Internal fixation methods are familiar to orthopedists who treat nonpathologic fractures. Techniques can be classified according to their use of load-bearing devices (plates and screws) or load-sharing devices (intramedullary rods). A good indication for plate and screw fixation in metaphyseal fractures is densely sclerotic bone, for which intramedullary fixation or the insertion of a prosthetic device with a long intramedullary stem would be very difficult. One drawback of plate and screw fixation is that the entire bone is not stabilized in the same procedure. This leaves the patient susceptible to a future fracture proximal or distal to the fixation. Plating techniques also are more prone to failure than are intramedullary fixation methods. Dijkstra,<sup>75</sup> citing a series of 167 fractures, reported that plate fixation is associated with an 11% failure rate within 7 weeks and a 40% cumulative 5-year failure rate. However, intramedullary fixation of metaphyseal fractures often is impractical because of inadequate control of the epiphyseal fracture fragment by the device.

Prosthetic replacement of metaphyseal lesions can be very difficult. Generally, the bone in the surrounding apophyseal areas should be saved because it helps to retain soft tissue attachments. Examples of these areas are the greater and lesser trochanters of the hip and the greater and lesser tuberosities of the humerus. Securing these attachments to a hemiarthroplasty device in a dependable fashion is difficult. When necessary, supplemental fixation methods with mesh, tension bands, wires, or cable systems can be used, but the constructs are usually unsatisfactory and result in persistent muscle weakness and pain. In addition, it is difficult to assess bone alignment and length accurately when treating metaphyseal fractures with prosthetic replacement. In these instances, the significant bone loss resulting from the metastatic lesion that indicates prosthetic replacement also eliminates or distorts the typical bony landmarks needed to orient the reconstruction. Problems with limb length inequality, joint instability, and limb weakness typically follow such surgical attempts.

**DIAPHYSEAL FRACTURES.** Diaphyseal lesions are treated successfully by intramedullary fixation. The method requires the establishment of excellent fixation proximal and distal to the fracture. This often is possible even when there is total destruction of the affected area. Fixation is achieved by combining interlock screw fixation with cementing of the bony defect. Flexion and bending strength are well restored with intramedullary rods.<sup>76</sup> Compression strength depends on the magnitude and extent of the bone deficiency. Methyl methacrylate cement used to fill bone gaps restores strength in compression. Torsional strength and stiffness are restored poorly by intramedullary devices; therefore, successful use of such devices requires the limitation of torsional forces and the use of appropriate interlocking technique and cement to control the proximal and distal bone fragments.<sup>77,78</sup> If such control is lacking, plate fixation should be considered.

When diaphyseal lesions are combined with a metaphyseal tumor deposit, prosthetic replacement with a long-stemmed device removes the metaphyseal disease and stabilizes the diaphyseal shaft fracture with strong intramedullary fixation.<sup>78,80</sup> The secondary tumor deposit should be treated, in most instances, even if this necessitates opening of the fracture site. Closed intramedullary fracture treatment should be reserved only for those fractures that will heal with stabilization and supplemental radiation or in patients with rapidly advancing preterminal disease in whom the fixation alone will outlast the patient's projected survival. Long-term success of the technique requires good apposition of bone fragments and removal of local tumor so that healing occurs.

**OTHER MANAGEMENT OPTIONS.** Although most surgeons and patients choose internal fixation or prosthetic replacement as the most effective treatment of pathologic fractures, other management options are available. These include external fixation, cast or brace immobilization, and amputation.

External fixation and cast or brace immobilization can be considered in patients (1) with extensive localized disease that cannot be immobilized by internal means; (2) who are preterminal and in whom analgesic modalities such as narcotics or rhizotomy can control symptoms; or (3) in whom infection, nadir sepsis, pneumonia, or other temporary medical problems prevent surgery. These measures can be used in the hospital and translate well to outpatient, home, or hospice care situations.

Amputation continues to play a role in the management of metastatic cancer, with complications of disease and therapy triggering the need for amputation.<sup>81,82</sup> The indications for amputation fall into three categories: (1) extremity lesions that cannot be reconstructed or are inappropriately reconstructed; (2) complications of the tumor or treatment, such as a fungating infected lesion; and (3) intractable pain.

Acrometastases (metastases that occur in the distal extremity) present at variable times during the progression of metastatic disease. They are rare, occurring in 0.007% to 0.3% of patients with osseous metastasis, and usually represent a preterminal event. Lung, renal, and esophageal cancer accounted for 48% of the primary lesions causing the 31 cases of acrometastases reviewed by Healey et al.<sup>83</sup> In this review, seven of the cases were the first presentation of cancer, and another seven cases constituted the first presentation of metastatic disease.

Amputation is quite suitable for a distal extremity lesion, particularly in the foot. Depending on the primary diagnosis, amputation may provide an opportunity for extended disease control of early or solitary metastases. Because rehabilitation of distal sites can be difficult and time-consuming, amputation presents the best way to relieve symptoms and resume function.<sup>83,84</sup> More proximal amputations are considered in the lower extremity, particularly when complex reconstruction would be required. The aggressive treatment methods developed for limb salvage in primary bone tumors are an inappropriate use of time and resources in skeletal metastases. Intractable pain is sometimes an indication for amputation, but rhizotomy and chordotomy can accomplish the same goal while retaining the extremity.

Recent interest has been demonstrated in a technique that uses radiographically guided percutaneous injection of polymethyl methacrylate into certain metastatic bony lesions. The basic goal of this technique is to address mechanical symptoms by improving the mechanical stability, particularly in compression, of bones involved by lytic lesions. In vertebroplasty, under radiographic guidance, liquid methyl methacrylate is injected directly into vertebral body lesions. One of the major complications of the injection technique is the extravasation of cement from within the contained bony space, with impingement on adjacent structures. This is particularly important in the spine, where spinal cord compression by cement can cause catastrophic neurologic compromise and requires immediate surgical decompression.<sup>85,86</sup> With use of this technique for pelvic lesions, reported complications include intraarticular extension of cement into the hip joint and extravasation around the sciatic nerve.<sup>87</sup> One of the contraindications of the technique is associated fracture, which allows for extravasation of the injected cement outside the bone. Because of the complications associated with percutaneous injection of polymethyl methacrylate, it is important to coordinate the procedure to allow for emergent surgical backup to address acute extravasation issues.<sup>85</sup>

### **Tumor Excision**

The metastatic tumor deposit should be excised under most fracture circumstances and in selected instances of bone biopsy, treatment of impending fracture, and solitary bone metastasis. Treatment options consist of intralesional excision, wide excision, or excision plus a surgical adjuvant.

Intralesional therapy occurs either at the time of biopsy or as a planned intervention. Once the biopsy confirms metastatic disease, a decision must be made as to whether to remove all gross disease, debulking the tumor, or to rely on external irradiation and systemic therapy for local control of the lesion. It is helpful if the members of the oncology team discuss the treatment options before beginning a course of therapy. Judgment, sensitivity, and skill are needed to integrate the biopsy process with overall tumor management and to prepare the patient and his or her family appropriately before surgery. Combining biopsy with tumor removal and bone stabilization best meets the goals of diagnosis, pain relief, and functional restoration. This is particularly important because biopsy further disrupts the already weakened bone.

Intralesional curettage of tumor in and around the fracture site is the principal strategy in addressing metastatic lesions involving bone. Eliminating gross tumor achieves an immediate "partial response" that could take weeks to be achieved by other methods, improving local tumor control. Furthermore, the remaining structural bone is identified. The resultant defect can be filled much more effectively with methyl methacrylate cement, giving better long-term stability to the fractured bone.<sup>88</sup>

Extralesional excision can be accomplished by either marginal or wide excision. The appeal of complete local excision is obvious. It is the most effective way to eliminate the biologic contribution to pain while correcting the structural deficiency. Isolated solitary metastases should be evaluated for potential resectability.<sup>7,89</sup> Occasional cures are reported after resection of bone metastases, but these are infrequent. Radical ablative surgery usually is not appropriate. A long interval between primary tumor presentation and the development of a metastatic focus argues well for cancer resectability. Patients with a projected long survival, such as those with renal or thyroid cancers, are best suited to undergo extralesional excision of metastases. The sacroiliac region and spine are common sites of a solitary metastasis. Tumors in these areas are large and bulky, and the surgery is dangerous. Plasmacytomas should also be considered for resection. Even if systemic disease later develops, some clinicians contend that survival may be prolonged in surgically resected cases.<sup>14,90</sup>

Surgical adjuvants are helpful, whether intralesional or excisional procedures are considered, and include angiography, cryosurgery, chemotherapy, and radiation therapy. Preoperative angiography and tumor embolization greatly reduce blood flow and intraoperative hemorrhage, particularly in vascular tumors such as thyroid and renal cell carcinoma.<sup>91,92,93</sup> and <sup>94</sup> Cryosurgery can be used in the local management of bone lesions<sup>95</sup>; Marcove<sup>96</sup> pioneered its use in metastatic disease. It is particularly suited for cancers that have failed to respond to systemic treatment or local radiation therapy and in which local tumor progression is expected.

The addition of chemotherapeutic agents to the methyl methacrylate bone cement used in implant and fixation constructs is under investigation as a method of local delivery of antineoplastic drugs for enhanced local, and potentially systemic, disease control. Preliminary studies show promising results, but further clinical investigation is required before this method can be entered into the therapeutic armamentarium.<sup>97,98</sup>

Radiation therapy remains the principal surgical adjuvant. It should be delivered to the entire surgical field and extend the length of any prosthesis or internal fixation device.<sup>41,52</sup> This addresses tumor cells that have been spread by the surgical procedure along the intramedullary canal and soft tissues. Local tumor control helps to prevent destabilization of the implant construct by preventing local tumor progression from affecting the structural integrity of the bone in which the implant is fixed.

### **Impending Fractures: Prophylactic Fixation**

There is no specific definition of an impending fracture, and the indications for operative treatment of impending fractures continue to be controversial. This controversy remains extant in part because of the evidence in the literature. Snell and Beals,<sup>99</sup> in their review of 19 pathologic femur fractures due to metastatic breast cancer, found that a lesion of 2.5-cm diameter involving the femoral cortex with pain, irrespective of location, was a positive predictor of pathologic fracture. Parrish and Murray<sup>100</sup> reported on their experience with 104 pathologic fractures due to metastatic disease and identified increasing pain, more than 33% cortical destruction, and lack of radiographic improvement after radiation therapy as indicators of impending fracture. Fidler,<sup>101</sup> in his retrospective study of 19 long bone fractures, showed that with 50% or more cortical involvement in a long bone, there is at least a 50% incidence of spontaneous fracture. Zickel and Mouradian,<sup>102</sup> in their retrospective review of 34 patients, found that size did not correlate with risk of fracture and that, instead, pure lysis on radiography, medial cortical involvement at the hip, and increasing pain were indicative of a high risk of fracture. Harrington,<sup>103</sup> in his review of the literature, summarized the positive predictors of pathologic fracture through a metastatic lesion as (1) a lesion of 2.5-cm or larger diameter involving the femur, (2) lytic destruction of at least 50% of the cortex of a long bone, and (3) continued pain with weight bearing after radiation therapy.

Keene et al.<sup>104</sup> evaluated clinical and radiographic risk factors in an attempt to predict pathologic fracture of the femur. This study involved 2673 breast cancer patients who had undergone skeletal surveys. Of these, 203 patients had evaluable proximal femoral metastases. The authors found no criteria to identify the bone at risk for fracture. They concluded that plain radiographic measurements are insufficient to identify high-risk lesions. This study, however, was limited to the single anteroposterior radiographic evaluation present in the skeletal survey.

Mirels<sup>105</sup> proposed a graduated scoring system that further refined the risk-factor criteria. Included are clinical and radiographic factors, which generate a composite score from 0 to 12 that correlates with fracture risk. Four factors—*anatomic site, pain pattern, radiographic nature, and lesion size*—were each evaluated on a 0 to 3 scale. [Table 52.4-1](#) depicts this scoring system and its ability to predict pathologic fracture. Mirels investigated 78 lesions followed up over the course of 6 months. Fifty-one lesions resulted in fracture, and 27 did not. The mean score for the nonfracture patients was 7, versus a mean score of 10 for the fracture patients; however, there was significant overlap between the two groups. The author concluded that lesions with scores of less than 7 could be irradiated, whereas those with a higher score should be managed with internal fixation followed by postoperative irradiation.

Variable	Points		
	1	2	3
Site	Upper extremity	Lower extremity	Periacetabular
Pain	Mild	Moderate	Mechanical
Radiograph	Blatant	Mixed	Lytic
Size (% of shaft)	0-33	34-67	68-100
<b>Sum</b>	<b>No. of Patients</b>	<b>Fracture Rate (%)</b>	
0-6	11	0	
7	19	5	
8	12	33	
9	7	57	
10-12	15	100	

**TABLE 52.4-1.** Mirels' Scoring System to Predict Pathologic Fracture<sup>105</sup>

Equally valuable is the ability of this scoring system to predict which lesions would not fracture.<sup>105</sup> The fracture rate was small (5%) when the lesion was less than two-thirds of the bone diameter, but it increased to 81% for lesions larger than two-thirds of the shaft diameter. It was stressed that standard radiographs are inadequate to grade many lesions, and CT scanning was recommended to improve diagnostic accuracy. Mirels<sup>105</sup> also made an important distinction between pain and “functional” pain, the latter being pain that worsens with weight bearing. Thus, functional pain reflects the structural insufficiency of bone and was found to be the most significant indicator of bone failure, enjoying an almost universal success in predicting fracture. Lesions measuring larger than twice the bone diameter were closely associated with functional pain. Fracture probability in patients with smaller lesions was only 10%.

The scientific foundation for predicting fracture risk has been improved and summarized by Callaway and Healey.<sup>106</sup> Computer modeling of the proximal femur in *in vitro* testing has allowed some investigators to predict femoral strength more accurately.<sup>107,108 and 109</sup> Evaluating intertrochanteric and subtrochanteric lesions subject to bending forces, these researchers found that endosteal reabsorption of one-half the cortical width weakens the bone by 70% and leaves the patient at high fracture risk. Similar analysis is not available for other anatomic sites.

At the MSKCC, a functional system has been used that has practical implications.<sup>30,110,111</sup> In each of the following four circumstances, major bone loss has usually been encountered surgically, and the bone was found to be essentially fractured:

- A painful medullary lytic lesion resulting in endosteal reabsorption of at least 50% of the cortical thickness
- A painful lytic lesion involving the cortex that is larger than the cross-sectional diameter of the bone
- A painful cortical lesion more than 2.5-cm long
- A lesion producing functional pain after radiation therapy

Prophylactic fixation should be performed as described earlier in [Fracture Treatment](#).

## SPECIFIC ANATOMIC SITES

For each site, unique patterns of metastases and functional and prognostic implications exist. The spine, proximal femur, and pelvis cause the most problems and will be dealt with individually.

### SPINE

Metastatic disease most often affects the vertebral bodies. The lumbar spine is the site of the greatest number of metastases.<sup>112</sup> However, any site within the spine can develop symptomatic metastases. The primary cancers responsible for spinal metastases are breast, lung, and prostate. Among reports regarding the prevalence of spine metastases, most emanate from referral centers. However, Stark et al.<sup>48</sup> note that from a general hospital, lung cancer was responsible in 33%, breast cancer in 28%, other identifiable sites in 25%, and unknown primary lesions in 14% of cases. Remarkably, in 47% of the 131 patients with neurologic symptoms reported by Stark et al.,<sup>48</sup> the spinal metastases were the initial presentation of malignant disease. In an autopsy study of 832 patients dying of metastatic cancer, 36% were found to have spinal metastases, and 26% of these patients had negative plain radiographs of the spine despite the gross evidence of tumor.<sup>113</sup>

Pain is the most common presenting symptom. It may be caused by intraosseous disease, motion segment instability, vertebral fracture, epidural compression, or nerve root impingement. Vascular insufficiency of the spine can also occur due to tumor or to associated spinal instability, surgery, radiation therapy, or embolization of the spinal arteries.<sup>114</sup> Neurologic deficit is seen commonly in symptomatic patients. Myelopathy, radiculopathy, or cauda equina syndromes are recorded. Of particular importance is loss of proprioception and sphincter function. These are harbingers of serious neurologic damage and are much less likely to return after any form of treatment.

Various staging systems for vertebral involvement have been advanced.<sup>115,116</sup> The Tomita system is the most logical and offers the greatest clinical applicability.<sup>117</sup> It identifies disease involving the vertebral body, pedicle, posterior spinous elements, epidural space, and paraspinal region as distinct components. Clinical staging has also been identified as an important prognostic factor. Tokuhashi et al.<sup>118</sup> have identified six parameters for staging, each of which is assigned 0 to 2 points: (1) general condition, (2) number of extraspinal bone metastases, (3) number of vertebral metastases, (4) visceral metastases, (5) primary cancer site, and (6) severity of spinal cord palsy. Outcome was correlated to total score. These authors recommended that an excisional operation be performed in patients with 9 or more points, whereas palliative surgery is indicated for the more seriously ill, those patients scoring fewer than 5 points.<sup>118</sup>

The natural history of metastases is variable. Influential factors are anatomic location of metastases, functional status, treatment, and primary tumor histology. Tomita et al.<sup>119</sup> reported on a group of 78 patients with epidural metastases who were treated with irradiation and high-dose steroids. Among the patients, 2 improved and 11 became paraplegic, whereas in 65, symptoms stabilized. There was a major difference in outcome based on the ability to restore ambulation. Ambulators had a 53-week survival in contrast to nonambulators, who survived less than 5 weeks.

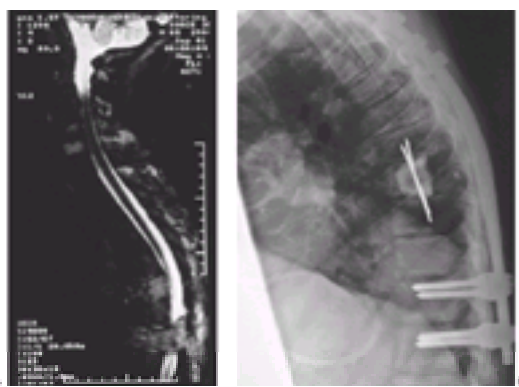

Radiation is the first line of treatment for most patients with spinal metastases and pain. Rao et al.<sup>120</sup> reported on 19 patients with cervical metastases without neurologic deficits. All patients received radiation therapy or chemotherapy. Symptomatic control lasted for 6 months, with subsequent deterioration that necessitated another treatment. Median survival was less than 15 months. The authors concluded that nonoperative treatment is appropriate for most patients without neurologic signs, particularly if the expected survival is in the 6- to 12-month range.<sup>120</sup> Similarly, Young et al.<sup>47</sup> performed a randomized trial of radiation therapy versus laminectomy and posterior decompression of the spinal cord. They found no benefit from this form of surgery and therefore favored nonoperative treatment. However,

the series was small, was not stratified for tumor location, and preceded the application of modern spine instrumentation methods.

Surgery may be important to improve the quality of life of these patients.<sup>121</sup> The goals of surgery in metastatic spine disease are to decompress the spinal cord and neural elements and to stabilize the spine. Laminectomy alone rarely accomplishes these goals and may further destabilize the spine.<sup>47</sup> It is indicated for rare posterior element disease or peripheral root compression only.

The debate continues as to whether an anterior, posterior, or combined anterior-posterior approach is better. Proponents of anterior decompression contend that it is often preferable because it addresses the primary site of the disease.<sup>122,123</sup> Harrington,<sup>122</sup> in his original report of 14 patients, found that 9 of 12 patients with major neurologic dysfunction recovered completely, 2 recovered partially, and 1 was unchanged. Vertebral body resection and cement and rod vertebral body reconstruction achieved excellent pain relief in 13 of 14 patients. Sundaresan et al.<sup>124</sup> reported on 101 vertebral body resections. Patients were stabilized anteriorly or posteriorly as required; pins and cement usually were inserted to replace the vertebral body. Seventy-eight percent regained ambulatory ability, and 85% experienced pain relief. Morbidity was the least in patients who were treated *de novo* and underwent subsequent radiation therapy. In a follow-up study of 54 patients with *de novo* surgery, Sundaresan et al.<sup>115</sup> noted that 25 patients survived 2 years or more, with 92% maintaining ambulatory ability. The overall complication rate in this series was a low 15%.

Rosenthal et al.<sup>125</sup> reviewed a 3-year experience at the MSKCC, where anterior corpectomy and reconstruction with pins and cement were used for metastatic disease. Deterioration in function or pain control occurred in 7 months for cervical lesions, in 11 months for lumbar lesions, and in 22 months for thoracic lesions. Junctional sites were more unstable, leading to early deterioration. Anterior surgery alone was satisfactory for patients with short survival times. If survival was expected to exceed the durability of the anterior reconstruction, then staged, posterior stabilization was recommended. Currently, the group at MSKCC is advocating a posterolateral, transpedicular approach that permits circumferential neural decompression, corpectomy, anterior pin and cement fixation, and segmental posterior fixation (Fig. 52.4-2).<sup>126</sup> This strategy has achieved excellent tumor control, pain relief, and neurologic preservation in a preliminary series of 25 patients. It is particularly suitable for patients with extensive epidural disease and those who have had a previous thoracotomy or thoracic irradiation or who have significant pulmonary disease, which is a relative contraindication for thoracotomy.

**FIGURE 52.4-2.** Metastatic disease involving the spine with fracture and spinal cord compression at T9. **A:** T2 stir, fat-suppressed magnetic resonance imaging scan demonstrating multiple-level vertebral involvement with extension of tumor involving the T9 vertebral body into the spinal canal with cord impingement. **B:** Postoperative radiograph after decompression and stabilization using the single-stage posterolateral, transpedicular approach with anterior reconstruction with pins and cement and long posterior fusion with pedicle screw fixation.

Segmental spine fixation, including pedicle fixation, has greatly improved the ability to stabilize the spine posteriorly.<sup>127</sup> Anterior devices, including plates or multiple rod fixation, have greatly expanded the options for vertebral body reconstruction.<sup>128,129,130</sup> and <sup>131</sup> Each anterior construct can be combined with bone or synthetic replacements for the vertebra. The choice here depends on the expected survival of the patient. In most situations, survival is insufficient for bone healing to occur and is well within the limits of synthetic durability. This is in distinction to the case for curative resection of solitary metastases or primary tumors.

Finally, Tomita et al.<sup>132</sup> have described total *en bloc* spondylectomy for metastatic and primary disease in a selected series of 24 patients. This is the most oncologically sound procedure described to date, removing the posterior elements as a single segment and resecting the vertebral body as a single segment. Careful spine stabilization and meticulous technique have prevented neurologic damage. Eighteen patients had substantial neurologic improvement. Among the 12 patients who were alive at 14-month review, no local recurrence was found. These results are in contrast to the high local recurrence rates (up to 49%) that have been reported by King et al.<sup>133</sup> and other experienced spine surgeons.

Current surgical indications agreed on by most authors are (1) cord compression with myelopathy, (2) bone impinging into the spinal canal and producing thecal compression, (3) spinal instability with unremitting mechanical pain, (4) fracture-dislocation of the spine, (5) radiculopathy with progressive or uncontrolled symptoms, (6) tumor growth unresponsive to radiation therapy, and (7) direct tumor extension from primary lesions, such as Pancoast tumor invading the vertebra.

Embolization of spinal metastases from renal carcinoma has been recommended as the sole treatment for patients with late-stage disease. O'Reilly et al.<sup>93</sup> described this treatment in four patients who achieved progressive neurologic improvement that lasted for 12 weeks or more. Preoperative tumor embolization is warranted in renal carcinoma and, possibly, in other hypervascular lytic tumors. Olerud et al.<sup>92</sup> noted that the average blood loss was cut by two-thirds after embolization in 11 cases of renal cancer, as compared with 18 similar procedures in which embolization was not performed. The value of embolization in the treatment of other tumors has not been as well documented, but it is often useful in the treatment of metastases to difficult sites such as the acetabulum.

## PROXIMAL FEMUR

Fractures of the proximal femur are the most common surgical problem in bony metastatic disease. Sixty-six percent of pathologic long bone fractures involve the femur, and 80% of these occur in the proximal portion. The femoral neck is the location for approximately 52% of these fractures, with the intertrochanteric region responsible for another 15% and the subtrochanteric region for the remaining 33%.<sup>134</sup> Walking, rising from a chair, climbing stairs, and even lifting the leg to swing out of bed all apply forces in excess of three times one's body weight on the hip joint and proximal femur. Underlying mechanical weakness from even a treated metastasis leaves the bone unable to withstand the forces of normal activity.

It is a tragic mistake to spare the patient an operation when the procedure can make an important improvement in the quality of the patient's remaining life. This is true even for patients in whom anticancer therapy and resuscitation are no longer indicated. As in other anatomic locations, the goal of treatment is to reduce pain and maintain function. Maintenance of function usually means preservation of walking ability but, in severely disabled patients, functional restoration means regaining transfer ability, which facilitates nursing care. General indications for surgery are a life expectancy of at least 1 month, a general physical condition adequate to tolerate surgery, a result from surgery that will expedite patient mobilization and facilitate general care, and bone adequate to support fixation or a prosthesis proximal or distal to the fracture.<sup>134</sup> Conversely, patients with major neurologic impairment or potential large persistent narcotic requirement are unlikely to benefit greatly from surgery.

Generally, all fractures require supplemental radiation therapy to treat underlying tumor. Treatment of the fracture frequently exposes new areas to tumor spread. Tumor can be seeded down the femoral canal during intramedullary reaming, insertion of an intramedullary device, or injection of cement down the canal. This newly contaminated region must be treated with radiation to avoid tumor proliferation and a new fracture distal to the implant.

Surgical treatment is largely dependent on fracture location and anatomy, which is discussed earlier, in [Fracture Treatment](#).

## PELVIS AND ACETABULUM

Most patients with pelvic and acetabular metastases have pain; however, it does not always arise directly from the hip joint. Avulsion fractures of the iliac crest or

anterior-inferior iliac spine are common and should be treated nonoperatively. However, mechanical insufficiency of the acetabulum can be managed only surgically. The general surgical indications for metastatic disease involving the acetabulum are (1) continued acute symptoms despite management with protected weight bearing, antineoplastic treatment, and analgesics; (2) unsatisfactory function and pain control 1 to 3 months after irradiation; (3) a pathologic fracture of the acetabulum; or (4) an impending fracture in the ipsilateral femur requiring surgery.

Harrington and Rock<sup>135,136</sup> described four types of acetabular bone deficiency and their surgical management among 58 patients with pelvic metastases. Their classification system is based on the extent of bony involvement by tumor and reflects surgical treatment. Overall results were good for most patient groups. Pain relief was effective for at least 6 months in 67% of patients and for more than 2 years in 43%. Eighty percent of patients remained ambulatory for 6 months or more. Harrington did, however, treat a generally favorable group of patients, with 30 of 58 (51%) surviving 2 years or more after surgery.

Preoperative evaluation, including Judet radiographs, must be performed carefully, to define disease in the anterior and posterior acetabular columns.<sup>137,138</sup> CT scanning is indispensable to evaluate the medial acetabulum and acetabular dome and to define any associated soft tissue mass. It is the best study for assessing overall bone integrity. Pathologic anatomy is better described by a four-part system that assesses the anterior column, posterior column, acetabular dome, and medial wall as separate components. Bone in each region can then be graded as sufficient or insufficient, whereby sufficient bone provides adequate support for the acetabular component and insufficient bone does not. Thus, the classification system combines both anatomic and reconstructive considerations.

At the MSKCC, this four-part system was used to analyze a series of 55 patients who required surgical reconstruction of the acetabulum for metastatic disease.<sup>139</sup> In this series, ten patients (18%) had insufficiency of both anterior and posterior columns, whereas 36 patients (65%) had single column insufficiency. Forty-two of 55 patients (76%) had an insufficient medial wall combined with either an insufficient column or dome, and 47 patients (85%) had an acetabular fracture. In all 55 patients, the reconstruction was reinforced with pins or cannulated screws incorporated into cement, using a modified Harrington technique. This allows for bypass of major acetabular defects with proximal fixation of the socket into the remaining iliac bone. Insertion of pins or screws can be performed in an antegrade fashion from the iliac crest, using a vector guide, or retrograde from the bone defect. A protrusio ring "revision" hip socket can be used to transfer load to the remaining intact cortical bone when medial wall defects are present (Fig. 52.4-3). Of the 41 out of the 55 patients (75%) in this series that were evaluable at 3 months, 34 (83%) experienced significant pain relief, 9 of 18 nonambulatory patients had regained walking ability, and 14 of 17 patients maintained their ability to ambulate in the community. Fourteen of 55 patients (25%) developed significant local disease progression, but only 5 patients (9%) experienced fixation failure. Early complications developed in 12 patients (22%). Of the 21 patients (38%) who had more than 1 year of follow-up, 14 (67%) continued to experience improved pain relief and 12 (57%) remained community or household ambulators. In this series, despite the fact that patients with significant acetabular metastasis had a short life expectancy, the positive effect on both pain relief and functional improvement validated the role of surgery in managing this group. Acetabular reconstruction using the outlined techniques showed a low incidence of fixation failure, supporting the biomechanical stability of the construct and providing sufficient durability in these patients.

**FIGURE 52.4-3.** Reconstructions using the techniques outlined for metastatic cancer to the pelvis and acetabulum. **A:** Plain radiograph shows the use of antegrade cannulated screws, a protrusio ring acetabular component (Healey Cup, Biomet, Warsaw, IN) with fixation screws, and cement to reconstruct a large acetabular defect with medial wall deficiency. **B:** Reconstruction of a large lesion involving the posterior column, medial wall, and acetabular dome using antegrade pins, a protrusio ring acetabular component, and cement. The prominent lateral iliac pin demonstrates pin back-out. The protrusio ring acetabular component lateralizes the socket and helps to bypass the central defect.

Finally, massive pelvic involvement can be treated by acetabular resection and reconstruction using a saddle prosthesis (Waldemar Link, Hamburg, Germany), as reported by Aboulafia et al.,<sup>140</sup> or with a pelvic endoprosthesis. Such aggressive surgical approaches may help selected patients with intermediate-term life expectancies.

When coupled with systemic measures to control bony metastases, local care with radiation therapy and/or judicious surgery can achieve the goals of pain relief and functional preservation in patients surviving with metastatic cancer that involves bone.

## MALIGNANT PLEURAL EFFUSION

Forty percent of all pleural effusions are due to malignancy,<sup>1</sup> and cancer is the second leading cause of pleural effusion in patients older than 50 years of age. Approximately 100,000 cases of malignant pleural effusion (MPE) occur annually in the United States, and MPE is the initial manifestation in 10% to 50% of cancer patients.<sup>2</sup> Two-thirds of MPEs are attributable to lung carcinoma (35%) or breast carcinoma (23%) and lymphoma (10%). Carcinomas of unknown primary origin account for an additional 12% of MPEs.<sup>3</sup> Presence of MPE frequently indicates advanced and incurable disease. Although the overall prognosis of patients with MPE depends on the histology and extent of their primary disease, significant palliation can be achieved in these individuals by accurate and timely diagnosis and interventions associated with minimal morbidity.

### PATHOGENESIS OF MALIGNANT PLEURAL EFFUSION

The pleural space functions as a mechanical coupling system between the lung and the chest wall. The normal pleural space is between 7 and 27  $\mu\text{m}$  in width and is filled with 10 to 40 mL of hypoproteinemic plasma.<sup>4,5</sup> Most of the pleural fluid originates from the capillary bed of the parietal pleura. The major route of pleural fluid efflux is through the parietal pleural lymphatics, which have a clearance capacity 28 times greater than the rate of fluid formation.<sup>6</sup> Under normal conditions, a dynamic equilibrium exists between the osmotic and hydrostatic pressures that control the secretion and absorption of the pleural fluid. Accumulation of fluid within the pleural space may be the consequence of any of the following<sup>7</sup>:

- Increased hydrostatic pressure in the microvascular circulation
- Decreased oncotic pressure in the microvascular circulation
- Decreased pressure in the pleural space
- Increased permeability of the microvascular circulation
- Impaired lymphatic drainage from the pleural space
- Transudation of fluid from the peritoneum via lymphatics or anatomic defects in the diaphragm

MPEs typically arise as the result of altered microvascular permeability, as well as diffuse metastatic involvement of mediastinal or subpleural lymphatics. Pulmonary parenchymal tumors (primary or metastatic) may erode the visceral pleura, spilling cells and disrupting the normal resorption of fluid by the visceral pleura. Alternatively, the parietal and visceral pleura themselves are common sites of deposits, resulting in increased capillary permeability due to inflammation, overt endothelial disruption, or obstruction of efferent flow with elevated lymphatic hydrostatic pressure. Primary or metastatic involvement of hilar or mediastinal lymph nodes obstructs normal visceral and parietal lymphatic drainage, resulting in pleural effusion.<sup>8</sup> In an autopsy study of 29 patients with lung cancer, Meyer<sup>9</sup> observed that the development of pleural effusion was closely related to malignant infiltration of mediastinal lymph nodes but not the extent of pleural metastases. Typically, involvement of the mesothelial surface results in exfoliation of tumor cells into the pleural fluid; however, few malignant cells will be found in the pleural fluid in the setting of submesothelial involvement.

Occasionally, pleural effusions in cancer patients are negative for malignancy despite exhaustive diagnostic efforts. Although related to the underlying cancer, these paramalignant effusions are not due to metastatic disease involving the pleura but rather are caused by obstruction of the hilar-mediastinal lymph nodes or bronchial obstruction, resulting in pneumonitis or atelectasis. Such paramalignant effusions, if associated with non-small cell lung cancer, should not preclude patients from undergoing potentially curative resection if otherwise indicated. However, in most lung cancer patients, cytologically negative pleural effusions eventually are found to be inoperable.<sup>10,11</sup> Decker et al.<sup>11</sup> observed that only 4 of 73 patients (5.5%) with lung cancer and cytologically negative pleural effusions had resectable disease,<sup>11</sup> demonstrating that pleural effusions of any kind in lung cancer patients typically are indicative of locally advanced, incurable disease. Furthermore, occult malignant cells have been detected by pleural washing in nearly 15% of patients undergoing resection of presumed stage I non-small cell lung cancer<sup>12</sup>; survival of these individuals is as poor as that reported for patients with stage III disease, indicating the ominous nature of pleural space metastases of any kind in lung cancer patients.

### CLINICAL PRESENTATION

MPE is often an initial manifestation of cancer; nearly 50% of individuals presenting with MPE have no history of malignancy.<sup>13,14</sup> Most patients with MPE are symptomatic, with dyspnea of varying severity being the predominant symptom; cough and chest discomfort ranging from dull ache (often characterized as heaviness or pressure) to sharp pleuritic pain may also be present.<sup>13</sup> Physical examination usually reveals decreased breath sounds, with dullness to percussion and diminished tactile fremitus. Tracheal deviation and low cardiac output related to mediastinal compression occasionally may be seen with large effusions.

### DIAGNOSIS AND EVALUATION

#### *Radiographic Examinations*

As little as 200 mL of pleural fluid, evidenced by blunting of the costophrenic angle, can be detected by standard posterolateral and lateral chest radiographs. Upright posteroanterior, lateral, and lateral decubitus chest radiographs that allow assessment of "free-flowing" pleural effusion should be performed as initial investigations. Particularly in the setting of a newly diagnosed effusion, computed tomographic (CT) scan of the chest should be performed to define fluid loculations or hilar lymphadenopathy, pleural masses, and parenchymal disease. Complete opacification of the hemithorax occurs in approximately 15% of MPE; an opacified hemithorax with mediastinal shift toward the contralateral side indicates massive effusion, whereas opacification without a shift may be due to a combination of pleural fluid and lung collapse resulting from proximal airway obstruction, effusion with mediastinal fixation by malignant lymphadenopathy, or malignant mesothelioma.<sup>15</sup>

#### *Invasive Diagnostic Maneuvers*

After appropriate radiographic assessment, thoracentesis should be performed to obtain fluid for biochemical and cytopathologic analysis, to relieve symptoms, and to determine the extent of lung expansion after pleural fluid drainage. In the presence of free-flowing effusion, thoracentesis can be safely performed at the level of the posterior sixth or seventh intercostal space, removing 500 to 1000 mL of fluid. In the presence of a large pleural effusion occupying more than 50% of the pleural

cavity, gradual drainage of the fluid is prudent to avoid postexpansion pulmonary edema.<sup>16,17</sup> and <sup>18</sup> If the pleural collection is loculated, ultrasound- or CT-guided drainage is recommended. A small sample of pleural fluid should be sent for biochemical analysis; the remaining fluid should be processed for cytopathologic examination.

After thoracentesis, patients frequently experience less dyspnea and chest heaviness, even in situations in which the lung fails to expand after evacuation of the effusion due to encasement with malignant or inflammatory "peel." Possible complications of thoracentesis include bleeding, pneumothorax requiring tube thoracostomy (in approximately 5%), vagovagal reaction, pain from reexpansion of the lung and apposition of pleural surfaces, and reexpansion pulmonary edema.<sup>19,20</sup>

The initial cytology result is positive in approximately one-half of patients who are ultimately found to have MPE. If initial cytology results are negative, repeat thoracentesis should be performed, since malignant cells will be identified in an additional 20% of patients. Closed pleural biopsy performed either by random sampling of the pleura just before thoracentesis (to minimize lung injury) or using CT guidance may be considered to expedite diagnosis of patients with presumed MPE. However, recent data indicate that closed pleural biopsy is complementary to pleural fluid cytology and only slightly increases the yield in diagnosing malignancy.<sup>21</sup> In a direct comparison of closed pleural biopsy with cytologic examination, Nance et al.<sup>22</sup> observed that pleural biopsy was diagnostic in 45% of patients with MPE, 75% of whom had positive cytology results; pleural biopsy was informative in only 3% of patients whose cytology results were negative.<sup>22</sup> The low yield of closed pleural biopsy is related to the focal nature of metastatic disease in the pleural space. In contrast, thoracoscopy performed either by direct pleuroscopy under local anesthesia with intravenous sedation or with video assistance under general anesthesia has a diagnostic yield of nearly 100% for malignant disease involving the pleura.<sup>23,24</sup> and <sup>25</sup> Therefore, patients whose effusions remain undiagnosed after two thoracentesis procedures should be referred for thoracoscopy.

### **Biochemical and Pathologic Analysis**

Pleural fluid obtained by diagnostic thoracentesis should be routinely sent for protein, glucose, and lactate dehydrogenase (LDH) analysis and for cell counts, cultures, and pathologic examinations. MPE is most commonly exudative (LDH >200 U/mL; fluid-serum LDH ratio >0.6; fluid-serum protein ratio >0.5).<sup>26</sup> Frequently, fluid is blood-tinged or grossly hemorrhagic, owing to disruption of capillaries or venules by direct tumor invasion or cytokine-mediated vasodilation.<sup>15</sup> Typically, the pleural fluid is hypercellular, with leukocytes (1000 to 10,000 cells/mm<sup>3</sup>, predominantly lymphocytes and monocytes), reactive mesothelial cells, and exfoliated tumor cells. Approximately one-third of MPEs are acidic (pH <7.3), with glucose-serum ratios of less than 0.5. These biochemical parameters correlate with advanced disease, poor response to palliative pleurodesis maneuvers, and diminished survival in patients with MPE.<sup>27,28</sup>

The diagnosis of MPE is confirmed in approximately 50% of patients after initial cytopathologic evaluation. Second and third thoracentesis procedures may increase the diagnostic yield to 65% and 70%, respectively.<sup>3,29</sup>; analysis of carcinoembryonic antigen has not proven to be specific enough to discriminate benign from malignant epithelial effusions.<sup>30</sup> Pleural fluid cytology is positive in fewer than 33% of patients with lymphomas and leukemias; cytogenetic studies can confirm the malignant nature of pleural effusions in 80% of these individuals.<sup>3</sup>

Almost all patients with malignant pleural mesothelioma present with effusions. Atypical mesothelial cells are nearly always present in all pleural effusions irrespective of the underlying malignancy, and differentiating malignant mesothelioma from metastatic adenocarcinoma can be difficult. Analysis of hyaluronidase levels (which frequently are elevated in malignant pleural mesothelioma) has not proven to be sufficiently sensitive to be diagnostic<sup>31</sup>; as such, immunohistochemistry techniques must be used to distinguish epithelial pleural mesotheliomas from pulmonary adenocarcinomas. In general, pulmonary adenocarcinomas tend to express carcinoembryonic antigen, LeuM1, B72.3, and BerEP4; in contrast, the majority of epithelial mesotheliomas do not express these antigens.<sup>32</sup> Histopathologic diagnosis of malignant mesothelioma frequently requires relatively large tissue samples obtained by thoracoscopy techniques.

