an equivocal biopsy. Those individuals with obstructive tumors should undergo examination of the whole colon as soon as is practical after management of the obstructing tumor.

A wide variety of abdominal symptoms and signs are consistent with colorectal cancer. These include rectal bleeding, discovery of occult blood in the stool, abdominal pain, change in bowel habits, nausea, vomiting, distention, weight loss, fatigue, and anemia. Rectal bleeding is more commonly associated with rectal cancer than colon cancer. Because it can be such an obvious symptom, patients who develop rectal bleeding come to medical attention sooner than those who do not have obvious rectal bleeding. Patients who present with rectal bleeding must not be managed for hemorrhoids without workup, even though many more patients will have benign causes for rectal bleeding as compared to the number who will have rectal carcinoma.

Abdominal pain in colorectal cancer may be caused by partial obstruction, which is commonly a cramping type of pain. A more diffuse type of abdominal pain may occur with the development of perforations, leading to signs of generalized peritonitis. Other pain syndromes that may be present in colorectal carcinoma can develop from involvement of the pelvic floor by rectal cancer–caused tenesmus. Locally advanced rectal cancer may be associated with involvement of the sciatic nerve or obturator nerve, producing a neuropathic pain syndrome.

Partial or complete obstruction may occur in 2% to 16% of newly diagnosed cases of rectal cancer. The presence of obstruction has been found to reduce the 5-year survival rate to 31%, as compared with 72% for patients without obstruction. <sup>181</sup>

Malignancy of the colon can result in a free perforation with peritonitis or a contained perforation and fistula formation. Approximately half of perforations caused by colorectal cancer are into the free abdominal cavity. Contained perforation with involvement of adjacent organs is most commonly seen in cecal or sigmoid carcinomas. Either type of carcinoma may involve loops of small bowel, bladder, abdominal wall, or the retroperitoneum. When there is such involvement in the setting of a sigmoid colon carcinoma, the condition may mimic diverticulitis. Diagnosis in these circumstances can be difficult. It is justifiable to pursue surgery in such patients to clarify the diagnosis as well as to treat. Radiologic signs indicating diverticulitis include the presence or absence of intramural fistulas and the degree of mucosal abnormality. Tumor perforation can occur either at the site of a primary tumor or in the cecum when it is dilated because of obstruction. Perforation is a bad prognostic factor, not only because it heralds an increased risk of cancer spread but also because of the mortality associated with peritonitis.

In the 10% to 15% of patients who present with metastatic disease, signs and symptoms are usually present. Pain in the right upper quadrant, especially when accompanied by palpable hepatomegaly or a mass, often will indicate the presence of liver metastases. This finding should prompt investigation with imaging as well as endoscopy. Fever without an overt cause may also be a manifestation of metastatic disease. Patients with diffuse liver involvement or carcinomatosis may manifest ascites with signs of abdominal distention or symptoms of early satiety or bowel obstruction. Development of umbilical nodules may occur as a sign of intraperitoneal disease. In patients with advanced colorectal cancer, supraclavicular adenopathy may be present. Inguinal adenopathy may develop in patients with an advanced low rectal carcinoma.

## PATHOLOGIC FEATURES

### Gross Appearance

Size alone is not a reliable predictor of outcome from colorectal cancer because of the predominance of biologic behavior in predicting outcome. A 1-cm, clinically detectable colorectal neoplasm may contain 30 or more successive generations of malignant cells prior to detection. Colorectal cancers can be exophytic or fungating, or tumors may be ulcerated. In general, ulcerated tumors predominate. Annular tumors produce obstructive symptoms and have the classic appearance of an apple-core lesion on barium enema. Tumors of the right colon often are fungating masses that grow into the lumen and for which the symptom is occult bleeding as opposed to obstruction; they often present with a palpable mass. Left-sided tumors tend to be more annular and cause obstructive symptoms.

Residual adenomas can often be found in addition to invasive cancer. Assessment of the colon specimen for synchronous lesions is important. In 3% to 5% of primary colorectal cancers, a synchronous carcinoma will be found. The number and type of neoplastic lesions, polyps, or invasive carcinomas in a colorectal specimen are important in identifying associated inherited colorectal cancer syndromes.

### Histologic Types

Adenocarcinoma represents 90% to 95% of all colorectal tumors. Tumors can be further classified by grade and histologic subtypes ( [Table 33.7-4](#) ).

---

Mucinous adenocarcinoma  
Signet-ring adenocarcinoma  
Adenosquamous carcinoma  
Squamous carcinoma  
Small cell carcinoma  
Choriocarcinoma  
Medullary carcinoma

---

**TABLE 33.7-4.** World Health Organization Classification of Malignant Primary Tumors of the Large Intestine: Histopathologic Variants of Colorectal Carcinoma

The vast majority of colorectal cancers are moderately differentiated, gland-forming adenocarcinomas. Less common variants are classified on the basis of the predominance of an unusual pattern as compared with the usual adenocarcinoma of the colon. Mucinous or colloid carcinomas exhibit the majority of tumor in mucin pools, which are often of low cellularity. <sup>182</sup> Signet-ring tumors display a large amount of intracellular mucus pushing the nucleus to the side of the cell. These often are associated with diffuse intramural spread beyond the obvious mucosal lesion. In poorly differentiated cancers, features of neuroendocrine differentiation may appear.

Approximately 4% to 17% of carcinoid tumors appear in the rectum, and 2% to 7% are found in the colon. <sup>183</sup> They often present as submucosal masses with normal colonic mucosa overlying lesions. Sarcomas may account for 0.1% to 0.3% of all colorectal malignancies. These are chiefly leiomyosarcomas.

**DEGREE OF DIFFERENTIATION.** Broders (1925) designated four grades of differentiation based on the percentage of differentiated tumor cells found in the overall tumor

specimen. The degree of differentiation for colonic adenocarcinoma commonly refers to the degree to which there are well-formed glands. There is a spectrum of histopathologic findings used to assess differentiation in typical cancers of the colon and rectum. Glands may range from large and dilated to small and compact. Gland formation is usually associated with tumors that are well or moderately differentiated. At the other extreme of differentiation, glandular architecture may form sheets of infiltrating individual cells, which characterize a poorly differentiated tumor.

Dukes' (1932) grading system was based on cytologic characteristics as well as glandular formation and nuclear polymorphism. The system ranges from stage A through stage D, the latter stage being the most poorly differentiated, with only occasional gland formation and markedly pleomorphic cells marked by a high incidence of mitoses. Jass et al. (1986) provided a system of classifying differentiation based on histologic type, overall differentiation, nuclear polarity, tubal configuration, pattern of growth, lymphocytic infiltration, and amount of desmoplastic reaction. Other aspects of the histopathologic evaluation of a colorectal tumor include assessments for vascular or lymphatic invasion. Extramural venous invasion is considered an indicator of worsening prognosis. Invasion of perineural spaces can be identified.

The degree of fibrosis present in tumors will vary widely. The pattern of infiltration at the edge of tumors can be pushing, expansile, or infiltrative. The host inflammatory response at the periphery of tumors can be composed of lymphocytes, neutrophils, mast cells, and macrophages. Angiogenesis may be noted at a tumor's periphery.

The inclusion of lymphoid nodules and germinal centers at the periphery of infiltrating carcinomas is termed a *Crohn's-like lymphoid reaction*. This is sometimes considered to be associated with HNPCC or with a high incidence of microsatellite instability.<sup>184</sup> Many of these adjunctive characteristics of the histopathologic assessment of a tumor are subject to considerable intraobserver and interobserver variability in reporting.

**DEGREE OF LOCAL INVASION.** Invasion into the submucosa is the hallmark of the development of the potential for metastatic spread and is the key histopathologic characteristic of colorectal cancer. It is best assessed by histopathologic assessment. In colon carcinoma, the mesentery and serosal surfaces are at greatest risk for violation by tumor penetration. In rectal cancer, perirectal fat and adjacent organs are most commonly involved by direct invasion through the bowel wall. Gross assessment of local extent can be misleading in some cases due to desmoplastic response, the effect of neoadjuvant therapies, or infection surrounding tumor perforation. Locally recurrent tumors are characterized by the predominance of the tumor mass in or around the bowel wall or an anastomotic site rather than in the mucosa itself.

### **Lymph Node Pathology**

Gross pathologic evaluation of lymph nodes in colorectal cancer specimens is unreliable. Large nodes may show only lymphoid hyperplasia, whereas smaller nodes may harbor micrometastases detectable only by histologic examination, immunohistochemistry, or molecular techniques. This factor is important in understanding the inaccuracy of imaging techniques that typically rely on the size of lymph nodes as criteria for determining nodal involvement with tumor.

The number of lymph nodes found directly influences the accuracy and frequency of findings of Dukes' grade C cases.<sup>185</sup> By using more intensive methods of lymph node assessment such as fat clearance, fewer false-negative lymph node stagings occur.<sup>186</sup>

Goldstein et al.<sup>187</sup> showed an increase in the percentage of patients with at least one lymph node metastasis when 12 to 20 lymph nodes were recovered from each specimen, as compared with specimens in which fewer lymph nodes were found. Wong et al.<sup>188</sup> found, in a sample of patients statistically similar to a sample in the National Cancer Database Report, that examination of at least 14 T2 or T3 carcinoma colorectal cancer specimens was required to stage patients accurately.

### **Molecular Detection of Micrometastases**

Owing to the effective use of adjuvant therapies for node-positive colorectal cancer, there is a theoretic advantage to the use of a more intensive method of detecting cancer cells in the lymph nodes of resected specimens. This improved detection is necessary of the approximately 20% rate of distant metastases in patients with resected stage II colon carcinoma who could theoretically benefit from systemic adjuvant chemotherapy. An increase in the detection of micrometastases has been demonstrated with fat-clearing techniques, serial sectioning, and immunohistochemistry, detection of epithelial antigens, and molecular screening with polymerase chain reaction–based (PCR-based) methods to detect tumor-specific RNA.<sup>189</sup> The detection of micrometastases in regional lymph nodes by PCR technique has been demonstrated to have prognostic value in stage II colon carcinoma.<sup>189</sup> Though the potential for the use of these techniques is great, currently gross pathology and histopathology are the mainstays of pathologic staging of colorectal carcinoma.

## **SPREAD OF COLORECTAL CANCER**

The capability of a tumor to invade and metastasize is not only the most visible hallmark of cancer but also the leading cause of death in cancer patients. Colorectal cancers can spread locally or distantly via the lymphatic and venous systems. In addition to unregulated tumor growth, imbalances in regulation of motility and proteolysis are required for those events to occur.<sup>190</sup> We owe much of our current knowledge in this area to the pioneering work of Dukes et al. in the early 1930s involving careful analyses of rectal cancer cases. Although Dukes's work helped to explain the natural history of colorectal cancer and this information remains largely current, it hypothesized a very rigid pattern of spread. Dukes believed that lymph node invasion and distant metastasis could occur only after the tumor had extended through the bowel wall. Although years earlier, Miles had described metastasis with earlier-stage primaries, Dukes considered these rare events. Dukes hypothesis could not explain why a large number of patients with complete surgical resection eventually die of tumor recurrence.

### **LOCAL SPREAD**

Percival Cole, in 1913, was the first to report that colorectal cancers usually grow preferentially in the transverse direction rather than in the horizontal direction. After reviewing 20 rectal cancer specimens, he made the important observation that the long axis of the ulcerating tumor was always transverse, with the lesion tending to involve the bowel circularly rather than longitudinally. Therefore, the tumors tended to narrow and constrict the bowel wall. Contrary to the previously held belief, Cole theorized that recurrences were due to extramural deposits of tumor cells that were not removed by local excision and not to persistence of tumor along the bowel wall. Several authors corroborated Cole's findings.

One notable exception to this common pattern of circumferential growth is seen in tumors showing perineural invasion. Tumor cells may reach as far as 10 cm from the primary tumor when spreading through the perineural spaces, and local recurrences are 2.5 times more frequent in patients who present with perineural invasion than in patients who do not. This preferential mural growth, the importance of which was recognized early, may result in local failure and peritoneal seeding. Staging systems from the initial work by Dukes to the tumor, node, metastasis (TNM) system used today have included degree of mural invasion as one of the most important prognostic factors.

### **LYMPHATIC EXTENSION**

As early as 1925, Miles described cases of early rectal cancers presenting with lymph node involvement. Although Dukes initially incorrectly considered these events to be rare, he and Bussey (1958) demonstrated the direct relationship of the extent of local spread to the incidence of lymphatic metastasis. Grinnell (1964) was able to demonstrate that tumor limited to the submucosa and muscularis propria metastasized to lymph nodes in 13% of patients. More recent studies have corroborated these findings, with a 10% to 20% incidence of lymph node metastasis for tumors limited to the bowel wall.<sup>191</sup>

In 1935, Gabriel et al. analyzed 62 specimens with lymphatic metastasis and described the orderly and predictable course of lymphatic spread in rectal cancer. One-half of the patients studied had three fewer glands involved, and half had four or more. Dukes hypothesized that if the spread from gland to gland had been rapid, patients would either have no lymph node involvement or multiple glands at the time of diagnoses. Hence, he concluded that the lymphatic spread was a slow process. The first glands to be involved were situated in the perirectal tissues at the level of the primary tumor or immediately above it, followed by the chain along the superior hemorrhoidal vessels. In an advanced case, the involved lymph nodes extended to the ligature of the inferior mesentery vessels. The same orderly progression was demonstrated by Gilchrist and David.<sup>192</sup>

Exceptions to this orderly spread are possible and have been well-documented by Gabriel et al. (1935). Atypical presentations could be due to spread through aberrant lymphatic routes, which were described as early as 1925. Several authors have documented the existence of these discontinuous or skip metastases. Wood

and Wilkie (1933) found them in 6 of 51 specimens, Gabriel et al. (1935) in 1 of 62, and Grinnell (1939) in 4 of 118 specimens.