## **TREATMENT**

The treatment of MPE should focus on palliation of symptoms and must be tailored to the patient's physical condition and prognosis. Overall, 54% and 84% of patients with MPE succumb within 1 month and 3 months, respectively, after diagnosis. However, survival is related to the histology of the underlying disease. Patients with malignant effusions secondary to breast cancer may live 1 year or more, whereas individuals with ovarian cancer have an average survival of 9 months. In contrast, patients with lung or gastric carcinomas typically do not survive more than 3 months after detection of MPE.<sup>2</sup>

### **Thoracentesis**

Thoracentesis may be an appropriate treatment for MPE in patients with limited life expectancy who cannot tolerate any surgical procedure. Recurrent effusions are observed in 97% of individuals within 30 days after thoracentesis. In general, pleurodesis immediately after thoracentesis is not effective, since residual pleural fluid dilutes the sclerosing agent, thus diminishing its irritant effects on the pleura. Loculations may form after such treatment, rendering definitive therapy of the pleural effusion more complicated. In patients presenting with MPE as the initial manifestation of breast cancer, small cell lung cancer, germ cell tumors, or lymphoma, thoracentesis followed by systemic chemotherapy may successfully treat disease in the pleural space. However, most patients with MPE require more aggressive intervention to prevent recurrence.

### **Tube Thoracostomy with or without Pleurodesis**

After thoracentesis and reexpansion of the lung, pleural fluid should be completely evacuated with a tube thoracostomy to allow apposition of the visceral and parietal pleura. Recurrent effusions are noted in 60% to 100% of patients after tube thoracostomy drainage alone; in general, obliteration of the pleural space, either by parietal pleurectomy or instillation of sclerosants causing inflammation and subsequent pleural symphysis, is required to ensure durable relief. Chemical pleurodesis is the preferred treatment for patients with MPE, and the efficacy of this intervention depends on (1) complete drainage of the pleural space and reexpansion of the lung to ensure apposition of the pleural surfaces and (2) instillation of an effective sclerosing agent into the pleural space and retention of this agent in the chest for several hours to induce an inflammatory fibrosis.

The chest tube (28 Fr. to 32 Fr.) is routinely inserted at the level of the sixth or seventh intercostal space laterally and directed posteriorly to the most dependent portion of the pleural cavity. Once complete drainage is achieved (as confirmed by chest radiograph and daily drainage of <150 mL), the sclerosing agent (suspended or dissolved in 100 to 150 mL of normal saline) is instilled into the pleural space via the chest tube. The tube is then clamped for 1 to 2 hours, during which time the patient changes position periodically to enhance distribution of the sclerosant; subsequently the tube is unclamped and connected to suction. The tube is removed when the daily drainage is again less than 150 mL.

Traditionally, this method of treatment requires hospitalization for 4 to 6 days and placement of a large-bore chest tube for complete evacuation of the exudative effusion prior to chemical pleurodesis. However, several studies have indicated that pigtail catheter drainage and sclerosis may be as successful as more traditional chest tube pleurodesis procedures.<sup>33,34</sup> Recently, outpatient management of MPE with a small-bore all-purpose drainage catheter (10.3 Fr.) and bleomycin pleurodesis has been described.<sup>35</sup> Pleural fluid was drained by a catheter connected to a collection bag until drainage was less than 100 mL/day. Bleomycin (60 U in 50 mL of 5% dextrose in water) was then instilled to the chest via the drainage catheter, and the tube was removed 24 hours after pleurodesis. Fifty-three percent of patients treated in this manner experienced complete responses, and an additional 25% had partial responses. In another study, MPE was drained by a 12-Fr. van Sonnenberg pigtail catheter inserted under ultrasound guidance in 15 patients, 11 of whom had loculated pleural effusion (which necessitated this method of drainage).<sup>36</sup> Talc (5 g suspended in 100 mL of injectable normal saline) was instilled into the pleural cavity once pleural fluid drainage was less than 100 mL/day. Control of MPE was achieved in 80% of these cases; additional talc instillation was required in two patients to treat residual pockets of effusion with good results. These data suggest that outpatient management of MPE may be appropriate in patients with MPE who typically have limited life expectancies.

### **Pleurodesis Agents**

Various agents have been used in the last 50 years to induce adhesive obliteration of the pleural space. Nitrogen mustard was one of the first agents used to treat MPE. The overall response rate was 52%.<sup>37,38</sup> The main complications related to its use were bone marrow suppression, pain, fever, nausea, and vomiting. Thiotepea, 5-fluorouracil, and bacille Calmette-Guérin<sup>39,40</sup> were also used but were found to have limited efficacy and unacceptable toxicity. Radioactive zinc, gold, chromium, or phosphorus were used in the 1940s to treat MPE, with a cumulative response rate of approximately 53%.<sup>41,42</sup> The main disadvantages of radioactive colloids were

cost, short half-lives, and potential hazards to treatment personnel; these agents are no longer used clinically.

Certain chemicals have been extensively evaluated in both randomized and nonrandomized clinical studies for their efficacy as pleurodesis agents. None of them except bleomycin are known to possess antitumor activity. They induce intense pleural inflammation and, subsequently, adhesive fibrosis of the parietal and visceral pleurae.

**TETRACYCLINE-DOXYCYCLINE.** Tetracycline was extensively used as a sclerosing agent to treat pleural effusions of benign and malignant etiologies because of its efficacy, low cost, and safety. The overall efficacy of tetracycline in controlling MPE was 70%.<sup>43,44</sup> The usual dose was 500 to 1000 mg diluted in 100 mL of normal saline. The main side effects were pleuritic pain (20% to 70%) at the time of drug instillation and low-grade fever (33%). Lidocaine (20 mL of 1% or 2% solution) could be mixed with tetracycline prior to administration to decrease pleuritic pain. Injectable tetracycline is no longer available in the United States since 1991, because the drug preparations did not meet the U.S. Food and Drug Administration purity standards; as such, the tetracycline derivatives doxycycline and minocycline have been used for pleurodesis. Three small, uncontrolled clinical trials have reported response rates of 67% to 88% after doxycycline pleurodesis.<sup>45,46</sup> and<sup>47</sup> The side effects are similar to those observed with tetracycline. Most patients require repeated doxycycline instillation for successful pleurodesis. In these reported series, only 15% of patients responded to a single treatment, and 9% required more than four instillations. Intraleural minocycline (300 mg with 1% lidocaine) was given to seven patients with MPE, of whom six responded (86%).<sup>48</sup> The small number of patients studied, unspecified criteria for success, and duration of treatment response make for difficult comparisons of minocycline with other agents.

**BLEOMYCIN.** Intraleural administration of bleomycin (60 to 120 U) achieves pleurodesis in 65% of patients with MPE (range, 62% to 81%).<sup>49,50,51</sup> and<sup>52</sup> Intraleural bleomycin is well tolerated and associated with few side effects.<sup>53</sup> In a multicenter, randomized trial,<sup>43</sup> bleomycin was superior to tetracycline for pleurodesis; 70% of patients treated with bleomycin had successful control of their MPE, as compared to only 47% of patients treated with tetracycline. However, bleomycin is expensive; typically, each treatment dose ranges from US \$1100 to \$1300. Bleomycin has been compared with less expensive talc pleurodesis in a prospective randomized study of 29 women with MPE secondary to breast cancer. Of 22 evaluable patients (with 3 patients having had bilateral pleurodesis), all 10 patients (100%) treated with talc had complete control of their MPE, as compared to 10 of 15 patients (67%) receiving bleomycin.<sup>51</sup>

**TALC.** Chambers<sup>54</sup> was the first to use talc to treat MPE.<sup>54</sup> Talc produces an intense chemical pleuritis that effectively obliterates the pleural space.<sup>55</sup> Asbestos-free, gas-sterilized, or heat-sterilized talc USP may be administered via chest tube as a slurry (5 g in 100 mL of normal saline) or insufflated as a powder during thoracoscopy or thoracotomy. Talc pleurodesis is highly effective, with the overall response rates ranging from 80% to 100%.<sup>54,56,55,56,57,58,59,60,61,62,63,64,65,66</sup> and<sup>67</sup> The most commonly reported adverse effects of talc pleurodesis are fever (16%) and pain (7%). Less common complications include empyema, pneumonitis (similar to acute respiratory distress syndrome), and respiratory failure.<sup>65,68,69</sup> Pulmonary complications noted in earlier series have not been observed as frequently in more recent trials and tend to occur in patients who receive 10 to 12 g of talc or undergo either bilateral pleurodesis or unilateral pleurodesis in conjunction with pleural biopsy (raising the possibility of talc emboli). Vierrat et al.<sup>64</sup> reviewed their experience with thoracoscopic talc poudrage pleurodesis for MPE in 360 cases, including 88 mesothelioma patients and 272 individuals with effusions secondary to a variety of malignancies. Approximately 3 to 4.5 g of heat-sterilized asbestos-free talc was insufflated via atomizer during thoracoscopy. Pleurodesis was successful in 90% of 327 evaluable patients at 1 month, and 82% of individuals had lifelong pleurodesis. Complications included fever (10%), empyema (2.5%), pulmonary infection (0.8%), and malignant invasion of the thoracoscopy trocar site in a mesothelioma patient. Aelony et al.<sup>67</sup> reported effective talc pleurodesis using thoracoscopy in patients whose pleural fluid was acidic (<7.2), with a response rate of 88%. This high success rate compares favorably with the low response (57%) previously reported by Rodriguez-Panadero and Mejias.<sup>28</sup> Failure of talc thoracoscopic pleurodesis in these two studies was more closely correlated with the presence of trapped lung than with low pleural fluid pH.

Talc has consistently been shown to be superior to other commonly used sclerosing agents, such as tetracycline-doxycycline and bleomycin. The efficacy of past and currently used pleurodesis agents is summarized in [Table 52.5-1](#). In a randomized controlled trial, Fentiman et al.<sup>56</sup> compared the efficacy of talc poudrage and tetracycline in 33 breast cancer patients with MPE. Ninety-two percent of patients receiving talc had successful pleurodesis, as compared to only 42% of patients receiving tetracycline. In another study, successful pleurodesis was observed in 97% of patients undergoing intrapleural talc insufflation by thoracoscopy, as compared to 70% and 47% of patients receiving bleomycin and tetracycline, respectively.<sup>63</sup> Thoracoscopic talc poudrage was also very effective in producing durable pleurodesis in patients with recalcitrant MPE who failed prior treatment with tetracycline.<sup>67</sup> Zimmer et al.<sup>70</sup> prospectively evaluated the efficacy of either bleomycin (60 U; 14 patients) or talc slurry (5 g; 19 patients) administered at the bedside via tube thoracostomy in 33 patients. Permanent control of MPE was noted in 79% of patients receiving bleomycin and 90% of patients treated with talc pleurodesis. The difference, however, did not reach statistical significance ( $P = .34$ ). Due to the high cost of bleomycin, the authors recommended talc as the agent of choice for bedside chest tube pleurodesis. Talc poudrage has traditionally been performed by insufflating dry sterilized talc powder into the pleural cavity via the thoracoscope to ensure proper distribution and coating of the pleural surfaces. This technique incurs high costs due to operating room charges and specialized equipment. Pleurodesis achieved via talc slurry administered by thoracostomy tube appears to be more cost-effective than thoracoscopic talc poudrage ([Table 52.5-2](#)). A phase III randomized clinical trial comparing talc slurry via chest tube and talc insufflation by thoracoscopy is being conducted in North America with the participation of the Cancer and Leukemia Group B, the Eastern Cooperative Oncology Group, the Southwest Oncology Group, and the North Central Cancer Treatment Group<sup>71</sup>; the primary end points are evaluation of efficacy and cost-effectiveness of these two pleurodesis techniques.

Agents	Response (%)	
	Mean	Range
Talc	98	72-100
Bleomycin	64	31-85
Tetracycline	72	25-100
Doxycycline	73	68-88
Quinacrine	86	64-100
Nitrogen mustard	44	27-95

**TABLE 52.5-2.** Efficacy of Talc Pleurodesis by Thoracoscopic Talc Poudrage or Talc Slurry by Tube Thoracostomy for Malignant Pleural Effusion

**QUINACRINE.** Quinacrine (mepacrine), an antimalarial agent, has been a popular drug for pleurodesis of pleural effusion in Scandinavian countries. As with other aforementioned sclerosing agents, intrapleural instillation of quinacrine produces significant chemical pleuritis that promotes intrapleural adhesion formation.<sup>72</sup> The response rates to intrapleural quinacrine range from 75% to 100% and 70% to 90% after thoracentesis or chest tube drainage, respectively, in controlled clinical

series.<sup>72</sup> Toxicities associated with quinacrine include fever, hypotension, and hallucination.<sup>73</sup>

**CORYNEBACTERIUM PARVUM.** Injection of the lipopolysaccharide extracts of *C parvum* (an anaerobic gram-positive bacterium) into the pleural space induces a strong, nonspecific inflammatory reaction.<sup>74</sup> Clinical experience with this agent was described in reports from nine studies performed in Europe, but *C parvum* is not available in the United States. Intrapleural injection of 3.5 to 14.0 g of *C parvum* (commercially available as Copravax, Wellcome Research, Beckenham, Kent, UK) has resulted in a cumulative response rate of 76% (129 of 169 evaluable patients), although significant variability has been noted in these studies (response rates ranging from 32% to 90%). The main untoward side effects include pain (43%), nausea (39%), and fever (5%). *C parvum* has been reported to be as effective as bleomycin or tetracycline<sup>75,76</sup> and <sup>77</sup> for chemical pleurodesis.

**BIOLOGIC RESPONSE MODIFIERS.** Chemical agents used for pleurodesis induce inflammatory adhesion of the pleurae, thus obliterating the pleural space and preventing reaccumulation of pleural effusion. Biologic response modifiers, such as interferons and interleukins, have been used to treat MPE primarily on the basis of their antitumor activity. Adequate drug levels can be achieved only by high systemic doses that are associated with severe side effects. Regional intrapleural administration of these agents yields biologically relevant drug concentrations with fewer systemic side effects. None of these agents, however, are routinely used to treat MPE. (They are briefly discussed here for academic interest.)

**Interferons.** Goldman et al.<sup>78</sup> studied the toxicity and efficacy of intrapleural administration of interferon-2b (50 million to 75 millions units) for MPE associated with cancers of different histologies in 23 patients. The pleural fluid was completely evacuated, and interferon was instilled via the chest tube for a maximum of three treatments per patient. Complete and partial resolution of MPE was documented in 14 of 20 evaluable patients (70%). The most common side effect was the flu-like syndrome followed by grade 3 hematologic toxicity in three patients who received high doses of 75 million units. Other studies also indicated somewhat lower response rates and similar toxicity profiles.<sup>79,80</sup>

**Interleukin-2.** Intrapleural administration of recombinant interleukin-2 (rIL-2) as a means to treat MPE has been evaluated in numerous small phase I trials.<sup>81,82,83</sup> and <sup>84</sup> Yasumoto and Ogura<sup>82</sup> treated 43 patients with MPE due to non-small cell lung cancer with daily intrapleural administrations of rIL-2 for an average of 14 days (5 to 33 days) after pleural effusion had been completely evacuated. Control of MPE was achieved in 21 of 35 evaluable patients (60%), with 13 experiencing complete disappearance of MPE. More impressive was the observation of disappearance of malignant cells in the pleural fluid samples sequentially obtained during treatment for cytologic analysis. This was noted in 26 of 35 evaluable patients (74%) and the effect lasted for more than 4 weeks in 19 patients (54%). This observation had also been reported by other investigators.<sup>84</sup> Viallat et al.<sup>81</sup> studied the effects and toxicity profiles of intrapleural injections of rIL-2 in 23 patients with MPE associated with cancers of various histologies. Objective responses were observed in 5 of 21 evaluable patients (24%). Side effects included fever, transient increase in pleural effusion, skin rash, and pruritus. Staphylococcus empyema attributed to prolonged chest tube drainage was noted in two patients.<sup>81</sup>

**OK432.** OK432 is a heat- and penicillin-treated lyophilized powder of the SU substrain of *Streptococcus pyogenes* A3. This immune modulator has recently been found to be useful in treating malignant ascites. Malignant ascites may decrease in volume and even disappear. The OK432 therapy increases neutrophils, macrophages, and lymphocyte<sup>85</sup> counts and augments autologous tumoricidal activity of large granular lymphocytes in ascites fluid.<sup>86</sup> Luh et al.<sup>87</sup> conducted a randomized trial to compare the efficacy of OK432 and mitomycin C in controlling MPE caused by lung cancer. Twenty-six patients received weekly injections of OK432 for 4 weeks. The overall response rate was 88%: 73% (19 of 26 patients) had complete response, and 15% (4 of 26 patients) experienced partial response. Fever, chills, and local pleuritic chest pain were the most common side effects and were observed in 80% of cases.

### **Intrapleural Chemotherapy**

Few clinical studies were conducted to investigate the efficacy of intrapleural chemotherapy for MPE. Regional chemotherapy in the form of intrapleural chemotherapy for malignant mesothelioma is discussed in [Chapter 40.2](#). The overall response rates of intrapleural chemotherapy are low, and the treatments, even though regional, are associated with significant systemic side effects. Unless studied within a context of a clinical trial, intrapleural chemotherapy has no role in the management of MPE.

Intrapleural combinations of cisplatin (100 mg/m<sup>2</sup>) and cytosine arabinoside (600 to 1200 mg/m<sup>2</sup>) have been used to treat MPE in two studies.<sup>88,89</sup> This combination produced a complete response in only 27% of the patients, and adverse effects including pain (66%), cardiopulmonary symptoms (54%), bone marrow suppression (52%), and renal toxicity (34%) were noted in 76% of the patients, suggesting that significant systemic absorption of the chemotherapeutic agents occurred in these individuals. Intrapleural doxorubicin at doses ranging from 10 to 40 mg has produced complete responses in 12 of 55 (22%) evaluable patients.<sup>90,91</sup> and <sup>92</sup> Adverse effects included pain (29%), fever (15%), nausea and vomiting (29%), and anorexia (24%). Repeated, escalating doses of etoposide (100 to 225 mg/m<sup>2</sup>) have been administered intrapleurally to nine patients with MPE,<sup>93</sup> of whom none experienced clinical responses.

### **Cost-Effectiveness of Pleurodesis for Malignant Pleural Effusions**

The most effective and economic method for the treatment of MPE is still a matter of debate. It is important for physicians who manage patients with MPE to be knowledgeable regarding the efficacy, toxicities, and costs of available treatment modalities. Even though the sclerosant is not expensive (\$0.15 to \$0.50 for a 2.5- to 10-g dose), the cost of talc pleurodesis performed by thoracoscopy is high because of operating room and professional fees. The total cost of treatment has been determined to be \$20,996 (1992 U.S. dollars). The high success rate may justify the expense of talc pleurodesis. The 6-month cost of talc pleurodesis, estimated to be \$149 per symptom-free day, should drop significantly if the procedure is performed by pleuroscopy under intravenous sedation and local anesthesia or by instillation of talc slurry via chest tube. Both these techniques are as effective as talc poudrage performed by video-assisted thoracoscopic surgery under general anesthesia. Bleomycin is the most expensive pleurodesis agent, the cost per dose averaging \$1104; however, the total cost of treatment is relatively low, owing to the high efficiency of pleurodesis achieved with a single administration of this drug. The 6-month cost per symptom-free day was approximately \$132 in an analysis reported by Belani et al.<sup>71</sup> Tetracycline and its currently available substitute, doxycycline, are costly (\$159 and \$218 per symptom-free day, respectively), given the fact that repeated administrations of these agents are required to achieve successful pleurodesis, thus prolonging hospitalization and increasing the risk of treatment-related complications.

### **Pleurectomy**

Stripping of the parietal pleura is 100% effective in controlling MPE. Although it may have a role in the treatment of malignant pleural mesothelioma,<sup>94</sup> pleurectomy via thoracotomy is not routinely performed because the morbidity (23%) and mortality (10%)<sup>95,96</sup> cannot be justified in debilitated patients for whom less invasive and equally successful treatment options may be available. However, several recent studies have indicated that parietal pleurectomy can be performed via video-assisted thoracoscopic surgery (VATS) with acceptable risk in patients. Waller et al.<sup>97</sup> performed VATS parietal pleurectomy in 19 patients with MPE secondary to mesothelioma or metastatic adenocarcinoma. Symptomatic recurrent effusion occurred in three patients (15.7%). Tumor seeding at the thoracoscopic trocar sites occurred in 5 of 13 mesothelioma patients. More recently, Harvey et al.<sup>98</sup> performed VATS pleurectomy in 11 (5 non-small cell lung cancer, 4 breast cancer, 1 mesothelioma, 1 cancer of unknown primary) patients, with no recurrence and one death (1 of 11; 9%) due to sepsis from a necrotic tumor involving the liver. Other complications included prolonged air leak (one patient) and bleeding requiring reoperation and transfusion (one patient). The results of these two small series should not be viewed as justifications for more liberal application of VATS parietal pleurectomy as the first line of treatment for MPE. Instead, parietal pleurectomy should be reserved for malignant effusions that are refractory to less invasive and less expensive interventions.<sup>96</sup>

### **Pleuroperitoneal Shunt**

The pleuroperitoneal shunt, introduced in 1982, has been evaluated as a therapeutic option for the treatment of MPE.<sup>97</sup> It may be used for recurrent effusions that are refractory to tube thoracostomy and pleurodesis or for MPE associated with trapped lung.<sup>99,100</sup> and <sup>101</sup> The most commonly used device is the Denver pleuroperitoneal shunt (Denver Biomaterials, Inc., Golden, CO). The shunt is a silicone rubber conduit consisting of a unidirectional valved pump chamber connecting to pleural and peritoneal catheters. The pumping chamber can be implanted into a subcutaneous pocket or exteriorized as an external pumping chamber. Because of the negative pressure differential between the pleural and peritoneal cavities, manual compression of the pumping chamber is required for fluid drainage from the chest. Each compression transports 1.5 mL of fluid, and patients are frequently asked to compress the pump for 5 to 10 minutes four times daily. Implantation of the shunt can be performed under local or general anesthesia. Petrou et al.<sup>100</sup> used pleuroperitoneal shunt in 63 patients with recurrent MPE and trapped lung. There were no operative deaths, and complications were noted in 5 patients (8%). Effective palliation was achieved in more than 95% of cases. Catheter occlusion was noted in eight patients (12%) at 1 week to 4 months after insertion, with five patients requiring replacement or revision of the shunt and three patients requiring shunt removal

and treatment of empyema. Contraindications include pleural infection, multiple loculations, inability of the patient to press the chamber, short life expectancy, and obliterated peritoneal space.<sup>102</sup> The need for active pumping of the chamber a minimum of 400 times per day limits its usefulness to patients with excellent performance status. In addition, the shunt may malfunction over time, further limiting its usefulness. As such, the pleuroperitoneal shunt should be considered as one of the last alternatives for patients with refractory effusions.<sup>71</sup>

### Indwelling Pleural Catheter

Malignant pleural fluid can be drained for prolonged periods by a small-caliber biocompatible silicone rubber indwelling catheter. The Tenckoff (Quinton Instrument, Seattle, WA) and Denver (Denver Biomaterials) catheters have similar design, consisting of a 15-Fr. translucent silicone rubber tube with a radiopaque stripe, a felt or polyester cuff, and a plastic occluding device that may be opened to drain the fluid. The catheter is inserted in the operating room under local anesthesia. Two small skin incisions are made in the anterolateral chest. The catheter is brought through a 15-cm subcutaneous tunnel between these two incisions. The pleural cavity is accessed with a needle and, using the Seldinger technique and a Tear Apart Introducer kit (Quinton Instrument), the catheter is introduced into the pleural cavity and positioned so that the felt cuff on the catheter lies just within the exit wound. The advantages of pleural catheter placement are the ease of insertion and minimal discomfort due to the catheter, rapid drainage of recurrent symptomatic effusion, and minimal or no hospitalization required for catheter insertion and care. Robinson et al.<sup>103</sup> used the Tenckoff catheter to manage MPE in nine patients, with three patients having bilateral catheter placement for a total of 12 catheters inserted. Four of the nine patients had recurrent pleural effusion after failed tube thoracostomy and chemical pleurodesis. None of the patients had trapped lung. The authors reported excellent palliation of symptoms in all patients. Complications were minor, with insertion-site cellulitis that was easily managed with oral antibiotic in 3 of 12 catheter sites (25%).

A phase III trial comparing the efficacy of the Denver pleural catheter versus chest tube and doxycycline sclerotherapy for recurrent symptomatic MPE in 144 patients was recently completed (99 patients had Denver catheter, and 45 patients had doxycycline pleurodesis).<sup>104</sup> The Denver pleural catheter was as effective as doxycycline pleurodesis in relieving symptoms related to MPE and improving quality of life. At 90 days, pleurodesis was achieved in 69% of patients treated with Denver pleural catheter alone, as compared to 50% of patients treated with doxycycline. No patient in the catheter group experienced fluid reaccumulation. Moreover, patients treated with pleural catheter had shorter hospital stay (mean, 1.83 days) than those treated with chest tube and doxycycline pleurodesis (mean, 6.83 days). Pleural catheter, either a Tenckoff or a Denver catheter, is indicated for recurrent MPEs refractory to pleurodesis or those associated with trapped lung. The pleural catheter is particularly useful in debilitated patients in whom a reliable and painless method of fluid drainage is required or in patients with effusions secondary to chemosensitive malignancies.

### External-Beam Irradiation

Only lymphomatous pleural effusions seem to respond favorably to external-beam irradiation. Close to 90% of malignant lymphoma effusions have been controlled by mediastinal and hemithorax irradiation in a small series of patients (1.4 to 2.3 Gy).<sup>105</sup>

### SUMMARY

The prognosis of patients with MPE varies with the histologic type of the primary tumor. In general, 65% of patients with MPE are dead within 3 months and 80% within 6 months. As such, treatment of MPE should focus on expeditious and cost-efficient palliation. Our approach to patients with MPE having good performance status is talc pleurodesis. Indwelling pleural catheters have been frequently used for intermittent drainage of effusions in patients with trapped lung or limited life expectancies, as well as individuals on protocols requiring sequential analysis of molecular end points in tumor cells readily obtained from malignant effusions. The algorithm for the diagnosis and treatment of malignant pleural effusion is outlined in [Figure 52.5-1](#).

FIGURE 52.5-1. Treatment algorithm for malignant pleural effusion. CT, computed tomography.

## MALIGNANT PERICARDIAL EFFUSION

Patients with malignant pericardial disease may be asymptomatic or may present with a number of manifestations, with pericardial effusion being the most common. Pericardial tamponade due to malignant pericardial effusion (MPCE) accounts for at least 50% of all reported cases of pericardial fluid collection that require intervention. Similar to cancerous pleural effusions, MPCEs are frequently indicative of advanced incurable malignancy; overall median survival of patients with MPCE is less than 6 months.

### PATHOGENESIS AND ETIOLOGY

Malignant cells gain access to the pericardium either via direct invasion from an adjacent tumor or by hematogenous or lymphatic routes.<sup>106,107 and 108</sup> Many cardiac and pericardial metastases as well as pericardial effusions result from retrograde progression of disease through lymphatic channels draining the heart and pericardium.<sup>106,108</sup> The normal lymphatic circulation of the heart and pericardium consists of an extensive subendocardial plexus that drains via an intercommunicating system of myocardial channels into a subepicardial plexus. Efferent branches form from this subepicardial plexus and unite into larger trunks that initially follow, then subsequently diverge from, the coronary artery vessels near the aortic root and drain either directly into a cardiac node between the innominate artery and superior vena cava or into a pretracheal node and then into the cardiac node.<sup>108</sup> The cardiac node, in turn, drains into the mediastinal system. In addition, the subepicardial plexus interconnects with a superficial adventitial plexus of lymphatics surrounding the aorta.<sup>109</sup> The latter plexus drains through the paraaortic node and enters directly into the thoracic duct or the paratracheal system.<sup>110</sup> The parietal pericardium contains a relatively unimportant lymphatic system.<sup>110</sup> Thus, pericardial fluid drains primarily via the subepicardial plexus through a few large trunks to the cardiac node and then into the mediastinal nodal system; a secondary pathway involves communication with the lymphatic plexus of the aortic adventitia. Thus, lymphatics from the heart and pericardium appear to have a vulnerable isthmus-like section near the base of the heart. Consequently, impairment of cardiac lymphatic drainage with retrograde epicardial invasion may occur with limited mediastinal metastases.<sup>108</sup> Obstruction of epicardial venous and lymphatic drainage by neoplastic invasion alters the equilibrium between hydrostatic and osmotic forces and capillary filtration favoring fluid accumulation in the pericardial space. The rate of fluid accumulation (which can be rapid if accompanied by intrapericardial hemorrhage) and the degrees of pericardial compliance (which can be low from prior inflammation, irradiation, or tumor infiltration) determine the severity of clinical manifestations of MPCE.

Metastases involving the heart or pericardium (or both) occur relatively frequently in cancer patients.<sup>111,112 and 113</sup> Several autopsy series,<sup>114,115 and 116</sup> including one by Klatt and Heitz,<sup>114</sup> have indicated that cardiac metastases occur in approximately 10% of patients dying from cancer; the epicardium is involved in 75% of metastatic lesions, and pericardial effusions are present in one-third of these cases.<sup>115,116</sup> Metastasis from the lung (all histologies) and breast and hematologic malignancies account for three-fourths of MPCEs, with lung cancer being the most common etiology; virtually all malignancies (except primary brain tumors) may cause MPCE.

Neoplasms that invade the mediastinal lymphatics and obstruct pericardial lymphatic flow are commonly associated with pericardial effusion. Kline<sup>117</sup> observed cardiac metastases in 61 of 716 cancer patients; all the patients with cardiac involvement had metastases in mediastinal lymph nodes and lymphatics of the epicardium and

pericardium. Metastases to the pericardium or heart have been noted in approximately 30% of patients dying from lung cancer, <sup>118</sup> 65% of whom have pericardial effusion; the predominant metastatic pathway involves the hilar lymphatics in these individuals.

## CLINICAL PRESENTATION

In most cases, MPCE is observed in patients with a previous diagnosis of cancer, typically at late stages of their disease. MPCE is rarely seen as the initial manifestation of extracardiac malignancy; only 90 cases were reported in the English-language literature over a 55-year period. <sup>119</sup> The most common symptoms attributed to pericardial effusion are dyspnea, cough, chest pain, fever, and edema. Nonspecific complaints are also frequent; as such, pericardial effusion may remain unsuspected in patients in whom nonspecific symptoms are attributed to disease progression. The frequency of cardiac tamponade as the initial manifestation of malignant effusion is highly variable and depends on the rate of fluid accumulation, volume of the fluid, and underlying cardiac function. The pericardium may distend over a period to accommodate a large volume of fluid prior to the clinical appearance of tamponade. Impedance of right atrial and ventricular filling by pericardial fluid results in cardiac tamponade. Signs and symptoms of cardiac tamponade include dyspnea, orthopnea, low output (peripheral vasoconstriction, cold clammy extremities, poor capillary refill, and diaphoresis), jugular venous distention, distant heart sounds, pulsus paradoxus, and narrowed pulse pressure. Electrocardiography may show low voltage complexes in all leads and electrical alternans.

## DIAGNOSTIC MODALITIES

### *Radiographic and Echocardiographic Studies*

Pericardial effusion in asymptomatic patients is most frequently detected by plain posteroanterior and lateral chest radiographs. The typical finding on chest radiograph is an enlarged globular water-bottle pericardial silhouette ( [Fig. 52.5-2](#)). Moreover, when pericardial effusion and tamponade are caused by malignancy, concomitant parenchymal involvement or pleural effusion (or both) are observed in 30% to 50% of cases, respectively. <sup>120</sup> Once disease is suspected, echocardiography should be performed to confirm the presence and hemodynamic significance of pericardial effusion. Two-dimensional echocardiography can define the location and amount of effusion, as well as the presence of pericardial or intracardiac masses. Right atrial and ventricular collapse are the most common echocardiographic signs of cardiac tamponade, with sensitivity ranging from 38% to 60% and specificity ranging from 50% to 100% ( [Fig. 52.5-3](#)).<sup>121</sup> Echocardiography is frequently used to provide guidance for safe and accurate pericardiocentesis. <sup>122,123</sup>

**FIGURE 52.5-2.** Posteroanterior chest radiograph of a patient with significant pericardial effusion as indicated by an enlarged cardiac silhouette.

**FIGURE 52.5-3.** An early diastolic frame from the transthoracic echocardiogram (four-chamber view) of a patient who had classic clinical findings of pericardial tamponade. Note the large pericardial effusion (2-cm dark “echo-free” space) circumferentially around the heart. Early diastolic collapse of the right atrium—a useful, characteristic echo finding of tamponade physiology—is clearly seen where the right atrial cavity (RA) wall ( *arrow*) is deviated inward, into the RA chamber. LV, left ventricle; RV, right ventricle. (Courtesy of Eben E. Tucker, M.D., NHLBI, National Institutes of Health, Bethesda, MD.)

Pericardial effusion can also be diagnosed by CT scan, which can detect as little as 50 mL of pericardial fluid ( [Fig. 52.5-4](#)). This is not the diagnostic method of choice for pericardial effusion, since it is time-consuming to perform and is no more accurate than echocardiography. CT scan may be helpful in evaluating intrapericardial masses as well as defining the nature of the pericardial fluid, as the attenuation coefficients for exudates, chyle, serous fluid, or blood may differ. <sup>121,124,125</sup>

**FIGURE 52.5-4.** The chest computed tomographic scan of this patient with metastatic ovarian carcinoma shows a large malignant pericardial effusion and bilateral malignant pleural effusions (right more than left).

### *Cytopathology and Histopathology*

The foregoing imaging techniques provide information regarding the amount and hemodynamic significance of pericardial effusion but not its benign or malignant nature. Only 50% to 60% of pericardial effusions in cancer patients are confirmed by cytologic examination to be malignant. <sup>126,127</sup> and <sup>128</sup> Posner et al. <sup>129</sup> studied 31 patients with pericardial disease associated with various malignancies. Fifty-eight percent of the patients had MPCE, 32% had idiopathic pericarditis, and 10% had

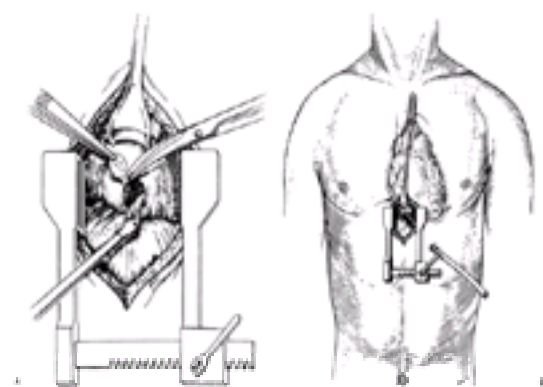

radiotherapy-induced pericarditis. Pericardiocentesis and cytologic examination of the fluid identified malignancy in 85% of positive cases; open biopsy was required for diagnosis in the remaining 15%. Weiner et al. <sup>116</sup> reviewed 95 cases of pericardial effusion treated initially by pericardiocentesis. Malignant cells were identified in pericardial fluid from two-thirds of cancer patients; cytology correlated with histologic diagnosis of the underlying malignancy in 100% of these individuals. Press and Livingston <sup>130</sup> reviewed 190 cases of MPCE diagnosed by pericardiocentesis. Pericardial fluid was positive for malignant cells in 151 patients with documented neoplastic pericarditis (specificity, 79%); hence, cytologic examination of pericardial fluid remains valuable in the diagnosis of MPCE, especially when positive for malignant cells. In contrast, parietal pericardial biopsy is frequently nondiagnostic, since the principal site of malignant infiltration is the visceral pericardium and its subepicardial lymphatics. Clarke and Cosgrove <sup>131</sup> performed a prospective study to determine the diagnostic value of pericardial biopsy in 25 patients with malignancy and pericardial effusions. Fluid cytology revealed malignant cells in 11 patients (44%), of whom only 5 had histologic evidence of malignancy in pericardial biopsy specimens.

## TREATMENT

The goals of treatment for MPCE include relief of immediate symptoms, confirmation of the malignant nature of the fluid, and prevention of recurrence. Although simple pericardiocentesis may be life-saving in cases of cardiac tamponade, this procedure alone is rarely adequate therapy for MPCE because of the high rate of fluid reaccumulation <sup>120</sup>; thus, if initially performed, pericardiocentesis should be followed by a more definitive medical or surgical procedure to prevent recurrence. Therapy for MPCE should be tailored to the performance status and prognosis of each patient; options include surgical procedures, such as subxiphoid pericardiostomy (pericardial window), transthoracic pericardial window or pericardiectomy (either by video-assisted thoracoscopy or thoracotomy), and medical interventions, such as percutaneous tube pericardiostomy with or without intrapericardial instillation of sclerosing agents.

### Subxiphoid Pericardiostomy (Subxiphoid Pericardial Window)

The subxiphoid pericardiostomy approach is now the most commonly performed surgical procedure for benign as well as MPCEs. This procedure can be performed under local anesthesia with intravenous sedation or general anesthesia ( Fig. 52.5-5). It can be performed as the initial procedure for MPCE in medically stable patients or after needle pericardiocentesis in patients with signs and symptoms of significant cardiac tamponade. A small vertical skin incision is made from the xyphoid process caudally for 4 to 6 cm. The upper linear alba is divided in the midline, and the xyphoid is either bisected or resected. The peritoneum is not open. The preperitoneal fat is dissected cephalad by blunt finger dissection. The plane between the posterior sternum and the anterior pericardium is then developed to allow insertion of a retractor to elevate the lower end of the sternum. The pericardium is identified as the bulging, grayish white, fibrous membrane. The anterior pericardium is then incised, fluid is drained, and samples are collected for cytologic and microbiologic analyses. The pericardium then is explored digitally to identify adhesions and tumor masses. A piece of pericardium (2 to 4 cm<sup>2</sup>) is excised and submitted for pathologic studies. Through a separate stab wound in the upper abdomen, a 28-Fr. curved chest tube is placed in the pericardial space through the pericardial window for postoperative drainage. Some authors advocate leaving the tube in place for 4 to 5 days, regardless of the drainage amount, to promote local inflammation and fusion of the visceral and parietal pericardium. No attempts are made to create a communication between the pericardial space and either the pleural or peritoneal space. Allen et al. <sup>132</sup> noted that autopsies of six patients who had undergone the subxiphoid procedure revealed complete pericardial symphysis with extensive adhesions. A comprehensive review of the clinical experience pertaining to 654 patients with effusion of different etiologies who underwent subxiphoid pericardiostomy has indicated an overall mortality rate of approximately 0.46% (range, 0% to 5%), an overall morbidity rate of approximately 1.53% (range, 0% to 10%), and a recurrence rate of approximately 3.5% (range, 0% to 9.1%). These low mortality, morbidity, and recurrence rates compare very favorably with those attributable to percutaneous pericardiocentesis and pericardiostomy with or without sclerosis (0.7% mortality, 3% morbidity, and 13% recurrence; Table 52.5-3, Table 52.5-4).