A second exception to the usual mode of lymphatic spread is seen when the lymphatics are blocked by tumor. When this occurs, the natural interconnection of lymphatic channels allows lymph nodes at a great distance from the relevant chain to be affected. Lymphatic obstructions are responsible for the retrograde extension of tumor below the primary lesion.<sup>193</sup> In a review of 913 specimens from patients with colorectal cancer, Grinnell (1966) found 34 (3.7%) to have this type of spread. In colon carcinoma, the lymphatic flow follows the major arteries, with three levels of lymph nodes: pericolic, intermediate, and principal. Tumors located between more than one major vessel may metastasize in any direction.

Dukes divided 985 rectal cancers into four different categories depending on the tumor grade. Stage A tumors were very well differentiated, whereas stage D tumors were anaplastic. There was a close correlation between the tumor grade and the incidence of local spread, lymph node involvement, and venous spread. The same correlation between tumor grade and lymphatic involvement has been demonstrated by other researchers.

With the advent of advanced staging techniques such as sentinel node biopsy and molecular analysis of lymph nodes, the existence of discontinuous or skip metastases needs to be taken into consideration when planning changes in current surgical techniques.

## HEMATOGENOUS SPREAD

Despite our continuous efforts toward early detection, approximately 10% to 15% of colorectal cancer patients have evidence of distant metastasis at the time of the initial diagnosis. The liver is by far the most commonly involved organ. The colon is drained by the portal venous system. The rectum is drained by two different systems: The superior hemorrhoidal veins enter the portal system to the liver, whereas the middle and inferior hemorrhoidal veins drain to the inferior vena cava and spread to the lungs via the systemic circulation. This dual venous drainage system has important implications in the pattern of hematogenous spread. Brown and Warren<sup>194</sup> retrospectively analyzed the results of 70 autopsies in patients with rectal cancer. They identified 23 patients (33%) with metastasis to the liver only and 6 patients (9%) with metastasis to the lung only. Metastasis to other sites without liver or lung involvement were rare, seen in only three patients (4%). The patients with lung metastasis only were found to have lower primary lesions. In a larger study involving 506 patients, Dionne (1965) described rectal cancer patients with upper rectal lesions and lung metastasis only. However, because metastasis was determined in routine clinical examinations, liver metastasis may have been missed in those patients.

Brown and Warren reported that 14% of the patients they analyzed had vertebral involvement. In his larger series, Dionne (1965) described 6% of the patients with spread to the pelvis and lumbosacral spine. Even though some (or even most) of those lesions were the result of direct extension or were present in patients with widespread metastases, at least some patients have isolated metastases to the spine. Although the vertebral venous plexus is a high-pressure system, it may open during special circumstances, such as defecation. This would allow tumor cells to invade vertebral bones and the central nervous system using communications between the portal system and the paravertebral veins.

## IMPLANTATION

*Implantation* refers to the capability of cancer cells to deposit and grow on another surface after being released from the primary tumor. Most normal human cells, regardless of their origin, are in constant contact with an extracellular matrix and cannot survive for long when away from it, undergoing apoptosis or cell-cycle arrest.<sup>195</sup> However, cancer cells have been known to be able to survive without interaction with an extracellular matrix. The ability of cancer cells to detach from the primary tumor and either to penetrate into the circulation or to implant in a different surface away from their original extracellular matrix is most likely related to changes in the cell adhesion molecules.<sup>195</sup>

Implantation may occur when cancer cells are shed intraluminally, from the serosal surface, and by surgical manipulation.<sup>196</sup> Umpleby and Williamson (1987) determined the viability of tumor cells shed into the intestinal lumen in 49 patients. Viable exfoliated tumor cells were demonstrated in 52 of 74 specimens collected (70%).<sup>197</sup> The number of viable tumor cells recovered from the distal resection margin was inversely related to the distance of the tumor from that margin, confirming earlier observations made by McGrew et al. (1954). Zeng et al.<sup>196</sup> prospectively scraped the serosa overlying the primary tumor mass in 65 patients who underwent surgery for colon cancer. Malignant cells were present in the cytologic analysis of 23% of all patients and 26% of those with tumors invading through the muscularis propria but not through serosa. After reviewing clinical, reoperation, and autopsy series, Brodsky and Cohen<sup>198</sup> determined the incidence of peritoneal seeding followed by peritoneal failure to be fairly frequent among patients who experience recurrence of colorectal cancer. The risk of colorectal cancer spread caused by surgical manipulation is well recognized, and the improvement of surgical technique has been considered a way of preventing recurrences since the early decades of the twentieth century.

## STAGING AND PROGNOSTIC FEATURES

The most reliable prognostic factor identified to date in colorectal cancer is the staging of disease at the time that treatment is initiated.<sup>199</sup> The staging of colorectal cancer has been an evolving field since the beginning of the twentieth century, with multiple authors attempting to develop a reliable and reproducible system. The first widely used system was introduced by Dukes in the 1930s and, like the majority of staging systems developed to date, relied on information obtained during surgery. Imaging techniques used preoperatively have not been successful in reliably staging colorectal cancer.<sup>200</sup> Both conventional computed tomography (CT) scanning and conventional magnetic resonance imaging have an unacceptably low accuracy for identifying the early stages of primary colorectal cancers.<sup>200</sup> The low staging accuracy of these imaging techniques is related to the fact that neither method can assess the depth of tumor infiltration within the bowel wall, and both have difficulty in diagnosing lymph node involvement. For colorectal cancer patients evaluated with CT scans or magnetic resonance imaging, the overall accuracy of primary tumor staging is approximately 70%, with sensitivity for lymph node detection of only approximately 45%. The sensitivity for positive lymph nodes is higher for rectal tumors.<sup>200</sup> The development of new imaging techniques such as positron emission tomography (PET)<sup>201</sup> and endoscopic ultrasonography<sup>202,203</sup> may enhance the usefulness of imaging studies in the staging of colorectal cancer. These imaging techniques would be especially important in rectal cancer, wherein preoperative treatment with chemotherapy and radiation therapy is a viable therapeutic option.<sup>204</sup>

Besides the pathologic staging determined by depth of penetration through the bowel wall and involvement of lymph nodes, distant organs, or both, several other potential independent factors for survival have been identified. The number of factors reported to have an impact on the overall survival of patients with colorectal cancer continues to grow, but the prognostic value of few of these factors has been confirmed in larger trials. The presence of obstruction or perforation,<sup>205</sup> vascular or lymphatic invasion (or both), perineural invasion,<sup>206</sup> peritumoral lymphocytic invasion,<sup>207</sup> the character of invasive margin and tumor type,<sup>208</sup> presence and number of mast cells,<sup>209</sup> age and gender, tumor grade,<sup>210</sup> DNA content,<sup>211</sup> increased mitosis and low *Bcl-2* expression, low apoptosis rate,<sup>212</sup> vascular endothelial growth factor (VEGF) levels, and allelic loss of chromosome 18q<sup>213,214</sup> are among the growing number of prognostic factors used in the analysis of colorectal cancer. The rapidly evolving field of molecular biology holds the promise of accurate staging and, it is hoped, individualized prognosis and treatment tailoring in the not-so-distant future.

## DUKES' CLASSIFICATION

At the beginning of the twentieth century, surgery became routine for the treatment of colorectal cancers, including those arising in the colon and rectum. Almost immediately, the need arose for a staging system that allowed for comparisons among different surgical experiences and for determination of prognosis. A number of authors have tackled this challenge, with varying results. Based partially on earlier experiences, Dukes<sup>315</sup> developed the first practical system in the early 1930s. The initial Dukes' system was directed to rectal cancers and was remarkable for its simplicity and ability to give adequate prognostic information. The tumors were classified from A to C, with stage A indicating penetration restricted to the bowel wall, stage B indicating penetration through the bowel wall, and stage C indicating lymph node involvement. Over the years, several authors have attempted to make improvements on the initial work by Dukes, and the system has been extended to include both colon and rectal cancers. Dukes himself made a few changes in his system, first dividing stage C into C1 (local lymph nodes involved) and C2 (lymph nodes at the point of ligature involved) and later adding a fourth stage for distant metastasis, which was denoted as stage D by subsequent authors.

Kirklin et al. (1949) divided Dukes' stage A into a more restricted stage A (mucosa and submucosa involvement only) and a new B1, which involved the muscularis propria (but not penetration through it). The old stage B became B2. One problem seen with the earlier version of the Dukes' system was its inability to separate the depth of wall penetration and the involvement of lymph nodes. The revision by Astler and Collier in 1954 changed that feature, introducing the concept of stages C1 and C2, which are used commonly today. Gunderson and Sosin further modified the Astler-Collier system, subdividing the patients based on the presence of microscopic (B2m or C2m) and gross penetration (B2m + g, and C2m + g) through the bowel wall.

One of the problems not addressed by any of the commonly used variations of the Dukes' system is its inability to classify patients further based on the extent of their lymph node involvement. After the initial revision by Gabriel and Dukes in 1935 in which the location of the affected lymph nodes was considered, the issue was left unaddressed. The ideal number of lymph nodes that should be evaluated before the specimen can be considered negative for lymph node involvement remains controversial. It is well-known that up to 70% of affected lymph nodes in colorectal cancer are less than 5 mm in diameter, making them easy to overlook.<sup>215,216</sup> In 1994, Hernanz et al.<sup>185</sup> analyzed 193 specimens and suggested that at least six nodes had to be identified before the specimen could be called negative. Wong et al.<sup>217</sup> recently readdressed the same question and, after analyzing 196 cases, concluded that at least 14 nodes should be evaluated in each specimen. The advent of improved pathologic techniques and sensitive methods such as PCR may have an impact on the number of positive lymph nodes detected.<sup>186</sup> However, the prognostic value of these positive lymph nodes, which otherwise would not be detected, is still undetermined.

The National Surgical Adjuvant Breast and Bowel Program (NSABP) carried out an analysis of the prognostic variables in 844 patients with Dukes' stage C lesions.<sup>218</sup> The level of positive nodes provided little information over and above that provided by the two most important prognostic factors, depth of tumor penetration and the number of positive nodes. The subset of patients with one to four positive nodes fared remarkably better than did patients with larger numbers of involved nodes, and the number of positive nodes appeared to be the single most important prognostic factor.<sup>218</sup> The newer classifications of colorectal cancer have incorporated the number of involved lymph nodes as an important prognostic factor.

The size of the primary tumor in colorectal cancer, contrary to most solid tumors, does not seem to influence prognosis. A review of 391 patients treated surgically at the University of Texas M. D. Anderson Cancer Center from 1955 to 1975 demonstrated that the mean diameter of Dukes' stage B2 tumors was actually greater than the mean diameter of stage C2 tumors ( $P < .001$ ) and D tumors ( $P < .05$ ). The size of the primary tumor showed no relationship to 5-year adjusted survival. These results were confirmed by the NSABP experience.

Even though the modified Dukes' staging still is commonly used worldwide, the number of applied variations makes correlation of different studies less than ideal. Therefore, use of the TNM staging has been encouraged. This system is compatible with and is gradually replacing the Dukes' system.

## THE JASS SYSTEM

The traditional Dukes system was primarily anatomic; the influence of the tumor grade and other pathologic features remained largely ignored. After analyzing 447 patients treated surgically for rectal cancer, Jass et al. (1986) were able to assess a number of histopathologic factors using the Cox regression model. The important variables included lymphocytic infiltration, tubule configuration, and pattern of growth. Subsequently, the authors compared the grade-related parameters with the established stage-related parameters. The best prognostic model included the number of affected lymph nodes, the presence of lymphocytic infiltration, and extent of spread through the bowel wall. The model was tested on a second data set comprising 331 patients, and similar results were derived. The authors concluded that their classification was simple to use and was superior to staging by the method of Dukes. The NSABP compared the Jass classification with the traditional Dukes system and validated its results.<sup>219</sup> However, the criteria used in the Jass prognostic system for colorectal cancer have been found to be less than optimal in routine practice and are not readily reproducible.<sup>220</sup>

Others have also questioned the superiority of the Jass system over the conventional Dukes' system. In a retrospective study of 312 colorectal carcinomas, Deans' et al.<sup>221</sup> found the Dukes classification to be of greater prognostic value and more reproducible than the components of Jass's classification. The simplicity and reproducibility of the new TNM staging system has discouraged further use of the Jass system by the major clinical groups.

## TUMOR, NODE, METASTASIS (TNM) CLASSIFICATION

Despite its initial shortcomings, the TNM classification is the preferred system for colorectal cancer patients ( [Table 33.7-5](#)). Starting in the late 1970s, both the American Joint Committee on Cancer (AJCC) and the Union Internationale Contre le Cancer (UICC) made attempts to unify the staging system for colorectal cancer with a simple classification similar to the TNM system used for most solid tumors. However, the initial TNM classifications were complicated and failed to provide adequate prognostic information for the different stages. The survival for patients with stage II disease was the same as or worse than that for patients with stage III cancer.<sup>222,223</sup> and <sup>224</sup> One of the main problems with those initial classifications was the fact that the number of positive lymph nodes was ignored.

Stage	Tumor (T)	Lymph Nodes (N)	Metastasis (M)
0	Tis	N0	M0
I	T1	N0	M0
	T2	N0	M0
II	T3	N0	M0
	T4	N0	M0
III	Any T	N1	M0
	Any T	N2	M0
IV	Any T	Any N	M1

**TABLE 33.7-5.** Tumor, Node, Metastasis Stage Grouping

Eventually, the AJCC and the UICC unified their TNM systems, creating a simpler system with greater prognostic value. The 1988 and 1994 revised systems included the number of affected lymph nodes as an important variable, and the newest system was found to have greater prognostic accuracy.