**TABLE 52.5-4.** Percutaneous Catheter Drainage for Pericardial Effusions

### Partial Pericardiectomy or Pericardial Window via Thoracotomy

Before the recent resurrection of subxiphoid pericardial window as the preferred surgical treatment for pericardial effusion, pericardial window or even pericardiectomy

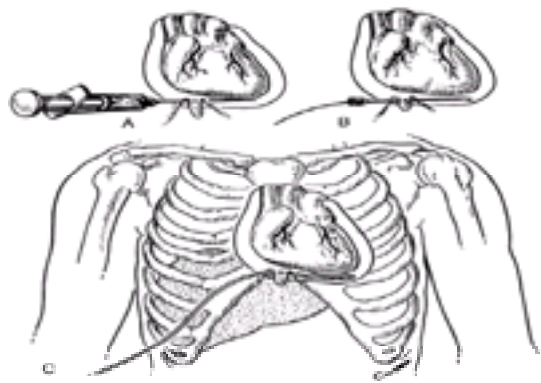

via a thoracotomy incision were advocated. Piehler et al.<sup>133</sup> reviewed their experience with surgical management of pericardial effusions in 145 patients and suggested that the extent of pericardial resection influenced incidence of recurrent effusions. However, several recent series indicate no difference in recurrence rates of patients treated by subxiphoid pericardiostomy as compared to those undergoing transthoracic drainage.<sup>134,135</sup> More importantly, postoperative complications (pneumonia, pleural effusion, respiratory failure, cardiac arrhythmia, deep vein thrombosis, and pulmonary embolism) are much less frequent after subxiphoid pericardial drainage as compared to transthoracic pericardial resection (10% vs. 50%, respectively). Thus, transthoracic pericardial resection is not a suitable initial procedure for drainage of MPCE.

If possible, VATS<sup>136,137</sup> and <sup>138</sup> should be used if transthoracic pericardial resection is required for recurrent effusion after subxiphoid pericardiostomy or for diagnosis and treatment of simultaneous pleural-parenchymal pathology. Compared to thoracotomy, minimally invasive approaches are more suitable interventions in debilitated cancer patients. The potential limitation of VATS pericardiectomy is the need for general anesthesia and single-lung ventilation. Pericardial resection via laparoscopy or video-assisted subxiphoid pericardial window have been reported<sup>139</sup>; however, there is no added benefit of these expensive minimally invasive techniques compared to standard subxiphoid pericardiostomy. Pericardial-peritoneal shunt, using a Denver pleuroperitoneal catheter with pumping chamber, has been used to treat MPCE in a limited number of patients<sup>140</sup>; experience with this technique is too limited to allow adequate assessment of its clinical utility, although it may be suitable for pericardial effusions that are refractory to repeated pericardiostomy procedures.

### Pericardiocentesis

Pericardiocentesis can be life-saving when performed on patients with hemodynamically significant cardiac tamponade. Removal of as little as 50 mL of pericardial fluid can significantly improve signs and symptoms of acute tamponade. Traditionally, after subcutaneous infiltration of 1% lidocaine (Xylocaine) local anesthetic solution, the needle is inserted at the right side of the xyphoid process and directed 45 degrees dorsally, aiming toward the tip of the left scapula ( Fig. 52.5-6). In cancer patients with symptomatic pericardial effusion, pericardiocentesis may be performed to stabilize patients prior to more definitive drainage procedures, such as percutaneous tube pericardiostomy or subxiphoid pericardial window.

**FIGURE 52.5-6.** Percutaneous pericardiocentesis and placement of an indwelling catheter for pericardial effusion. (From DWO Moores, SW Dziuban. Pericardial drainage procedures. *Chest Surg Clin North Am* 1995;5:359, with permission.)

As the sole treatment for MPCE, pericardiocentesis is associated with recurrence requiring further treatment in up to 70% of cases.<sup>141</sup> This procedure has been associated with a significant incidence of complications, some of which are fatal even when performed by experienced physicians. Allen et al.<sup>132</sup> observed clinically significant complications in 5 of 23 patients (22%) undergoing percutaneous pericardiocentesis, including three right ventricular perforations (with one fatality) requiring surgical interventions, one ventricular arrhythmia requiring cardioversion, and one pneumothorax. The complication rate observed by Allen et al. exceeds that reported by Vaitkus et al.,<sup>142</sup> who summarized experience with pericardiocentesis in 139 patients with MPCEs. Percutaneous pericardiocentesis successfully alleviated symptoms in 97% of the cases; morbidity and mortality in this series were 3% and 0.7%, respectively.

Echocardiography may reduce complications and improve the success of the pericardiocentesis by delineating the size and location of the effusion relative to cardiac structures. Overall rates of complication and success are approximately 2.4% and 100%, respectively, after ultrasound-guided pericardial drainage<sup>144,145</sup> as compared to 4.8% and 90%, respectively, after unassisted pericardiocentesis.<sup>131,146</sup>

### Percutaneous Tube Pericardiostomy and Pericardial Sclerotherapy

The rates of fluid reaccumulation have been reported to range from as low as 44% to as high as 70% after pericardiocentesis.<sup>147</sup> It is now a common practice to place a 9-Fr. pigtail draining catheter into the pericardial space after successful needle pericardiocentesis using the Seldinger technique to enable more complete evacuation of the effusion and provide access for sclerotherapy. Although several agents have been used in the past, tetracycline and its currently available derivative, doxycycline, have been most extensively evaluated as sclerosing agents for pericardial effusion. Maher et al.<sup>147</sup> reported their experience with 93 patients with MPCE treated by percutaneous pericardial drainage followed by tetracycline or doxycycline sclerotherapy. Successful placement of the pericardiostomy tube was achieved in 85 patients (91.4%). Pericardial effusion was controlled in 75 of the 85 patients (88%); 10 of the 85 patients (12%) did not respond to sclerosis, of whom 8 subsequently underwent surgical pericardiostomy. Sclerotherapy necessitated one to eight instillations of tetracycline or doxycycline (median, 3); 50 patients required three or more instillations to control their effusions. Treatment-related complications (in decreasing order of frequency) included pain, catheter occlusion, fever, and atrial arrhythmias. The apparently favorable results of this minimally invasive treatment strategy are offset by the need for repeated instillations of the sclerosing agent to achieve pericardial symphysis. Liu et al.<sup>148</sup> recently conducted a prospective study to evaluate the efficacy and toxicity of bleomycin versus doxycycline as the sclerosing agents for MPCE. Bleomycin was found to be as effective as doxycycline in achieving satisfactory control of MPCE, yet with much less retrosternal pain. As a result, these authors recommended that bleomycin be considered the first-line chemical sclerosing agent for treating MPCE. In addition to bleomycin or doxycycline, other sclerosing agents used for treating MPCE include OK-432 (a penicillin-treated and heat-treated lyophilized powder of the *Staphylococcus aureus* substrain A3),<sup>148</sup> cisplatin,<sup>149</sup> vinblastine,<sup>150</sup> and sterile talc. The clinical utility of these adjunctive sclerosing agents is not known, and their use cannot be considered standard of care at this time.

### Percutaneous Balloon Tube Pericardiostomy

Percutaneous balloon tube pericardiostomy, initially advocated by Ziskind et al.<sup>151</sup> and subsequently studied by others,<sup>152,153</sup> appears to be an extension of the more commonly performed percutaneous tube pericardiostomy. After successful pericardiocentesis, dilatation of the needle tract is performed under fluoroscopy using a balloon catheter. Ziskind et al.<sup>151</sup> reported that this technique was effective in relieving pericardial effusion in 46 of 50 patients (92%). Procedure-related complications included fever (six patients), pleural effusion requiring chest tube placement or thoracentesis (eight patients), small pneumothorax (two patients), and right ventricular injury requiring surgery (one patient), for an overall clinically significant complication rate of 18%. Even though this is an effective minimally invasive technique of pericardial drainage, its widespread application may be limited by the need for specialized equipment as well as for interventional cardiologists or radiologists. The high incidence of inadvertent pleural effusions requiring drainage renders this technique less attractive compared with others discussed.

### Local or Systemic Therapies for Malignant Pericardial Effusion

Radiotherapy is generally reserved for MPCE associated with lymphoma or breast carcinoma. Vaitkus et al.<sup>142</sup> reviewed the experience of 54 patients treated with radiotherapy as the primary mode of therapy for MPCE. Of these patients, 39 (72%) underwent initial pericardiocentesis. The majority received neither systemic nor other direct pericardial intervention. Radiation therapy was successful in controlling MPCE in 36 patients (66.7%). The highest success rates were noted in leukemia-lymphoma and breast cancer patients (93% and 71%, respectively). Surprisingly, 45% of patients with other solid tumors had adequate control of their effusions. Although noninvasive, radiotherapy requires repeated visits or even prolonged hospitalization and may theoretically cause acute pericarditis or myocarditis. These potential complications may not be relevant in many patients, owing to their limited survival.

Patients with MPCE secondary to lymphoma or breast carcinoma may have effusions controlled with systemic chemotherapy. Vaitkus et al.<sup>142</sup> reported their

experience with 46 patients with breast tumor (n = 38), lymphoma (n = 2), or other solid tumors (n = 6) treated with systemic chemotherapy. Thirty-six patients (78%) underwent initial therapeutic pericardiocentesis. Systemic chemotherapy prevented recurrence of effusion in 31 patients (67%); successful control of effusion was achieved in more than two-thirds of these individuals irrespective of whether pericardiocentesis preceded systemic therapy.

## SUMMARY

MPCE is frequently an indication of advanced, incurable malignancy. Hence, the goals of intervention include relief of symptoms and prevention of recurrence. The treatment of MPCE should proceed in a stepwise fashion (Fig. 52.5-7). Surgical interventions (subxiphoid pericardiostomy) or medical interventions (ultrasound-guided percutaneous tube pericardiostomy and sclerotherapy) have acceptable risks and provide excellent results. We favor surgical drainage as the primary approach for patients with MPCE because of its simplicity and extremely high success rate without the need for intrapericardial instillation of sclerosing agents and tube manipulations that may be associated with patient discomfort. Recurrent MPCE can be managed either by repeat pericardiostomy or insertion of a shunt. Patients responding to treatment with complete control of the effusion should have a meaningful survival with life expectancy (average, 9 months) contingent on the histology of the underlying malignancy.

Only a minority of all causes of ascitic fluid collections is malignancy, particularly in children,<sup>22</sup> and approximately one-third of patients with known malignancy have nonmalignant causes of ascites.<sup>26</sup> Thus, assays have been described that help determine the neoplastic origin of the ascites.<sup>27,28</sup> and<sup>29</sup> A prognostic significance has been attributed to biochemical or immunologic markers.<sup>30,31</sup> and<sup>32</sup> Peritoneal fluid cytology yields a diagnosis in a large proportion of patients.<sup>26</sup> The presence of elevated ascitic/serum ratios of protein or lactic dehydrogenase, carcinoembryonic antigen, CA-125, fibronectin, or cholesterol favor neoplasm.<sup>24,33</sup> Others proposed the measurement of human chorionic gonadotropin in serum and ascitic fluid for the identification of gynecologic malignancies.<sup>34</sup> Vascular endothelial growth factor levels have been noted to be significantly elevated in malignant ascites compared with ascites from benign causes.<sup>35</sup> Immunochemical combinations have been described for the diagnosis of adenocarcinomas and other malignancies.<sup>27,36</sup> El-Habashi et al.<sup>36</sup> reported the use of a battery of monoclonal antibodies against p53, B72.3, and c-erbB-2 as complement to conventional cytology to enhance diagnostic sensitivity and accuracy.

Approximately 20% of patients with malignant ascites present without an identified primary cause.<sup>37</sup> In these patients, particularly women,<sup>23</sup> attempts to identify the tumor of origin should be undertaken because the identification of the primary histology may influence the treatment strategy. Laparoscopy in 129 patients with unknown primary identified carcinomatosis in 60%<sup>38</sup> and laparoscopy with peritoneal biopsy was able to establish the cause of ascites in 86% of these cases. Although laparoscopy in patients with ascites has been rarely associated with prolonged leak from the port site<sup>38,39</sup> or port site recurrence,<sup>40</sup> it can be considered a safe tool for the evaluation of ascites. Approximately 75% of women presenting with malignant ascites of unknown origin have a gynecologic cause (ovary, uterus, or cervix) and another 10% a gastrointestinal cause, while in men the gastrointestinal etiology predominates.<sup>23,37,41,42</sup> Other histologies should be considered, particularly when a primary tumor deposit is not recognized after routine studies of the abdominal cavity. These unusual causes of malignant ascites may create a difficult diagnostic challenge such as the differentiation of mesothelioma cells from normal mesothelial cells<sup>28,29</sup> or the analysis of lymphoid-rich effusions in the case of lymphoma.<sup>42</sup> Unusually, ascites can be the result of cancer treatment.<sup>43</sup>

## TREATMENT OF MALIGNANT ASCITES

As the pathogenesis of malignant ascites differs from the pathogenesis of most ascitic fluid collections secondary to benign processes, the treatment is often different in many respects.<sup>23</sup> Excess fluid formation<sup>44</sup> as well as obstruction of lymphatic channels<sup>45,46</sup> are believed to be the most relevant factors inducing malignant ascites. Since most of the time there is no underlying venous obstruction, portal hypertension is unusual and vascular shunting procedures are not indicated. Several strategies have been used with the primary goal of achieving palliation, as the presence of malignant ascites is perceived as a sign of end-stage disease. A survey of practicing physicians suggested that the most common mean of managing malignant ascites is paracentesis, which is also believed to be the most effective.<sup>17</sup> After paracentesis, diuretics and peritoneovenous shunting were most commonly used. In particular cases, radical surgical procedures or aggressive intracavitary therapies have been advocated, however, to date no well-controlled prospective randomized trial has been performed to compare alternative treatments. The encouraging results reported by many pilot phase I or II studies involving intracavitary instillation of chemotherapeutic agents have not matured, with few exceptions, into randomized phase III trials. The median survival of patients with symptomatic malignant ascites is approximately 2 months (Table 52.6-3).<sup>23</sup> In general for nonovarian malignant ascites, the focus is on palliation of symptoms. Patients with malignant ascites secondary to ovarian cancer represent an exception because they have a significantly better survival expectation.<sup>47</sup> Thus, investigation of female patients presenting with ascites of unknown origin should be particularly thorough. Patients with large volume nonovarian ascites have a high mortality (41%) following major abdominal surgery. For these patients, Yazdi et al.<sup>48</sup> have suggested intraperitoneal chemotherapy or peritoneovenous shunt placement at the time of the abdominal operation.

TABLE 52.6-3. Patient Survival after Peritoneovenous Shunting

## DIURESIS AND RESTRICTION OF SALT AND FLUID INTAKE

Loop diuretics, salt restriction, and aldosterone-inhibiting diuretics are generally not beneficial since sodium retention is not a cause of malignant ascites, although spironolactone is seldom used. Pockros et al.<sup>49</sup> noted that cancer patients with portal hypertension-related ascites caused by massive hepatic metastases were most likely to experience palliation when treated with diuretics. The administration of albumin was never proven beneficial in delaying fluid reaccumulation nor more effective than crystalloid solutions in restoring intravascular volume depletion after drainage of large quantities of peritoneal fluid.

## REPEATED PARACENTESIS AND EXTERNAL DRAINS

Symptoms of malignant ascites may be relieved by repeated abdominal taps as needed. Gough et al.<sup>50</sup> reported no difference in survival and quality of life between patients treated with repeated abdominal paracentesis and patients treated with peritoneovenous shunts. However, several concerns are raised by this approach, including the risk of infection, electrolyte and fluid imbalances secondary to the sudden depletion of body fluids, and the risk of causing intraperitoneal visceral injury. For this reason multiple methodologies describing the implantation of permanent drains in the peritoneal cavity have been described.<sup>51</sup> Although good palliation can be achieved in this fashion, the life span of these drains is limited by the need for removal because of malfunction or infection. Lorentzen et al.<sup>52</sup> have reported the use of ultrasonically guided insertion of peritoneogastric shunts in patients with malignant ascites using a Denver shunt connected to a gastrostomy tube. This technique allows intermittent removal of fluid that, on pumping, is shunted to the stomach lumen. Others have advocated peritoneal-urinary drainage for the treatment of refractory ascites.<sup>53</sup> These methods have potential benefits compared with the external drain (in which the ascitic fluid is totally removed from the body) and peritoneovenous shunts (returning the drained fluid from the peritoneal cavity directly to the intravascular space).

## INTRACAVITARY THERAPY

Instillation of radioactive isotopes, including colloidal suspensions of <sup>32</sup>CrPO<sub>4</sub>, was originally reported with minimal side effects.<sup>16</sup> Weisberger et al. performed intraperitoneal administration of nitrogen mustard in seven patients with advanced ovarian cancer with effective reduction of the amount of ascites in all patients.<sup>54</sup> The rationale for this therapeutic approach is based on the intuition that, due to limited peritoneal absorption, some drugs could be administered in high concentrations in the peritoneum with relatively few systemic effects.<sup>55</sup> Cisplatin and mitoxantrone used alone or in combination with other agents have become first-line chemotherapeutic agents for the treatment of peritoneal carcinomatosis.<sup>5,56,57</sup> Cisplatin is mostly used for the intraperitoneal treatment of ovarian carcinoma because of its high effectiveness against this cancer when given systemically. To enhance the local effectiveness of intraperitoneally administered cisplatin while diminishing the side effects related to its systemic absorption, intravenous administration of thiosulfate has been recommended.<sup>56</sup> Kirmani et al. reported a 30% complete response rate in patients who underwent intraperitoneal cisplatin and etoposide administration after failure of first-line platin-containing systemic treatments.<sup>58</sup> This study was performed on patients with small bulk of disease (less than 2 cm) and suggested that, as for systemic therapy, the load of tumor may play a role in the response rate. Several authors have investigated the use of intraperitoneal treatment in combination with debulking surgery<sup>8</sup> or after first-line systemic therapy.<sup>59</sup> As previously discussed, Howell et al. reported a 49-month median survival with intraperitoneal instillation of cisplatin in 25 patients with microscopic disease (less than 0.5 cm) after first-line chemotherapy. The dose intensity of cisplatin administration has been increased without added toxicity. Bonetti et al. administered high-dose intraperitoneal cisplatin twice a week.<sup>60</sup> Hagiwara et al. reported a 92% response rate with the intraperitoneal administration of cisplatin lactic

acid oligomer microspheres in patients with malignant ascites.<sup>61</sup> Park et al. reported their experience in treating 18 patients with primary peritoneal mesothelioma with continuous hyperthermic peritoneal perfusion and cisplatin.<sup>3</sup> Thirteen of the 18 patients had associated malignant ascites. Continuous hyperthermic peritoneal perfusion with cisplatin was successful in 12 of the 13 cases. The median progression-free survival in this study was 26 months and the overall 2-year survival was 80%, superior to the survival reported in historical controls. The same group has evaluated the feasibility of a combination continuous hyperthermic peritoneal perfusion, cisplatin, and tumor necrosis factor.<sup>15</sup> This combination was evaluated in 27 patients with peritoneal carcinomatosis of multiple etiologies. There was no mortality, the complication rate was minimal, and the clinical outcome of this modality of treatment is presently under investigation. Gilly et al. reported resolution of malignant ascites in 11 of 12 patients treated with intraperitoneal chemotherapy and hyperthermia consisting of either cisplatin or mitomycin C after surgical resection of bulk disease. Intraperitoneal instillation of the chemotherapeutic agent was done after closure of the abdominal cavity and heated at the inflow temperature of 46° to 49°C.<sup>7</sup> Patients had ascites secondary to digestive or ovarian primary; the median survival was 11.2 months, and the 1-year survival rate was 46.9%. Similarly, Loggie et al. reported a median survival of 10.1 months in patients with nonovarian malignant ascites treated with cytoreductive surgery and intraperitoneal hyperthermic chemotherapy with mitomycin C.<sup>47</sup> Interestingly, in the same trial, 12 additional patients who did not present with ascites but had positive cytologic evaluations at the time of operation were treated with the same treatment protocol. None of these patients developed ascites subsequent to this treatment and their median survival was 32.7 months, suggesting that intraperitoneal hyperthermic chemotherapy may have a role in preventing the formation of malignant ascites. Several other authors have addressed the use of hyperthermia in combination with local chemotherapy for the treatment of gastrointestinal malignancies with similar results.<sup>8,9</sup>

To evaluate the relative effectiveness of intraperitoneal versus systemic administration of cisplatin in patients with ovarian cancer, Kirmani et al. completed a phase III randomized trial.<sup>62</sup> This is the only randomized trial addressing the efficacy of intracavitary versus systemic therapy for peritoneal carcinomatosis. In this study, patients (29) were randomized to receive six cycles of intraperitoneal cisplatin (22 mg/m<sup>2</sup>) and etoposide (350 mg/m<sup>2</sup>). As an example of the importance of prospective randomized trials, in spite of the anecdotally derived enthusiasm for intracavitary therapy, no difference was noted in response rate (48% intraperitoneally vs. 52% intravenously). The rate of complete response at second-look laparotomy was 31% and 33%, respectively, and at a median follow-up of 46 months there was no difference in response duration and survival. Furthermore, there was no difference in response rate in relation to the bulk of tumor present at the time of chemotherapy (less than or equal to or greater than 1 cm). The authors concluded that the small number of patients tested did not allow a definitive dismissal of the usefulness of the intraperitoneal approach. To our knowledge, no follow-up evaluation of a larger cohort of patients has been published since, and the same group has turned its interest toward the evaluation of new agents such as the intraperitoneal instillation topotecan.<sup>63</sup> Other alternatives to cisplatin have been suggested including the intraperitoneal administration of carboplatin, etoposide, and granulocyte-macrophage colony-stimulating factor,<sup>64</sup> with a partial response rate of 69%. Steller et al. reported the treatment of small-volume residual ovarian cancer with continuous hyperthermic peritoneal perfusion and carboplatin in the context of a phase I trial.<sup>4</sup> This well-tolerated modality of treatment may have important applications for novel therapies given intraperitoneally.

Biologic response modifiers have been used as an alternative to chemotherapeutic agents for the treatment of intraperitoneal carcinomatosis. Single-agent interferon-a,<sup>11,14</sup> or interferon-b,<sup>65</sup> tumor necrosis factor,<sup>66</sup> and interleukin-2, with or without adoptive administration of lymphokine-activated killer cells,<sup>12,13,65,67</sup> have been reported with variable success. A randomized trial has compared the effectiveness of interleukin-2, interferon-a or interferon-b for the control of malignant effusions, suggesting a higher efficacy of interleukin-2, particularly in patients with mesothelioma.<sup>65</sup> Others have reported effectiveness of the combined intraperitoneal administration of interleukin-2 and OK-423 in patients with ascites secondary to gastric malignancy.<sup>68</sup> The authors reported an incidence of cytologic disappearance of cancer and decrease of ascites in 81% of 22 evaluable patients. The role of interferon-g has also been explored in patients with malignant ascites because of the ability of this cytokine to induce up-regulation of tumor-associated antigens,<sup>69</sup> major histocompatibility complex molecules, or both in tumor cells.<sup>70</sup> This property suggested possible therapeutic usefulness combining this cytokine with the administration of major histocompatibility complex-restricted T cells in view of the enhanced lysability of tumor cells expressing higher amounts of major histocompatibility complex molecules.<sup>71</sup> Phase I studies of adoptive cellular immunotherapy with intraperitoneal injection of activated human blood monocytes have shown the feasibility of this approach.<sup>72</sup> Radioiodinated monoclonal antibodies directed against tumor markers have also been used.<sup>73</sup>

## RADICAL SURGERY

*Peritonectomy* has been advocated by Sugarbaker<sup>2</sup>: this is an extensive debulking procedure using a ball-type electrocautery device. It includes six possible steps: (1) greater omentectomy-splenectomy; (2) left upper quadrant peritonectomy; (3) right upper quadrant peritonectomy; (4) lesser omentectomy-cholecystectomy with stripping of the omental bursa; (5) pelvic peritonectomy with sleeve resection of the sigmoid colon; and (6) antrectomy. The purpose of the procedure is cytoreduction in preparation for intraperitoneal chemotherapy. The authors reported good long-term results in selected patients affected with peritoneal carcinomatosis, sarcomatosis, and mesothelioma.<sup>2,74,75</sup> Intraperitoneal chemotherapy included mitomycin C and 5-fluorouracil for patients with adenocarcinoma and cisplatin and doxorubicin for patients with sarcoma.<sup>75</sup> Among patients with enteric carcinomatosis, favorable prognostic characteristics were identified that include low-grade histopathology, absence of lymph nodal metastases, and completeness of the cytoreductive procedure (survival at 3 years was 99%).<sup>74</sup> A follow-up report from the same group identified a significant difference in 5-year survival between patients with stage III gastric cancer who had undergone surgery alone (18.4%) versus patients who underwent additional intraperitoneal chemotherapy (49.1%;  $F = .011$ ).<sup>63</sup> In this series patients had resectable gastric cancer and no ascites. This randomized study demonstrates, in principle, that intraperitoneal chemotherapy may have a role in the treatment of aggressive, nonovarian, intraabdominal cancers likely to lead to malignant ascites. A pilot study describing the use of photodynamic therapy as adjuvant therapy after aggressive debulking of disseminated intraperitoneal malignancies by Sindelar et al.<sup>10</sup> has shown a 26% disease-free survival rate at 18 months. These results in selected patients, however, still await confirmation by a randomized trial.

## PERITONEOVENOUS SHUNTING

An extensive discussion about the application of shunting procedures for the treatment of malignant ascites has been reviewed by Alexander and Fraker.<sup>76</sup> In patients with symptomatic malignant ascites, internal peritoneovenous shunting represents the standard modality of care. The devices consist of (1) a length of multiply perforated tubing to be inserted in the free peritoneal cavity, (2) a length of tubing to be inserted into the superior vena cava (or other large venous vessel), and (3) a unidirectional flow valve connecting the two limbs (Fig. 52.6-1). The two most popular devices are the LeVein shunt and the Denver shunt. The latter shunt has a one-way pump that can be manually pumped by the patient or physician to clear debris. Originally, the shunts were used for the treatment of ascites secondary to nonmalignant causes, but this technique was eventually applied to malignant ascites as well.<sup>77,78,79,80,81</sup> and <sup>82</sup> Briefly, the principle underlying the function of the shunt takes advantage of the pressure gradient (5 to 15 cm H<sub>2</sub>O) existing between the abdominal and the thoracic cavities. On inspiration, the further increase in pressure gradient (due to increased negative pressure within the thorax) drains fluid from the abdominal cavity by allowing the unidirectional valve to open. The surgical procedure for the placement of the shunt can be done under local or general anesthesia. Prophylactic antibiotic coverage is recommended, as with the placement of any prosthetic material. In the traditional approach, a muscle-splitting subcostal incision is performed and the intraperitoneal portion of the shunt is placed using a nonabsorbable pursestring suture to secure the limb in a watertight fashion. Current product guidelines recommend the percutaneous insertion of the peritoneal catheter using a peel-away introducer if allowed by the patient's anatomy. A second incision is performed in the neck to expose the internal jugular vein in which the venous portion of the shunt will be introduced. Alternatively, the venous catheter may be inserted percutaneously into the subclavian vein. A subcutaneous pocket is fashioned for the pump over the lower rib cage (in the case of a Denver shunt) and a subcutaneous tunnel is developed linking the abdominal and neck or chest incision. The venous limb is passed through the tunnel and introduced in the central venous system according to the chosen technique. Before placement of the intravenous portion of the shunt, the flow of ascitic fluid through the device needs to be demonstrated to exclude malpositioning or kinking within the abdominal cavity. Before terminating the procedure, shunt placement needs to be checked either fluoroscopically or with a portable chest and abdominal radiograph as malposition or kinking of the catheter may be responsible for immediate malfunction.

**FIGURE 52.6-1.** The peritoneovenous shunt *in situ*.

The indication for the placement of a peritoneovenous shunt has traditionally been the relief of symptoms caused by malignant ascites refractory to medical management. It is, therefore, reasonable to expect that, with the development of more effective systemic or intraperitoneal therapy the need for this procedure will decline. The median survival of 674 patients with refractory malignant ascites (gastrointestinal primary in 33%, ovarian primary in 27%, and other malignancies in 39%) undergoing placement of a peritoneovenous shunt is 5 to 33 weeks with 0% to 13% of patients alive at 1 year ( [Table 52.6-3](#)). Therefore, the goal of the peritoneovenous shunt placement is to minimize the side effects caused by the procedure and the presence of a foreign body and provide significant palliation. The wide variation in the range of patient survival after placement of a peritoneovenous shunt is most likely due to differences in patient selection criteria. Other variables such as protein content<sup>83</sup> or number of neoplastic cells in the ascitic fluid<sup>83</sup> have accounted for differences in shunt function and patient survival. A comparison of survival and quality of life in patients receiving shunting procedures versus repeated paracentesis failed to demonstrate significant differences.<sup>50</sup>

Immediate postinsertion complications related to placement of the peritoneovenous shunt include shunt malfunction due to technical reasons and pulmonary congestion due to sudden flow of ascitic fluid within the intravascular space.<sup>78,84</sup> Checking the position of the device fluoroscopically before ending the surgical procedure can prevent malfunction; fluid overload can be prevented by removing a significant proportion of ascitic fluid at the time of placement of the shunt.<sup>85,86</sup> Careful preoperative patient selection and postoperative monitoring of fluid and electrolyte balance is important to minimize this complication. Disseminated intravascular coagulation following shunt placement is a rare event in malignant ascites when compared with cirrhotic ascites<sup>87</sup> because of the significantly decreased fibrinolytic activity present in malignant effusion.<sup>88</sup> However, the coexistence of liver malfunction (e.g., liver metastases) may enhance the risk of coagulopathy.<sup>89</sup> The development of a coagulopathy after placement of a shunt needs to be managed according to standard treatment for this condition. A common postoperative symptom associated with placement of a peritoneovenous shunt is fever and should not be considered by itself as a sign of sepsis.<sup>77,79,90</sup> Finally, a rare complication of placement of a peritoneovenous shunt is the development of pulmonary tumor embolization with a possibly fatal outcome.<sup>91</sup>

A significant proportion of shunts stop functioning before the patient's demise because of occlusion, which is independent of the type of device used.<sup>50,78,79</sup> and <sup>80,84,86</sup> Although the Denver shunt provides a pump that allows manual flushing at periodic intervals, the literature has failed to demonstrate functional superiority of this device. It has been reported, however, that flushing of the Denver shunt combined with the administration of thrombolytic agents can occasionally restore shunt function.<sup>84</sup> Relocation of the catheter is usually necessary to establish patency since thrombolytic agents are infrequently successful in this situation. The goal in reestablishing flow in the system is correction of the source, avoiding replacement of the entire shunt. Shunt malfunction is usually manifested by recurrence of ascites and can be demonstrated by visualization of nucleotide in the lungs after intraperitoneal injection of 99mTc macroaggregate albumin.<sup>92</sup> A shuntogram performed by percutaneous injection of radiographic contrast agents into the venous limb of the shunt (into the pump reservoir if a Denver shunt) helps determine the site of obstruction. We previously described shunt occlusion by thrombofibrinous encasement of the venous limb, manifesting as a characteristic contrast outline of the tubing during shuntogram.<sup>93</sup>

Another complication of peritoneovenous shunt placement is infection in the peritoneal cavity. This can be associated with postoperative leakage of peritoneal fluid around the insertion site and is prevented by placing watertight double-pursestring sutures. The development of spontaneous bacterial peritonitis, unrelated to operative infection or to perforation of a viscous due to the malignant process, is, for unknown reasons, less likely in patients with malignant ascites than in cirrhotic patients. It has been noted that malignant peritoneal fluid has significantly higher concentrations of transferrin than cirrhotic ascites. As transferrin concentration in peritoneal fluid is inversely correlated with bacterial growth, it is possible that patients with malignant ascites are somewhat more protected against peritonitis than cirrhotic patients.<sup>94</sup> Evidence of hematologic dissemination of tumor cells from the ascitic fluid and tumor growth along the shunt tract has been reported and it is likely to occur relatively often.<sup>78,91,95,96</sup> However, this theoretical risk has not been a problem, most likely because of the limited survival of these patients.

The decision to place a peritoneovenous shunt should be made after consideration of the various risks and potential benefits. According to Souter et al.,<sup>97</sup> a patient with malignant ascites whose only considered therapeutic goal is palliation, should first undergo repeated paracentesis and medical management with diuretics. If the rate of reaccumulation of the fluid is rapid, fluid consistency is not viscous or bloody, there is no evidence of intracavitary loculation,<sup>83</sup> and the expected survival is more than 3 months, shunting should be considered. Contraindications for placement of the shunt are presence of intraperitoneal infection and cardiac or renal insufficiency. To avoid the massive fluid shifts associated with drainage of refractory ascites, Daimon et al. proposed the use of extracorporeal ultrafiltration of the ascites followed by intravenous reinjection of the ultrafiltered fluid.<sup>98</sup> Among the various patients treated in this fashion, two had malignant ascites. This approach was well tolerated and both patients died of their primary disease free of symptoms related to ascites.

In summary, malignant ascites represents in most instances a debilitating symptom of end-stage cancer. Purely palliative measures on one extreme and aggressive therapeutic intervention on the other represent the wide range of treatment options. Reported survival of patients treated with curative intent, in general, is better than that of patients receiving palliative procedures, but clearly reflects differences in patient selection (differences in stage, histology, extent of disease, and so forth). No randomized studies have been performed to evaluate the treatment of malignant ascites. Several questions remain unanswered, such as the value of a peritoneovenous shunt insertion compared with medical management or intermittent drainage; the role of external versus internal drains; and the effectiveness of locoregional curative efforts. Scant information is available regarding the effectiveness of intracavitary versus systemic therapy.

## INTRODUCTION

Despite the increasing use of hematopoietic growth factors, transfusion therapy continues to play an important role in the care of oncology patients. In fact, transfusion therapy has become increasingly critical as improved therapeutic regimens prolong the survival of patients with malignant disease. These patients often require frequent blood transfusions when they develop severe anemia, hemorrhage, thrombocytopenia, and coagulation disorders caused by their disease, treatment, or both.

The development of sterile, disposable, and flexible plastic containers has resulted in the concept of *blood component therapy*.<sup>1</sup> Whole blood is first separated into cellular and noncellular components including red blood cells, platelets, and plasma. Individual blood components are then stored under optimal conditions and only that portion of blood required by the patient is transfused ( [Table 53.1-1](#) ). Thus, blood resources that often reach critically low inventory levels in the blood bank are more efficiently used.<sup>2</sup> Anticoagulants and additives currently used in blood collection containers allow storage of liquid red cells for up to 42 days. These advances have essentially eliminated the use of whole blood for allogeneic blood transfusion. Cancer patients may also require coagulation factor concentrates, albumin, or immune globulin, all of which are prepared by fractionating human plasma. Cell separators capable of collecting platelets, plasma, granulocytes, peripheral blood stem cells, and more recently, red blood cells,<sup>3</sup> are playing an increasingly important role in transfusion medicine.

Component	Special Indications for Oncology Patients
Red blood cells	Severe anemia and chronic anemia
Red blood cells frozen and deglycerated	Severe anemia in patients who have developed alloantibodies to common red cell antigens
Leukocyte reduced components	Severe anemia, reduce febrile reactions from leukocyte antibodies, alternative to cryoprecipitate-removed components, prevent HLA alloimmunization
Washed components	Reduce potentially harmful plasma antibodies, may decrease severe febrile reactions if leukoreduction is not effective
Platelet components	Thrombocytopenia with bleeding or as a prophylactic measure
HLA-matched, selected platelets and crossmatch-compatible platelets	HLA alloimmunized thrombocytopenic patients with decreased platelet survival by immune mechanisms
Fresh frozen plasma	Replacement of labile and stable plasma coagulation factors for which specific factor concentrates are not available, liver dysfunction, disseminated intravascular coagulation, hypofibrinogenemia
Cryoprecipitate	Fibrinogen replacement
Granulocytes by apheresis	Neutropenic patients with documented infection unresponsive to antibiotics

**TABLE 53.1-1.** Use of Blood Transfusion Components in Oncology Patients

Routine blood bank procedures including ABO typing, antibody screening, and compatibility testing identify most patients at risk for serious immune-mediated red cell transfusion reactions. Furthermore, a better understanding of red cell, platelet, and leukocyte antigen structure, as well as the immune responses to these antigens, has vastly improved transfusion therapy. Changes in recruiting and screening blood donors, as well as advances in the testing of donor blood, have drastically reduced the risk of viral transmission in the United States and Europe. All units of blood collected in the United States are tested for hepatitis B, hepatitis C, human immunodeficiency virus 1 and 2 (HIV), human T-cell lymphotropic virus-I and II (HTLV-I/II), and syphilis. Nucleotide amplification testing for hepatitis C and HIV is now performed in most European countries and the United States. Nevertheless, there remain significant risks of transfusion therapy. Complications that are not unique to oncology patients include acute and delayed hemolytic, febrile nonhemolytic, allergic, and septic reactions. Of particular concern in patients who receive large numbers of allogeneic transfusions is the development of HLA alloimmunization and graft-versus-host disease (GVHD). The presence of numerous recipient red cell alloantibodies can also severely limit the number of compatible units that will be available for a patient. Development of platelet alloantibodies can result in a refractory state to platelet transfusions. Fortunately, routine precautions taken in oncology patients including leukoreduction and irradiation of all cellular blood products have reduced the incidence of alloimmunization and GVHD.

Although the hazards of blood transfusion are relatively small, the expected benefit of a transfusion must still outweigh any risk to the patient. Therefore, practitioners of hematology and oncology need to clearly understand the indications and complications of blood transfusion therapy to minimize the exposure of patients to unnecessary allogeneic blood products and to prevent wasting of limited blood resources.

## BLOOD COMPONENT THERAPY

### RED BLOOD CELLS

#### Preparation and Storage

Red blood cells, formerly called *packed cells*, are prepared by first centrifuging whole blood and then by removing most of the plasma. A standard whole blood collection involves removing 450 ± 45 mL of whole blood<sup>4</sup> into sterile containers containing an anticoagulant and preservative solution. Solutions composed of citrate, phosphate buffers, and dextrose (CPD) originally allowed storage of red cells for 21 days at 1 to 6°C. It was later found that red cell shelf life could be increased to 35 days by adding adenine to the preservative solution (CPDA-1). Adenine improves cell viability by increasing intracellular adenosine triphosphate (ATP) levels, whereas dextrose provides a substrate for red cell metabolism. Shelf life is further extended to 42 days by using an additive solution that contains a higher concentration of adenine than is present in CPDA-1 units.<sup>5</sup> The hematocrit of red cell units varies from 70% (CPDA-1) to 55% to 60% (additive solution). Citrate contained in blood preservatives inhibits clotting by binding calcium. Symptomatic hypocalcemia and alkalosis related to citrate toxicity are rare complications of red cell therapy limited to massively transfused patients. Red blood cells with rare antigen profiles can be frozen within 6 days of collection and stored for up to 10 years. They are frozen in approximately 40% glycerol to avoid cell dehydration and damage during the freezing process. Frozen red cells are indicated for oncology patients who have an alloantibody to a high-incidence antigen or have multiple alloantibodies.