The rules for classification of colorectal cancer are relatively simple.<sup>225</sup> Colorectal cancers are commonly staged after surgical exploration and pathologic evaluation of the resected specimen. Tumors invading the stalk of polyps are classified according to the same definitions adopted for colorectal cancers. Carcinoma *in situ* (Tis) includes cancers confined to the glandular basement membrane or lamina propria. T1 tumors invade the submucosa, T2 tumors invade the muscularis propria, and T3 tumors invade through the muscularis propria into the subserosa or into nonperitonealized pericolic or perirectal tissue. T4 tumors invade other organs or structures or perforate the visceral peritoneum. Tumors invading other colorectal segments by way of the serosa (i.e., carcinoma of the cecum invading the sigmoid) are classified as T4.<sup>225</sup> Recurrent tumors at the site of surgery are assigned to the proximal segment of the anastomosis.<sup>225</sup>

The new TNM classification calls for at least 12 lymph nodes to be analyzed. N0 denotes that all nodes are negative. N1 includes tumors with metastasis in one to three regional lymph nodes. N2 indicates metastasis in four or more regional lymph nodes. Metastatic nodules or foci found in the pericolic, perirectal, or adjacent mesentery without evidence of residual lymph node tissue are equivalent to regional node metastasis. Involvement of the external iliac or common iliac lymph nodes is classified as metastatic disease (M1).<sup>225</sup> The concept of distant metastasis is virtually self-explanatory.

The TNM system also classifies a tumor based on its histologic grade, including four levels from well-differentiated to undifferentiated, and should not be used for sarcomas, lymphomas, and carcinoids arising in the colorectum. Additional independent prognostic factors worthy of attention include the histologic type, carcinoembryonic antigen (CEA) level, and vascular invasion.<sup>225</sup> The authors strongly recommend that the TNM staging system be used routinely ( [Table 33.7-6](#)).

PRIMARY TUMOR (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Carcinoma in situ (intraepithelial or invasion of lamina propria)*
T2	Tumor invades submucosa
T3	Tumor invades muscularis propria
T4	Tumor invades through muscularis propria into subserosa, or into mesoperitonealized peritoneal or perirectal spaces
T4a	Tumor directly invades other organs or structures, and/or perforates visceral peritoneum†
REGIONAL LYMPH NODES (N)	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in 1 to 3 regional lymph nodes
N2	Metastasis in 4 or more regional lymph nodes
DISTANT METASTASES (M)	
Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

\*In situ lesions consist of cells confined within the glandular mucosa or submucosa (intraepithelial) or lamina propria (intramucosal), with no extension through the muscularis mucosae into the submucosa.  
†Direct invasion by T4 includes invasion of other organs or structures of the colon/rectum by way of the serosa (e.g., invasion of the adjacent colon by a carcinoma of the cecum).

## ADDITIONAL PROGNOSTIC FEATURES

### Clinical Features

**AGE.** Although colorectal cancer is a disease that occurs predominantly in older adults, it also affects a significant number of younger patients. Starting with the 1958 article by Hoerner, several investigators have reported more aggressive tumor behavior and a worse overall survival rate for patients with colorectal cancer whose disease was diagnosed before the patient had reached the age of 40. Several explanations for this finding have been explored, including the notion that younger patients are more prone to delayed diagnoses. They seem to have a higher frequency of high-grade tumors, and their disease is more commonly diagnosed at an advanced stage. Recio and Bussey (1965) noted an increased percentage of mucinous tumors in younger patients. In their study, high-grade tumors accounted for 53% of all tumors in the young group and only 20% in the older group. The most common histologic pattern in young patients is an aggressive, mucin-producing adenocarcinoma,<sup>226</sup> particularly in patients younger than 20 years old. When comparing patients with colorectal cancer who were younger than 40 years with older patients, Behbehani et al. (1985) found both a higher incidence of poorly differentiated tumors (21% vs. 8%, respectively) and a more advanced stage at presentation in the young patients. The survival rate for young patients was 23% versus 61%, respectively, for the general population. Stage III patients had a survival rate of 56% in the general population, as compared with 34% in young adults. Data compiled by the Commission on Cancer Data from the National Cancer Database from hospital cancer registries across the United States showed that the very elderly tended to present with an earlier stage of disease than younger patients.<sup>227</sup> Others have supported the notion that young patients tend to present with more advanced disease,<sup>228</sup> reflecting a more aggressive tumor or a delay in diagnosis; however, most analyses have failed to show a significant difference in prognosis when stage-adjusted survival is analyzed.

The prognosis for elderly patients with colorectal cancer is less well studied. Patients older than 80 years submitted for curative surgery have similar operative mortality when compared with patients in their fifties to seventies.<sup>229</sup> data supplied by cancer registries in 17 countries in Europe on patients in whom colorectal cancer was diagnosed between 1978 and 1989 showed a possible decreased survival rate with increasing age.<sup>230</sup> Additional data on the prognosis for very elderly patients affected by colorectal cancer is greatly needed in view of the expected rapid growth of this segment of society.

**GENDER.** Several older analyses have shown a survival advantage for women (as compared to men) with colorectal cancer. Among known associations with reduced colorectal cancer risk, women appear to ingest more dietary fiber, to benefit more from physical activity and body mass, and to consume less alcohol. Hormonal characteristics may also affect a woman's risk of developing colorectal cancer.<sup>231</sup> However, others have failed to demonstrate a significant difference in prognosis based on gender alone.<sup>232,233</sup>

An inverse association has been detected between the number of pregnancies and the risk of colon cancer.<sup>234</sup> Parity appears to exert its predominant effect on risk of cancer of the right colon.<sup>235</sup> The use of oral contraceptives has also been linked to lower risk of colon and rectal cancer.<sup>236</sup> However, some investigators have recently questioned the true effect of reproductive events or oral contraceptives. Interestingly, parity could have no effect on the absolute risk of colorectal cancer but appears to have led to a decrease in proximal and an increase in distal colon cancer. Increasingly, the use of estrogen replacement therapy in postmenopausal women has been linked with a decrease in risk of subsequent colorectal cancer.<sup>237</sup> The confirmation of this finding would have far-reaching implications in public health.

Although the risk of colon cancer is similar in men and women, women frequently have the perception that colorectal cancer is a male disease and so they underestimate their true risk.<sup>238</sup> Partially in consequence, women are less likely than men to undergo screening studies.<sup>239</sup> This represents a true public health problem.

**SYMPTOMS.** As the natural history of colorectal cancer becomes better understood,<sup>240</sup> we are compelled to believe that the length of time required for the development and growth of colorectal cancer allows a window of opportunity for early detection and an increase in cures for colorectal cancer.<sup>241</sup> Indeed, screening efforts have been proven to reduce mortality from colorectal cancer.<sup>242</sup> Cancers detected by routine screening are less likely to have spread to lymph nodes or adjacent organs and, consequently, are less likely to be symptomatic. Beahrs and Sanfelippo (1971) reported that the 5-year survival for symptomatic colorectal cancer patients was 49%, as compared with 71% for asymptomatic patients, confirming that patients who present with symptoms from their tumors are more likely to have advanced disease and less likely to have a favorable outcome.

The duration of symptoms has not been conclusively proven as a prognostic factor. Contrary to what could be expected, several large studies have failed to demonstrate a direct relation between the duration of symptoms prior to diagnosis and pathologic stage at the time of surgery for colorectal cancer.<sup>243</sup> Patients in whom disease is diagnosed and treated prior to the development of any symptoms do tend to have early-stage colorectal cancer and improved survival.<sup>243</sup> However, patients with a short symptomatic history of colon cancer do not have a better prognosis than patients with a long history.<sup>437</sup> Pescatori et al.<sup>436</sup> found that, in a relatively small study, those patients with symptoms lasting more than 6 months actually had a significantly lower postoperative mortality and a higher 5-year survival rate than patients with symptoms lasting for less than 6 months. Copeland et al.,<sup>438</sup> in a much larger trial (1084 patients), reported a slightly worse 5-year survival rate for patients with symptoms lasting longer than 6 months. The available data support the notion that patients in whom colorectal cancer is diagnosed prior to the development of any symptoms tend to have a better prognosis than do symptomatic patients. The duration of symptoms does not seem to yield any significant prognostic value.<sup>372</sup>

**OBSTRUCTION AND PERFORATION.** Carcinoma of the colon that is complicated by obstruction or perforation has been recognized as having a poorer prognosis.<sup>205</sup> Data obtained from 1021 patients with Dukes stage B and C colorectal cancer who were entered into randomized clinical trials of the NSABP showed that the presence of bowel obstruction strongly influenced the prognostic outcome. The effect of bowel obstruction was more pronounced when the obstruction was located in the right colon. The larger-sized tumor needed to block the ascending colon completely might allow a longer time for these tumors to grow and spread when compared with tumors located in the descending colon.

A review of the Massachusetts General Hospital records compared patients presenting with obstruction or perforation with a control group undergoing curative resection. The actuarial 5-year survival rate seen in patients presenting with obstruction was 31%, in contrast to 59% in control patients. For patients with localized perforation, the 5-year actuarial survival rate was 44%.

According to a study involving 709 patients who underwent resection for colorectal carcinoma, stage was the strongest prognostic variable. However, obstruction had an independent effect in the same multivariate analysis. The Gastrointestinal Tumor Study Group (GITSG) multivariate analysis concluded that obstruction was an important indicator of prognosis, independent of Dukes stage. Bowel perforation was a poor prognostic factor only for disease-free survival.

**HEMORRHAGE OR RECTAL BLEEDING.** Cancers characterized by erosion are believed to manifest earlier than those characterized by invasion. Therefore, tumors presenting with bleeding are thought to be found earlier and to be associated with a better prognosis. This belief has not been confirmed in other studies. In the GITSG multivariate analysis, the presence of melena or rectal bleeding showed a trend as a prognostic factor for prolonged survival but failed to reach statistical significance ( $P = .08$ ). Chapuis et al. (1985) demonstrated by univariate analysis in a large study conducted in Australia that the presence of rectal bleeding predicted

longer survival; however, the significance of this symptom disappeared on multivariate analysis.

**PRIMARY TUMOR LOCATION.** Multiple analyses have shown that cancers arising at or below the peritoneal reflection (rectosigmoid and rectum) have a worse 5-year survival rate than those arising above the reflection.<sup>232</sup> With regard to colon primary tumors, different authors have reached different conclusions. Some, including Wolmark et al. (1967, 1983) in a large retrospective review of data from the NSABP, reported that lesions in the right side carry a worse prognosis. Poorer prognosis for patients with disease in the left colon has been reported. Several investigators report no difference based on the location of the primary tumor. The large GITSG colon cancer experience showed that tumor location (left, right, and rectosigmoid or sigmoid) was of low prognostic value.

**PRIMARY TUMOR SIZE.** In contrast to most solid tumors, the size of the primary tumor is not considered in the staging of colorectal cancer, reflecting the unusual nature of these cancers. Even though some authors have shown improved survival with smaller tumors, most studies have failed to demonstrate a significant prognostic value for the size of the primary tumor at the time of diagnosis.<sup>191</sup> Data collected by the NSABP also underscore the lack of a relation between tumor size and lymph node metastasis. Indeed, an M. D. Anderson Cancer Center review demonstrated that patients with Dukes B2 tumors frequently had larger primary lesions than did patients with Dukes stage C and D tumors.

**PRIMARY TUMOR CONFIGURATION.** When compared with ulcerating tumors, exophytic tumors tend to penetrate the bowel wall less frequently (24% vs. 39%, respectively) and have less frequent nodal metastases and fewer hematogenous metastases (23% vs. 31%, respectively). Analysis of a GITSG colon adjuvant study revealed that the presence of an exophytic lesion had a beneficial effect on survival when compared with ulcerating lesions.

**BLOOD TRANSFUSION.** Considerable controversy has surrounded the association of perioperative blood transfusions and the recurrence rate of colorectal cancer.<sup>244</sup> Some investigators have reported worse disease-free survival in patients who require transfusions.<sup>245</sup> The reason for this outcome would be a transfusion-related form of immunosuppression.<sup>246</sup> However, when differences in confounding background variables are accounted for, the significance of transfusion seems less evident,<sup>247</sup> and several authors believe it to have no direct relation to prognosis.<sup>248</sup> By multivariate analysis in a prospective study, no negative influence of transfusion on survival could be detected.<sup>249</sup>

A retrospective analysis evaluating 1051 patients treated with curative surgery for stage II or III colorectal adenocarcinoma at the Mayo Clinic demonstrated that the use of blood components probably had no impact on disease recurrence, and the documented adverse impact of transfusions is more likely due to other variables or to the underlying illness necessitating the transfusion.<sup>250</sup> This was confirmed in a study in which patients were randomized to receive, when needed, perioperative transfusions with either allogeneic or autologous blood.<sup>251</sup> There were no differences in disease-free survival between the two groups. Disease-free and cancer-specific survivals were increased in the group that donated but did not receive any transfusions, as opposed to those who received the transfusions, suggesting that the conditions that necessitate transfusion may be more important than the transfusion itself.<sup>251</sup>

### **Pathologic Features**

**VASCULAR ENDOTHELIAL GROWTH FACTOR.** VEGF is an important factor in the angiogenic process. Several studies have demonstrated a correlation between the expression of VEGF and vessel count in the tumor specimen, and a combination of vessel count and expression of VEGF may be useful for predicting distant recurrence in patients with node-negative colon cancer.<sup>252</sup> VEGF is being evaluated as a possible prognostic marker and also is currently an important new target for novel therapeutic agents in the treatment of cancer.<sup>253</sup>

**LYMPH NODE MICROMETASTASIS.** Lymph node status has long been recognized as one of the best prognostic markers in patients with colorectal cancer. To minimize false-negative results, a minimum number of lymph nodes should be evaluated, though there is no clear consensus on the ideal number. The TNM classification calls for at least 12 nodes to be examined,<sup>225</sup> whereas a recent review suggested that 14 nodes may be a better target.<sup>217</sup> New techniques directed at increasing the number of lymph nodes available for analysis are being developed, including new staining procedures<sup>254</sup> and sentinel lymph node mapping.<sup>255</sup> Unfortunately, despite all efforts, a significant number of patients with grossly negative lymph nodes eventually experience disease recurrence, and many of those patients who experience recurrence are believed to have had microscopic involvement of their lymph nodes.