### **Indications for Red Cell Transfusion**

The decision to transfuse red cells is no longer based solely on a patient's hematocrit.<sup>6</sup> The patient's overall clinical status and laboratory parameters are both considered when deciding to transfuse a patient. Symptoms and signs of anemia include excessive fatigue, malaise, headache, tachycardia, and hypotension. Acute blood loss of greater than 30% total blood volume leads to hypotensive shock. Oncology patients typically have more slowly developing chronic anemias that are tolerated better than rapid onset anemias due to the ability of the body's fluid compensatory mechanisms. Red cell transfusion is rarely indicated when the hemoglobin is greater than 10 g/dL and is often not considered until the hemoglobin is less than 7 g/dL.<sup>7</sup> Younger patients usually tolerate a given degree of anemia better than older patients who may have underlying coronary, myocardial, or pulmonary disease. Patients with unstable angina or acute myocardial infarction may benefit from red cells when their hemoglobin is less than 10 g/dL.<sup>8</sup> Thus, red cell transfusion should be based on clinical criteria rather than broadly applied threshold hemoglobin values. Transfusing a single red cell unit typically increases the hemoglobin by 1 g/dL (hematocrit by 3%) in the absence of active red cell destruction.

### **Antibody Screening, Antibody Identification, and Cross-Matching**

Even in emergency situations, a properly labeled sample must be sent to the blood bank before a red cell unit is issued. This sample is used to type a patient's red cells for ABO and Rh status. *Front typing* involves reacting patient red cells with commercial antibodies directed against the A, B, and D antigens. Blood grouping is confirmed during *back typing* in which patient serum is tested for anti-A and anti-B antibodies using commercial type A and B cells. Following blood grouping, recipient serum or plasma is screened for atypical red cell antibodies. Antibody screening is performed by incubating a patient's serum with two to four commercial group O red screening cells that together express most clinically significant red cell antigens on their membrane surface. If an antibody is present in the patient sample, it reacts with the screening cell(s) and causes red cell agglutination. Antibody screening is often referred to as the *indirect antiglobulin test*. Antigen-antibody reactions can be enhanced by adding various substances such as polyethylene glycol, low-ionic strength saline, and albumin. Most blood banks perform *tube testing* in which red cell agglutinates are identified in standard test tubes, but there are a number of newer techniques that are being used to detect antigen-antibody reactions. These include gel systems based on the differential mobility of red cell agglutinates through gel columns, and capture systems in which test red cells are immobilized on microtiter plates. Newer automated and semiautomated systems will likely replace tube testing for the majority of ABO grouping, Rh typing, and antibody screening in the future.

Antibody identification is performed by testing a patient's serum against a *panel* of 8 to 12 commercial group O red cells of known antigen phenotype. The antibody can usually be identified based on the reactivity pattern. A number of techniques are used to facilitate red cell antibody identification. Most use substances that either enhance or suppress the reactivity of a specific antibody. Some patient's serum reacts with all panel cells, a situation termed *panreactivity* or *panagglutinins*. Panagglutinins can be caused by (1) a single antibody directed against a high-incidence antigen present on all panel test red cells, (2) multiple antibodies that in total react with all test cells, or (3) an autoantibody. Autoantibodies are often found in warm autoimmune hemolytic anemias, in which case the patient's serum also reacts with his or her own red cells (positive auto control).

The direct antiglobulin test (DAT), or direct Coombs, is performed to identify *in vivo* coating of red cells with globulins, IgG and C3d in particular. It is performed by incubating a suspension of patient red cells with antihuman antibodies directed against IgG, IgA, IgM, C3, or C4. A positive DAT result implies that the patient's red cells are coated with the corresponding globulin. DATs are no longer performed on volunteer blood donors because they are positive in up to 1 per 7000 blood donors, and more importantly, have no clinical significance.<sup>9</sup> In addition, DATs are not routinely performed at most large medical centers as part of routine pretransfusion testing; the test must be specifically requested. Positive DAT results are also seen in patients with delayed hemolytic transfusion reactions (DHTRs), autoimmune hemolytic anemias, autoimmune disorders (systemic lupus erythematosus), and malignancy (especially B-cell malignancies such as chronic lymphocytic leukemia).

Cross-matching is performed by reacting patient serum with donor red cells from the unit selected for transfusion. If no reaction is observed, the unit is released as *compatible*. Cross-matching is only omitted in emergency life-threatening situations in which there is truly insufficient time to perform compatibility testing. Many hospitals supply group O Rh negative red cells in the emergency or operating rooms until a patient sample is received in the blood bank. Type-specific uncross-matched blood (e.g., A positive unit transfused to A positive recipient) is permitted only when the recipient's ABO Rh status is known with certainty. Use of type-specific blood is particularly helpful when supplies of O negative red cells are severely limited during blood shortages. More recently, *computer cross-matches* have been instituted at several hospitals in North America.<sup>10</sup> Patients of known ABO and Rh types and who have a negative antibody screen are provided computer-selected ABO compatible blood while omitting the cross-match step described previously. Although a true serologic cross-match is not performed, the computer cross-match is safe in the vast majority of transfusions if appropriate safeguards are in place to prevent typing errors and to ensure proper patient identification.

### **Red Cell Autoantibodies**

Oncology patients may develop autoimmune hemolytic anemias as a direct result of their disease or from treatment of that disease. In particular, patients with chronic lymphocytic leukemia, non-Hodgkin's and Hodgkin's lymphoma, and plasma cell disorders frequently develop warm autoimmune hemolytic anemia. Autoantibodies consist of immunoglobulins (IgG, IgM) that react with a wide range of self-antigens including membrane and intracellular components, adsorbed plasma proteins, and nuclear antigens. The DAT result is positive in most cases. Patients with warm autoimmune hemolytic anemia often require transfusion. The blood bank may have difficulty identifying compatible red cell units because the patient's serum not only reacts with his or her own red cells, but also with those of all donor red cells. Therefore, additional time may be required to exclude the presence of a significant underlying alloantibody that is obscured by the autoantibody. Upward of 25% of previously transfused autoimmune hemolytic anemia patients may have an underlying alloantibody.<sup>11</sup> An underlying alloantibody, if undetected, may result in accelerated red cell destruction of a transfused red cell unit that carries the corresponding antigen. Therefore, transfusion therapy must be carefully planned and used in these patients. Autoimmune antibodies often appear to have specificity for Rh antigens (e.g., anti-E), but transfusing antigen-negative red cells (e.g., E negative) is not indicated as *in vivo* red cell survival of antigen-negative cells is usually no better than with antigen-positive cells.

## **BLOOD DONATIONS**

Blood donations can be divided into several categories as follows: (1) *autologous* is donation of one's blood for one's own use, (2) *allogeneic* or homologous is donation of one's blood for use by others, and (3) *directed* is donation of one's blood for use by a specific recipient. Directed donations are important to some cancer patients. A friend or family member of a potential recipient typically donates a directed donor unit. In fact, blood supplies can be greatly supplemented by relatives and friends of oncology patients during critical periods of their treatment. Depending on institutional guidelines directed units not needed by the intended recipient may be *crossed over* to the general blood bank stock and distributed to other patients provided the donor meets all requirements for allogeneic donation.

### **Autologous Transfusions**

The most commonly used forms of autologous transfusion include preoperative blood donation, acute normovolemic hemodilution, and autologous blood salvage. Each type of autologous transfusion may be useful in certain oncology patients.<sup>12</sup> Many blood centers provide autologous preoperative blood donation services in which a patient's blood is drawn and stored for later use, usually during a surgical procedure.<sup>13</sup> Although the criteria for autologous donations are less stringent than those for allogeneic donors, oncology patients are often too anemic to donate their own blood. Patients must feel well on the day of donation and cannot be hypotensive, febrile, or septic because of the risk of bacterial contamination. Thus, the donor cannot have open wounds, such as from a recent biopsy, or have indwelling vascular or urinary catheters. Platelets and granulocytes contained in an autologous blood unit rapidly degrade with storage and are essentially nonfunctional by the time the unit is transfused. If the autologous unit is stored as whole blood, the plasma contained in this unit has low levels of labile coagulation

factors. Plasma can be separated from autologous whole blood and frozen to maintain the activity of all coagulation factors. Although autologous blood is intended for the patient–donor, most blood centers test autologous units for the same transfusion disease markers required for allogeneic blood. Preoperative blood donation can be used in older oncology patients, although there is a higher risk of anemia and more serious cardiovascular complications associated with the donation.<sup>14</sup> The use of autologous blood decreases the risk of viral infection, but the risk of bacterial contamination remains. Autologous preoperative blood donation is not crossed over because most of these patients do not meet all requirements for allogeneic blood donation.

Acute normovolemic hemodilution is performed by removing blood from a patient immediately before surgery and replacing the blood volume with crystalloid or colloid solutions to maintain hemodynamic stability.<sup>15</sup> The withdrawn blood is then later reinfused. Autologous blood salvage is performed by collecting and then returning blood lost during or shortly following operative procedures using intraoperative salvage devices.<sup>16</sup> This technique is primarily employed in cardiac and orthopedic surgery. Autologous blood salvage is generally contraindicated in cancer surgery because of the risk of returning contaminating tumor cells to the systemic circulation. There is some evidence that irradiating salvaged blood with 50 Gy can destroy the proliferative ability of malignant cells, but more studies are needed before this technique can be safely applied to cancer surgery.<sup>17</sup>

### **Autologous Platelet Donation**

Although oncology patients can *bank* their own red cells through autologous donation, it is not usually feasible for these patients to donate autologous platelets. Platelets stored in the liquid phase at room temperature have a shelf life of only 5 days. Platelets collected by apheresis and frozen preserved in dimethyl sulfoxide can be stored at  $-80^{\circ}\text{C}$ .<sup>18</sup> They are then thawed, washed, and resuspended in autologous plasma or other solutions before transfusion. Platelets prepared by this technique do undergo a number of structural and metabolic changes that decreases their recovery and survival as compared with liquid-stored platelet concentrates.<sup>19</sup> Furthermore, most patients cannot donate enough platelets to support a full course of induction chemotherapy. It is possible, however, to store significant numbers of frozen autologous platelets for patients who are refractory to platelet transfusion provided the blood bank is technically capable of preparing and storing these specialized products.<sup>20</sup>

### **Directed Blood Donation and Dedicated Donor Units**

Directed blood donations are those donations made for a specific patient. These units, most frequently obtained from family members or friends, can greatly augment the blood supply. Donors wishing to make directed donations must meet the same criteria for blood donation as other allogeneic donors. These units undergo all required testing for transmissible diseases. Therefore, due to the possibility of unexpected test results, it is important that the donor understand his or her blood will be tested for viral diseases such as HIV and hepatitis C. In fact, directed blood donors are more likely to be positive for some infectious disease markers than other allogeneic blood donors.<sup>2</sup> This increased frequency of positive infectious disease markers most likely reflects in part the higher percentage of first-time donors in the directed donor group who were not previously screened.

The cytomegalovirus (CMV) status of the blood donor and the needs of the oncology patient also affect the use of directed blood donation. CMV-seronegative blood products are often required by oncology patients, in particular, those patients who are marrow transplant candidates or recipients. As in the allogeneic donor pool, many directed donor units are seropositive for CMV. Thus, units from some directed donors may not be appropriate for the intended recipient. In this situation, the patient's oncologist must decide if a CMV-seropositive directed unit can be transfused to that patient. CMV status of directed units may be less of a concern as prestorage leukodepleted blood products prepared using cyclic good manufacturing practices gain further acceptance as an alternative to CMV-seronegative products.

Dedicated donor blood units are primarily used by pediatric oncology patients to reduce their exposure to blood from different donors. A dedicated unit is simply a unit of allogeneic red cells that is specifically set aside by the blood bank for use by a single patient. The unit is obtained from the general blood bank stock or from a directed donor. When necessary, small aliquots are removed from the units for transfusion. This approach is not feasible in adult oncology patients because of the larger blood volume requirements. However, a single dedicated unit could supply as many as ten separate transfusions in a pediatric patient, thus dramatically reducing multiple donor exposures.

## **PLATELET TRANSFUSION THERAPY**

### **Preparation and Storage**

Plastic primary collection bags with attached satellite containers allow harvesting of platelets as a by-product of red cell separation. In the United States, platelets are usually prepared by the platelet-rich plasma method, whereas the buffy coat method is used in Europe.<sup>21</sup> Each *random donor* platelet unit (RDP) prepared by differential centrifugation of a single whole blood collection contains at least  $5.5 \times 10^{10}$  platelets suspended in 50 mL of plasma. The shelf life of all platelet preparations is 5 days when stored at  $20$  to  $24^{\circ}\text{C}$  under constant agitation in plastic containers that allow oxygen diffusion. Storage longer than 5 days is precluded by the increased risk of bacterial growth and the development of platelet function abnormalities. RDP are typically administered in four to six unit *pools*. In the absence of conditions associated with decreased platelet survival, each RDP unit should increase a recipient's platelet count by 5000 to 10,000/ $\mu\text{L}$ . Single donor platelets (SDPs) prepared by apheresis are often transfused to oncology patients in order to minimize their exposure to multiple donors. SDPs contain more than  $3 \times 10^{11}$  platelets suspended in approximately 200 mL of plasma. Thus, one SDP is equivalent to five to six average RDP units.

ABO type-specific platelets are provided whenever possible. This is because transfusing out-of-type platelets may result in a postplatelet increment 10% to 20% less than that expected for ABO type-specific platelets. In addition, Rh antigens found on the small number of contaminating red cells present in platelet concentrates are sufficient to immunize a small number of Rh-negative recipients. If Rh-negative platelet concentrates are not available for an Rh-negative patient, Rh-positive platelets can be transfused followed by administration of Rh immune globulin within 72 hours of transfusion. Until relatively recently, only intramuscular Rh immune globulin was available to prevent Rh immunization. These injections could be dangerous in oncology patients who have low platelet numbers and coagulation disorders. Fortunately, an intravenous preparation has been licensed for preventing Rh alloimmunization (WinRho, NABI, Boca Raton, FL).<sup>22</sup> This therapy has been proven effective, and is clearly more convenient and less painful to the patient.

### **Indications for Platelet Transfusion**

Platelets are transfused to thrombocytopenic patients who are actively bleeding or to severely thrombocytopenic patients as a prophylactic precautionary measure.<sup>23</sup> Spontaneous bleeding is rarely encountered when a patient's platelet count is more than 20,000/ $\mu\text{L}$ . In fact, studies suggest that oncology patients receiving chemotherapy can tolerate platelet counts as low as 5,000 to 10,000/ $\mu\text{L}$ .<sup>24,25</sup> and <sup>26</sup> Postsurgical patients with platelet counts more than 50,000/ $\mu\text{L}$  may require platelet transfusions to control or prevent postoperative bleeding. Overall coagulation status should also be considered because patients with plasma coagulation factor disorders are more likely to bleed at marginal platelet counts. Actively bleeding patients on aspirin, an irreversible inhibitor of platelet function, may require transfusions at higher platelet counts. Obviously, transfused platelets are similarly inhibited if the patient remains on aspirin.

### **Platelet Refractory State**

Platelet refractoriness is a major problem for cancer patients who are dependent on platelet transfusions. There are many causes of an apparent lack of response to platelet transfusions, either through immune or nonimmune mechanisms (Table 53.1-2). In most cases, platelet refractoriness is attributed to nonimmune causes including sepsis, splenomegaly, and disseminated intravascular coagulation.<sup>27</sup> The corrected count increment (CCI) is used to identify patients who are refractory to platelet transfusions through either HLA or platelet alloimmunization. The CCI is calculated as follows:

$$\text{CCI} = \frac{\text{Post}(\text{ /}\mu\text{L}) - \text{Pre}(\text{ /}\mu\text{L})}{\text{Number of platelets} \times 10^{-11}} \times \text{BSA}(\text{m}^2)$$

Notimmune	Immune
Hypersplenism	HLA antibodies
Disseminated intravascular coagulation	Platelet-specific antibodies
Sepsis	Circulating immune complexes
Drugs (amphotericin, and so forth)	Autoantibodies (autoimmune thrombocytopenia)
Viremia	
Bleeding	
Radiotherapy, chemotherapy, or both	
Vasculitis	

**TABLE 53.1-2.** Potential Causes of Platelet Refractoriness in Cancer Patients

where Pre is pretransfusion platelet count, Post is posttransfusion platelet count drawn 1 to 4 hours after completion of the transfusion, number of platelets transfused (1 RDP unit approximately  $0.5 \times 10^{11}$  platelets; 1 SDP unit approximates  $3.0 \times 10^{11}$  platelets), and BSA is body surface area in square meters. Patients with a low CCI (less than 5000) may benefit from cross-match-compatible platelets or HLA-matched single donor platelets.

Platelet cross-matching is performed by adding recipient serum to wells coated with donor platelets. After appropriate antibodies and an indicator reagent are added, the compatibility of the patient's serum and the donor's platelets is determined based on reactivity patterns. An incompatible cross-match predicts a poor CCI more than 90% of the time, whereas a negative cross-match is only 50% predictive of a successful transfusion.<sup>28</sup> Depending on a particular hospital's blood supplier, cross-match-compatible platelets or HLA-selected platelets may be more readily available.<sup>25</sup> Some centers use a combination of the two techniques: Platelet units are selected for cross-matching based on the HLA type of the donor and recipient.

Cross-match-compatible and HLA-selected platelets are not readily available in all blood banks. Increasing the dose of standard platelet concentrates can be considered until these products are obtained. For example, a dose of eight to ten RDPs is transfused instead of the more typical four to six unit pools. In fact, investigators have suggested that higher platelet doses (approximately  $4$  to  $6 \times 10^{11}$  platelets per dose) given prophylactically to patients with hematologic malignancies reduce the number of platelet transfusions and thus, the number of donor exposures.<sup>30</sup> Ideally, the platelets are ABO identical because ABO incompatibility may decrease posttransfusion platelet increments by 10% to 20%.<sup>31</sup> Some medical centers provide *platelet drips* to bleeding refractory patients. Three-unit RDP pools are continuously infused through an electromechanical pump every 4 hours, providing a total of 18 RDP units over 24 hours. Electromechanical pumps do not appear to harm platelets.<sup>32</sup> Platelet drips could theoretically maintain a lower platelet count, but this has not been proven. There are no studies that have fully compared the efficacy of intermittent platelet boluses and platelet drips in refractory patients. Corticosteroids, chemotherapy, splenectomy, and intravenous immunoglobulin, effective treatments for many autoimmune thrombocytopenias, are not useful in platelet refractory patients.

Leukocyte reduction filters, as well as ultraviolet B irradiation, decrease the rate of HLA alloimmunization to platelets.<sup>33,34</sup> Therefore, leukocyte reduced filtered blood products should be provided to oncology patients who require many platelet transfusions (see [Leukoreduction](#), later in this chapter). Presumably, leukoreduction removes donor antigen-presenting cells, which may play a key role in initiating HLA alloimmunization.

## GRANULOCYTES

Granulocytes continue to play a small role in the supportive care of neutropenic oncology patients with serious infections, including allogeneic and autologous marrow transplant recipients. Improvements in apheresis collection technique now allow collection of larger numbers of granulocytes ( $6$  to  $8 \times 10^{10}$ ) from volunteer donors than was previously possible.<sup>35</sup> These changes include the administration of corticosteroids or growth factors to white cell donors before apheresis.<sup>36</sup> Granulocytes are typically transfused to neutropenic oncology patients who have developed gram-positive or gram-negative bacterial sepsis unresponsive to antibiotic therapy for a minimum of 24 to 48 hours ([Table 53.1-3](#)).<sup>37</sup> Granulocytes collected from nonstimulated (no corticosteroids or growth factors) healthy donors contain at least  $1 \times 10^{10}$  neutrophils per unit. These units can be stored for only 24 hours at 20 to 24°C without agitation. Granulocyte units contain 20 to 25 mL of red cells and thus must be cross-matched with the recipient's serum. Donated granulocytes are rarely HLA matched for the recipient, even for those patients with known HLA antibodies because there are little data suggesting that HLA-matched granulocytes have improved survival and recovery. Granulocytes should be irradiated (2500 cGy) to inactivate the large number of lymphocytes found in the product. They are considered for patients who have an absolute neutrophil count less than 500/ $\mu$ L and a reasonable chance of marrow recovery.

Absolute neutrophil count <500/ $\mu$ L

Reversible myeloid hypoplasia caused by chemotherapy or disease

Documented infection that has not responded to appropriate antibiotics for a minimum of 24 to 48 hours

Fever of unknown origin unresponsive to broad-spectrum antibiotics

**TABLE 53.1-3.** General Guidelines for Granulocyte Transfusions

Because of their short half-life, granulocytes are typically provided daily until the patient can maintain an absolute neutrophil count greater than 500/ $\mu$ L without transfusion or until the infection resolves. Infusion of larger numbers of granulocytes (on the order of  $6$  to  $8 \times 10^{10}$  granulocytes) produces measurable increases in adult recipient neutrophil counts, but the optimal dose and frequency remain undefined. Febrile reactions to granulocytes are common, the reactions seem to be more severe when amphotericin is infused near the time of granulocyte transfusions. Overall, the additional benefit of granulocyte transfusions for these neutropenic patients as compared with antibiotic treatment alone is unclear as there are no well-controlled clinical trials. In addition, the clinical benefit of transfusing larger numbers of granulocytes collected from donors stimulated by corticosteroids or growth factors has not been proven. The collection of granulocytes, or any blood component, by apheresis is not an entirely innocuous process. The donor is at risk for uncommon, but potentially serious adverse reactions including hydroxyethyl starch-related hypotension and anaphylaxis and citrate-induced hypocalcemia. Hydroxyethyl starch is used as a sedimenting agent to maximize granulocyte yields. Minor, but typically tolerable, side effects of pretreating granulocyte donors with dexamethasone (insomnia, flushing), granulocyte colony-stimulating factor, or both (bone pain, headaches, insomnia) occur in a substantial number of donors.<sup>38</sup> The long-term effects of granulocyte colony-stimulating factor on volunteer donors are unknown.

Adverse recipient reactions to granulocytes are common because of the activity of transfused white cells, as well as their degradation products. These reactions are typical of febrile nonhemolytic transfusion reactions (FNTRs) following other blood product administration. Granulocytes should be transfused slowly, 1 to 2 mL/min through a standard microaggregate filter. Obviously, a leukocyte reduction filter should *never* be used to administer granulocytes. In addition, the recipient should be premedicated with acetaminophen or some other antiinflammatory agent before the granulocyte transfusion.

## PLASMA

Plasma is prepared by centrifuging whole blood and then freezing the removed plasma within 8 hours of collection. Rapid freezing maintains the activity of labile

coagulation factors such as factors V and VIII. The most commonly available form of plasma, fresh frozen plasma (FFP), contains all coagulation factors, other plasma proteins, and complement. FFP should not be used for volume expansion because there is a risk of transfusion-transmitted disease (TTD); other safer nonplasma substitutes are available. A unit of FFP contains from 180 to 270 mL of plasma. The primary indications for FFP transfusion in oncology patients include deficiencies of multiple coagulation factors as seen in liver disease, disseminated intravascular coagulation, and hypofibrinogenemia.<sup>39</sup> It is often used for urgent reversal of warfarin therapy in bleeding patients and before procedures. FFP is not the treatment of choice for replacing most individual clotting factors because of the large volumes that would be required to obtain adequate factor levels. The patient's cardiovascular and fluid status may preclude the use of large amounts of plasma. In fact, large transfusions of FFP can produce fluid overload and subsequent heart failure in some patients. FFP is not the treatment of choice for coagulopathies in cases in which virally inactivated or recombinant products exist such as for deficiencies of factor VIII (hemophilia A) or factor IX (hemophilia B).

## CRYOPRECIPITATE

Cryoprecipitate is prepared by thawing FFP between 1 and 6°C. A single 10- to 15-mL unit of cryoprecipitate contains fibrinogen (100 to 350 mg/U), Factor VIII (at least 80 IU/U), and some von Willebrand factor. Thus, a similar dose of fibrinogen can be provided in a much smaller volume as compared with FFP. Use of cryoprecipitate is generally limited to patients with severe hypofibrinogenemia (less than 100 mg/dL) and von Willebrand's disease. It should *not* be used alone in disseminated intravascular coagulation because it contains no factor V. Cryoprecipitate, thrombin, and calcium are combined to make *fibrin glue*.<sup>40</sup> This biologic sealant is most often used to limit surgical bleeding. Since cryoprecipitate is used, the recipient is exposed to the risks of TTD. A fibrin sealant that contains solvent and detergent-treated plasma has been approved by the Food and Drug Administration.

## PLASMA DERIVATIVES

### Albumin

Solutions containing 5% human albumin in saline are primarily used to replace intravascular volume and more rarely, to treat hypoalbuminemia. Its use as a volume expander has decreased because other nonplasma colloidal solutions such as dextran and hydroxyethyl starch are readily available. Albumin is also used to replace plasma removed during apheresis. Albumin prepared in the United States is virally inactivated by heat treatment. Properly prepared albumin has not been reported to transmit viral disease including hepatitis B virus, hepatitis C virus (HCV), and HIV types 1 and 2. Albumin is not a viable nutritional source for patients with chronic protein deficiency states seen in oncology patients.<sup>41</sup>

### Immunoglobulins

Immune globulin products include intravenously administered immune globulin, intramuscularly administered immune globulin, and several specialized products such as Rh(D) immune globulin and hepatitis B immune globulin. In the United States, immune globulin products are prepared from donor plasma screened for TTDs. Individual plasma units are then pooled and separated by alcohol fractionation or by anion exchange chromatography that results in a product that is considered safe from virus transmission.<sup>42</sup> Polyspecific intravenous immune globulin is used to treat immune-mediated thrombocytopenias, autoimmune hemolytic anemias, and demyelinating polyneuropathies such as Guillain-Barré syndrome. It is also provided to patients with primary and secondary immune deficiencies. Patients who are IgA-deficient are at risk of anaphylaxis due to production of IgG anti-IgA immunoglobulin. For these patients, IgA-deficient preparations should be used. Some immunoglobulin preparations use a chemical inactivation step employing solvent and detergent processing to reduce infectivity for lipid enveloped viruses including HIV and hepatitis C. Specific immune globulin preparations are made from donors with hyperimmune serum and can be used prophylactically or after exposure to prevent infections from viruses such as hepatitis B.

### Clotting Factors

Antihemophilic factor (factor VIII) and factor IX are commercially available derivatives prepared from large pools of human plasma. These products were originally high risk for transmitting viruses until virus-inactivation methods were developed that did not damage the product's coagulant activity. These methods include heat inactivation and solvent and detergent exposure. Individual coagulation factors of extremely high purity are produced using antibody-affinity purification procedures. Recombinant factors VIII, IX, and VIIa are currently available and should be considered as an alternative to pooled products in specific situations. The use of these products in cancer patients is generally limited to replacement of individual clotting factors or to the treatment of specific factor inhibitors.

## TRANSFUSION REACTIONS AND COMPLICATIONS

Oncology patients, like other transfusion recipients, experience adverse reactions to blood component therapy. Although cancer patients per se are not at an increased risk for the more common febrile and allergic transfusion reactions, they are likely to experience one of these reactions if they are or have been multiply transfused during their treatment. Most reactions occur during or shortly after a blood transfusion, but may present several hours to days later. In general, transfusion reactions are broadly categorized as immune or nonimmune based on their presumed mechanism ([Table 53.1-4](#)). Of particular concern to cancer patients is (1) the development of alloimmunization, or antibodies to red cell or platelet membranes components, through repeated allogeneic blood exposure, and (2) posttransfusion associated GVHD, a potentially fatal, but uncommon complication. Chronic iron overload and secondary hemochromatosis, long-term complications of red cell transfusion therapy, also occur in patients with hematologic malignancies who experience long-term survival.<sup>43</sup>

Immune Mediated	Nonimmune Mediated
Acute hemolytic transfusion reaction	Transfusion-associated bacterial sepsis
Delayed extravascular hemolytic reaction	Circulatory overload and cardiac failure
Febrile transfusion reaction	Viral transmission
Allergic transfusion reactions	Iron overload
Alloimmunization	Hypocalcemia
Transfusion-associated graft-versus-host disease	Hypothermia
Transfusion-associated acute lung injury	Factor depletion and thrombocytopenia by dilution

**TABLE 53.1-4.** Complications of Blood Transfusion Therapy in Cancer Patients

## ACUTE INTRAVASCULAR HEMOLYTIC REACTIONS

Acute intravascular hemolytic transfusion reactions (AIHTRs) are serious complications that are usually avoided by carefully adhering to standard protocols for administering blood products. These reactions occur in blood recipients who have preexisting antibodies directed against antigens present on the transfused red cells. ABO incompatibility remains the most common cause of immediate intravascular hemolytic reactions, but they are also caused by incompatibility within other blood group systems such as Duffy (Fy<sup>a</sup>, Fy<sup>b</sup>) and Kidd (Jk<sup>a</sup>, Jk<sup>b</sup>). Transfusion of ABO incompatible blood is typically due to clerical errors involving misidentification of the patient.<sup>44</sup> Proper labeling of clots used by the blood bank for compatibility testing and careful identification of patients are the best ways to prevent potentially fatal ABO incompatible reactions. Donor erythrocytes carrying either A, B, or both antigens avidly bind to the recipient's naturally occurring anti-A, anti-B, or both antibodies. This binding results in complement fixation, formation of the C5b-9 membrane attack complex, and finally, hemolysis. It is now clear that biologic response modifiers such as proinflammatory cytokines [interleukin-1 (IL-1), tumor necrosis factor- $\alpha$ ], chemokines (IL-8), and complement fragments (C3a, C5a) play a major role in the pathophysiology of AIHTRs.<sup>45</sup>

AIHTRs present as fever, chills, the sudden onset of back pain, hypotension, tachycardia, diaphoresis, and dyspnea. The symptoms are usually evident in recipients shortly after beginning the transfusion. Laboratory studies reveal an increase in unconjugated bilirubin up to 2 to 3 mg/dL and marked elevation of lactate dehydrogenase. The classic signs of intravascular hemolysis include acute onset hemoglobinuria and hemoglobinemia. The DAT or direct Coombs' test, becomes

reactive due to the coating of *donor* red cells with the *recipient's* antibodies. AIHTRs are medical emergencies. Treatment consists of immediately stopping the transfusion, close monitoring of vital signs, and use of intravenous fluids to maintain urine output greater than 100 mL/h with or without a loop diuretic ( [Table 53.1-5](#)). Blood pressure and airway support, pressors, and mechanical ventilation may be necessary. Dialysis should be considered in patients who develop renal failure as result of acute red cell hemolysis and subsequent acute tubular necrosis.

Reaction	Symptoms and Signs	Management
Acute intravascular hemolytic reaction	Back pain, fever, hypotension, shock, dyspnea, hemoglobinuria, hemoglobinemia, positive direct Coombs test result	Stop transfusion, 30 fluids, vasopressor support, maintain diuresis, corticosteroids, dialysis if indicated
Delayed extravascular hemolytic reaction	Anemia, jaundice, fever, positive direct Coombs test result	Stop transfusion, fluid support, follow laboratory results (hematocrit, lactate dehydrogenase, bilirubin)
Febrile reaction	Fever, chills, rigors, mild hypotension	Stop transfusion, antipyretics, consider leukoreduced product for subsequent transfusions
Allergic (mild)	Pruritus and urticaria only	Antihistamines, may continue transfusion if symptoms improve in 30 minutes, otherwise stop transfusion
Allergic (severe)	Urticaria, bronchospasm, dyspnea, cyanosis, hypotension	Stop transfusion, antihistamines, vasopressor support, corticosteroids, consider premedication or washed red blood cells for subsequent transfusions
Septic reaction	Rapid onset of chills, fever, hypotension	Stop transfusion, culture product and patient, vasopressor support, 30 fluids, broad-spectrum antibiotics

**TABLE 53.1-5.** Identification and Initial Management of Transfusion Reactions in Oncology Patients

## DELAYED EXTRAVASCULAR HEMOLYTIC REACTIONS

DHTRs typically occur in patients who initially have a negative antibody screen on pretransfusion testing, but who then experience accelerated destruction of transfused red cells 7 to 14 days posttransfusion. In most cases, red cell destruction is caused by an antibody that is of low titer, below the detection limits of most routine screening techniques. On reexposure to the offending antigen, the antibody rapidly forms and binds to the transfused red cells. DHTRs are also caused by primary sensitization in which a patient synthesizes a new antibody. Antibodies implicated in DHTRs usually fix complement only to the C3 level and thus, cause extravascular as opposed to intravascular hemolysis. Antibodies most commonly identified in DHTRs include those directed against Rh (E, c), Duffy, Kidd, and Kell blood group antigens. DHTRs are often diagnosed following an unexpected posttransfusion drop in hematocrit, an elevation of unconjugated bilirubin, and the appearance of a newly positive DAT. There is usually a delay of 3 days to 2 weeks between transfusion and the onset of extravascular hemolysis. Only rarely do delayed reactions cause intravascular hemolysis with associated hemoglobinemia and hemoglobinuria, but in any case, these patients should be followed until the hemolysis resolves. DHTRs should also be recognized to avoid unnecessary diagnostic procedures that are considered to evaluate an unexpected decrease in hematocrit. These patients typically do not develop cytokine storm and are for the most part asymptomatic.

## FEBRILE NONHEMOLYTIC REACTIONS

FNTRs following red cell and platelet transfusions are common in cancer patients. They are presumably caused by antibodies (leukoagglutinins) in the recipient that are directed against HLA-, leukocyte-specific, or both antigens on donor white blood cells and platelets. Reactions between leukoagglutinins present in the transfused product and recipient leukocyte antigens may also play a role. Formation of leukocyte antigen-antibody complexes then results in complement binding and release of endogenous pyrogens such as IL-1, IL-6, and tumor necrosis factor- $\alpha$ . Cytokines generated by leukocytes during platelet and red cell storage may also contribute to FNTRs.<sup>46</sup> Symptoms typically occur during or several hours after the transfusion and include low-grade (greater than 1°C increase) and high-grade fevers accompanied by shaking chills. Rarely vomiting, dyspnea, hypotension, and decreased oxygen saturation ensue. The severity of symptoms is often directly related to the number of leukocytes contained in the product or the rate of transfusion. Leukoreduction of blood components decreases, but does not eliminate, the frequency of FNTRs and therefore, white cell–reduced products should be considered in patients who have experienced febrile reactions. Premedication with an antipyretic such as acetaminophen may minimize mild FNTRs, but is not entirely effective. Antihistamines do not prevent or treat FNTRs. Corticosteroids can minimize FNTRs if they are administered several hours before the transfusion and should be considered for patients who have had several severe reactions. Intravenous or intramuscular meperidine can resolve severe rigors in a matter of minutes.<sup>47</sup> If symptoms do not resolve in less than 4 hours or are especially severe, other complications such as sepsis caused by contaminated blood products, or a hemolytic reaction should be seriously considered. Under some circumstances, it may be difficult to distinguish between FNTRs from other causes of fever in immunocompromised cancer patients. Specific conditions that can mimic benign FNTRs include preexisting or impending patient sepsis, infusion of a contaminated unit of blood or platelets, and a hemolytic transfusion reaction.

## ALLERGIC REACTIONS

Allergic reactions to plasma, platelets, and red cells are relatively common in cancer patients. They present as pruritus, urticaria, or both, usually in the absence of fever. Allergic reactions are classically IgE mediated and most symptoms are attributed to histamine release. At times it is difficult to distinguish between allergic and febrile transfusion reactions when urticarial symptoms are accompanied by low-grade fever. Other common symptoms and signs include pruritus, erythema, papular rashes, and wheals. Severe anaphylaxis resulting in bronchospasm and hypotension rarely occur, but can be life threatening. As in other allergic processes, symptoms are not dose related and severe manifestations can occur following small exposures. Treatment of mild allergic reactions consists of stopping the transfusion and administering diphenhydramine or other antihistamines. For mild allergic reactions (e.g., pruritus and hives only without fever or vasomotor instability), it is reasonable to resume transfusing the same unit provided the symptoms promptly resolve. If the symptoms recur after the transfusion is restarted, a new unit should then be obtained. Severe anaphylactic reactions with bronchospasm and cardiovascular collapse are fortunately rare and should be treated like any other anaphylactic reaction with corticosteroids, vasopressors, and airway support. Washed red cells in which the residual donor plasma has been removed and replaced by saline may benefit patients with repeated or severe allergic reactions.<sup>48</sup> Leukocyte reduction filters are not helpful because they do not remove the implicated soluble mediators.

## SEPTIC REACTIONS

Blood products are rarely contaminated by bacteria during the collection process. This may occur if the donor is transiently bacteremic at the time of collection or if the arm is improperly cleansed before venipuncture.<sup>49</sup> Transfusing blood products that are contaminated by bacteria is potentially dangerous and can result in profound hypotension, shock, and death. Currently, there are no laboratory tests to screen for bacterial contamination and contaminated units cannot be easily identified on pretransfusion inspection. The risk of septic transfusion reactions (STRs) is higher for platelet transfusions than for other blood components because platelets are stored at room temperature.<sup>50</sup> Refrigeration of red cells markedly diminishes the growth of most bacteria. Common organisms that cause STRs include gram-positive (*Staphylococcus* sp.) and gram-negative (*Enterobacter*, *Yersinia*, *Pseudomonas* sp.) bacteria.<sup>51</sup> *Yersinia enterocolitica* is a more common cause of red cell STRs because this organism grows at cold temperature and multiplies during refrigerated storage of red blood cell products.<sup>52</sup> Blood cultures should be obtained from patients who develop high fevers during or shortly after transfusion, especially if they become hypotensive. A Gram's stain or acidine orange stain of the suspected contaminated product is helpful when organisms are seen, but this test is not highly sensitive. Both the patient and the implicated blood unit should be cultured whenever a STR is suspected. Other symptoms associated with STRs are attributed to preformed endotoxin and cytokines and include skin flushing, severe rigors, and cardiovascular collapse. These symptoms may occur during or minutes to hours after completing the transfusion. Treatment includes fluids and cardiovascular support. Broad-spectrum antibiotics should be started immediately, even before culture results can guide further therapy. Severe febrile reactions can mimic STRs, but febrile reactions are self-limited in nature and are generally not associated with profound hypotension.

## TRANSFUSION-RELATED ACUTE LUNG INJURY

Transfusion-related acute lung injury (TRALI) is a rare but serious complication of blood transfusion that presents as noncardiogenic pulmonary edema. It typically occurs within 6 hours of transfusion and is clinically identical to the adult respiratory distress syndrome. The most common clinical findings include the rapid onset of dyspnea, tachypnea, cyanosis, fever, and hypotension.<sup>53</sup> Lung auscultation reveals diffuse crackling and decreased breath sounds. Invasive cardiac monitoring shows normal cardiac pressures and function with hypoxemia and decreased pulmonary compliance. Radiographic findings include diffuse, fluffy infiltrates consistent with pulmonary edema. The presumed etiology involves immune-mediated reaction of HLA antibodies or other leukoagglutinins with white cells, which subsequently leads to leukocyte activation.<sup>54</sup> Granulocytes are first activated in the peripheral circulation by HLA or other Ag-Ab complexes. The activated leukocytes then migrate to the lungs where they bind to the pulmonary capillary bed via integrins and other cell adhesion molecules. Proteolytic enzymes are then released that destroy tissue,

resulting in a capillary leak syndrome and pulmonary edema. More recently, reactive lipid products released from donor cell membranes have been associated with the development of TRALI.<sup>55</sup> TRALI should be suspected in patients with rapid onset respiratory distress following transfusion therapy or pulmonary edema without hypervolemia and congestive heart failure. Definitive diagnosis requires identifying HLA, granulocyte antibodies, or both in either the donor's or recipient's serum. The corresponding antigens should also be found on the recipient's or donor's leukocytes. This specialized testing is performed in few specialized laboratories. Approximately 80% to 90% of patients with TRALI survive with supportive care consisting of aggressive respiratory support, supplemental oxygen, and mechanical ventilation when necessary. Based on the presumed pathogenesis of TRALI, leukoreduced blood products could potentially decrease the incidence of TRALI. Drugs used to treat TRALI have included corticosteroids and diuretics, but there are no controlled studies demonstrating the efficacy of these agents because of the low incidence of TRALI.

## TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE

Transfusion-associated GVHD is a rare complication of blood transfusion that is fatal in approximately 90% of patients. Transfusion-associated GVHD occurs when donor immunocompetent T and natural killer cells attack recipient cells because these recipient cells appear foreign due to differences in major or minor histocompatibility antigens.<sup>56</sup> GVHD is commonly seen following allogeneic bone marrow transplant, but may also rarely occur in immunodeficient or immunosuppressed patients following blood transfusion. Removing T cells from donor grafts can minimize acute GVHD in oncology patients, but is associated with increased graft failure and a decrease in a beneficial graft-versus-leukemia or graft-versus-tumor effect. The risk of transfusion-associated GVHD is related to the number of viable T lymphocytes transfused, the recipient's immune status, and the HLA disparity between donor and recipient. Therefore, multiply transfused patients who receive cells from donors who share HLA haplotypes (haploidentical) with the recipient are at greatest risk. Clinically, transfusion-associated GVHD is characterized by the acute onset of rash, abdominal pain, diarrhea, liver function abnormalities, and bone marrow suppression beginning 2 to 30 days following transfusion. The maculopapular rash seen is similar to that observed in acute GVHD following bone marrow transplant. Biopsy of the skin can confirm the diagnosis. Pancytopenia in transfusion-associated GVHD may be severe and is attributed to destruction of recipient marrow stem cells by donor lymphocytes. Immunosuppressive therapy with prednisone and cyclosporine has not been reported effective in transfusion-associated GVHD. There is no known effective treatment for transfusion-associated GVHD, but therapeutic strategies have been proposed based on the presumed mechanism of its onset.<sup>57</sup> Fortunately, transfusion-associated GVHD can be prevented by irradiating products before transfusion. Specifically, irradiating cellular blood products with 2500 cGy inactivates donor lymphocytes and is the most effective method for preventing transfusion-associated GVHD.<sup>58</sup>

## TRANSFUSION-TRANSMITTED DISEASE

The risk of TTD, primarily viral transmission, has dramatically decreased over the past 25 years. Bacterial contamination of units is not usually considered a TTD, but actually is far more common than viral or fungal transmission. The use of volunteer donors and predonation screening questionnaires were the earliest effective steps taken to reduce the risk of transfusion-related hepatitis and HIV. These risks continue to drive government-mandated pretransfusion testing requirements.<sup>59</sup> The development of enzyme immunoassays in the 1970s and nucleotide testing in the late 1990s have further decreased the risk of TTD<sup>60</sup> (Table 53.1-6). Transfusion-associated HIV and hepatitis are a persistent problem in parts of the world that do not have access to screening tests.

Disease	Estimated Risk Per Unit Transfused in the United States Per Transfusion	Pretransfusion Testing
Hepatitis B virus	1:100,000	HBsAg, anti-HBc, serum alanine aminotransferase
Hepatitis C virus	1:100,000 (genetically testing); 1:1,000,000 (genetically with testing)	Anti-HCV, nucleic acid testing
Human immunodeficiency virus 1 and 2	1:1,000,000 to 1:750,000 (genetically testing); 1:1,000,000 (genetically with testing)	Anti-HIV 1/2, p24 antigen, nucleic acid testing
Human T-cell lymphotropic virus (HTLV I and II)	1:1,000,000	Anti-HTLV II
Cryptosporidium (CMV)	1:10 to 1:20 (per unit)	None (none tested for anti-CMV antibodies)
Bacterial contamination	1:200 to 1:2,000	None
Septicemia/pollution	None	Rapid plasma reagin
Respiratory (Pneumococcus, Staphylococcus aureus)	None	None
Streptococcus (Group B) (Group B streptococcus)	Theoretically possible	Deferral based on history

TABLE 53.1-6. Risks of Transfusion-Transmitted Disease

Pretransfusion TTD testing in the United States includes screening for syphilis, hepatitis B (HBsAg, anti-Hbc), hepatitis C (anti-HCV), HIV (anti-HIV-1/2, HIV-1 p24 antigen), and HTLV (anti-HTLV-I/II). Serum alanine aminotransferase, measured in most European countries as a nonspecific surrogate marker of hepatitis, is no longer required by American Association of Blood Bank standards.<sup>61</sup> Positive screening test results are confirmed by supplemental or confirmatory testing. Current estimates for the risk of transfusion-related HIV range from 1:500,000 to 1:750,000 units transfused.<sup>62</sup> Despite improvements in tests used to detect HIV antibodies in donors, the *window period* in which HIV could be transmitted by an infected, but HIV seronegative, donor remained in 1996 at approximately 25 days. The introduction of screening for HIV-1 p24 antigen in 1997 decreased the window period to approximately 15 days. The implementation of HIV nucleotide testing will further decrease the window period to an estimated 10 days.

Routine vaccination of infants and young children with hepatitis B vaccine should also decrease the risk of transfusion-transmitted hepatitis B as these children enter the blood donor pool. Chronic carriers of hepatitis B (HBsAg positive, anti-Hbc IgG positive, HBeAg positive or negative, anti-HBe positive or negative) can transmit the disease through blood donation or by other blood-borne exposures. Those carriers with measurable HBeAg are probably more infectious and accordingly, more likely to transmit disease through blood exposure or by vertical transmission. The chances of a health care worker contracting hepatitis B from a single contaminated needle stick is estimated to be between 2% and 40%. By contrast, the chances of acquiring HIV from a single contaminated needle stick is less than 1%. These differences may be at least in part related to the higher number of viral particles present in the blood of carriers of hepatitis B. The rate of transmitting hepatitis C through needle stick is probably on the order of 5%.<sup>63</sup> Nevertheless, health care workers must strictly adhere to universal precautions to protect themselves and their patients.

Genomic testing for HCV RNA was implemented in the United States and Europe to detect seronegative, yet infectious units. Nucleotide testing for hepatitis C and HIV is typically performed on samples pooled from multiple donors.<sup>64</sup> The importance of hepatitis C transmission in blood therapy has been confirmed in many countries by retrospective review. During these reviews, recipients of blood components from donors later found to be positive by anti-HCV screening (instituted in 1991) are examined. A large percentage of these recipients, up to 75%, are found to be anti-HCV positive.<sup>65,66</sup> Unlike hepatitis B, the majority of those recipients who become HCV seropositive develop chronic liver disease. Therefore, these patients must be offered counseling that addresses the complications of hepatitis C, as well as the risk to close contacts and family members.<sup>67</sup> Nucleotide amplification testing will decrease the incidence of transfusion-related hepatitis C by narrowing the window period from approximately 60 to 80 to 10 to 20 days. Hepatitis G virus has been transferred by blood transfusion, but its significance is unclear in that transfusion-acquired infection has not been associated with acute or chronic hepatitis.<sup>68</sup>

Several techniques have been developed to inactivate viruses in plasma including solvent and detergent treatment and photochemical inactivation using psoralens and long wavelength ultraviolet A light.<sup>69</sup> Methods used to inactivate infectious pathogens in cellular blood components such as platelets and red cells are not currently available but are under clinical development. Due to the low risk of viral infection by transfusion and the fact that most patients who receive plasma also receive cellular blood components, the cost-effectiveness of virally inactivated plasma is low.<sup>70</sup> Albumin, immune globulin, factor concentrates, and other plasma derivatives are also virally attenuated by standard treatment protocols.

Other pathogens such as CMV and parvovirus B19 are common in the general donor population and may pose a serious threat in immunocompromised and splenectomized patients.<sup>71</sup> Approximately 40% to 60% of blood donors have been exposed to CMV during their lifetime and thus, have developed antibodies directed against CMV. However, only approximately 2% of CMV-seropositive donors are actively infected, in which case transfusion of their blood to an immunocompromised recipient could cause potentially serious disease. The actual risk of posttransfusion seroconversion of a CMV-negative recipient who receives CMV-untested blood depends on the prevalence of CMV seropositivity in the donor population. This prevalence varies widely in different parts of the United States and other countries.

A number of other infectious diseases are known or are suspected to be transmitted by blood transfusion. These include malaria, Chagas' disease, leishmaniasis, and

toxoplasmosis.<sup>72</sup> Parvovirus B19, malaria, and babesiosis are of particular risk to immunocompromised patients. The risk of acquiring babesiosis by blood transfusion is unknown because it is endemic in many areas and often results in asymptomatic infection. Small clusters of blood transfusion–associated babesiosis have been described attributed to single asymptomatic blood donors.<sup>73</sup> Thus, oncologists should recognize that babesiosis can cause febrile hemolytic disorders after diagnosis because it is a potentially fatal, yet treatable disease. Transmission of *Borrelia burgdorferi* by transfusion has not yet been documented. The risk of new variant Creutzfeldt-Jakob disease, first described in 1996, is unknown. It is unclear whether new variant Creutzfeldt-Jakob disease is transmissible by blood transfusion, and this route of transmission has not been reported.<sup>74</sup> Fears of transmitting new variant Creutzfeldt-Jakob disease, however, have resulted in implementation of a universal white blood cell reduction policy in the United Kingdom.<sup>75</sup> In the United States, donors are now deferred *indefinitely* if they have spent 6 months or more, cumulatively, in the United Kingdom from 1980 through 1996. This policy will have a negative effect on blood supplies.

## USE OF SPECIAL BLOOD PRODUCTS IN ONCOLOGY PATIENTS

Cancer patients are often immunosuppressed as a result of their disease, treatment, or both. Accordingly, they are prone to a wide variety of viral and bacterial infections and to harmful cellular-mediated immune responses. By virtue of their frequent exposure to transfusions, they are highly susceptible to developing HLA alloantibodies that can adversely effect their therapy if appropriate precautions are not taken. Specifically, HLA antibodies are implicated in common febrile transfusion reactions and the development of refractoriness to platelet transfusions. Thus, oncology patients should receive blood products that have been specially processed to prevent these and other complications. Currently available special blood products include those that are leukoreduced, irradiated blood products, and CMV seronegative or CMV *safe*. Patients should be individually considered for each of these products, and the patient's needs must be periodically reevaluated.

### LEUKOREDUCTION

Leukocytes contained in blood components can provoke febrile nonhemolytic reactions, induce HLA alloimmunization, and transmit CMV to both immunocompetent and immunosuppressed recipients. Leukocytes are effectively removed from red cell and platelet concentrates by leukocyte reduction filters. Currently used third-generation leukocyte reduction filters remove 3 to 4 log<sub>10</sub> of the total intact leukocytes found in red cell and platelet concentrates. American Association of Blood Bank standards require that units labeled leukoreduced contain less than 5 × 10<sup>6</sup> residual white cells. Red cells are leukoreduced shortly after blood collection (pre-storage leukodepletion), following refrigerated storage (poststorage leukodepletion), or at the bedside during transfusion. Filters are similarly used to leukoreduce platelet concentrates. Platelets collected by modern apheresis devices are designed to directly collect leukoreduced platelets. Many physicians believe that these products do not require further leukoreduction. White cell reduction by each of these techniques requires quality control measures (using cyclic good manufacturing practices) that verify adequate leukoreduction of cellular blood products.

Leukoreduction reduces the incidence and severity of febrile transfusion reactions and decreases the risk of HLA alloimmunization. Specifically, leukoreduced products are less likely to stimulate the HLA alloantibodies implicated in both febrile transfusion reactions and antibody-mediated platelet reactions. Other generally accepted benefits of white cell reduction include delaying platelet refractoriness and decreasing the risk of transmitting white cell–related infectious agents including CMV and HTLV-I/II.<sup>76</sup> Thus, leukodepleted products are recommended for all autologous and allogeneic bone marrow and peripheral blood stem cell transplant recipients and candidates. They are also indicated for patients with leukemia, lymphoma, and aplastic anemia. Patients with solid tumors who are not transplant patients but who have large anticipated cellular blood product needs should also receive leukoreduced products, as should any patient with chronic transfusion needs (thalassemia, sickle cell disease).

Prestorage leukoreduced products are preferable because they are also devoid of cytokines and other biologic response modifiers that play a role in transfusion complications. Many of these proteins are not efficiently removed by leukocyte reduction filters.<sup>77</sup> This is particularly true in platelet concentrates stored at room temperature because there is continued elaboration of biologically active substances such as tumor necrosis factor, IL-1 and IL-6.<sup>78</sup> With the dramatic decrease in the risk of viral transmission, investigators are focusing on the immunomodulatory effects of blood transfusion.<sup>79</sup> These effects involve associations between allogeneic transfusion and bacterial infection, tumor progression, and tumor recurrence.<sup>80,81</sup> Universal leukoreduction of both red cells and platelets is required in a number of countries including the United Kingdom and will be implemented shortly in the United States.

### IRRADIATION

Blood components are irradiated to prevent potentially lethal transfusion-associated GVHD by interfering with the ability of lymphocytes to proliferate. Irradiation of supportive blood components is indicated in bone marrow or peripheral blood stem cell transplant recipients, patients with congenital immunodeficiency states, neonates, premature infants, and during intrauterine exchange transfusion.<sup>82</sup> Directed blood donations made by relatives should also be irradiated. Patients with acquired immunodeficiency syndrome commonly receive irradiated components, although there is no clear increased risk of transfusion-associated GVHD in this population. Standard guidelines recommend irradiating red blood cells, platelets, and granulocytes with a minimum dose of 2500 cGy.<sup>83</sup> Platelets and red cells are not adversely affected by this exposure. It is not believed necessary to irradiate FFP or cryoprecipitate because they do not contain viable leukocytes. Leukoreduction is *not* a substitute for irradiation as transfusion-associated GVHD has been described following transfusion of leukoreduced, nonirradiated blood.<sup>84</sup> Bone marrow or peripheral blood stem cells must never be irradiated before transplant for obvious reasons.

There is preliminary evidence from a murine transfusion model that photochemical treatment with psoralen S-59 and long wavelength ultraviolet light can prevent transfusion-associated GVHD.<sup>85</sup> Using a murine transfusion model, clinical and histologic evidence of GVHD could be prevented by both gamma irradiating or photochemically treating splenic leukocytes. Photochemical treatment was originally developed to inactivate contaminating viruses, bacteria, and leukocytes in blood components. This technology is currently under investigation in the United States and Europe.

### CYTOMEGALOVIRUS-SERONEGATIVE AND CYTOMEGALOVIRUS SAFE

CMV infection is a leading cause of morbidity and mortality in marrow and solid organ transplant patients. Most serious CMV infections develop in these populations as a result of latent reactivation of recipient CMV, but nevertheless, CMV can be transmitted by blood transfusion. Therefore, blood banks supply products that have a low potential of transmitting CMV. These products include CMV-seronegative units prepared from donors who are CMV IgG antibody negative and leukodepleted components. The latter refers to blood components leukoreduced in a blood center or laboratory using good manufacturing techniques and strict quality control measures. Depending on the donor population, as many as 80% to 90% of blood donors may be CMV seropositive. In this situation, the demand for CMV-seronegative products can easily exceed supply. In addition, CMV-seronegative products are capable of transmitting CMV disease; CMV seronegativity does not guarantee the product is incapable of causing acute CMV disease. Studies suggest that CMV seronegative and leukodepleted filtered products are equivalent in preventing CMV transmission.<sup>76</sup> In this study, however, all five deaths attributed to CMV pneumonitis occurred in patients who received leukoreduced products.

Many transfusion specialists consider quality-assured leukodepleted units as CMV “safe” in that they are unlikely to transmit CMV disease. In addition to CMV-seronegative marrow and solid organ transplant recipients, CMV-seronegative or -safe components are generally indicated for premature infants, during intrauterine transfusions, for patients with congenital immunodeficiencies, CMV-seronegative pregnant women, and seronegative patients with HIV. The British Committee for Standards in Hematology concluded that leukoreduced components are an “effective alternative” to seronegative products for preventing transfusion-related CMV transmission.<sup>86</sup>

### APHERESIS

*Apheresis*, derived from the Greek word meaning to take away, is the process of selectively removing one component of whole blood and returning the remainder to the donor or patient. Today, sophisticated and highly automated blood cell separators are available for processing large volumes of donor or patient blood to remove the desired blood component. There are two broad applications of apheresis: apheresis for blood component collection and therapeutic apheresis. Apheresis is currently used in blood centers to collect plasma, platelets, granulocytes, and peripheral blood stem cells. In the United States, most plasma used by the fractionation industry to produce coagulation factor concentrates, albumin, and immune globulin is obtained by *plasmapheresis*. *Plateletpheresis* provides many of the single donor platelets used by oncology patients. Collecting large numbers of platelets from specific donors is important to many patients who poorly respond to platelet transfusion as a result of alloimmunization to HLA or platelet-specific antibodies. *Leukapheresis* is used to describe the removal of granulocytes (used for granulocyte transfusions in neutropenic cancer patients), peripheral blood stem cells (autologous or allogeneic), and other mononuclear cells. Red cell units are being collected using automated cell separators.

Therapeutic apheresis is a procedure commonly performed for a variety of conditions.<sup>87</sup> Generally recognized indications for *plasma* exchange include thrombotic

thrombocytopenic purpura, Waldenström's macroglobulinemia, myasthenia gravis, chronic inflammatory demyelinating polyneuropathy, the Guillain-Barré syndrome, and rheumatoid arthritis. Plasma exchange may help prevent the initiation or continuation of dialysis in patients with rapidly progressive renal failure secondary to multiple myeloma.<sup>88</sup> Therapeutic plasmapheresis has been used in cancer patients who develop a wide array of paraneoplastic syndromes, but its efficacy has not been confirmed by clinical trials.<sup>89</sup> Simple removal of red cells from patients with polycythemia is performed by simple phlebotomy and does not require a cell separator. On the other hand, automated separators very efficiently exchange red cells in patients in sickle cell crisis and patients with *Babesia* infection. Oncology patients with myeloid leukemias may require cellular apheresis to reduce tumor burden before receiving chemotherapy.<sup>90</sup>

Leukapheresis is typically performed in acute or chronic myeloid leukemia in blast crisis when the blast count exceeds 100,000/ $\mu$ L. Patients may or may not have symptoms of leukostasis or hyperviscosity at these levels. Lymphoid leukemias are less likely to produce leukostatic symptoms, but are also treated by leukopheresis in certain situations, or when the blast count is rapidly increasing. As blood viscosity increases, flow in cerebral and myocardial circulations slows, resulting in tissue hypoperfusion and organ hypoxia. The presence of central nervous system or pulmonary symptoms may be an indication for more urgent care. A single leukapheresis can reduce the leukocyte count by 20% to 50% and reduce hyperviscosity symptoms. On occasion, the cell count may actually rise postleukapheresis as malignant cells are released from the spleen and lymphoid organs. Leukapheresis is rarely needed for chronic myelogenous leukemia in chronic phase. *Thrombocytapheresis* is used for patients with myeloproliferative disease who have platelet counts over 1,000,000/ $\mu$ L. These patients with significant thrombocytosis may be actively hemorrhaging or show signs of thrombosis. The platelet count invariably rebounds postprocedure unless chemotherapy is initiated. Prophylactic plateletpheresis is rarely indicated for such patients.

## CONCLUSIONS

### EFFECT OF GROWTH FACTORS ON TRANSFUSION MEDICINE

Hematopoietic growth factors as applied to oncologic transfusion therapy are designed to limit the exposure of patients to allogeneic blood.<sup>43,91</sup> The isolation, characterization, and subsequent synthesis of erythropoietin by recombinant technology (rHuEPO) was one of the most important advances in decreasing red cell transfusions. Use of rHuEPO has dramatically reduced the transfusion needs of patients with a various anemias.<sup>92</sup> rHuEPO has also been employed to increase the yield of autologous donations and to stimulate erythropoiesis after surgery. Granulocyte colony-stimulating factor has been shown to decrease infection rates in neutropenic patients undergoing chemotherapy, replacing marginally effective granulocyte transfusions. The limitations and risks of platelet transfusion therapy continue to drive the development of agents that stimulate platelet production in oncology patients.<sup>93</sup> There is rapid growth in the use of growth factors including FLT-3 ligand, c-MPL ligand (thrombopoietin),<sup>94</sup> and various combinations of growth factors. IL-11, in particular, has been approved by the U.S. Food and Drug Administration for preventing severe thrombocytopenia in patients receiving myelosuppressive chemotherapy. Thrombopoietic growth factors also have the potential to stimulate platelet apheresis donors, increase stem cell harvest yields, and expand progenitor cells *ex vivo*.<sup>95</sup> Development of neutralizing antibodies against endogenous thrombopoietin has plagued clinical testing of thrombopoietic growth factors.

### BLOOD SUBSTITUTES

Red cell substitutes currently in development include hemoglobin-based oxygen carriers (HBOCs), perfluorocarbon emulsions, and liposome-encapsulated hemoglobin.<sup>78</sup> The two major types of blood substitutes, HBOCs and perfluorocarbon emulsions, are in phase II and III clinical trials. None are currently approved for clinical use in the United States.<sup>96</sup> HBOCs are artificially derived products with oxygen-carrying properties. They are structurally similar to hemoglobin but do not contain red cell stroma, which is toxic and leads to renal damage. Development of HBOCs has been hampered by the relatively short half-life of these oxygen carriers in the circulation. Perfluorocarbons are synthetic hydrocarbons that have the ability to carry dissolved oxygen. The particles circulate for only a few hours until they are removed by the reticuloendothelial system. Research efforts to modify or remove red blood cell antigens from donor units is proceeding slowly, but a truly universal compatible red cell unit may one day be within reach.

## INTRODUCTION

High-dose chemotherapy and autologous proximal stem cell rescue is now considered standard therapy for relapsed Hodgkin's disease<sup>1</sup> and intermediate-grade lymphomas,<sup>2</sup> and it is currently being tested as part of initial therapy for patients with adverse risk features and one of the following diagnoses: Hodgkin's disease, non-Hodgkin's lymphoma (NHL), multiple myeloma, breast cancer, and germ cell tumors. The movement of high-dose therapy from a treatment of last resort to a more proximal position is due in large part to improvements in supportive care that have nearly eliminated treatment-related mortality and have, at the same time, facilitated the transfer of much of the care from the hospital to the outpatient setting.<sup>3,4</sup> and <sup>5</sup> Perhaps the most important advance in the ability to support patients receiving high-dose therapy has been the use of peripheral blood stem cells (PBSCs). The duration of neutropenia and thrombocytopenia after marrow "ablative" therapy and PBSC rescue is now only moderately longer than that expected after aggressive standard therapy. In most centers, advanced age has become much less important than comorbidity as an important barrier to treatment, and the improved therapeutic index of high-dose therapy has resulted in exploratory studies for the treatment of refractory autoimmune disorders, including systemic lupus erythematosus, rheumatoid arthritis, and multiple sclerosis.<sup>6</sup>

In many respects, because of the availability of PBSC and growth factors, treatment-induced myelosuppression is no longer considered an obstacle to treatment. However, several issues remain unresolved with the use of PBSCs, including the growing recognition that a substantial percentage of collections are contaminated with tumor cells. In fact, strategies for PBSC mobilization have focused on increasing the collections of progenitor cells with much less attention given to the impact on tumor cell mobilization. In addition, a small percentage of patients can still not achieve acceptable PBSC collections, a finding that highlights our ignorance of the biology of stem cell mobilization and the fact that only modest progress has been made in the ability to successfully expand progenitor cells *in vitro*.

Finally, as the general ease of collection and use of PBSCs compared with bone marrow has changed the focus from the procedure ("transplantation") to the treatment, it is clear that high-dose therapy has not been able to overcome significant drug resistance. These results suggest that newer drugs for preparative regimens (including monoclonal antibodies) and novel treatment strategies to eliminate minimal residual disease are needed to further substantially improve cure rates.

## HISTORY

In the aftermath of the destruction caused by the atomic bomb at the end of World War II and the subsequent nuclear arms race, a dramatic increase in research was directed at reducing or avoiding bone marrow injury from radiation. In a landmark paper published in 1949, Jacobson et al.<sup>7</sup> reported that lead shielding of the spleen prevented death from bone marrow aplasia in mice after a lethal dose of total body irradiation. Protected mice developed only transient leukopenia and thrombocytopenia and had histologic evidence of bone marrow regeneration 8 days after radiation. In contrast, control mice died without evidence of residual hematopoiesis. Although the authors recognized that a "cellular factor" from the spleen could be responsible for bone marrow recovery in the experimental group, they favored a humoral mechanism because survival in spleen-shielded mice was significantly increased even if the spleen was removed shortly after radiation.<sup>8</sup> Indeed, it was another 7 years before the humoral theory of bone marrow recovery was finally laid to rest.

In retrospect, survival in Jacobson's mice proved that stem cells circulate in the blood and restore hematopoiesis. Thus, bone marrow recovery in the mice that had a splenectomy soon after irradiation must have been due to migration of protected (by lead shielding) stem cells from the spleen to the blood and then to the bone marrow. However, investigators of several studies in mice,<sup>9</sup> guinea pigs,<sup>10</sup> and dogs<sup>11</sup> are generally given credit for confirming the normal presence of circulating hematopoietic progenitor cells in mammals, and in 1975, the presence of pluripotential stem cells in the blood of humans was unequivocally demonstrated.<sup>12</sup>

Although the presence of circulating progenitor cells was established, it was unknown whether enough cells could be collected to reconstitute hematopoiesis in a patient who had received marrow ablative therapy. Indeed, *in vitro* assays showed that an equivalent number of nucleated cells from the bone marrow produced substantially more granulocyte colonies than did the same number of cells from the blood.<sup>13</sup> An important exception to the latter finding was observed in patients in the chronic phase of chronic myelogenous leukemia (CML).<sup>14</sup> In affected patients, the percentage of colony-forming cells collected from the buffy coat layer was higher than in the bone marrow and was approximately fivefold higher than in bone marrow cells from healthy volunteers.<sup>14</sup> These data provided a rationale for rescuing aggressively treated patients in blast crisis with autologous cells harvested at the time of diagnosis,<sup>15</sup> but the data also clearly indicated that the results in CML patients could not be generalized to patients with other diseases.

In fact, the first clinical trials of PBSC rescue in the late 1970s and early 1980s appeared to establish important differences between the engraftment potential of blood stem cells of CML patients and normal donors. Goldman et al.<sup>15</sup> reported complete engraftment in 19 of 20 patients with CML in transformation who were given myeloablative therapy and then rescued with autologous chronic phase, buffy coat cells. In contrast, two patients, one with Ewing's sarcoma<sup>16</sup> and one with paroxysmal nocturnal hemoglobinuria,<sup>17</sup> did not engraft with blood stem cells from healthy identical twin siblings. In both patients, normal hematopoiesis was restored after bone marrow infusions from the same healthy donors. The effectiveness of syngeneic bone marrow but not PBSCs from normal donors used to restore hematopoiesis was in agreement with laboratory experiments that showed important differences in the capacity for self-renewal between blood and bone marrow cells.<sup>18</sup> Because no further reports of PBSC rescue in patients with diseases other than CML were published for the next 5 years, the results of these early clinical studies must have been particularly discouraging.

The first semi-successful PBSC transplantations were reported in 1985 by Juttner et al.<sup>19</sup> in two patients with acute nonlymphocytic leukemia (ANLL). These were also the first "mobilized" stem cell transplantations, as leukapheresis was timed to coincide with the period of hematopoietic recovery after induction chemotherapy. Previous work from the same group had shown that, after aggressive chemotherapy, granulocyte-macrophage colony-forming units (GM-CFUs) were increased 25-fold higher than the mean level in normal subjects and were also higher than the GM-CFU yield from 1 L of bone marrow.<sup>20</sup> In the clinical trial, both patients had rapid evidence of trilineage recovery after being given mobilized stem cells after high-dose therapy. In one patient, however, transient recovery was followed by significant neutropenia and thrombocytopenia before leukemia recurred; in the other patient, disease recurrence precluded assessment of the long-term viability of the graft.

Subsequently, five centers described PBSC transplantations in a total of eight patients.<sup>21,22,23,24</sup> and <sup>25</sup> In four of the studies, PBSCs were collected after chemotherapy, and in one report of two patients,<sup>24</sup> stem cells were collected during steady-state myelopoiesis. Although these studies showed the feasibility of PBSC rescue, important reservations remained about the broader use of PBSCs. For example, because four of the six patients with mobilized PBSC transplantations had acute leukemia, the mobilizing chemotherapy was intensively myelosuppressive and was associated with a prolonged period of aplasia. As a result, the applicability of chemotherapy mobilization for patients with other diseases was unclear. Similarly, in the patients who had nonmobilized collections, the long period (28 days in one patient) that was required to collect enough progenitor cells was impractical for patients with aggressive disease. Finally, these studies did not establish the number of progenitor cells necessary for engraftment, nor did they establish the durability of PBSC autografts. Thus, in view of the known effectiveness of autologous bone marrow rescue, most centers reserved PBSC transplantation for patients who were not eligible for autologous bone marrow transplantation. Potential candidates

included patients with marrow tumor involvement, previous pelvic irradiation, or bone marrow hypocellularity.

The transition toward the use of PBSCs, now complete for autologous rescue and moving in that direction for allogeneic transplantations, <sup>26</sup> has been made possible because of the tremendous number of progenitor cells that can be collected relatively easily and noninvasively.

## STEM CELL MOBILIZATION

In 1976, Richman et al.<sup>27</sup> reported that, as blood counts recovered after chemotherapy, a significant increase in circulating neutrophil progenitor cells was seen, and these authors speculated that large-volume apheresis could be used to collect enough stem cells to avert the myelosuppressive effects of chemotherapy. Twelve years later, hematopoietic growth factors were shown to mimic<sup>28</sup> as well as to potentiate the effect of chemotherapy<sup>29</sup> in mobilizing progenitor cells. In addition to neutrophil precursors, megakaryocyte progenitors also were increased<sup>28</sup>; however, in the absence of assays that measured self-renewal and pluripotential capacity, the ability of circulating “mobilized” progenitor cells to establish permanent trilineage engraftment remained speculative. Accordingly, in most early clinical trials, blood progenitor cells were used in addition to autologous bone marrow. These studies confirmed that neutrophil recovery was more rapid in patients given the blood progenitor cells, but the studies also showed an improvement in platelet and red blood cell recovery.<sup>30,31,32,33 and 34</sup> The latter findings provided the rationale for mobilized progenitor cells to be used alone with bone marrow held in reserve and, more recently, without the need to harvest “backup” bone marrow. In 1994, rescue with PBSCs surpassed the use of bone marrow after high-dose therapy.

The discovery of the CD34 antigen as a stem cell marker significantly facilitated the development of strategies to maximize the mobilization and collection of blood progenitor cells. The CD34 antigen was initially described in 1984 on tissue culture cells derived from a patient with ANLL and was subsequently found to be present on nearly all colony-forming progenitor cells detected by *in vitro* assays.<sup>35</sup> The “stemness” of CD34+ cells was established by successfully engrafting lethally irradiated baboons and, later, humans with CD34+-selected cells.<sup>36,37</sup> These studies suggested that both pluripotential and more committed progenitor cells are contained within the small fraction of bone marrow (1% to 2%) and peripheral blood mononuclear cells that are CD34+.

The presence of the semi-unique CD34 antigen on the surface of stem cells enabled the development of a flow cytometry assay that provides a rapid quantitative analysis of stem (CD34+) cell number.<sup>38</sup> Enumeration of stem cells by flow cytometry has virtually replaced more intensive and time-consuming *in vitro* assays in which the adequacy of stem cell collection is inferred from the number of progenitor colonies that are formed in agar after 2 weeks of growth. With the availability of same-day results of the CD34+ blood cell count permitted by flow cytometry, apheresis can be optimally timed to coincide with rising CD34+ cell counts rather than with a surrogate marker, such as neutrophil recovery. Similarly, because the collected number of CD34+ cells also can be counted quickly, apheresis procedures can be limited to the number required to reach the target number of CD34+ cells. In fact, well-mobilized patients often require only one procedure to achieve an adequate collection.

The CD34 count of the infused product is generally considered the most reliable factor for predicting the speed and durability of engraftment after high-dose therapy. After myeloablative therapy, the infusion of more than  $5 \times 10^6$  CD34+ cells per kilogram results in neutrophil and platelet recovery within 14 days in nearly 85% of patients, and 95% have recovery within 20 days.<sup>39</sup> With an intermediate dose (between  $2.5$  and  $5.0 \times 10^6$  CD34+ cells per kilogram), neutrophil recovery appears to be as rapid as at higher CD34+ cell numbers, but a detectable incidence of delayed platelet recovery is reported, particularly in more heavily pretreated patients and in those given posttransplantation myeloid growth factors.<sup>40,41</sup> A minimum number of CD34+ cells per kilogram that is required for engraftment has not been defined, in part because many regimens are not truly myeloablative. In a study of 48 patients who received  $1.0$  to  $2.5 \times 10^6$  CD34+ cells per kilogram, all patients achieved neutrophil engraftment at a median of day 11, but 19% had delayed platelet recovery beyond 21 days and 9% had a delay longer than 100 days.<sup>42</sup> The clinical significance of lower CD34 cell doses is longer duration of hospitalization, longer use of antibiotics, and an increased and more prolonged need for transfusions.<sup>43</sup> Taken together, these results suggest that the use of  $5 \times 10^6$  CD34+ cells per kilogram or more is optimal;  $2.5 \times 10^6$  CD34+ cells per kilogram or more is acceptable; and in patients who only achieve between  $1.0$  and  $2.4 \times 10^6$  CD34+ cells per kilogram, the decision to proceed to transplantation must be individualized.

At present, blood progenitor cells are mobilized in most patients with the use of chemotherapy followed by growth factors or with growth factors alone ( [Table 53.2-1](#)). The combination of myelosuppressive chemotherapy plus growth factors generally is considered the most productive strategy for mobilizing stem cells and, in comparison with the use of growth factors alone, offers the advantage of providing additional treatment against the underlying disorder. In fact, with the tremendous number of CD34+ cells that are often mobilized into the blood by chemotherapy plus growth factors, often only a single apheresis is required, and the costs and toxicities associated with multiple aphereses can be reduced. On the other hand, the apparent advantages resulting from a reduction in the number of aphereses may be more than offset by the costs and toxicity associated with the use of more myelosuppressive chemotherapy, including the prolonged use of growth factors as well the potential need for hospitalization, intravenous antibiotics, and transfusions. In addition, because no advantage may exist for giving more stem cells than the number necessary to ensure rapid neutrophil and platelet engraftment (between  $2.5$  and  $5.0 \times 10^6$  CD34+ cells per kilogram), a strong argument can be made for using a less toxic mobilization program.

Drug	Method	Advantage	Disadvantage
G-CSF	G-CSF 10-20 µg/kg beginning on Friday before 1st collection on Monday and continue daily until CD34+ cells are collected. G-CSF continued until last day of pheresis.	Avoid weekend pheresis; hospitalization often unnecessary.	2-3 day pheresis usually required; with growth factors, enough to do 2-3 collections.
Granulocyte colony-stimulating factor (G-CSF) plus G-CSF	Granulocyte colony-stimulating factor (G-CSF) 10 µg/kg plus G-CSF 10 µg/kg plus G-CSF 10 µg/kg after chemotherapy.	Additional treatment against underlying disease; higher yields.	No major hospitalization; difficult to perform one of pheresis; longer period of G-CSF use; possible greater expense.

G-CSF, granulocyte colony-stimulating factor; NK, natural killer cell.  
 \*New investigational granulocyte colony-stimulating factor, but available data do not support it as a better mobilizing agent than G-CSF.  
 †Higher yields may be obtained with more daily injections, but the degree is less consistent for patients.  
 ‡New investigational granulocyte colony-stimulating factor for CD34+ count is more than 10-fold yield.

**TABLE 53.2-1. Mobilization Strategies**

Although much of the earlier stem cell mobilizing literature was dominated by the use of intensively myelosuppressive regimens, it is clear that, in most patients, standard disease-specific chemotherapy followed by granulocyte colony-stimulating factor (G-CSF) is generally sufficient to collect an adequate number of stem cells. For example, in a group of patients with NHL in whom high-dose therapy and stem cell rescue was planned as part of initial therapy, Pettengell et al.<sup>44</sup> required only a single pheresis to collect more than  $2.5 \times 10^6$  CD34+ cells per kilogram after treatment with vincristine, doxorubicin, prednisone, VP-16, and bleomycin (VAPEC-B) and G-CSF. Even in more heavily pretreated relapsed NHL patients, the well-tolerated combination of ifosfamide, carboplatin, and etoposide followed by G-CSF resulted in successful mobilization ( $2.0 \pm 10^6$  CD34+ cells per kilogram or more) in 86% of patients, and 61% of patients had  $6.0 \times 10^6$  CD34+ cells per kilogram or more collected.<sup>45</sup> Similarly, the outpatient regimen of cyclophosphamide,  $1.5 \text{ g/m}^2$ , followed by G-CSF,  $10 \text{ µg/kg}$ , is a reliable and safe mobilizing program that can be timed to avoid the need for weekend pheresis.<sup>46</sup> In breast cancer patients, Taxol<sup>47</sup> or Taxol-based combinations<sup>48</sup> have been particularly potent in mobilizing stem cells. For example, compared with cyclophosphamide plus G-CSF, the addition of Taxol was associated with a greater than tenfold increase in CD34+ cells per kilogram per collection.<sup>48</sup>

An alternative to the use of chemotherapy plus growth factors for stem cell mobilization is the use of growth factors alone. Mobilization with growth factors, although generally not as productive as the combination of chemotherapy plus growth factors, offers several practical advantages. First, the potential morbidity and need for hospitalization secondary to myelosuppressive chemotherapy can be avoided. Second, the timing of pheresis can be scheduled, making weekend pheresis unnecessary. Finally, the lack of significant acute or known long-term toxicity with growth factors makes them acceptable for stem cell mobilization when normal donors are used for stem cell mobilization. G-CSF is the most commonly used cytokine when growth factors are used alone. GM-CSF is inferior to G-CSF as a mobilizing agent, but the combination of GM-CSF plus G-CSF may mobilize a higher number of early progenitor cells (CD34+, CD38-) than either cytokine used alone.<sup>49</sup> Because it is not clear that the increase in earlier progenitor cells resulting from the combination of cytokines offers any significant advantage, G-CSF is currently most often used alone.

## INADEQUATE MOBILIZATION OF STEM CELLS

The failure to mobilize stem cells (less than  $1.0 \times 10^6$  CD34+ cells per kilogram) is associated with the type and number of previous treatments. Thus, in a population of patients with Hodgkin's disease and NHL who received mobilizing chemotherapy and growth factors, an average decrease of  $0.2 \times 10^6$  CD34+ cells per kilogram was noted for every cycle of previous chemotherapy.<sup>50</sup> Although this study did not specifically correlate the type of chemotherapy and its impact on stem cell mobilization, it is known that some drugs are more toxic to stem cells than others. Because of their association with myelodysplasia (MDS) and leukemia, it is not surprising that melphalan, nitrosourea agents, nitrogen mustard, and procarbazine are potent stem cell toxins. Less well known for causing stem cell toxicity are fludarabine<sup>51,52</sup> and high cumulative doses ( $7.5 \text{ g/m}^2$  or more) of cytosine arabinoside.<sup>53</sup> The use of prior wide-field radiation also has been correlated with a reduction in stem cell mobilization. Mediastinal radiation appears to be as toxic as pelvic radiation.<sup>50</sup>

When stem cell collections are inadequate after treatment with growth factors or chemotherapy plus growth factors, inconsistent results have been achieved with alternative strategies. In patients who do not have effective mobilization with G-CSF alone, the use of myelosuppressive chemotherapy plus G-CSF may be worthwhile, but it is unproven as an effective strategy. In patients who do not have adequate mobilization after chemotherapy plus G-CSF, no data are available to suggest that the benefits of more myelosuppressive regimens outweigh the risks associated with more prolonged neutropenia.