Determining the actual lymph node status of patients who received potentially curative surgery would be a valuable tool in the treatment of colorectal cancer. This is especially true for those patients with stage II disease in whom the need for adjuvant therapy remains an intensely debated topic. Several different techniques are being explored, including immunohistochemistry,<sup>256</sup> radioimmunologically guided surgery,<sup>257</sup> and histochemical detection of micrometastatic deposits in bone marrow aspirates.<sup>258</sup> An area of intensive research is the use of reverse transcriptase–PCR (RT-PCR) targeting different primers in blood, bone marrow, and lymph nodes. Primers used thus far with varying degrees of success have included matrilysin (matrix metalloproteinase 7), cytokeratin, and guanylyl cyclase C.<sup>259,260 and 261</sup>

Perhaps no other primer has been sought and studied as much as CEA.<sup>262</sup> Mori et al.<sup>263</sup> performed both histologic and molecular examination of CEA-specific RT-PCR in 406 lymph nodes obtained from 65 patients with breast or GI carcinomas. Patients were followed prospectively for 2 years, and the positive detection rate increased from 20% by histologic examination to 60% by RT-PCR. The recurrence rate was 40% in 15 cases showing positive results in the histologic and molecular examinations, 14% in 29 cases showing histologically negative but RT-PCR-positive results, and 0% in 21 cases showing negative results in both examinations. The positive detection rate in peripheral blood samples increased with advancing stage of disease. With respect to 62 cases in which curative surgery was performed, CEA was detected in 12 cases. In 4 of these 12 cases, metastatic disease developed after surgery, whereas, at the time of the study's publication, metastasis had failed to develop in any of 50 cases that were negative by RT-PCR.<sup>263</sup> Novel potential targets for diagnostic PCR and RT-PCR are constantly being sought.

**ADJACENT ORGAN INVOLVEMENT.** Involvement of adjacent organs has long been considered an important adverse prognostic factor. Furthermore, the surgical removal of the affected organ did not seem to alter overall survival for such patients. The prognostic value of adjacent organ invasion seems to be more pronounced in node-negative patients, and the type and duration of presenting symptoms had no effect on the survival in a series reported by Eldar et al.<sup>264</sup> The presence of pathologically confirmed organ invasion had a significant impact on overall survival when compared with clinical involvement only in a series of colon cancer patients reported by Minsky et al.<sup>199</sup> The 5-year survival for stage B3 patients with pathologic involvement was only 27% versus 88% for the others. Interestingly, the same authors failed to demonstrate this difference in patients with stage B3 tumors of the rectum.<sup>191</sup>

**RADIAL (LATERAL) MARGINS.** Whether the proximal and distal margins are involved in colorectal cancer has traditionally been emphasized in pathologic reports. However, the fact that penetration of the primary tumor carries significant prognostic value should be carefully considered. Quirke et al.<sup>265</sup> reported an 85% incidence of local failure in patients with rectal cancer and positive lateral margins, versus only 3% in the patients with completely negative margins. Some reports have found up to an impressive 33% positive lateral margins in patients with negative proximal and distal margins.<sup>266</sup> A large review of 325 patients who underwent curative surgery for rectal or rectosigmoid cancer demonstrated 29% local recurrence for patients with positive radial margins versus 8% local recurrence for those with negative radial margins.<sup>267</sup> Radial margins seem to be particularly important in rectal cancer, and the concept of total mesorectal excision explores the idea that clean lateral margins improve local control.

**DEGREE OF DIFFERENTIATION (GRADE).** The degree of tumor differentiation, also known as *tumor grading*, has long been suspected to be a prognostic factor in colorectal cancer. Several recent metaanalyses and multivariate analyses confirm the importance of tumor grading as an independent prognostic factor for survival.<sup>205</sup> Grade has been associated with several other prognostic factors, and most patients with poorly differentiated tumors will have multiple poor prognostic factors. Interestingly, patients with lower-grade tumors at the initial diagnosis may be more likely to undergo a second curative surgery for recurrences than patients whose original tumors were of a higher grade.<sup>268</sup>

**COLLOID (MUCINOUS) CANCER.** Colonic mucins are high-molecular-weight glycoproteins produced by goblet cells of colonic epithelium. Some studies have indicated that colon cancers that produce high amounts of mucin have a poorer prognosis and are frequently diagnosed at advanced stages<sup>269</sup> and in younger patients.<sup>270</sup> In animal models, mucin-producing cancer cells form tumors larger than those of low-mucin variants and seem to have increased metastatic potential.<sup>271</sup> In humans, mucinous tumors are associated with a clear, gelatinous fluid, present either within or outside the cancer cells. The variant in which the mucin remains inside the cell is commonly referred to as signet-ring carcinoma. This rare variant of colorectal cancer accounts for only 1% to 2% of all colorectal cancers but is well-known for its aggressiveness.<sup>271a</sup>

Initial reports emphasized the fact that signet-ring carcinoma is capable of growing and spreading intramurally, sparing the mucosa and forming a linitis plastica appearance. This presentation is uncommon and is seen in fewer than 20% of the signet-ring carcinoma cases but has important implications for diagnosis, as the

cancer may not be easily detected on a routine colonoscopy. Despite a few reports indicating otherwise, most authors report a worse prognosis for signet-ring carcinomas than for common adenocarcinomas and even the conventional mucinous carcinoma. The 5-year overall survival rate is poor and varies from 0% to 36%, with most series falling toward the lower value.<sup>271a</sup> Signet-ring carcinoma patients tend to have a higher rate of peritoneal seeding, and several series have demonstrated that peritoneal carcinomatosis is more frequently seen than liver metastasis.<sup>271a</sup>

The extracellular variant, commonly termed *mucinous carcinoma*, is considerably more common. In a series of 352 patients with colorectal cancer, Secco et al.<sup>272</sup> identified 39 cases (11%). The same incidence had been reported previously.<sup>273</sup> Mucinous carcinomas seem to have a predilection for the rectum and the sigmoid colon.<sup>272</sup> Several series have indicated that the prognosis for mucinous carcinoma is intermediate between that for signet-ring carcinoma and the prognosis for regular adenocarcinoma.<sup>272</sup> Some authors have argued that the worse outcome for these patients is due to the more advanced stage at presentation.<sup>269</sup>

Recent reports showing a reduced incidence of the K-ras mutation in patients with signet-ring and poorly differentiated carcinomas in relation to ordinary colorectal carcinoma suggest that these types of carcinomas may have a different genetic background than well- or moderately differentiated colorectal carcinoma.<sup>274</sup> Mucinous carcinomas seems to exhibit less apoptotic activity than does regular colorectal cancer (19% vs. 51%, respectively;  $P = .01$ ).<sup>275</sup>

**CELL-CYCLE PARAMETERS AND PLOIDY.** Aneuploidy is an abnormal balance of chromosomes, and recent evidence seems to indicate that it may cause genetic instability, leading to the karyotypic and phenotypic heterogeneity commonly seen in cancer cells.<sup>276</sup> Even though the results of DNA analysis of colorectal adenocarcinomas varies greatly depending on study methodology,<sup>277</sup> aneuploidy is commonly observed in colorectal cancer cells, especially in advanced stages.<sup>211</sup> In a series of 51 cases analyzed by Sacconi et al.,<sup>211</sup> normal mucosa adjacent to aneuploid tumors showed only a 7% incidence of aneuploidy, whereas the mucosa adjacent to diploid cancers demonstrated only diploid characteristics.

Despite the controversies, there is enough evidence to suggest that a greater proportion of the higher-stage tumors are aneuploid and that aneuploid tumors tend to have a higher growth rate and poorer survival than diploid tumors.<sup>278</sup> When various prognostic factors are analyzed, aneuploid tumors are associated with factors that are indicative of a poor prognosis.<sup>278</sup> The prognostic value of the tumor's ploidy is especially important in stage II patients. In a small study by Nori et al. (1995), the DNA content of colon cancers in 20 stage II patients with evidence of disease relapse was measured and compared with 20 stage II patients in whom there was no evidence of relapse. Aneuploidy occurred in 16 patients (80%) with recurrence, as compared to only 8 patients (40%) in the control group. Aneuploidy was associated with significantly higher tumor recurrence rate ( $P = .024$ ) and a shorter overall survival ( $P < .002$ ). These results are consistent with an earlier North Central Cancer Treatment Group (NCCTG) analysis of 694 patients with stage II or III colorectal cancer enrolled in some of their adjuvant trials. Patients with diploid tumors had a higher survival rate than did those with aneuploid tumors ( $P < .001$ ). The proliferation index (the sum of the percentage of cells in S phase plus those in G<sub>2</sub>/M phase) was also a strong prognostic factor ( $P < .001$ ). When the ploidy and proliferation data were combined, the patients in the favorable group had a 5-year survival rate of 74%, as compared with 54% for the unfavorable group ( $P < .001$ ).<sup>279</sup> Despite some negative reports,<sup>280,281</sup> most series and multivariate analyses have confirmed that the DNA content is an important independent prognostic factor for survival in colorectal cancer.<sup>279,280,282,283 and 284</sup>

**BLOOD VESSEL INVASION.** Vascular invasion can be divided into blood vessel and lymphatic invasion. *Blood vessel invasion* generally refers to venous invasion, as arterial invasion is considered a rare phenomenon. *Intramural* blood vessel invasion refers to the involvement of vessels located within the bowel wall, whereas *extramural* invasion refers to the involvement of vessels located outside the bowel wall. The incidence of blood vessel invasion in colorectal cancer varies from as low as 17% to as high as 81%, depending on the series reported and on whether special elastic tissue stains were used.<sup>285</sup> The prognostic value of the presence of blood vessel invasion for overall survival remains controversial. Whereas some researchers have found it to be an independent prognostic factor,<sup>286</sup> others have not been able to confirm this finding.<sup>285</sup>

Minsky et al. (1988) have evaluated the prognostic value of blood vessel invasion independently in colon and in rectal cancers. Analysis of 294 patients who had curative surgery for colon cancer showed that blood vessel involvement resulted in a significant decrease in the 5-year actuarial survival rate. However, when examined by proportional hazards analysis, blood vessel invasion was not an independent prognostic variable. The same group retrospectively reviewed 168 patients who had curative surgery for rectal cancer. A significant decrease in 5-year actuarial survival was seen in patients with extramural blood vessel involvement as compared with patients who had tumors with intramural or no blood vessel involvement. When the intramural and extramural types of involvement were combined, no significant impact was noted on the patterns of failure or survival.<sup>287</sup>

Krasna et al.<sup>288</sup> and Inoue et al. have used elastic tissue stains and evaluated the prognostic value of blood vessel invasion independently from lymphatic vessel involvement. In the first series, metastases were seen in 60% of patients with vascular invasion as opposed to 17% of those with no vascular invasion ( $P < .0001$ ). Survival in these patients was 29.7% and 62.2%, respectively ( $P < .003$ ). In the second series, a higher incidence of vascular invasion was seen in patients who died of cancer within 2 years of surgery. These differences were not evident with the use of routine hematoxylin and eosin staining.

**LYMPHATIC VESSEL INVASION.** In contrast to blood vessel invasion, the presence of lymphatic vessel involvement has been almost uniformly reported as a poor prognostic factor. Minsky et al.<sup>289</sup> retrospectively reviewed 61 patients with colorectal carcinoma who were found to have lymphatic vessel invasion and compared them with 401 patients who had tumors without such invasion. In patients with lymphatic vessel invasion, the incidence of positive lymph nodes was 59% as opposed to 25% for the control group ( $P = .0004$ ). The 5-year survival rate also was statistically lower for the patients with lymphatic vessel invasion. Proportional hazards analysis confirmed that lymphatic vessel invasion is an independent prognostic factor for survival.<sup>289</sup> Other authors have reached a similar conclusion in their own reviews, suggesting that the presence of lymphatic vessel invasion should be considered a useful prognostic factor for survival in colorectal cancer.<sup>290</sup>

**PERINEURAL INVASION.** The ability of colorectal cancers to invade perineural spaces as far as 10 cm from the primary tumor was first reported in 1943 by Seefeld and Bargen. This was also the first work in which the presence of perineural invasion was demonstrated to be associated with increased disease recurrences and worse 5-year survival. This conclusion has been confirmed by others. Krasna et al.<sup>288</sup> reported a 73% incidence of metastasis in patients with perineural invasion, as compared with 27% in those without such invasion ( $P < .01$ ) and a 30% survival rate versus 58%, respectively ( $P < .003$ ). Several other authors have confirmed that perineural invasion can be considered an independent prognostic factor for survival,<sup>206</sup> whereas Bouvet et al.<sup>291</sup> failed to demonstrate that perineural invasion is a significant prognostic factor for recurrence in treated rectal cancer. Investigators from the M. D. Anderson Cancer Center found by univariate analysis (but not by multivariate analysis) that the presence of perineural invasion was a significant prognostic factor for time to cancer recurrence.<sup>252</sup>

**CARCINOEMBRYONIC ANTIGEN.** Since it was first described in 1965, CEA has become the most reliable tumor marker for use in the detection of colorectal cancer. It is recommended as a monitoring tool for patients who have been treated with curative intent. Further, it is a poor prognostic factor for cancer recurrence in patients in whom the CEA level is elevated preoperatively and who failed to normalize after a potentially curative operation.<sup>54</sup> The prognostic potential of the preoperative CEA level remains unclear, and even the value above which the CEA is considered significantly elevated has varied from as low as 2.5 ng/dL to as high as 10 ng/mL, depending on the series reported.

Since the 1970s, several authors have presented evidence indicating that CEA is an independent prognostic factor.<sup>292</sup> In one of the largest reports, Harrison et al.<sup>293</sup> reviewed 572 patients who underwent curative resection for node-negative colon cancer at the Memorial Sloan-Kettering Cancer Center. The preoperative CEA level and the stage of disease predicted survival by both univariate and multivariate analysis.