The use of autologous bone marrow in poorly mobilized patients also has been disappointing and suggests that the inability to collect adequate stem cells should be considered a marker for an injured bone marrow. For example, Watts et al.<sup>54</sup> described 12 patients in whom fewer than  $1.0 \times 10^6$  CD34+ cells per kilogram and fewer than  $1 \times 10^5$  granulocyte-monocyte colony-forming cells per kilogram were mobilized. When a subsequent bone marrow harvest was given in addition to collected stem cells, 5 of the 12 patients experienced transplantation-related mortality; 4 of 11 assessable patients had neutrophil recovery delayed beyond 21 days, and eight patients had delayed platelet recovery.<sup>54</sup>

In patients who experience a poor mobilization either with G-CSF alone or with chemotherapy plus G-CSF, it appears that a variable number can achieve an acceptable (but rarely optimal) number of stem cells after higher doses of G-CSF alone. In a preliminary report, Fraipont et al.<sup>55</sup> studied 27 patients, 25 of whom had collections of less than  $2.0 \times 10^6$  CD34+ cells per kilogram after chemotherapy plus G-CSF. Seven patients remobilized with chemotherapy plus G-CSF achieved similar stem cell collections to the first mobilization. In patients remobilized with  $10 \mu\text{g/kg}$  G-CSF alone, the peripheral CD34 count, as well as the number of CFU-GM and CD34+ cells collected per apheresis, was statistically increased in the group treated with G-CSF only.<sup>55</sup> Similarly, Jennis et al.<sup>56</sup> studied 20 patients who had unsuccessful initial mobilization (median total collection of  $0.57 \times 10^6$  CD34+ cells per kilogram), 16 of whom previously had been treated with chemotherapy plus G-CSF,  $5 \mu\text{g/kg}$  twice daily, and four of whom had been treated with G-CSF alone. After a 7-day period of G-CSF withdrawal, G-CSF was given at a dose of  $16 \mu\text{g/kg}$  twice daily. The median total collection for the second collection was  $1.53 \times 10^6$  CD34+ cells per kilogram, and only two patients did not achieve a cumulative stem cell collection considered adequate to undergo high-dose therapy.<sup>56</sup> Using a slightly different strategy, Gazitt et al.<sup>57</sup> immediately treated mobilization failures (fewer than  $0.2 \times 10^6$  CD34+ cells per kilogram after 2 to 3 days of pheresis) with G-CSF,  $32 \mu\text{g/kg/d}$ , with apheresis beginning approximately 5 days later. An adequate number of CD34+ cells was collected in 15 of 17 patients.<sup>57</sup> In all three of the studies just described, patients who went on to receive high-dose therapy and stem cell rescue recovered neutrophil and platelets at a median time that was only slightly prolonged compared to more optimally mobilized patients.

Weaver et al.<sup>58</sup> showed that, in patients who obtained fewer than  $2.5 \times 10^6$  CD34+ cells per kilogram after first mobilization, the yield of second stem cell collections was significantly increased, regardless of whether chemotherapy plus G-CSF or G-CSF alone was used.<sup>58</sup> These results suggested that the first mobilization attempt had a priming effect on the second or that other factors may have compromised the first attempt. Chemotherapy plus G-CSF and G-CSF alone proved equally but only mildly effective, because fewer than one-half of the patients had enough (more than  $2.5 \times 10^6$  CD34+ cells per kilogram) collected to proceed to transplantation. A relationship appears to exist between G-CSF dose and the yield of CD34+ cells collected, but it did not reach statistical significance.

The sum of the studies discussed suggest that, in patients who achieve suboptimal first collections ( $1.0$  to  $2.4 \times 10^6$  CD34+ cells per kilogram), approximately one-half or more may achieve a safe ( $2.5 \times 10^6$  CD34+ cells per kilogram or fewer) cumulative stem cell collection after a second mobilization with high-dose ( $32 \mu\text{g/kg}$ ) G-CSF alone. However, a significant qualitative difference may exist between "hard-to-mobilize" patients who achieve marginal yields ( $1.0$  to  $2.4 \times 10^6$  CD34+ cells per kilogram) and "nonmobilizable" patients (fewer than  $1.0 \times 10^6$  CD34+ cells per kilogram).<sup>59</sup> Indeed, more recent engraftment data suggest that the former group may not really need or significantly benefit from the second collection,<sup>42</sup> whereas the latter group has a high incidence of transplantation-related mortality, despite the use of backup bone marrow in addition to blood stem cells.<sup>54</sup> Further studies clearly are required to determine whether high-dose G-CSF is effective in nonmobilizing patients.

Combinations of GM-CSF and G-CSF also have been tested in patients who did not achieve a blood CD34 level considered appropriate (10 cells per microliter) for collection or in whom an institutionally acceptable number of CD34 cells could not be collected with the first collection. In one preliminary report, 10 of 11 patients treated with  $10 \mu\text{g/kg}$  GM-CSF for 2 days followed by G-CSF,  $10$  to  $16 \mu\text{g/kg}$ , for 4 days achieved CD34+ cell collections of more than  $1 \times 10^6$  cells per kilogram, including four patients who obtained more than  $4 \times 10^6$  per kilogram.<sup>60</sup> Nine patients who went on to receive high-dose therapy achieved neutrophil engraftment at a median of 11 days. The median time to platelet engraftment was delayed at 27 days. In a second study, GM-CSF ( $10 \mu\text{g/kg}$ ) and G-CSF ( $10 \mu\text{g/kg}$ ) were used concurrently, and a statistically significant increase in the collected number of CD34 cells was seen in the second mobilization, including 13 of 23 patients who achieved an "acceptable" cumulative CD34+ cell dose of more than  $3 \times 10^6$  CD34+ cells per kilogram.<sup>61</sup> After high-dose therapy, neutrophil and platelet engraftment were said to be rapid. However, in neither study just described was the cytokine combination compared with high-dose G-CSF alone. In addition, it would appear that many of the patients in the second study would not be considered nonmobilizable. Thus, successful results in this group cannot necessarily be extrapolated to those who have previously shown very little or no evidence of progenitor mobilization.

Although the optimal cytokine cocktail for mobilization is unknown, promising results have been achieved with the combination of stem cell factor (SCF) and G-CSF. In a phase I/II randomized trial, patients with NHL in chemosensitive first relapse were randomized to either G-CSF alone ( $10 \mu\text{g/kg/d}$ ) or the same dose of G-CSF with escalating doses of SCF ( $5$  to  $20 \mu\text{g/kg/d}$ ).<sup>62</sup> Leukapheresis was performed on days 5 to 7. Although no significant differences were observed in the yield of CD34+ cells between the two groups, a second analysis limited to the cohort that had been extensively pretreated showed a sixfold increase in the median number of CD34+ cells per kilogram that were collected in the group receiving G-CSF plus any dose of SCF. A second randomized study in patients with multiple myeloma compared cyclophosphamide (Cytoxan),  $4 \text{ g/m}^2$ , followed by G-CSF,  $5 \mu\text{g/kg/d}$ , with or without the addition of SCF,  $20 \mu\text{g/kg/d}$ .<sup>63</sup> The median number of CD34+ cells per kilogram collected was nearly three times higher in the group receiving SCF, and 65% of the patients had more than  $5 \times 10^6$  CD34+ cells per kilogram collected in a single leukapheresis, compared with 40% in the group given G-CSF alone. Like the studies of GM-CSF already discussed, it is possible that, in these two cohorts, similar results could have been achieved with higher doses of G-CSF. The apparent dramatic impact of the addition of SCF to the heavily pretreated patients in the first study, however, suggests more than a simple dose-response effect.

To date, only one preliminary report of the combination of SCF and G-CSF in previously nonmobilizable (fewer than  $1 \times 10^6$  CD34+ cells per kilogram) patients has been published.<sup>64</sup> Ten patients were treated with SCF,  $20 \mu\text{g/kg/d}$ , and G-CSF,  $10 \mu\text{g/kg/d}$ . Pheresis was timed to a blood CD34 count of 10 cells per microliter and continued until a minimum "engraftable dose" of  $1 \times 10^6$  CD34 cells per kilogram was achieved. If the CD34 count did not reach 10 cells per microliter by day 8, patients were removed from study. All ten patients achieved an engraftable dose after a median of 2.5 collections. These results, although exciting, are incomplete, because no information was presented on subsequent engraftment after high-dose therapy. If a defective bone marrow microenvironment plays a role in poor mobilization, then it is at least theoretically possible that such patients might require more rather than fewer stem cells.

The conflicting and somewhat disappointing results in nonmobilizing patients underscores how little is known about the biology of stem cell mobilization. In fact, the mechanism(s) of progenitor cell mobilization is unknown, including whether cytokines and chemotherapy act through the same or different pathways. Similarly, it is not known whether alternative mobilization strategies differentially impact on tumor cell mobilization, a variable that ultimately may prove to be more important than optimizing the number of stem cells harvested.

## TUMOR CONTAMINATION

One of the early indications for the use of PBSCs was pathologic evidence of bone marrow tumor involvement. Implicit in this recommendation was the probability that the blood was likely to be less contaminated with tumor cells than bone marrow. In fact, several studies in breast cancer and neuroblastoma patients show that the concentration of tumor cells is significantly less in blood stem cell collections.<sup>65,66,67,68</sup> and <sup>69</sup> This advantage may be reduced or eliminated because of the larger number of cells in the PBSC graft and because of the effects of mobilization.<sup>70</sup> In a study of lymphoma patients, for example, less than 1 log fewer tumor cells was

found in the bone marrow than in the blood under baseline conditions.<sup>71</sup> However, the advantage of blood over marrow disappeared and in some cases was reversed after mobilization.<sup>71</sup> In six of seven patients followed closely during mobilization, tumor cells increased and, in two cases, tripled compared to baseline levels. Similarly, in patients with multiple myeloma, neoplastic plasma cells appear to be concomitantly mobilized with progenitor cells after treatment with high-dose cyclophosphamide and G-CSF.<sup>72</sup> In six patients who underwent CD34+ cell selection, tumor cells were decreased by 2 to 3 logs, but were still detectable in five of six patients.

Chemotherapy can also result in tumor cell mobilization in patients with solid tumors. In 42 previously untreated patients with solid tumors and no evidence of blood involvement, circulating tumor cells were detected in nine patients (21%) after mobilization with chemotherapy and G-CSF, including 100% of patients with breast cancer and 50% of patients with small cell lung cancer.<sup>73</sup> The peripheralization of tumor cells with stem cell mobilization is related to stage of disease and appears to be substantially reduced by prior effective chemotherapy. In a study of breast cancer patients in whom leukapheresis was performed after each of three planned cycles of chemotherapy plus G-CSF, tumor cell contamination was significantly lower, albeit not eliminated, after the second and third courses of treatment.<sup>74</sup> In addition, the use of effective chemotherapy in the mobilization regimen may have the additional benefit of inhibiting tumor clonogenic growth.<sup>75</sup> Nevertheless, the effect of different mobilization strategies on tumor cell contamination has not been well studied.

The clinical significance of administering tumor-contaminated stem cells is unclear. Gene marking studies in three different malignancies show that infused tumor cells contribute to relapse,<sup>76,77</sup> and <sup>78</sup> but no data suggest that they are the sole or even principal cause of recurrence. In patients with breast cancer, two studies have shown comparable outcomes in patients who did and did not have occult tumor in their stem cell product.<sup>79,80</sup> In patients with multiple myeloma, higher numbers of circulating tumor cells were associated with a shorter time to recurrence and a decrease in overall survival, but the presence of circulating tumor cells was not significant in a multivariate analysis that included plasma cell labeling index and b<sub>2</sub> microglobulin.<sup>81</sup> These latter results suggest that the presence of circulating tumor cells was a sign of more aggressive disease rather than a direct cause of failure.

To date, studies in which occult tumor cells are reduced by purging or CD34 selection have shown the most impressive results in patients with low-grade lymphoma. Investigators from the Dana Farber Cancer Institute have updated their experience with patients with follicular lymphoma treated with total body irradiation (TBI)/cyclophosphamide and a purged bone marrow product.<sup>82</sup> Of 113 patients who were evaluable by polymerase chain reaction (PCR) technology, 48 patients had PCR-negative marrows after purging, only six of whom relapsed. In contrast, 49 of 65 patients with a persistently positive PCR relapsed after transplantation. Importantly, no obvious differences were noted between the two populations of patients with respect to stage, B symptoms, gender, bulky disease, remission status at harvest, or histologic evidence of marrow involvement. Although it can be argued that the pattern of relapse in previous sites of disease is evidence against the importance of infused tumor cells, it is also possible that infused tumor cells homed to sites of prior disease because of a favorable microenvironment.<sup>83</sup> In another study of patients with lymphoma, a potential positive impact of purging was inferred from the observation that patients who received lower doses of GM-CFU after purging had a lower relapse rate.<sup>84</sup> A similar correlation between the effectiveness of *ex vivo* purging as reflected by a more profound reduction in postpurging GM-CFU colony formation was previously established in patients with leukemia.<sup>85</sup> A case-matched comparison of purged versus unpurged marrow in lymphoma patients by the European Blood and Marrow Transplant Registry showed a benefit for purging in overall survival but not in progression-free survival.<sup>86</sup> However, the use of different purging protocols and imbalances in the use of conditioning regimens make it difficult to interpret these data.

In patients with multiple myeloma, a randomized study showed that CD34 selection reduced tumor cell contamination of stem cells by a mean of 3.1 logs, but a preliminary analysis showed no benefit in terms of disease-free or overall survival rates.<sup>87,88</sup> As noted earlier in this section, the failure of CD34 selection to improve the clinical outcome in this group of patients likely represents incomplete tumor cell purging<sup>72</sup> as well as the inability to eradicate disease with the conditioning regimen.<sup>81</sup> Importantly, CD34 selection may not be benign. Because of the concomitant T-cell, natural killer cell, and monocyte depletion, there may be an increased risk of opportunistic infections that are otherwise rare in the autologous setting. In a study from Seattle, 7 of 31 patients (22.6%) seropositive for cytomegalovirus developed cytomegalovirus disease, and four patients (12.9%) died. In patients given unselected cells at the same institution, the risk of infection and disease were only 4.2% and 2.1%, respectively.<sup>89</sup>

Prospects for further improvement in tumor purging appear strongest for patients with CD20+ B-cell lymphoma; Rituximab (Rituxan) alone or in combination with chemotherapy results in profound B-cell depletion and achievement of a PCR-negative status in some patients with low-grade lymphomas.<sup>90</sup> Rituxan, perhaps in combination with other B-cell depletion strategies, will be intensively tested over the next several years. For patients with aggressive lymphomas, myeloma, and breast cancer, however, it seems clear that even substantial improvement in tumor purging will have little clinical benefit in the absence of better conditioning programs and more effective posttransplantation therapy.

## PRACTICAL CONSIDERATIONS FOR THE POTENTIAL HIGH-DOSE THERAPY AND AUTOLOGOUS STEM CELL RESCUE PATIENT

Because of the potential deleterious effect of prior therapy on stem cell mobilization, the possibility that a patient may be a candidate for high-dose therapy should be considered from the time of diagnosis. For example, given the current importance of high-dose therapy in multiple myeloma<sup>91</sup> and the stem cell toxicity of melphalan and prednisone combination therapy, induction with VAD (vincristine, doxorubicin, dexamethasone) or dexamethasone alone should be considered for initial treatment.<sup>41</sup> Similarly, MOPP (Mustargen, Oncovin, procarbazine, and prednisone)-like regimens, which are already considered second-line for most patients with Hodgkin's disease, should probably not be used until stem cells are collected. More recently, fludarabine, which is playing an increasingly important role in the treatment of low-grade B-cell lymphomas, has been identified as a stem cell toxin in some studies,<sup>51,52,92</sup> but not in others.<sup>93</sup> These results suggest that potential high-dose therapy candidates should have stem cells collected before fludarabine therapy, or at least before extensive treatment.

Stem cell mobilization can be accomplished with chemotherapy plus G-CSF or with G-CSF alone. In general, chemotherapy plus G-CSF is favored by most clinicians because of the additional antineoplastic effect afforded by chemotherapy.<sup>94</sup> If CD34+ cell selection also is being considered, the higher yields achieved with chemotherapy plus G-CSF may be important because of the obligatory loss of CD34+ cells that occurs during selection.

Despite evidence of a dose-response effect when G-CSF is used alone for mobilization,<sup>95</sup> the data are conflicting regarding the efficacy of higher doses of G-CSF when used in conjunction with chemotherapy. Demiret et al.<sup>96</sup> have presented unpublished data showing that, after treatment with three different cyclophosphamide-based regimens, G-CSF, 16 µg/kg/d, resulted in higher yields than 10 µg/kg/d. On the other hand, a preliminary report of a randomized study did not show a greater effect for higher doses of G-CSF when combined with chemotherapy.<sup>97</sup> Currently, in most patients, G-CSF, 10 µg/kg/d, is started 1 to 4 days after chemotherapy to hasten hematopoietic recovery and to increase the yield of stem cells.<sup>98</sup> However, in nonheavily pretreated patients (i.e., those in first remission) who are treated with highly myelosuppressive mobilizing regimens, the brisk myeloid rebound that occurs with higher doses of G-CSF can be associated with symptoms of hyperleukocytosis.<sup>99</sup> Lower doses of G-CSF can be considered in such patients.

The timing of stem cell collection after chemotherapy plus G-CSF can be optimized (lower number of procedures) by measuring the blood CD34+ cell count during the period of brisk neutrophil recovery. If collection is started when the CD34 count exceeds 20 cells per microliter, the majority of patients can collect more than  $2 \times 10^6$  CD34+ cells per kilogram in one or two procedures.<sup>100,101,102</sup> and <sup>103</sup> However, because patients who show less evidence of mobilization (5 to 15 cells per microliter) may also obtain a potentially engraftable number of CD34+ cells (more than  $1 \times 10^6$  cells per kilogram) with three or more leukaphereses,<sup>104</sup> the use of the 20 cells per microliter value should be limited to patients who can be anticipated to be good mobilizers (nonheavily pretreated). In settings in which the blood CD34 count is unavailable, it would appear that the best time to begin collection is when the white blood cell (WBC) count has increased to more than 3,000 to 10,000 per microliter<sup>44,48,105,106</sup> and the patient has a rising platelet count.<sup>96,107</sup>

The target number of stem cells is generally at least  $2.5 \times 10^6$  CD34+ cells per kilogram, but at more than  $5.0 \times 10^6$  CD34+ cells per kilogram, most patients have WBC and platelet recovery within 2 weeks.<sup>39</sup> Particularly if CD34+ cell selection or tandem transplantations are possible, higher doses are clearly desirable. Although, as noted earlier in this section, more than  $1 \times 10^6$  CD34+ cells per kilogram is considered sufficient to establish engraftment in most patients, 10% to 20% have slowed or incomplete platelet recovery.<sup>42</sup> In addition, because a substantial percentage of patients who are transplanted relapse and require additional treatment, it is unclear whether marrow reserve in such patients is adequate to sustain treatment.

After stem cell infusion, considerable controversy exists regarding the utility of hematopoietic growth factors.<sup>108,109,110,111,112,113,114</sup> and <sup>115</sup> Although most studies show a favorable impact of G-CSF on shortening the period of neutropenia, it is much less certain that G-CSF is of significant clinical benefit. For example, it is possible that shorter reported periods of hospitalization with the use of posttransplantation G-CSF may simply reflect clinicians' tendency to discharge patients once they reach a certain WBC count.<sup>109,116</sup> It also seems possible that patients who are most likely to benefit from the addition of G-CSF are those who have received fewer progenitor

cells<sup>110</sup>; however, the administration of posttransplantation G-CSF in this group is also associated with delays in platelet engraftment, suggesting that G-CSF may drive a limited number of progenitor cells toward neutrophil differentiation.<sup>40,114,117</sup>

If G-CSF is used after transplantation, most but not all<sup>118</sup> studies suggest that there is no benefit to beginning G-CSF immediately versus delaying 5 to 7 days after stem cell infusion.<sup>119,120,121</sup> and <sup>122</sup> In addition, in patients who were treated with G-CSF beginning on day 0, the use of G-CSF at a dose of 16 µg/kg/d was no more effective than at a dose of 5 µg/kg/d for accelerating neutrophil engraftment.<sup>123</sup> Larger randomized trials clearly are necessary to define the value, if any, for the use of posttransplantation G-CSF.

## HIGH-DOSE THERAPY REGIMENS: NEW DIRECTIONS

In contrast to allogeneic transplantation, for which increasing evidence indicates that cure can, and perhaps most often is, achieved by an immunologic effect of the graft, cure after autologous rescue requires complete tumor eradication by the high-dose regimen. As a result, it seems likely that preparative programs for the two procedures eventually may radically diverge. Allogeneic conditioning programs have moved toward less acutely toxic, more intentionally immunosuppressive programs to facilitate donor engraftment.<sup>124,125</sup> In contrast, further improvement in autologously rescued patients will require the development of programs with greater antineoplastic activity. However, little evidence of progress in the construction of more effective autologous high-dose regimens has been seen over a period of 15 years, and it seems likely that the better outcomes reported more recently are more likely due to improvements in patient selection and supportive care.

Alkylating agents have been the nucleus of most preparative programs, primarily because they demonstrate a disproportionate ratio of marrow to nonmarrow toxicity that is uniquely amenable to dose escalation followed by stem cell replacement. In addition, *in vitro* studies show a steep dose-response curve against tumor cell lines and minimal cross-resistance with other alkylating agents.<sup>126,127</sup> Indeed, in contrast to drugs such as anthracyclines, vinca alkaloids, and topoisomerase inhibitors, it is extremely difficult, even under tissue culture conditions, to make tumor cells more than a few-fold resistant to alkylating agents. As a result, minor degrees of drug resistance can theoretically be overcome by dose escalation or by the addition of other alkylating agents. Finally, analogous to other curative regimens, the combination of alkylating agents with nonoverlapping extramarrow toxicity is theoretically possible with maintenance of near-maximum tolerated doses of each agent.<sup>128</sup> Thus, most high-dose drug regimens, particularly exemplified by the different generations of STAMP (solid tumor autologous marrow program), have used two or more alkylating agents.<sup>129</sup> External-beam radiation, which shares many of the same advantageous biologic features of alkylating agents, cannot be dose-escalated, except to very limited fields; thus, the use of TBI has been limited to highly radiation-sensitive neoplasms, such as leukemia and lymphoma. It is not certain that radiation is superior to chemotherapy, however, even in the latter two diseases.

In clinical practice, dose escalation of alkylating agent-based regimens has been limited by excessive nonmarrow toxicity, including mucositis, pneumonitis, and veno-occlusive disease.<sup>128,129</sup> In fact, new toxicities not predicted by single-agent studies have emerged when high doses of alkylating agents have been used in combination. As a result, the initial promise of all of the currently used programs has not been realized: Significant drug resistance has not been overcome by the modest dose escalation permitted by stem cells and growth factors. In fact, with the exception of a small percentage of patients with refractory Hodgkin's disease, the vast majority of cures after high-dose therapy and autologous stem cell rescue have been observed in patients with chemosensitive lymphoid malignancies.<sup>130,131</sup> and <sup>132</sup>

Currently, several strategies are being explored to improve the results of high-dose therapy (Table 53.2-2). First, as morbidity, mortality, and cost are reduced, high-dose therapy will increasingly be explored earlier in treatment, when there is less likelihood of significant drug resistance. Promising results with early high-dose therapy have already been achieved in randomized studies of patients with multiple myeloma<sup>91</sup> and NHL<sup>133</sup> and is being further tested in ongoing trials.

Regimen	Advantage	Disadvantage	Comments	Response
Early HDT	Reduces tumor burden; facilitates drug response	Stem cell rescue in patients who are not candidates for HDT	Protein death in HDT; multiple relapses; poor response in patients with relapsed disease	50, 100, 100, 100
Standard HDT	Facilitates response; reduces relapse rate	Increased toxicity; relapse rate; relapse rate	Relapse rate in patients with high relapse rate; relapse rate in patients with low relapse rate	50, 100, 100
Rescue transplantation	Reduces relapse rate; facilitates response	Relapse rate in patients who are not candidates for HDT	Relapse rate in patients who are not candidates for HDT	100, 100, 100
<b>INTERMEDIATE-DOSE THERAPY (IDT) IN PATIENTS WITH NHL</b>				
Relapse after HDT	Facilitates response; reduces relapse rate	Relapse rate in patients who are not candidates for HDT	Relapse rate in patients who are not candidates for HDT	50, 100
Relapse after IDT	Facilitates response; reduces relapse rate	Relapse rate in patients who are not candidates for HDT	Relapse rate in patients who are not candidates for HDT	100, 100
Relapse after IDT with growth factors	Facilitates response; reduces relapse rate	Relapse rate in patients who are not candidates for HDT	Relapse rate in patients who are not candidates for HDT	100, 100
Relapse after IDT with growth factors and stem cell rescue	Facilitates response; reduces relapse rate	Relapse rate in patients who are not candidates for HDT	Relapse rate in patients who are not candidates for HDT	100, 100
Relapse after IDT with growth factors and stem cell rescue and stem cell rescue	Facilitates response; reduces relapse rate	Relapse rate in patients who are not candidates for HDT	Relapse rate in patients who are not candidates for HDT	100, 100
Relapse after IDT with growth factors and stem cell rescue and stem cell rescue and stem cell rescue	Facilitates response; reduces relapse rate	Relapse rate in patients who are not candidates for HDT	Relapse rate in patients who are not candidates for HDT	100, 100

**TABLE 53.2-2.** Improving the Results of High-Dose Therapy (HDT): New Approaches and Limitations

A second approach has been to increase the intensity of preparative regimens. Based on favorable reports from single-institution studies,<sup>134,135,136</sup> and <sup>137</sup> the Southwest Oncology Group tested the addition of high-dose etoposide to Cytoxan and TBI in patients with either relapsed or refractory NHL.<sup>138</sup> Patients who were not candidates for TBI received BCNU (bischloroethylnitrosourea), along with the same doses of Cytoxan plus etoposide used in the TBI regimen. The authors reported that, in primary induction and salvage therapy failures, the results with the more aggressive regimens appeared to be superior than their previous results with cyclophosphamide and TBI but without etoposide. In patients with chemosensitive disease, the more intensive regimen was not better than the group's previous experience. Patients treated with this regimen had a high incidence of grade III–IV mucosal (63%) and grade II or lower skin toxicity (30%) and a 10.6% treatment-related mortality. As a result, further increments in treatment are unlikely. A preliminary report of a study in which amifostine was added to decrease mucosal and skin toxicity did not show any obvious benefit.<sup>139</sup>

Another method of intensifying high-dose therapy in patients with NHL or leukemia is to deliver all or part of the TBI in the form of targeted radioactive monoclonal antibody. Theoretically, radiation delivered in the form of tagged monoclonal antibodies could allow higher doses of radiation to be delivered to tumor-bearing areas without a similar increase in radiation to the lungs and liver. The Seattle group has shown the feasibility of such an approach in patients with lymphoma<sup>140</sup> and leukemia.<sup>141</sup>

In view of the difficulties inherent in increasing the doses or the number of drugs included in high-dose regimens, an alternative approach is to give “conventional” high-dose therapy for two or more cycles. At modestly escalated doses, this strategy can be safely accomplished with growth factors alone, but at higher doses of therapy, stem cells with or without growth factors can be used to accelerate myeloid recovery. At the Dana Farber Cancer Institute, four courses of high-dose CHOP [cyclophosphamide (Cytoxan), doxorubicin, vincristine, prednisone], in which the Cytoxan dose was increased more than fivefold and doxorubicin was increased by 50%, were used in patients with poor-prognosis lymphoma. The study showed that 70% of patients achieved a durable complete response.<sup>142</sup> This regimen is currently being compared with CHOP in a randomized study. Gianni et al.<sup>133</sup> randomized patients with intermediate-grade lymphoma to standard MACOP-B (methotrexate-leucovorin, Adriamycin, cyclophosphamide, Oncovin, prednisone, bleomycin) versus sequential courses of high-dose therapy in which stem cell rescue is given after a final course of marrow ablative therapy. A highly statistically significant benefit was found in disease-free survival, and borderline significant improvement was noted in overall survival favoring the high-dose arm. Patients who relapsed after MACOP-B and then were treated with high-dose therapy did poorly. The latter finding suggests either that drug resistance is more easily overcome earlier in treatment or, alternatively, that several cycles of standard therapy induces a level of drug resistance that makes later dose intensification less effective. Tandem cycles of high-dose therapy also have shown promising results in patients with refractory Hodgkin's disease,<sup>143</sup> recurrent germ cell tumors,<sup>144</sup> and as consolidation therapy for patients with multiple myeloma.<sup>145,146</sup> The use of tandem versus single courses of high-dose therapy is being tested in ongoing clinical trials.

Finally, although high-dose therapy alone may not be curative in most patients, interest is increasing in using the achievement of minimal residual disease as a platform for additional posttransplantation therapy. Several approaches are being explored, including the induction of an autologous graft-versus-host reaction<sup>147,148,149,150</sup> and <sup>151</sup>; posttransplantation vaccination with tumor-specific proteins<sup>152</sup>; subsequent therapy with monoclonal antibodies, such as Rituxan<sup>153,154</sup> and trastuzumab (Herceptin); and, finally, the use of additional non-cross-resistant chemotherapy.<sup>155</sup>

## LATE TOXICITY: MYELODYSPLASIA

A review of published studies suggests that extensive prior alkylating-agent chemotherapy and TBI-containing preparative regimens are the most important risk factors for the development of MDS and ANLL after high-dose therapy and autologous stem cell rescue.<sup>156,157,158,159,160,161,162,163,164,165</sup> and <sup>166</sup> In individuals with neither risk factor (e.g., breast cancer patients), the risk of MDS and ANLL does not appear to be substantially increased above that expected after conventional treatment.<sup>161,166</sup> Similarly, in patients with Hodgkin's disease and multiple myeloma who are conditioned with high-dose chemotherapy alone, most of the risk of MDS and ANLL appears to be due to prior cumulative stem cell injury from agents such as mechlorethamine, chlorambucil, melphalan, and nitrosourea agents.<sup>162,165</sup>

On the other hand, there appears to be an increased risk of MDS after treatment with TBI-based regimens that is independent of prior therapy. In a study from Nebraska, late MDS in NHL patients was limited to those who received TBI.<sup>158</sup> Of even greater concern is the observed risk of MDS and ANLL in follicular lymphoma patients transplanted in first remission. In one series of patients conditioned with TBI/cyclophosphamide, 5 of 75 patients (6.6%) at risk developed MDS.<sup>167</sup> Before transplantation, these patients had only received 6 to 8 cycles of CHOP, suggesting that the preparative regimen of TBI/cyclophosphamide was the major cause of the subsequent MDS.

The mechanism(s) by which TBI in the preparative regimen contributes to the development of MDS is unclear, because the infused stem cells are not exposed to the radiation and the remaining *in situ* marrow is theoretically destroyed. Although damage to the bone marrow stroma leading to late marrow injury is possible, the rarity of MDS after allogeneic transplantation despite identical conditioning regimens is evidence against a toxic microenvironment. A more likely probability is that most, if not all, preparative regimens are not completely myeloablative<sup>168,169</sup> and that marrow that is genetically damaged but not destroyed eventually achieves a growth advantage, leading to MDS and leukemia. This sequence of events presumably does not occur after allogeneic stem cell transplantation because host hematopoiesis is destroyed or suppressed by a graft-versus-endogenous marrow effect.<sup>170</sup> MDS may be more common after TBI-based regimens either because radiation is a more potent mutagen or because it is less myeloablative than high-dose chemotherapy regimens.

Some studies have implicated blood stem cells as a risk factor for the development of MDS and ANLL. Traweek et al.<sup>157</sup> and, more recently, Andre et al.<sup>164</sup> reported a trend toward an increased incidence of MDS and AML in patients who received PBSC alone or in combination with bone marrow compared with bone marrow alone. Similarly, in an update of an earlier series from the University of Minnesota,<sup>156</sup> Bhatia et al.<sup>160</sup> reported a significantly higher actuarial incidence of MDS in patients who received PBSC (35.8%) than bone marrow (4.1%) in patients transplanted for Hodgkin's disease and NHL. These data are difficult to interpret because the use of PBSC versus marrow was not random, and in some patients, PBSC may have been used because of a prior marrow injury (e.g., hypocellular marrow or previous pelvic radiotherapy) more likely to be associated with late MDS and ANLL. In contrast to these results, investigators from the University of Nebraska have not found an increased incidence of MDS and ANLL in patients who received PBSC.<sup>170</sup> The uncertain susceptibility of stem cells to the damaging effects of prior therapy provides a further rationale for the early collection of stem cells in potential candidates for high-dose therapy.

It seems likely that the risk of MDS and ANLL should be lower in the future, given the trend away from the use of high cumulative doses of agents toxic to stem cells in potential high-dose therapy candidates. For example, in a study from Arkansas<sup>162</sup> no cases of MDS and ANLL were reported in 71 patients with multiple myeloma treated with a brief course of VAD followed by tandem transplantations. In contrast, cytogenetic abnormalities suggestive of MDS and ANLL were observed in 7 of 111 patients who had received an average of 2 years of chemotherapy before receiving tandem courses of high-dose therapy and stem cell rescue.

It should also be emphasized that bone marrow cytogenetic abnormalities after transplantation do not indicate that MDS or ANLL is inevitable. In a preliminary report, only 28% of patients with clonal cytogenetic abnormalities developed MDS and ANLL.<sup>171</sup> Even in patients with notoriously ominous abnormalities, such as partial or complete deletions of chromosome 5, 5 of 17 patients did not develop MDS. Similarly, 16 of 37 patients with deletions of chromosome 7 did not develop MDS, and deletions of chromosome 20 were not predictive of MDS. These results show that clonal cytogenetic abnormalities (estimated to be present sporadically in as many as 50% of patients transplanted at the Dana Farber Cancer Institute<sup>159</sup>) are far more common than the true incidence of bone marrow morphologic dysplasia or late ANLL. This fact would also suggest that the reported 15% to 20% incidence of posttransplantation MDS is much higher than the true incidence of clinical MDS.

## FUTURE DIRECTIONS

During the first decade of the twenty-first century, clinical trials in patients with unfavorable prognostic factors should provide substantial insight into the effectiveness of early high-dose therapy. Even for patients who are not cured, quality-of-life studies may provide a further rationale for treating patients briefly but intensively. In patients with drug-sensitive, potentially curable disease, strategies to measure and eliminate tumor cell contamination from stem cell products may incrementally improve cure rates. However, a theoretically perfect purging program will appear ineffective in the absence of more effective antineoplastic therapy. In this regard, the incorporation of monoclonal antibodies into conditioning regimens may allow more intensive therapy to be delivered without proportional toxicity. Posttransplantation immune modulation will likely assume a more important role in overall treatment, especially for patients with a high likelihood of microscopic disease.

#### HISTORICAL PERSPECTIVE

The concept that allogeneic hematopoietic progenitor cells could be used to rescue marrow function in humans after myeloablative doses of whole body irradiation or high-dose chemotherapy arose predominantly from research in mouse models. Mice, after exposure to lethal doses of irradiation, could be reproducibly rescued from marrow aplasia after intravenous infusion of splenocytes or bone marrow cells.<sup>1,2</sup> These observations were followed by mostly unsuccessful clinical applications of bone marrow transplantation (BMT) in humans in the late 1950s, predominantly owing to a limited knowledge of the methods required for the safe application of dose-intensive chemotherapy or total body irradiation (TBI).<sup>3</sup> However, through the dedicated persistence of researchers such as Thomas et al.,<sup>4</sup> who pioneered in the field, the biology and mechanisms required to optimize the procedure were gradually defined. Identification of the HLA system as the major determinant of transplantation outcome was the breakthrough required to establish the field of allogeneic BMT as a successful clinical discipline.<sup>5</sup>

By the 1970s, BMT began to gain acceptance in the medical community as its application expanded from the treatment of patients with hematologic malignancies, such as acute leukemia and chronic myelogenous leukemia (CML), to the treatment of patients with nonmalignant hematologic conditions, such as congenital immunodeficiency syndromes and aplastic anemia. The improved safety and efficacy of dose-intensive treatment regimens, as well as the development of better supportive care measures, laid the foundation for successful allogeneic BMT during this period.

The potential of allogeneic BMT to cure otherwise fatal hematologic malignancies rapidly became established. However, the numerous toxicities associated with the procedure—namely, severe organ toxicity from dose-intensive conditioning, graft rejection, opportunistic infections, and graft-versus-host disease (GVHD)—were quickly defined as well.<sup>4</sup> Although a number of effective drugs became available to prevent or manage many of these complications, such as cyclosporin A (CSA) for the prevention of acute GVHD and ganciclovir for the treatment of cytomegalovirus (CMV) infection, transplant-related mortality remained high, in the range of 30% to 40%.<sup>6</sup> Furthermore, attempts to improve transplantation outcome by preventing disease relapse through intensification of the conditioning regimen proved to be largely unsuccessful, mostly owing to an increase in toxicities associated with these intensified regimens.

Great strides were made in the field of allogeneic hematopoietic stem cell transplantation (SCT) in the 1990s, in improving both transplantation safety and efficacy. The association of an increased risk of leukemic relapse after T-cell depletion of the allograft, as well as the observation that relapse was less likely in patients with a history of acute or chronic GVHD, lent credence to the concept that a donor immune-mediated antimalignancy effect, called *graft-versus-leukemia* (GVL), occurred after such procedures.<sup>7,8</sup> The most compelling evidence for the GVL effect is seen in patients with relapsed CML after transplantation who are successfully induced back into a complete and durable remission following the infusion of donor lymphocytes. Similar GVL effects after donor lymphocyte infusion (DLI) have been observed in other malignancies, including acute leukemias, chronic lymphocytic leukemia (CLL), Hodgkin's and non-Hodgkin's lymphoma, and multiple myeloma.

The success of DLI, particularly in relapsed CML, has generated intense interest in exploring the nature of this powerful immune effect and has raised the question of whether GVL alone, without toxic high-dose chemotherapy or radiotherapy, could be sufficient to eradicate some hematologic malignancies. To answer this question, a number of investigators have explored the concept of using low-intensity, immunosuppressive but nonmyeloablative conditioning regimens to permit engraftment of the donor immune system for the generation of GVL effects while sparing patients the toxicities associated with myeloablative therapy. Early results have been encouraging, demonstrating that such transplantation regimens are well tolerated, with a decreased incidence of transplant-related morbidity and mortality, even in high-risk patients.<sup>9,10,11,12,13,14</sup> and <sup>278,279,280,281,282,283,284</sup> and <sup>285</sup> More important, they have demonstrated that GVL alone, without toxic myeloablative conditioning, is sufficient to cure some hematologic malignancies.<sup>279,282,286</sup> These findings highlight the unique and potentially curative immune aspects that are intrinsic to this form of therapy.

#### ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR HEMATOLOGIC MALIGNANCIES

The relationship between the intensity of chemo/radiotherapy and the antitumor effect led to the development of most high-intensity BMT strategies. Myeloablative doses of chemo/radiotherapy, which are intended to eradicate the malignancy completely, are followed by the infusion of compatible donor hematopoietic progenitor cells to rescue the patient from conditioning-induced bone marrow aplasia. This concept is applied most appropriately to malignancies such as leukemia that originate from the bone marrow itself. However, increasing evidence reveals that even the most intense of conditioning regimens often does not completely eradicate leukemic clones. Rather, a powerful immune reaction generated from donor cells against residual leukemia (GVL) ensues in the majority of responding patients, rendering them leukemia-free.<sup>9,10,11,12,13,14</sup> and <sup>15</sup> It is through the combination of these two components—dose-intensive tumor killing followed by the GVL effect—that allogeneic hematopoietic SCT has its curative potential.

## ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR NONMALIGNANT DISORDERS

Allogeneic hematopoietic SCT can be used to successfully treat nonmalignant diseases associated with defective bone marrow function or metabolic disorders associated with lysosomal enzyme defects. These disorders, although nonmalignant, often result in an extremely poor quality of life and may have long-term life-threatening sequelae, thus justifying the risks of morbidity and mortality associated with the procedure. The list of nonmalignant diseases curable by allogeneic hematopoietic SCT is long and includes severe aplastic anemia, Fanconi's anemia, thalassemia major, chronic granulomatous disease, sickle cell anemia, and a number of immunodeficiency syndromes, such as the severe combined immunodeficiency syndrome, Chédiak-Higashi disease, and the Wiskott-Aldrich syndrome.<sup>16,17,18,19 and 20</sup> Because the eradication of malignant cells is not a concern, the preparative regimens used in these diseases usually are of lower intensity or do not include irradiation, serving primarily to provide sufficient immunosuppression to allow for the engraftment of normal donor bone marrow cells. In some diseases, particularly sickle cell anemia and thalassemia major in children, excellent results have been achieved with disease-free survivals greater than 95%.<sup>21,22 and 23</sup>

### PREPARATIVE REGIMENS

In the treatment of malignant diseases, the primary purpose of the preparative regimen is to eradicate malignant cells and to induce immunosuppression in the recipient so that rejection is prevented and engraftment of the donor hematopoietic system is permitted. The decision to use a particular preparative regimen often is guided by the sensitivity of the underlying malignancy to the agents contained within that regimen. Although a number of different agents have been used for their antitumor effects in hematologic malignancies, in general, they can be divided into two categories: TBI-based and chemotherapy-based.

Most regimens based on TBI are composed of high-dose cyclophosphamide given as 60 mg/kg IV on 2 consecutive days, followed by varying doses of fractionated TBI to a cumulative dose of 1200 to 1500 cGy.<sup>24,25 and 26</sup> Although there is some evidence that the higher doses of TBI may be more effective in terms of preventing disease relapse, toxicity appears to increase concomitantly, thus negating any overall benefit.<sup>27,28 and 29</sup> Results, in terms of toxicity and disease-free survival, appear similar between regimens composed of TBI and etoposide (60 mg/kg) and those composed of TBI and cyclophosphamide.<sup>30</sup>

Although a number of chemotherapy-based regimens that do not include irradiation have been used,<sup>31,32,33 and 34</sup> the combination of cyclophosphamide (60 mg/kg IV on 2 consecutive days) and busulfan (4 mg/kg PO on 4 consecutive days) has gained increasing popularity and use since its conception in the early 1980s.<sup>35</sup> Similar to the experience with TBI, dose intensification of chemotherapy-based regimens usually results in increased toxicity, thus negating any potential survival benefit that might occur as a result of less disease relapse.

The decision guiding which preparative regimen to use often is based on the predicted tumor-specific activity of that regimen. In general, radiation- and chemotherapy-based regimens are associated with an equal probability of achieving long-term disease-free survival. Two randomized trials evaluating cyclophosphamide (60 mg/kg × 2) and busulfan versus TBI and cyclophosphamide (60 mg/kg × 2) in patients with chronic-phase CML revealed equal efficacy between both regimens.<sup>36,37</sup> However, in acute lymphocytic leukemia (ALL), TBI-based regimens may be the treatment of choice, as a randomized trial reported a significantly increased risk of relapse in patients with ALL who received conditioning with chemotherapy alone (busulfan and etoposide).<sup>38</sup>

The toxicity profile of preparative regimens varies considerably, a factor that often determines the choice of which regimen to use for an individual patient. In general, TBI-based regimens are associated with a higher risk of secondary malignancies and growth retardation, while chemotherapy-based regimens, particularly those containing busulfan, are associated with a higher risk of severe mucositis and venoocclusive disease (VOD), with minimal effects on growth and development.<sup>39,40,41,42,43 and 44</sup>

A number of investigators have explored the concept of using low-intensity preparative regimens (either low-dose chemotherapy, low-dose TBI, or both) in attempts to decrease the risk of toxicity and mortality associated with myeloablative conditioning.<sup>45,46,47 and 48</sup> The preparative regimen in such nonmyeloablative stem cell transplantations (NSTs; discussed later in [Nonmyeloablative Allogeneic Stem Cell Transplantation](#)) does not eradicate host hematopoiesis and is used primarily to induce immunosuppression in the recipient to allow for engraftment of donor cells for the subsequent generation of GVL effects. Such low-intensity transplantations rely completely on the GVL effect to eradicate malignancy. Although these regimens vary considerably between institutions, preliminary results are promising, showing high degrees of donor engraftment with considerably less conditioning-related toxicity than is seen with conventional high-dose myeloablative regimens, even in older (older than 55 years) and debilitated patients. Most of the severe and life-threatening complications associated with conventional preparative regimens, such as VOD, pneumonitis, and severe mucositis, have rarely been observed with NST. More important, sufficient engraftment of donor immune cells has been achieved to induce complete remission in a number of different hematologic malignancies.<sup>278,279,280,281,282 and 283</sup> The improved safety profile of NST, in both the short and long term, will likely make this transplantation approach the procedure of choice for patients at high risk for complications with conventional dose-intensive regimens (i.e., older or debilitated patients). Furthermore, NST may have its greatest benefit among younger patients in whom growth retardation, sterility, and the risk of secondary malignancy may be completely avoided. The toxicity profiles of TBI-based, chemotherapy-based, and nonmyeloablative transplantation regimens are shown in [Table 53.3-1](#).

	TBI	Chemotherapy Alone	NST
Sterility	++	+	-
Mucositis	+	++	-
Venoocclusive disease	±	++	-
Growth retardation	++	±	-
Secondary malignancies	++	±	?
Cataracts	++	±	-

NST, nonmyeloablative stem cell transplantation; TBI, total body irradiation; +, moderately associated with; ++, highly associated with; -, not associated with; ±, occasionally to rarely associated with; ?, unknown but anticipated to be low.

## GRAFT-VERSUS-LEUKEMIA EFFECT

### CLINICAL SIGNIFICANCE

The concept that donor immune cells might make an important contribution to the antileukemic effect of allogeneic BMT was first suggested in the 1950s on the basis of observations in animal models. Mice with leukemia given syngeneic BMTs died of leukemia, whereas mice given allogeneic cells were rescued from leukemia but died from acute GVHD.<sup>50</sup> Subsequently, a large body of evidence began to point toward similar antileukemic effects in humans, mediated through donor cells after allotransplantation. Observations supporting this donor-mediated antileukemic (GVL) effect initially were based on the observation that relapse of leukemia was less likely in patients who developed GVHD after BMT than in those who never developed GVHD.<sup>51</sup> Additional support for the GVL effect included the observation that leukemic relapse occurred more frequently in identical twin transplants and in transplantations in which recipients received T-lymphocyte-depleted marrow for the prevention of GVHD.<sup>52,53</sup> Furthermore, recipients of T-cell-depleted transplants have an increased risk of relapse even after adjusting for GVHD, further supporting an antileukemic effect of donor immune cells separate from acute GVHD. Patients with a history of both acute and chronic GVHD were observed to have the lowest risk of relapse.<sup>9</sup> Data from the International Bone Marrow Transplant Registry showing the relationship of GVHD, T-cell depletion, and the type of allograft to the probability of relapse are shown in [Figure 53.3-1](#).<sup>54</sup> Data from this registry suggest that these effects vary according to the type of leukemia but are most evident in patients with chronic-phase CML undergoing transplantation. Further indirect evidence for the GVL effect includes the observation that up to 50% of patients with CML have small numbers of cells that are Philadelphia-chromosome positive or remain positive for the bcr/abl transcript for months after allogeneic BMT. In the majority of cases, these abnormal cells and bcr/abl transcripts become undetectable over time.<sup>55,56,57 and 58</sup> Additionally, abrupt discontinuation of CSA after detection

of disease relapse in CML has been associated with reinduction of cytogenetic remission. [59,60](#)

**FIGURE 53.3-1.** Actuarial probability of relapse after bone marrow transplantation for early leukemia according to type of graft and development of graft-versus-host disease (GVHD). AGVHD, acute GVHD; CGVHD, chronic GVHD. (From ref. 9, with permission.)

Finally, the most compelling evidence supporting the powerful and potentially curative nature of the GVL effect is the observation that complete and durable remissions can be induced by the transfusion of lymphocytes from the marrow donor, without chemotherapy or radiotherapy, in patients with CML who have relapsed after marrow transplantation. [61,62,63,64,65](#) and [66](#) The efficacy of DLI for the treatment of relapsed leukemia is disease-dependent, with remission induction occurring in a substantially higher percentage of patients with chronic-phase CML than in patients with advanced CML or other acute leukemias. [49](#) In general, 70% to 80% of patients with cytogenetic or hematologic relapse of CML can be expected to achieve a molecular remission after DLI, with 87% of these patients remaining disease-free at 3 years. [67,68](#) Remissions usually are not observed until months after DLI, consistent with the time required to expand antileukemic clones ( [Fig. 53.3-2](#)).

**FIGURE 53.3-2.** Time to complete remission in acute (AML) and chronic myelogenous leukemia (CML) patients treated with donor lymphocyte infusion (DLI). (From ref. 49, with permission.)

In contrast to the relatively high efficacy of DLI in relapsed chronic-phase CML, only a minority of patients with relapsed acute leukemia achieve remission after this approach. In a report from the European Group for Blood and Marrow Transplant, only 29% of patients with relapsed acute myelogenous leukemia (AML) and none with relapsed ALL (0 of 11) achieved remission after DLI. [67,68](#) Unlike chronic-phase CML, remission after DLI for advanced-phase CML and acute leukemia appears to be of limited duration, with the majority of responders experiencing relapse within 1 year of treatment. The poor response of accelerated or blast crisis CML to DLI is perhaps due to clonal evolution of the leukemia leading to selective expansion of malignant cells capable of escaping immune recognition. [69](#)

Disease regression after DLI has also been described in patients with multiple myeloma, CLL, and non-Hodgkin's lymphoma who experience relapse after allotransplantation, although too few have been treated to define the efficacy of this approach in these diseases. [70,71](#)

The major complication associated with DLI is acute and chronic GVHD. Acute GVHD, which may be severe or life-threatening (grade III or IV) in 15% to 20% of cases, may develop after DLI in up to 70% to 80% of patients. [64,65,66,67](#) and [68,72](#) The propensity for GVHD after DLI is likely affected by the relatively large dose of T lymphocytes that traditionally have been infused (1 to 10  $\times 10^7$  CD3 cells/kg), as well as the fact that these cells are usually given without GVHD prophylaxis. Two approaches to reduce the incidence of GVHD after DLI have been developed. One approach is to selectively infuse lymphocytes depleted of CD8+ T cells: This approach was investigated based on the experience that allografts depleted of CD8+ cells were associated with a low incidence of GVHD without an increased risk of relapse. [73,74](#) and [75](#) Several nonrandomized trials have shown that DLI depleted of CD8+ cells can reinduce remission, with a rate of GVHD that is lower than that observed with unmanipulated DLI. [76,77](#) The other strategy involves the infusion of donor lymphocytes in multiple aliquots, starting at low cell numbers and escalating the dosage at variable intervals until a GVL effect is achieved. [78](#) This approach is based on the premise that lower T-cell numbers might induce remission while decreasing the risk of GVHD. One trial comparing these two different lymphocyte infusion approaches in patients with relapsed chronic-phase CML revealed a significantly lower incidence of GVHD in the group that received dose-escalating lymphocyte infusions than in the group receiving traditional single "bulk-dose" regimens (10% vs. 44%). Importantly, although the incidence of acute GVHD was extremely low in the escalating-dose group, the GVL effect was preserved, with 91% of these patients achieving a complete remission by 2 years ( [Fig. 53.3-3](#)). [79](#)

**FIGURE 53.3-3.** Probability of achieving cytogenetic remission for 48 patients who received escalating-dose (EDR) or bulk-dose infusion regimens (BDR) dated from the first (or only) infusion of donor lymphocytes (DLI). (From ref. 79, with permission.)

The other potentially life-threatening complication of DLI is marrow aplasia. Approximately 30% to 40% of patients who receive DLI for relapsed CML develop pancytopenia, which typically occurs at the time of the GVL response. [67,68](#) Although most patients still have mixed or complete T-cell chimerism at the time of DLI, myeloid chimerism may be predominantly recipient in origin, originating from the leukemic clone, thus leaving the marrow aplastic after a graft-versus-host hematopoietic effect occurs. The duration of aplasia is variable and is directly dependent on the number of residual donor hematopoietic progenitor cells. Although, in most cases, spontaneous reconstitution of marrow by donor cells usually occurs, some patients have persistent aplasia and may require additional donor stem cell

infusions to rescue marrow function. Reconditioning before such stem cell infusions is not required, as most patients have predominantly donor immunity and therefore are tolerant of donor stem cells. Although the infusion of donor lymphocytes with stem cells has been used successfully to treat relapsed leukemia, it is unclear whether the incidence and severity of bone marrow aplasia is mitigated. <sup>80</sup>

## MECHANISMS

Although considerable evidence supports the existence and clinical significance of the GVL effect, the dominant antigens on leukemic cells and the effector cells mediating the antileukemic effect are not well characterized. The high incidence of leukemic relapse in syngeneic transplantations suggests that a significant component of the GVL effect is allogeneic in nature. Minor histocompatibility antigens, disparate between patient and donor, are likely targets for both GVHD and the GVL effect. <sup>81,82,83,84,85,86</sup> and <sup>87</sup> The tissue-restricted pattern of minor histocompatibility antigens (mHa) likely explains why some patients respond to DLI without the development of GVHD: T-cell populations mediating an antileukemic reaction through mHa restricted to hematopoietic cells would not be expected to cause GVHD, in contrast to T cells targeting such antigens expressed broadly on both normal tissue and leukemic cells, where both GVHD and a GVL effect would occur. Indeed, T-cell clones have been generated *in vitro* that specifically recognize mHa restricted to leukemic cells and normal hematopoietic cells. <sup>81,86</sup>

Although leukemia-restricted peptides would appear to be an attractive target for donor immune cells, convincing evidence has not yet been found to implicate a specific antileukemic effect in GVL. However, the observation that some patients with relapsed leukemia achieve remission after DLI without GVHD lends credence to the notion that GVL may occasionally be a targeted antileukemic process. *In vitro*, it is possible to generate T-cell clones against leukemia cells as well as leukemia-specific peptides. Peptides corresponding to the binding region of P210 BCR/ABL in CML, and the fusion region of the hybrid protein PML/RAR in acute promyelocytic leukemia, can be used to generate T-cell populations with leukemia-specific cytolytic activity. <sup>88,89,90,91,92</sup> and <sup>93</sup> Although potentially attractive for targeted immunotherapeutic approaches, no clear evidence supports the hypothesis that these leukemia-specific peptides are a target for GVL. <sup>94</sup>

The nature of the effector cells mediating the GVL effect is not entirely known. In animal models, these effectors often are leukemia- and mouse strain-specific, thus limiting insight into the GVL process in humans. Both CD4+ T helper cells and CD8+ cytotoxic T cells with direct antileukemic activity have been isolated from patients after allogeneic BMT, therefore implicating both as having a role in GVL. <sup>95,96,97,98,99</sup> and <sup>100</sup> CD4+ T cells appear to play a particularly important role in the GVL effect in CML. Indeed CD4+ T cells have been generated that are cytolytic to CML cells *in vitro* and can be used successfully to treat relapsed leukemia in patients after BMT. <sup>76,77</sup> Although other cell populations such as natural killer cells, lymphokine-activated killer cells, and gd T cells may have antileukemic activity, it is not clear what their overall contribution is to the GVL effect. <sup>101,102</sup> The ability to separate GVL from GVHD will depend on the future delineation of these effector populations and their target antigens.

## COMPLICATIONS OF ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Allogeneic hematopoietic SCT is associated with a number of complications, many unique to this type of therapy, which can be divided into two general categories: toxicities related to conditioning and toxicities related to the transplantation of an allogeneic immune system into the patient—specifically, graft rejection, GVHD, and infectious complications associated with immunosuppression.

The complications associated with myeloablative doses of chemo/radiotherapy vary in terms of incidence and severity, depending on the intensity and type of agents used in conditioning. These complications may occur as an immediate side effect, at or shortly after administration of the preparative regimen, or in a delayed fashion, years after transplantation. Commonly observed immediate toxicities include nausea and vomiting, mucositis, parotid gland inflammation related to TBI, and neutropenia with associated fever or opportunistic bacterial or invasive fungal infection.

High-dose cyclophosphamide may be associated with hemorrhagic cystitis or, more rarely, rapidly progressive heart failure. <sup>103,104</sup> The routine use of mesna, hydration, and forced diuresis has largely eliminated early hemorrhagic cystitis. <sup>105</sup> In contrast, late hemorrhagic cystitis, occurring beyond 72 hours after cyclophosphamide infusion, remains a continuing problem in allogeneic BMT and usually is viral in origin (polyoma virus BK or adenovirus). <sup>106</sup> High-dose busulfan is associated with grand mal seizures; many busulfan-containing regimens use seizure prophylaxis with phenytoin (Dilantin) or phenobarbital. <sup>107</sup>

Opportunistic infections as a consequence of preparative regimen-induced neutropenia remain a significant complication associated with allogeneic BMT. Most fungal and bacterial infections originate from microorganisms colonizing the skin, oral cavity, perianal area, or gastrointestinal or respiratory tract. The most common life-threatening infections occur during the neutropenic period and involve gram-negative and aerobic gram-positive bacteria. These pathogens gain entry into the host through indwelling vascular catheters or as a consequence of the breakdown of gastrointestinal mucosa related to high-dose chemo/radiotherapy. Decontamination of the gastrointestinal tract with nonabsorbable antibiotics such as neomycin or vancomycin have met with mixed success, with poor patient compliance being a major drawback to this approach. <sup>108,109</sup> Such prophylactic oral quinolones as ciprofloxacin and norfloxacin appear to decrease the incidence of febrile neutropenia and gram-negative infections, although possibly at the expense of more episodes of gram-positive bacteremia. <sup>110,111</sup>

*Candida* and *Aspergillus* species are the most common fungal pathogens, frequently causing infection during periods of neutropenia or systemic corticosteroid use for GVHD. Oral triazoles, such as fluconazole, have been shown in randomized trials to decrease the incidence of opportunistic candidal infections but have no impact on the incidence of infections with resistant species such as *Aspergillus* or *Candida krusei*. <sup>112,113</sup> It is unclear whether the shortened duration of absolute neutropenia associated with the use of recombinant hematopoietic growth factors [i.e., granulocyte colony-stimulating factor (G-CSF)] will lead to a decrease in the incidence of infections by these opportunistic pathogens.

## VENOOCCLUSIVE DISEASE

One of the most serious life-threatening complications of dose-intensive chemo/radiotherapy is hepatic VOD. VOD produces a clinical syndrome of jaundice, tender hepatomegaly, and unexplained weight gain or ascites. <sup>114,115</sup> Clinically evident VOD occurs in approximately 30% of allogeneic BMT patients conditioned with busulfan-containing regimens, with approximately 25% of those affected having severe life-threatening disease leading to progressive liver failure, hepatic encephalopathy, or hepatorenal syndrome. The exact pathogenesis of VOD is unknown, although the earliest event is believed to be endothelial damage due to BMT conditioning, leading to fibrinogen and collagen deposition in vessel walls at the interface of hepatic sinusoids and terminal venules, which ultimately become obstructed. Damage to zone three hepatocytes also is present. Predisposing factors for VOD include a history of liver disease, advanced age, elevated liver enzymes before transplantation, dose intensity of the conditioning regimen, presence of acute GVHD, and transplants from alternative donors such as matched, unrelated donors or haploidentical donors. <sup>116,117</sup> and <sup>118</sup> The diagnosis of VOD is based on the presence of clinical criteria (jaundice, tender hepatomegaly, and unexplained weight gain or ascites); there is a 90% correlation between the presence of all three criteria and a histologic confirmation by liver biopsy. <sup>119</sup>

Therapy for established VOD is unsatisfactory and consists mostly of measures to support renal function, fluid balance, and coagulation status. Recombinant tissue plasminogen activator (tPA) and prostaglandin E<sub>1</sub> have had mixed success, making it unclear what, if any, role these agents should play in the treatment of established disease. <sup>120,121,122</sup> and <sup>123</sup> In a single-institution trial, defibrotide, a polydeoxyribonucleotide with activity in several vascular disorders, was used to treat patients with severe VOD after SCT. The drug was well tolerated and showed promising efficacy, with 42% of patients having complete resolution of VOD, warranting further investigation of this agent. <sup>124</sup> The therapeutic drug monitoring of busulfan, with appropriate dose adjustments, appears to be useful in reducing the incidence of VOD in patients receiving this agent. Data regarding pharmacologic prophylaxis against VOD have been contradictory. One double-blind, randomized trial showed a significant reduction in the incidence of VOD in patients taking ursodiol prophylaxis as compared to those taking placebo (50% vs. 15%). Ursodiol was well tolerated and may prove particularly useful as prophylaxis in patients defined to be at high risk for VOD. <sup>125</sup>

## PULMONARY COMPLICATIONS

Pulmonary complications occur frequently after allogeneic BMT and may be related to infectious agents, diffuse alveolar hemorrhage, or pulmonary edema, or may have an idiopathic origin. Common infectious etiologies include *Aspergillus* species or other fungi, respiratory syncytial virus, and CMV. Late pneumonia from *Pneumocystis carinii* may occur up to 1 year after transplantation and usually is related to prolonged CD4+ lymphopenia associated with T-cell depletion of the allograft or GVHD. Interstitial pneumonitis (IP), characterized by fever, hypoxia, and diffuse pulmonary infiltrates, occurs in 20% to 40% of patients, usually within the first 3 months of transplantation, and may be lethal in up to one-half of cases. <sup>126,127,128,129</sup> and <sup>130</sup> Nearly 90% of the cases of IP either are related to CMV infection or have an idiopathic origin [idiopathic interstitial pneumonitis (IIP)]. <sup>131</sup> The incidence of early CMV pneumonitis appears to have decreased significantly in the 1990s

through the use of both effective prophylactic regimens (intravenous immunoglobulin and ganciclovir) and better methods for early detection of CMV reactivation. Patient-specific risk factors for IP include older age, prior history of exposure to pulmonary toxic drugs such as bleomycin, history of acute or chronic GVHD, dose intensity of the conditioning regimen, or use of TBI.<sup>126,127,128,129</sup> and <sup>130,132,133</sup> Regimens that use a lower dose rate or total dose of TBI, as well as hyperfractionated TBI, may be associated with a lower risk of IP.

Bronchoscopy with bronchoalveolar lavage should be used in all patients with IP to differentiate IIP from infectious causes or diffuse alveolar hemorrhage. Empiric use of anti-CMV agents such as ganciclovir or foscarnet should be considered when bronchoalveolar lavage is not feasible. Although evidence exists supporting the efficacy of high-dose steroids in patients with diffuse alveolar hemorrhage, their effectiveness in the treatment of IIP remains equivocal.<sup>134,135</sup>

## LATE COMPLICATIONS

The delayed complications associated with allogeneic SCT depend on patient age at transplantation and are a consequence of the effects of long-term damage to normal tissues by either the preparative regimen or chronic GVHD. These effects include growth retardation, infertility, endocrine failure, cataracts, renal insufficiency, restrictive pulmonary defects, neurocognitive defects, and secondary malignancies.<sup>136,137</sup> The use of TBI in the conditioning regimen seems to be the major factor associated with secondary malignancies.<sup>138,139</sup> and <sup>140</sup> On long-term follow-up of 1036 patients undergoing BMT for a wide range of malignant and nonmalignant conditions, a 12.6% incidence of secondary neoplasms was reported at 15 years, a rate that was 3.8 times higher than that for an age-matched control population.<sup>141</sup> The most frequently observed secondary neoplasms were of the skin and oral cavity, with older patient age and use of CSA for chronic GVHD being significant risk factors for new malignant disease.

## EPSTEIN-BARR VIRUS LYMPHOPROLIFERATIVE DISORDER

Posttransplantation Epstein-Barr virus (EBV)-associated lymphoproliferative disorder (LPD) represents an aggressive and potentially fatal B-cell lymphoid proliferation that occurs after 5% to 30% of allogeneic transplantations. This lymphoma originates from B cells infected with EBV, typically of donor origin, and usually stems from a deficiency of EBV-specific cytotoxic T cells associated with the use of immunosuppressive drugs or T-cell depletion of the allograft.<sup>142,143</sup> and <sup>144</sup> EBV LPD can be successfully treated by infusing unmanipulated donor leukocytes that contain cytotoxic T cells presensitized to EBV.<sup>145</sup> One trial in children receiving T-cell-depleted transplants from HLA-mismatched donors demonstrated that the prophylactic infusion of *ex vivo*-generated EBV-specific T cells can successfully prevent EBV LPD without causing acute GVHD.<sup>146</sup> Others have shown that B-cell depletion of the allograft can also be used to prevent this disorder.<sup>147</sup> The use of Rituximab (Rituxan), a monoclonal antibody to the B-cell antigen CD20, has recently been shown to be an alternative strategy that can successfully treat established LPD.<sup>148</sup>

## GRAFT-VERSUS-HOST DISEASE

GVHD is the consequence of immunocompetent donor T cells targeting recipient tissues that possess antigens absent from the donor.<sup>149,150</sup> and <sup>151</sup> The major target tissues of GVHD are the skin, liver, and gastrointestinal tract, although other tissues may be involved. The diagnosis of acute GVHD may be based on one or a myriad of characteristic clinical and laboratory findings.<sup>152,153,154</sup> and <sup>155</sup> Skin manifestations include an erythematous maculopapular rash often involving the palms and soles and, under severe circumstances, may be associated with desquamation. Hepatic involvement is characterized by a rise in alkaline phosphatase and total bilirubin, often in association with a mild to moderate increase in hepatic transaminases. Gastrointestinal GVHD predominantly involves the distal small bowel and colon and clinically is associated with cramping abdominal pain and watery diarrhea, which may be voluminous and bloody under severe circumstances. Endoscopic findings are variable and may range from mild bowel edema to total denuding of intestinal mucosa; colonic biopsy usually reveals classic pathologic features showing crypt cell necrosis with apoptotic bodies and lymphocytic infiltrates, although disease involvement can be patchy and missed on random biopsy. Upper gastrointestinal involvement, although more rare, may be associated with recurrent nausea, vomiting, and dyspepsia.<sup>156</sup> Traditionally, acute GVHD has been divided into severity grades I through IV, depending on the extent of skin involvement, volume of diarrhea, or level of bilirubin elevation ( [Table 53.3-2](#)).<sup>157</sup>

Stage	Site	Liver	Intestinal Tract
I	Maculopapular rash <10% of body surface	Bilirubin <2.0 mg/dL	>100 mL diarrhea/d
II	Maculopapular rash 10-30% of body surface	Bilirubin 2-3.0 mg/dL	>100 mL diarrhea/d
III	Generalized erythroderma	Bilirubin 3.0-5.0 mg/dL	>100 mL diarrhea/d
IV	Generalized erythroderma with bullae formation and desquamation	Bilirubin >5.0 mg/dL	Severe abdominal pain with or without ileus

Grade	Degree of Organ Involvement
I	Stage I-II skin rash, no gastrointestinal tract involvement, no liver involvement, no decrease in clinical performance
II	Stage I-II skin rash, stage I gastrointestinal tract involvement or stage I liver involvement or both, mild decrease in clinical performance
III	Stage I-II skin rash, stage II-III gastrointestinal tract involvement or stage II-III liver involvement or both, marked decrease in clinical performance
IV	Stage III-IV skin rash with stage III-IV organ involvement, severe decrease in clinical performance

(From [Table 53.3-2](#) and [Table 53.3-3](#), with permission.)

**TABLE 53.3-2.** Glucksberg Clinical Stage and Grade of Acute Graft-Versus-Host Disease

Donor T cells are the principle mediators of GVHD. In an HLA-mismatched setting, CD8+ T cells may target major histocompatibility complex (MHC) class I mismatched antigens, while CD4+ T cells are responsible for the recognition and targeting of MHC class II mismatched antigens.<sup>158,159,160,161</sup> and <sup>162</sup> The antigens that are disparate between patient and donor and serve as a target for GVHD in HLA-identical sibling transplants are referred to as *minor histocompatibility antigens* (mHa). Relatively few mHa have been characterized to date, although there is increasing evidence to suggest that the degree of disparity between recipient and donor mHa is a major determinant for the development of both acute and chronic GVHD.<sup>163,164,165</sup> and <sup>166</sup> The development of GVHD is a multistep process in which recipient tissues are recognized as foreign by the donor immune system, followed by the activation and expansion of GVHD effector populations, ultimately leading to T-cell-mediated direct cytotoxic damage of target tissues.

GVHD remains a significant contributor to transplant-related morbidity and mortality. The incidence and severity of GVHD is determined by a number of variables, including degrees of HLA disparity between patient and donor, use of a T-cell-replete versus T-cell-depleted allograft, patient age, and the agents used in GVHD prophylaxis.<sup>167,168</sup> and <sup>169</sup> Furthermore, acute GVHD after T-cell-replete allogeneic BMT often is most severe within the first month after transplantation and appears to be exacerbated by conditioning-induced cytokine release from damaged recipient tissues. In general, the incidence of clinically significant acute GVHD (grades II through IV) in patients undergoing a T-cell-replete allogeneic SCT (from an HLA-identical sibling) in which conventional GVHD prophylaxis is used (CSA and methotrexate) is on the order of 30% to 40%, with approximately 15% of patients developing severe grade III or IV disease.<sup>167</sup> In recipients of partially matched related donor or partially matched unrelated donor transplants, acute GVHD occurs more frequently, affecting more than 70% of patients.<sup>170</sup>

The two most common methods for preventing acute GVHD include the use of prophylactic immunosuppressive agents and the use of allografts from which donor T cells have been depleted. Although the combined use of CSA and methotrexate has been found to be superior to either agent alone in the prevention of GVHD, the addition of prednisone to these agents does not appear to offer any additional benefit.<sup>171,172</sup> and <sup>173</sup> In both HLA-identical sibling and unrelated transplantations, T-cell depletion is the most effective method for preventing GVHD but is associated with an increased risk of graft rejection, opportunistic viral infection, and leukemic relapse. Although the risk of disease relapse is leukemia-specific, a large retrospective analysis from the International Bone Marrow Transplant Registry showed clear evidence that T-cell depletion was associated with a lower disease-free survival in CML.<sup>174</sup> Novel methods of T-cell depletion that appear to decrease this risk of acute GVHD without increasing the risk of disease relapse include the use of allografts that have been selectively depleted of CD8+ T cells and the use of T-cell-depleted transplants followed by a delayed infusion of donor lymphocytes months after the original transplantation to preserve the GVL effect.<sup>174,175,176</sup>

The mainstay of therapy for the treatment of acute GVHD is corticosteroid therapy, usually in association with CSA or FK506. Approximately 40% to 60% of patients with grade II to IV GVHD can be expected to respond to these agents.<sup>176,177</sup> and <sup>178</sup> One randomized trial of low-dose (2 mg/kg) versus high-dose (10 mg/kg) methylprednisolone for acute GVHD showed no difference in response rates with either regimen.<sup>179</sup> Response to steroids appears to predict survival, with steroid-refractory patients being at a significantly higher risk of transplant-related mortality than steroid-responsive patients. Antithymocyte globulin (ATG) has been

used with minimal success in patients with steroid-refractory disease, and it appears to be inferior to steroids or CSA as an initial therapy for acute GVHD. <sup>180</sup> Other approaches that have shown early promise for the treatment of steroid-resistant disease include the use of the immunosuppressive drug mycophenolate mofetil, monoclonal antibodies that target a number of different T-cell antigens, and extracorporeal photopheresis. <sup>181,182,183,184,185,186 and 187</sup>

Chronic GVHD occurs in 15% to 50% of long-term survivors of allogeneic BMT and typically manifests with symptoms 3 months to 2 years after transplantation. The etiology of chronic GVHD appears to be related to alloreactive T cells that infiltrate and damage tissues and cause abnormalities in immune regulation. <sup>188,189 and 190</sup> The greatest risk factor for chronic GVHD is a prior history of acute GVHD, although older patient age, use of mismatched or unrelated donors, a history of DLI for relapsed malignancy, and use of peripheral blood stem transplants also appear to increase the risk. <sup>191,192</sup> Patients with chronic GVHD often are severely immunocompromised, either as a consequence of the immunosuppressive therapy used to treat the disorder or from the underlying immune dysregulation associated with the disease process. Chronic GVHD is lethal in approximately 20% to 30% of cases, with death being predominantly related to infectious causes. <sup>193</sup> Patients with a particularly poor prognosis include those with hepatic involvement or thrombocytopenia.

Chronic GVHD is traditionally classified as either limited or extensive, limited disease being defined as localized skin involvement with or without mild hepatic involvement and extensive disease being generalized skin involvement with or without other target organ involvement. The characteristic clinical manifestations are numerous and include lichenoid or sclerodermatous skin involvement, hepatic cholestasis, friable nails, dry eyes (Sjögren's syndrome), fasciitis, xerostomia, lichenoid buccal changes, bronchiolitis obliterans, vaginal dryness, serositis, malabsorption, diarrhea, gastrointestinal dysmotility, and pancytopenia. Treatment depends on the extent of disease. Systemic disease typically is treated with alternate-day CSA or FK506 and low-dose corticosteroids. <sup>194</sup> Patients not responding to standard therapy often benefit from alternative therapies, including mycophenolate mofetil, psoralen and ultraviolet A for skin involvement, thalidomide, total lymphoid irradiation and, more recently, extracorporeal photopheresis. <sup>186,195,196 and 197</sup> As infections are the main cause of death, prophylaxis for organisms such as *P carini* and encapsulated bacteria usually is warranted, particularly in those patients receiving systemic immunosuppressive therapy.

## GRAFT FAILURE

Failure to achieve or maintain sustained donor hematopoietic engraftment after allogeneic transplantation is referred to as *graft failure*. Graft failure may manifest as persistent neutropenia, without evidence of engraftment (primary graft failure) or as initial engraftment followed by a delayed fall in blood counts (late or secondary graft failure). *Graft rejection* is the term used to describe graft failure that occurs as a consequence of the active rejection of donor hematopoietic cells by residual immunocompetent host cells. Clinically, graft rejection manifests as transient donor engraftment followed by a lymphocytosis of recipient origin, which ultimately leads to the rejection of donor hematopoietic cells and pancytopenia or, in some cases, autologous hematopoietic recovery. The mediators of graft rejection include natural killer cells or residual recipient T cells recognizing donor-mismatched MHC molecules or, in an HLA-matched setting, mHa. <sup>198,199 and 200</sup>

Primary graft failure should be suspected in all transplant patients who remain pancytopenic for longer than 3 to 4 weeks. It is associated with a significant risk of death from hemorrhage or infection. Although graft failure occurs in fewer than 2% of patients undergoing allogeneic SCT from an HLA-identical sibling, the incidence increases for recipients of T-cell-depleted transplants, particularly those from HLA-mismatched or unrelated donors. <sup>201,202 and 203</sup> Other risk factors for graft rejection include the infusion of low stem cell numbers (i.e.,  $<1 \times 10^6$  CD34+ cells/kg), history of multiple blood transfusions, HLA disparity between the patient and donor, use of low-intensity or dose-reduced conditioning regimens, and transplantation for severe aplastic anemia. <sup>204,205</sup> Although graft rejection is more common after BMT for aplastic anemia, the addition of TBI or ATG to the conditioning regimen (usually high-dose cyclophosphamide) has decreased the incidence from 30% to less than 10%. <sup>206</sup>

Differentiating graft failure from pancytopenia related to other causes, including marrow suppression from infection, medications, or chronic GVHD, is important. Furthermore, it is important to give early consideration for a second donor stem cell infusion, given the difficult logistics of collecting more donor cells. Non-immunologically mediated graft failure has been successfully treated with hematopoietic growth factors such as granulocyte-macrophage colony-stimulating factor or G-CSF, followed by a second infusion of donor stem cells in those who fail to experience hematopoietic recovery. <sup>207,208 and 209</sup> Graft rejection, in which donor hematopoietic cells are no longer detectable by cytogenetic or molecular methods, requires repeat conditioning to eradicate these host "rejection" cells, followed by the infusion of a second donor allograft. Although the outcome in patients requiring a second donor marrow infusion for graft failure often is poor, successful and sustained donor engraftment has been reported in 57% of primary and 37% of secondary graft failure patients. <sup>210</sup>

## CYTOMEGALOVIRUS INFECTION

CMV is a member of the herpesvirus family and may be associated with serious and life-threatening pathology after allogeneic BMT. <sup>211,212</sup> Most patients who develop CMV disease do so as a consequence of viral reactivation from a previous primary infection. The cellular immune system plays an important role in the suppression of viral reactivation. Disruption of cellular immunity associated with T-cell depletion, GVHD, or immunosuppressive therapy can lead to CMV reactivation and subsequent disease. The clinical features of CMV disease include pneumonitis, hepatitis, upper gastrointestinal involvement, and colitis. Reactivation tends to occur 3 weeks to 100 days after transplantation and is most strongly associated with acute GVHD and pretransplantation seropositivity of the recipient to CMV. Prior to the development of reactivation screening techniques and prophylactic drug regimens, CMV pneumonitis was observed in 10% to 30% of patients and was fatal in 50% to 90% of cases. <sup>213</sup>

Effective prevention can be achieved through the use of CMV-negative or leukocyte-filtered blood products (in seronegative patient-donor pairs) and prophylactic intravenous immunoglobulin and ganciclovir. <sup>214,215,216,217 and 218</sup> As CMV will never reactivate in 40% to 50% of patients, an alternative and effective approach is to reserve ganciclovir use for patients with detectable viral reactivation, either by polymerase chain reaction methods or by immunofluorescent techniques designed to detect viral antigen on the surface of neutrophils (CMV antigenemia). <sup>219</sup> Both techniques allow for early detection and treatment of CMV reactivation long before symptoms develop. Indeed, these early detection methods have dramatically decreased the incidence and mortality associated with CMV disease.

A recently investigated alternative to CMV drug prophylaxis is to infuse CMV-specific cytotoxic lymphocytes generated from donor cells *in vitro*, early after T-cell-depleted transplantation. <sup>220</sup> This cell-based approach for the prevention of CMV reactivation has shown early success and may serve as a paradigm for future protocols that use tumor-specific T cells to prevent disease relapse.

## SOURCES OF ALLOGENEIC HEMATOPOIETIC STEM CELLS

### ALLOGENEIC PERIPHERAL BLOOD STEM CELL TRANSPLANTS

Based on the success of autologous peripheral blood stem cell (PBSC) transplants, allogeneic transplantation regimens, which use peripheral blood-derived stem cells as apposed to marrow cells, have been used with increasing frequency since the mid-1990s, with early favorable clinical outcome. <sup>221,222,223,224,225,226 and 227</sup> The recombinant growth factor G-CSF usually is given to donors for 4 to 6 consecutive days (10 mg/kg/d) to mobilize hematopoietic progenitors into the circulation, followed by one or two leukapheresis procedures. G-CSF-mobilized PBSC transplants contain higher numbers of progenitor cells than do marrow grafts, usually in the range of  $5$  to  $10 \times 10^6$  CD34+ cells/kg. Although the use of lower doses of G-CSF is associated with a decreased incidence of cytokine-related side effects, the number of CD34+ cells mobilized into circulation may be lower, necessitating additional leukapheresis procedures. <sup>228</sup>

PBSC transplants have potential advantages for both the donor and the patient. Donors do not require hospitalization and are spared the pain and potential risks of general anesthesia associated with marrow harvesting, although the long-term consequences of G-CSF administration remain unknown. Also, PBSC grafts contain higher numbers of hematopoietic progenitor cells, natural killer cells, and T cells, as compared with bone marrow. <sup>229</sup> Engraftment, therefore, usually is faster, and the GVL effect may be enhanced. <sup>230</sup> Initial concerns that the 10- to 20-fold higher T-cell dose in peripheral blood allografts might be associated with a greater risk of acute GVHD have been dispelled. Indeed, two trials comparing allogeneic bone marrow to PBSC transplantation have shown that PBSCs are associated with a shorter period of neutropenia and red blood cell and platelet transfusion dependence, with an equal probability of acute and chronic GVHD. <sup>231,232</sup> The failure to observe a correlation between the number of T lymphocytes in the allograft and GVHD might be related to the polarizing of donor T cells by G-CSF to a type 2 (suppressor) cytokine profile.

A phase III trial of allogeneic transplantation in 138 patients with hematologic malignancies found that PBSC grafts were associated with more rapid engraftment and better disease-free and overall survival than marrow grafts, without a greater risk of acute GVHD. <sup>233</sup> Neutrophil engraftment occurred 6 days earlier (day 15 vs. day

21), and platelet recovery occurred 8 days earlier (day 13 vs. day 21) among those receiving PBSC transplants. The incidence of acute grade III or IV GVHD was equal between groups, occurring in 16% of PBSC graft and 13% of bone marrow graft recipients. The cumulative incidence of chronic GVHD was also similar, occurring in 38% of PBSC and 28% of marrow recipients. This study provided the first evidence that PBSC transplantation may be associated with a survival advantage over conventional marrow transplantation. Two-year survival in the PBSC group was 71%, as compared to 51% in the marrow group, a statistically significant difference that led to the early termination of this trial. These, as well as the previously mentioned benefits, make it likely that PBSC transplantation will replace BMT in the allogeneic setting.

## UMBILICAL CORD BLOOD TRANSPLANTATION

Umbilical cord blood is a new and promising source of hematopoietic progenitor cells for transplantation in both malignant and nonmalignant disorders. The realization that cord blood, obtained from the placenta after delivery, contained long-term repopulating progenitor cells led to its investigational use as a source of stem cells for allogeneic transplantation.<sup>234,235,236</sup> and <sup>237</sup> Cord blood has been shown to contain primitive hematopoietic stem cells with remarkable proliferative potential, which may overcome the limitation of relatively low absolute cell numbers.<sup>238,239</sup> and <sup>240</sup> Also, the immature lymphocytes in cord blood appear to decrease the risk and severity of acute and chronic GVHD, potentially permitting greater HLA disparity and expanding donor availability.

In a trial evaluating umbilical cord transplants in 44 children with malignant and nonmalignant hematologic diseases receiving grafts from an HLA-identical or single-antigen-mismatched donor, 85% engrafted and only 3% developed grade II or worse acute GVHD.<sup>235</sup> A subsequent multiinstitutional study from Europe reported similar engraftment rates in 78 recipients of cord blood from related donors, with acute GVHD occurring in 9% of the recipients of HLA-matched cord blood and in 50% of the recipients of HLA-mismatched cord blood.<sup>241</sup> Neutrophil engraftment was favorably associated with a younger patient age (younger than 6 years) and weight (<20 kg) and occurred in 85% of patients receiving 37 million or more mononuclear cells per kilogram of recipient body weight. In the recipients of unrelated cord blood, neutrophil engraftment occurred in 94% of those who received 37 million or more mononuclear cells per kilogram, with only 32% of patients developing grade II or worse GVHD.

These early successes have led to the creation of an increasing number of umbilical cord blood banks worldwide. However, graft failure, which is most closely associated with patient size, age, and low cord stem cell doses, remains a significant problem that will likely limit the applicability of this approach in adults.

## UNRELATED DONORS

Although allogeneic hematopoietic SCT is a potentially curative modality for a number of otherwise fatal malignancies, only one-third or so of patients have access to an HLA-identical sibling. The growing demand for donors has led to research in the development of techniques for the use of alternative sources of stem cells. The knowledge that the HLA system played a critical role in transplantation outcomes led to the successful use of HLA-matched unrelated donors (MUDs) and subsequent establishment of volunteer donor registries.<sup>242,243,244</sup> and <sup>245</sup> More than 5 million typed volunteer donors have been registered worldwide, and it is estimated that nearly 70% of white patients will have an HLA-A, -B and -DR-matched unrelated donor.<sup>246</sup> Because of the increasing availability of volunteer unrelated donors, it is anticipated that more than 2000 MUD transplantations will be performed in the year 2000.<sup>247</sup> Nonetheless, finding a suitable unrelated donor remains a significant problem for many patients, particularly ethnic and racial minority individuals.

Early MUD transplantations involved donors who were chosen on the basis of serologic HLA typing. The subsequent development of high-resolution molecular HLA typing revealed that many of these serologically typed donors often were mismatched, likely contributing to the increased risk of graft rejection and severe GVHD observed in these trials.<sup>248</sup> The results of extensive published data on unrelated donor transplantations reveal engraftment rates of 85% to 100%, grade II or worse acute GVHD in 21% to 98%, chronic GVHD in 50% to 74%, and disease-free survival rates of between 1% and 74%.<sup>247,249,250,251</sup> and <sup>252</sup> This wide range in outcome is explained mostly by variations in patient populations, transplantation methods, and HLA typing techniques. The use of molecular-based typing has been associated with a significant improvement in transplantation outcome, including a decrease in life-threatening acute and chronic GVHD.<sup>253,254</sup> Furthermore, typing beyond HLA-A, -B, and -DR loci may be of further benefit, as other MHC antigens appear to have a significant impact on transplantation outcome.<sup>256,257</sup>

More precise HLA typing has also increased the difficulty of finding a completely matched donor. T-cell depletion of MUD allografts is associated with a decrease in severe acute and chronic GVHD, although there appears to be no beneficial impact on overall survival.<sup>258</sup> There is some evidence, however, that survival may be better in the recipients of MUD transplants containing higher stem cell doses.<sup>259</sup> This observation has stimulated interest in the development of transplants that use higher total CD34+ cell doses—for instance, through the use of G-CSF-mobilized PBSC allografting. Whether this approach will improve the outcome of unrelated transplantations, particularly in terms of prolonging patient survival, remains to be determined.<sup>255</sup> Future trials that optimize donor selection, conditioning regimens, and GVHD prophylaxis will be required to improve the outcome of MUD transplantations.

## MISMATCHED RELATED DONORS

The availability of haploidentical (“half-matched”) related donors has led to the use of mismatched family members as an alternative source of stem cells for those patients who lack an HLA-identical sibling.<sup>259,260</sup> and <sup>261</sup> The majority of patients with living family members would be expected to have a relative who could serve as a partially mismatched donor. These donors may actually have a closer histocompatibility profile than MUDs, as the shared donor haplotype is genetically identical to that of the patient, which may be associated with better matching of mHa. Furthermore, potential family donors can usually be identified quickly and usually are more readily available than are MUDs. The number of mismatched MHC antigens in the patient is conventionally used to define the degree of mismatch and may range from three (haploidentical) to zero antigens, depending on the number of phenotypically shared antigens coming from the mismatched haplotype.<sup>247</sup>

Graft rejection, GVHD, and ineffective immunity leading to fatal opportunistic infection are the major immune-mediated complications associated with HLA disparity; the greater the HLA disparity, the higher these risks.<sup>262,263</sup> Early as well as recent trials comparing outcome in patients receiving partially mismatched related versus matched sibling donor allografts showed that engraftment, GVHD, and survival were inferior in the recipients of partially mismatched transplants.<sup>264,265</sup> More intensified conditioning regimens have resulted in better engraftment at the expense of more regimen-related organ toxicity.

Severe GVHD exceeded 50% in early trials using unmanipulated allografts, with T-cell doses in the allograft correlating with the probability of developing severe GVHD.<sup>266,267</sup> T-cell depletion, as in matched unrelated transplants, is associated with a significant decrease in the incidence of severe GVHD, although the incidence of graft rejection is increased.<sup>268,269</sup> and <sup>270</sup> Through the use of modified conditioning regimens and more effective T-cell depletion methods, several groups have begun to report improved outcome using mismatched family donors. Henslee-Downey et al.<sup>271,272</sup> were the first to report similar 3-year disease-free survivals in patients with lymphoblastic leukemia using partially matched related donors versus matched sibling donors (39% vs. 37%). Subsequently, other investigators have reported regimens with modified conditioning and T-cell depletion techniques associated with a high rate of donor engraftment and a low risk of GVHD, with long-term disease-free survivals in the range of 20% to 40%.<sup>273,274</sup> These results are significant, as most patients treated in these trials had advanced, high-risk hematologic malignancies associated with poor transplantation outcome, even in a matched sibling setting.

Another recently explored approach involves the induction of donor T-cell anergy to recipient alloantigens. This technique involves *ex vivo* culturing of haploidentical donor marrow with recipient lymphocytes in the presence of CTLA-4 immunoglobulin to inhibit the “second signal” required for T-cell activation. Donor T cells in this environment do not receive costimulation and are therefore rendered “tolerant” to recipient alloantigens. Although only a small number of haploidentical transplantations have been performed using this approach, early results have been encouraging, without the occurrence of graft rejection or death from acute GVHD.<sup>275</sup>

Although opportunistic infections and disease relapse remain problematic, modifications in this procedure have demonstrated that the use of full haplotype mismatched donors can be tolerated and is a viable transplantation alternative in patients lacking matched sibling donors. The improvement in haploidentical transplants will likely lead to randomized trials comparing partially mismatched related donors to MUDs to discern which alternative stem cell source is preferable.

## NONMYELOABLATIVE ALLOGENEIC STEM CELL TRANSPLANTATION

Allogeneic hematopoietic SCT using high-dose, myeloablative chemo/radiotherapy is associated with a high incidence of treatment-related complications and a 20% to 35% risk of transplant-related mortality. Debilitated or older patients with hematologic malignancies are at particularly high risk, thus limiting the applicability of this

potentially curative treatment modality to relatively younger patients with a good performance status.<sup>276,277</sup> The desirable antitumor effects of dose-intensive conditioning often are offset by their substantial and potentially life-threatening toxicities. A greater understanding and appreciation of the powerful and potentially curative nature of the GVL effect led to the notion that GVL alone, without intensive cytoreductive therapy, might be sufficient to obtain long-term control of hematologic malignancies. Patients with relapsed leukemia after allogeneic transplantation whose disease is induced into remission after DLI lend the greatest credence to this concept.

Subsequent to these observations, a number of investigators began to explore the concept of using low-intensity conditioning regimens, immunosuppressive enough to permit engraftment of the donor immune system for the generation of GVL effects while sparing patients the toxicities associated with myeloablative therapy.<sup>278,279</sup> and<sup>280</sup> Although NST is still in its infancy, a number of institutions investigating a variety of nonmyeloablative approaches have reported remarkable early success.<sup>281,282,283</sup> and<sup>284</sup> Despite the use of low-intensity conditioning, engraftment rates have been high, and long-term remissions, induced purely through a donor immune-mediated antitumor effect, have been observed in a variety of different hematologic and nonhematologic malignancies.<sup>285</sup> Importantly, regimen-related toxicity and mortality appear to be low, thus expanding eligibility for allogeneic transplantation to include older or debilitated patients, as well as allowing for exploration of graft-versus-tumor (GVT) effects in other treatment-refractory or incurable malignancies. Furthermore, the majority of late side effects attributed to myeloablative conditioning, including growth retardation, sterility, endocrinopathies, cataracts, and secondary malignancies, will likely be avoided using nonmyeloablative transplants.

### NONMYELOABLATIVE CONDITIONING REGIMENS

Although a variety of low-intensity conditioning regimens have been explored, they are all, by definition, nonmyeloablative, as recipient hematopoietic stem cells are not eradicated, allowing for the possibility of autologous hematopoietic recovery. Two features are common to all these regimens: First, they avoid acute and chronic toxicities of dose-intensive chemo/radiotherapy by using a relatively low-intensity nontoxic preparative regimen and, second, they attempt to induce sufficient host immunosuppression to allow for engraftment of the donor immune system.

The minimum amount of immunosuppression required to allow for donor engraftment is unlikely to be defined, as it depends on multiple variables, including the competence of the patient's immune system (related to the amount and intensity of prior therapy), degree of patient-donor HLA and mHa disparity, donor immunocompetence, and the dose of T cells in the allograft. Nonetheless, a number of different conditioning regimens with variable degrees of intensity have been used successfully to establish donor engraftment with minimum toxicity, including regimens consisting of purine analogs in combination with alkylating agents, low-dose TBI alone, or thymic irradiation in combination with cyclophosphamide with or without ATG.

Based on results from canine preclinical trials, Storb et al.<sup>286,287</sup> pioneered a novel NST approach that uses low-dose TBI (200 cGy) as well as pre- and posttransplantation immunosuppression with CSA and mycophenolate mofetil to prevent both graft rejection and GVHD. This regimen usually achieves a state of recipient-donor mixed chimerism, which can serve as a platform for the subsequent infusion of donor lymphocytes to enhance GVL effects. Although a heterogeneous population of patients has been treated with a variety of different regimens, conditioning-associated toxicity and mortality appear to be significantly lower than with conventional myeloablative approaches. Because host hematopoietic elements are not ablated, recovering myeloid cells are usually of both recipient and donor origin (mixed chimerism). This state of mixed chimerism has both beneficial and negative effects on transplantation outcome. Mixed chimerism is capable of inducing donor and recipient tolerance, thus preventing the development of acute GVHD.<sup>288,289</sup> However, mixed chimerism also is associated with an increased risk of graft failure, and the tolerance that it induces may inhibit beneficial GVL effects. These negative aspects of mixed chimerism can be overcome by infusing donor lymphocytes, which can shift chimerism from a mixed to a complete donor type, thus avoiding tolerance and enhancing the GVL effect.

### NONMYELOABLATIVE TRANSPLANTATION TOXICITY

Conditioning-induced toxicity is relatively mild with nonmyeloablative regimens as compared to myeloablative approaches (see [Table 53.3-1](#)). Most patients tolerate the preparative regimen well, without the occurrence of mucositis or requirement for total parenteral nutrition. VOD occurs infrequently, is usually mild, and is observed predominantly with the use of regimens that contain busulfan.<sup>279</sup> Although most patients become pancytopenic, the occurrence of partial autologous hematopoietic recovery appears to shorten the overall depth and duration of neutropenia while reducing platelet and red blood cell transfusion requirements. Most trials have reported transplantation-related mortality rates in the range of 10% to 15%, which is remarkably low given the advanced age and poor performance status of the majority of these patients. Some low-intensity protocols, particularly those that use low-dose TBI alone, appear ideally suited for outpatient use.<sup>286</sup> NST is too new to make any conclusions regarding long-term complications, although it is reasonable to assume that growth retardation, sterility, and secondary malignancies will be observed with reduced frequency as compared to conventional myeloablative transplantation.

### ENGRAFTMENT AFTER NONMYELOABLATIVE STEM CELL TRANSPLANTATION

The ability to establish engraftment of donor hematopoietic and lymphoid cells is directly related to the degree of host immunosuppression induced by the preparative regimen. Most, if not all, NST regimens result in some degree of early donor-recipient mixed chimerism. Although graft rejection occurs with a higher frequency than with myeloablative approaches, in general, more than 80% of patients can be expected to have long-term stable donor engraftment. Regimens that use low-dose TBI alone are associated with a higher incidence of graft rejection, although the addition of fludarabine appears to overcome this problem.<sup>290,291</sup>

We evaluated the engraftment kinetics in 50 patients with hematologic and nonhematologic malignancies receiving an NST from an HLA-identical or single-locus mismatched sibling donor using a preparative regimen of cyclophosphamide (60 mg/kg × 2) and fludarabine (25 mg/m<sup>2</sup> × 5).<sup>292</sup> Lineage-specific chimerism analysis using the polymerase chain reaction of minisatellite regions was performed on myeloid (CD14+ and CD15+) and T cells (CD3+) obtained weekly from peripheral blood. A unique pattern of engraftment was observed in which myeloid cells at the time of neutrophil recovery were mixed chimeric (both donor and patient), although predominantly recipient in origin, in contrast to T cells, which were also mixed chimeric but predominantly donor in origin ([Fig. 53.3-4A](#)). By day 30, half of the patients had made the transition to full-donor T-cell chimerism, while myeloid chimerism often remained mixed ([Fig. 53.3-4B](#)). After the withdrawal of CSA and, in some patients, after DLI, chimerism changed to a complete donor type in all cellular lineages in the majority of cases. The establishment of full-donor T-cell chimerism consistently preceded full-donor myeloid chimerism, compatible with a graft-versus-host hematopoietic effect.<sup>289</sup> Forty-eight of 50 patients (96%) ultimately achieved stable donor engraftment, with only 2 (4%) experiencing graft rejection, which was followed by complete autologous hematopoietic recovery. Of note, acute GVHD and GVL effects were usually not observed until full-donor T-cell chimerism was achieved. T-cell chimerism, therefore, appears to be of central importance and can be used successfully to guide posttransplantation immune manipulation.

**FIGURE 53.3-4.** Percentage of donor T (CD3+) cells (*black bars*) and myeloid (CD14+ and CD15+) cells (*gray bars*) in 15 individual patients on days 14 (**A**) and 30 (**B**) after transplantation. NE, nonevaluable. (From ref. 289, with permission.)

### GRAFT-VERSUS-HOST DISEASE

Although mixed T-cell chimerism is associated with GVHD tolerance, withdrawal of CSA and giving DLI, usually to enhance a GVL effect, often results in a rapid

transition to full-donor T-cell chimerism and may be associated with the onset of acute GVHD. Acute GVHD appears to be the major nonrelapse life-threatening complication associated with NST. Several trials have reported grade II through IV acute GVHD rates of 30% to 50%, this outcome being lethal in up to 15% of treated patients.<sup>278,279</sup> and <sup>280,290,292</sup> Older patient age, prior history of autologous transplantation, and rapid T-cell engraftment appear to be associated with an increased risk of GVHD. We observed a sixfold increase in acute GVHD in those patients who had 90% or more donor T-cell chimerism by day 14 after transplantation. The majority of NST regimens have used CSA or FK506 alone for prophylaxis of GVHD. Future strategies to decrease the incidence and severity of acute GVHD, which include the additional use of prophylactic drugs such as methotrexate or mycophenolate mofetil, or methods to deplete alloreactive T cells selectively, will likely improve the safety of these novel regimens.

### GRAFT-VERSUS-LEUKEMIA EFFECT AFTER NONMYELOABLATIVE STEM CELL TRANSPLANTATION

GVL effects after NST have been observed in a heterogeneous group of hematologic malignancies, with some patients achieving durable remissions.<sup>278,279,280,281,282</sup> and <sup>283,286,289,293,294</sup> and <sup>295</sup> To date, too few patients have been treated in any one disease category to make any generalizations regarding the antileukemic potential of this approach. However, the induction of molecular remissions in CML, CLL, and low-grade non-Hodgkin's lymphoma suggest that the GVL reactions induced after NST are at least as powerful as those after conventional BMT and will likely be of curative potential. Furthermore, complete remissions in advanced and chemotherapy-refractory diseases have been achieved in debilitated and older patients (i.e., older than 60 years) who normally would have been ineligible for a standard myeloablative transplantation due to an unacceptably high risk of treatment-related mortality.<sup>296</sup>

As autologous hematopoietic recovery usually occurs, recurrent and sometimes progressive disease may be observed during the first 3 to 6 months after transplantation. The onset of the GVL effect typically is delayed from the time of transplant conditioning and usually follows the establishment of full-donor T-cell chimerism and the withdrawal of GVHD prophylaxis or DLI.<sup>289</sup> Figure 53.3-5 shows the typical pattern of donor engraftment in myeloid and T-cell lineages in a 56-year-old man undergoing NST for CMML using this approach. Mixed T-cell chimerism on day 30 improved in the direction of the donor after withdrawal of CSA and a DLI of  $2 \times 10^6$  CD3+ cells/kg. Myeloid recovery was mixed but predominantly autologous in origin. After 100% donor T-cell chimerism was established, a brief period of leukopenia was followed by a rapid increase in the percentage of donor myeloid cells, consistent with a graft-versus-host hematopoietic effect. A 20q- cytogenetic abnormality, which was observed in all bone marrow metaphases on day 60, was no longer detectable by the day 100 analysis, and the patient remains in remission more than 24 months after transplantation without ever having developed GVHD. Similar patterns of delayed disease regression have been observed in patients with CML, CLL, and Hodgkin's and non-Hodgkin's lymphomas.

**FIGURE 53.3-5.** Typical pattern of donor engraftment in myeloid and T-cell lineages in a 56-year-old man undergoing nonmyeloablative stem cell transplantation for chronic myelomonocytic leukemia (CMML). CSA, cyclosporin A; DLI, donor lymphocyte infusion.

### GRAFT-VERSUS-TUMOR EFFECTS

The low risk of transplant-related mortality with NST renders this approach appealing for the investigation of GVT effects in patients with metastatic and treatment-refractory solid tumors. In 1997, my colleagues and I initiated a pilot trial to investigate for GVT effects in patients with metastatic renal cell carcinoma and melanoma in whom conventional therapy had failed and who had an HLA-compatible sibling.<sup>284,289,297,298</sup> We chose to investigate for GVT effects in these two malignancies owing to their highly immunogenic profiles and known sensitivity to immunomodulation-based therapy (interleukin-2 and interferon- $\alpha$ ), in which T cells are believed to be the principle mediators of an antitumor response. None of the first eight patients with melanoma had a sustained disease response. However, several patients with advanced, treatment-refractory metastatic renal cell carcinoma have had a disease response, including three with a complete response, two of whom remain in remission longer than 2 years after transplantation. The disease regressions we observed were typically delayed in onset, occurring at a median of 4 months after transplantation, and followed the withdrawal of CSA, establishment of 100% donor T-cell chimerism and, in one patient, following a DLI, all compatible with a donor-mediated GVT effect. These results illustrate that antitumor effects induced through an allogeneic immune system may be as or more potent than strategies designed to enhance autologous antitumor immunity. They also provide the first evidence that a GVT effect alone can induce complete and clinically meaningful regression of a metastatic solid tumor. Similar trials have been initiated to investigate for GVT effects in patients with other treatment-refractory tumors.

### FUTURE DIRECTIONS FOR NONMYELOABLATIVE STEM CELL TRANSPLANTATION

The results of these early trials have been encouraging, showing that low-intensity transplantation regimens are well tolerated with a low risk of transplant-related toxicity and mortality, even in high-risk patients. More important, the trials have shown that adequate engraftment of the donor immune system can be achieved for the generation of powerful antitumor effects, without the use of toxic myeloablative conditioning regimens. Indeed, they provide strong evidence that the GVL effect may be the primary modality, contributing to the curative potential of allogeneic hematopoietic SCT in some malignancies. Because toxicity is decreased, patient eligibility for allogeneic transplantation will likely be expanded to include older or debilitated patients who were historically ineligible for standard BMT. Furthermore, the ability to generate GVL effects resulting in complete remissions of hematologic malignancies will likely lead to prospective randomized trials comparing NST to more conventional myeloablative transplantations. Finally, NST appears to be the ideal platform from which to investigate safely for more targeted adoptive allogeneic immunotherapeutic approaches that use tumor-specific T cells to enhance the antimalignancy effect of allogeneic lymphocytes.

### RESULTS OF CONVENTIONAL ALLOGENEIC TRANSPLANTATION FOR HEMATOLOGIC MALIGNANCIES

Allogeneic hematopoietic SCT is potentially curative for a number of different hematologic malignancies, including acute and chronic leukemias, myelodysplastic syndromes, Hodgkin's and non-Hodgkin's lymphoma, and multiple myeloma. The indications for allogeneic SCT vary according to disease categories and are influenced by factors such as cytogenetic abnormalities, response to prior therapy, patient age and performance status, disease status (remission vs. relapsed), disease-specific prognostic factors and, most important, availability of a suitable allogeneic stem cell donor. The decision of whether to proceed with allogeneic transplantation often is difficult and controversial and ultimately is guided by the potential benefits and risks of such therapy. Diseases such as CML, curable only by allograft transplantation, are associated with an excellent posttransplantation outcome and high probability of long-term disease-free survival, justifying the risks of regimen-related toxicity. Conversely, diseases such as multiple myeloma are associated with a high risk of treatment-related mortality and disease relapse, making the decision to proceed with transplantation more difficult.<sup>298</sup> Nevertheless, for the majority of patients who undergo this approach, allogeneic SCT remains the only chance of cure.

### CHRONIC MYELOGENOUS LEUKEMIA

CML is a clonal myeloproliferative disease of hematopoietic stem cell origin, characterized by an early chronic phase of 3 to 5 years' duration followed by an accelerated phase of 3 to 6 months, which ultimately terminates in a fatal blastic phase. Although a minority of patients have sustained cytogenetic remission of the Philadelphia chromosome [t(9;22)] after treatment with interferon- $\alpha$ , allogeneic SCT remains the only treatment approach with definitive curative potential. Patient age, disease status (chronic phase vs. accelerated or blastic phase), and the time interval from diagnosis to transplant (i.e., <1 year vs. >1 year) are the most powerful predictors of long-term survival following allogeneic transplantation.<sup>299,300,301,302</sup> and <sup>303</sup> In general, 65% to 80% of patients with chronic-phase CML who receive a transplant can expect to be cured, in contrast to a minority (10% to 15%) who undergo transplantation in the accelerated or blastic phase. Patients with chronic-phase

CML who receive a transplant within 1 year of diagnosis have the best outcome, with long-term disease-free survivals of 75% to 80%. A study from the Fred Hutchinson Cancer Center involving 196 patients undergoing allogeneic SCT from a matched unrelated donor reported a 5-year survival of 75%, a rate that compared favorably to that institution's results using HLA-matched sibling donors. <sup>304</sup>

Among hematologic malignancies, CML appears most susceptible to the GVL effect. <sup>54</sup> The majority of CML patients who experience disease relapse after allogeneic SCT can expect to be induced back into remission with DLI. <sup>61,62,63,64,65</sup> and <sup>66</sup> This sensitivity to GVL has led to a number of trials investigating NST as a less toxic approach for patients with chronic-phase CML. Early results using NST have been promising, with several molecular remissions having been reported. <sup>279,282</sup> Notably, patients older than 60 years have been successfully treated with minimal conditioning-associated toxicity, an important finding given the median age at diagnosis of 65 years. <sup>296</sup> These favorable results will expand patient eligibility for this curative modality to include the majority of older patients who are diagnosed with CML and who have a suitable donor, and will likely lead to randomized trials comparing NST with conventional myeloablative approaches.

## ACUTE MYELOGENOUS LEUKEMIA

With the exception of those with favorable or low-risk karyotypic abnormalities [i.e., t(8;21), t(15;17), inv or del(16)], most patients with AML are at high risk for disease relapse after chemotherapy-induced remission. <sup>305,306</sup> Allogeneic SCT after first complete remission (CR1) is associated with a lower risk of relapse, with studies demonstrating 5-year disease-free survivals of 46% to 62%. <sup>306,307,308,309</sup> and <sup>310</sup> Patients in CR2 or with untreated relapsed AML usually are curable only by allogeneic SCT, although they are less likely to achieve long-term survival (22% to 30%). <sup>311,312</sup> Therefore, the decision to perform transplantation after CR1 is influenced by the predicted increase in disease-free survival versus the risk of regimen-related mortality. Based on these observations, it is reasonable to proceed to transplantation in CR1 in patients who are at intermediate or high risk of relapse (i.e., normal karyotype, abnormal chromosome 5 or 7, complex karyotype abnormalities), withholding the procedure until first relapse or CR2 in lower-risk patients. Primary chemotherapy-refractory AML, although associated with a significantly worse prognosis than AML in remission, is salvageable by allogeneic SCT in 10% to 20% of cases.

## ACUTE LYMPHOBLASTIC LEUKEMIA

Although 65% to 85% of adults with ALL achieve remission with primary chemotherapy, 60% to 70% eventually experience relapse, which is rarely curable with salvage chemotherapy. Factors associated with a poor outcome (high risk) include age older than 60 years, leukocyte count greater than 30,000 on presentation, and chromosomal translocations involving t(4;11), t(1;19), t(8;14), or the Philadelphia chromosome t(9;22), which can be found in 15% to 30% of adult ALL cases. <sup>313,314,315</sup> and <sup>316</sup> In adults, allogeneic SCT performed during CR1 usually is reserved for patients with high-risk features, for whom cure with chemotherapy is unlikely. <sup>317,318</sup> Several studies of allogeneic SCT in high-risk patients who received a transplant during CR1 have reported long-term disease-free survivals of 41% to 61%, rates considerably higher than those observed with chemotherapy alone. <sup>319,320</sup> Allogeneic SCT usually is recommended in CR2 for patients lacking high-risk factors, as disease will be cured in some with chemotherapy alone. Furthermore, the long-term disease-free survival rate (35% to 40%) is comparable in these patients, regardless of whether they undergo transplantation in CR1 or CR2. <sup>321</sup> As chemotherapy is considerably more effective in achieving durable remissions in children, allogeneic SCT usually is reserved for those who fail to be cured with primary therapy or who have Philadelphia chromosome–positive ALL. <sup>322</sup>

## MYELODYSPLASTIC SYNDROME

Allogeneic SCT is the only curative therapy available for patients with myelodysplastic syndrome (MDS). In general, 30% to 50% of patients with MDS can be expected to achieve long-term disease-free survival. <sup>323</sup> Factors associated with improved outcome include younger age, lower pretransplantation marrow blast percentage, shorter disease duration, and favorable cytogenetics. A retrospective trial of 131 patients with MDS undergoing allogeneic BMT reported disease-free and overall survival rates of 34% and 41%, respectively. <sup>324</sup> Disease-free survival depended on pretransplantation bone marrow blast percentages, with refractory anemia/refractory anemia with ringed sideroblasts (RA/RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEB-T), and secondary AML patients having disease-free survivals of 52%, 34%, 19%, and 26%, respectively.

A retrospective analysis of transplantation events in relation to the International Prognostic Scoring System cytogenetic categories showed that cytogenetic abnormalities alone were highly predictive of posttransplantation outcome. <sup>325</sup> The event-free survival for good-, intermediate-, and poor-risk cytogenetic subgroups were 51%, 40%, and 6%, respectively, with corresponding relapse rates of 19%, 12%, and 82%. International Prognostic Scoring System cytogenetic categories were defined as good-risk if patients had normal karyotype, -Y alone, del(5q) alone, or del(20q) alone; poor-risk if patients had anomalies of chromosome 7 or complex cytogenetics (three or more anomalies); and intermediate-risk if other karyotypic anomalies were present that did not meet the criteria for good- or poor-risk. The identification of an extremely high incidence of relapse in the poor-risk group (82%) is important, as new and more effective treatment strategies should be directed specifically toward these patients.

## OTHER HEMATOLOGIC MALIGNANCIES

The role of allogeneic SCT in multiple myeloma, CLL, and Hodgkin's and non-Hodgkin's lymphoma is less well defined than in the acute leukemias or chronic-phase CML. <sup>326,327,328,329,330</sup> and <sup>331</sup> Most studies published to date have consisted of small retrospective analyses or anecdotal case reports. Nevertheless, reports of durable remissions in patients with relapsed or chemotherapy-refractory disease, often in association with GVHD or after DLI, provide strong evidence that these diseases are susceptible to a potentially curative GVL effect.

The largest series to date of patients with CLL undergoing allogeneic BMT reported a 49% disease-free survival at 27 months, with an extraordinarily high treatment-related mortality of 46%. <sup>326</sup> Although a number of patients with multiple myeloma have achieved long-term disease-free survival after allogeneic SCT, transplant-related mortality may be as high as 50%, thus limiting the full therapeutic potential of this approach. <sup>327</sup> Regimens with reduced transplant-related toxicities, such as NST, may avoid these complications and improve disease-free survival. Indeed several studies exploring NST in diseases such as low-grade non-Hodgkin's lymphoma, CLL, and multiple myeloma have shown early promising results, with durable complete responses being achieved in all disease categories. <sup>278,280,283,284,294</sup> Although CLL and low-grade non-Hodgkin's lymphoma are notorious for delayed relapses, the observation of molecular remissions raises the prospect that NST may have curative potential in these diseases.

## FUTURE PROSPECTS

Allogeneic SCT remains the only curative treatment modality for a large number of patients with hematologic malignancies. Exciting advances in the field have made this approach an essential component in the treatment of an increasing number of malignant diseases. Furthermore, an expanded understanding of the requirements for the engraftment of donor cells and of the basic immunologic mechanisms involved in GVHD and GVL reactions have greatly improved both the safety and efficacy of the procedure. The eventual identification of leukemia- and tumor-specific antigens will likely lead to more targeted allogeneic immunotherapy approaches that avoid the morbidity associated with GVHD. The discovery that GVL effects alone have curative potential for a number of different malignancies already has led to new transplantation approaches that appear destined to reduce transplant-related mortality and improve long-term outcome for patients undergoing this procedure.

### INTRODUCTION

The hematopoietic growth factors (HGFs) are a family of cytokines that regulate the proliferation, differentiation, and viability of hematopoietic progenitor cells and mature blood elements. More than 20 different cytokines have been discovered, all of which are believed to have effects on blood cell development or function, and many of these have been tested in preclinical or clinical trials in cancer patients over the last 15 years. Four HGFs—erythropoietin (EPO), granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and interleukin-11 (IL-11)—have been approved by the U.S. Food and Drug Administration for specific uses (Table 53.4-1), and other approvals are likely in the future. Early phase I and II trials indicated that G-CSF or GM-CSF had the potential to ameliorate myelosuppression in many circumstances, and now there is abundant evidence from randomized, phase III trials that this is the case. Similarly, EPO has been shown to be an effective treatment for the anemia of cancer in some patients, and IL-11 has been shown to reduce chemotherapy-associated thrombocytopenia in some circumstances. In addition, G-CSF, GM-CSF, and other growth factors are now commonly used to induce transient mobilization of hematopoietic stem and progenitor cells into the blood to allow collection for both autologous and allogeneic stem cell transplantation. Finally, other new cytokines [such as thrombopoietin (TPO)] with well-defined effects on thrombopoiesis are being investigated in on-going clinical trials. Overall, the ability to use HGFs therapeutically to enhance hematopoiesis has now become an important and widely used part of the treatment of certain cancers and has led to improved safety of high-dose chemotherapy and bone marrow transplantation in particular. This is still a field with many questions, however, and the cost-effectiveness of cytokine use in many areas of cancer treatment is still unknown. This chapter focuses on the four HGFs currently approved by the U.S. Food and Drug Administration for one or more applications in cancer and then summarizes the current state of clinical development of other cytokines of potential interest in cancer medicine.

Hematopoietic Growth Factor	Gene/Source	Molecular Weight	Gene	Therapeutic Effect	Applications in Cancer
EPO	Epoetin alfa	30 kD	EPO	Red cell homeo	Chemotherapy or cancer-associated anemia
G-CSF	Filgrastim	31 kD	CSF3	Neutrophil homeo	Reduce white neutropenia in patients receiving myelosuppressive chemotherapy
GM-CSF	Sargramostim, Molgramostin	15-20 kD	CSF2	Neutrophils, monocytes, macrophages	Increase hematopoietic reconstitution after bone marrow transplantation, reduce febrile neutropenia after bone marrow transplantation
Interleukin-11	Oprelvekin	21 kD	IL11	Megakaryocyte	Chemotherapy-associated thrombocytopenia

EPO, erythropoietin; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor. See text for hematopoietic growth factors approved by the U.S. Food and Drug Administration for one or more clinical applications in cancer patients.

TABLE 53.4-1. Major Hematopoietic Growth Factors in Clinical Use for Cancer Treatment

### OVERVIEW OF HEMATOPOIETIC GROWTH FACTORS

All the formed elements of the blood—leukocytes, erythrocytes, and platelets—are derived from multipotent stem cells found primarily in the marrow. Because the life span of blood cells is relatively short, large numbers of cells need to be replenished daily, and this daily requirement may be further increased by bleeding or acute infection. Most of the stem cells are not actively cycling, and it is thought that hematopoiesis is maintained by the activity of only a small fraction of the total stem cell pool at any given point in time. As these cells mature, however, they become progressively more committed to a single lineage, creating a series of “progenitor” cells that are actively proliferating and very sensitive to regulation by HGFs. Interestingly, recent studies have identified stem cells with hematopoietic potential in other tissues, including brain and muscle.<sup>1</sup> The significance of these cells and their potential for clinical development is of considerable interest.

There has been a dramatic increase in the knowledge of the regulation of hematopoiesis as the genes for individual HGFs have been cloned and recombinant proteins produced (Table 53.4-2). The existence of HGFs has been recognized for more than 35 years but, before cloning of HGF genes, they could be studied only as partially purified “activities” secreted by activated normal cells or certain cancer cell lines. The large number of cytokines now believed to be involved in potentially regulating hematopoiesis and the complexity of that regulation were unanticipated, and the remarkable history of the development of this field has been extensively reviewed.<sup>2,3,4,5,6,7,8</sup> and <sup>9</sup> Some factors, such as Steel factor and Flt3 ligand, appear to have effects predominantly on stem and progenitor cells and minimal effects on more mature cells. In contrast, more lineage-restricted factors, such as EPO and G-CSF, have prominent effects on progenitor cells and mature cells and minimal effects on stem cells.

Factor	Gene Name	Chromosomal Location	Gene Location	Approved Cancer Application?
Erythropoietin (EPO)	EPO	19p13	19p13	Yes
Granulocyte colony-stimulating factor (G-CSF)	CSF3	10q24	10q24	Yes
Granulocyte-macrophage colony-stimulating factor (GM-CSF)	CSF2	5q31	5q31	Yes
Interleukin-11 (IL-11)	IL11	11p15.5	11p15.5	Yes
Thrombopoietin (TPO)	TPO	3p21.3	3p21.3	No
Flt3 ligand (Flt3L)	FLT3L	12p13.31	12p13.31	No

TABLE 53.4-2. Selected Hematopoietic Growth Factors and Other Cytokines in Clinical Development for Applications in Cancer Therapy

It is likely that a baseline production of growth factors maintains hematopoiesis in a steady state. Many HGFs are secreted by cells in the marrow microenvironment and may be concentrated either on the cell surface of stromal cells or on extracellular matrix proteins in the marrow. One exception to this is the apparently exclusive production of EPO outside the marrow, in the kidney and liver. In emergency situations, HGFs can be produced in many tissues. For example, keratinocytes, fibroblasts, and endothelial cells can produce large amounts of G-CSF, GM-CSF, IL-1, and others in response to inflammation or other types of activation. Interestingly, some HGFs circulate in detectable levels in the blood, while many others do not. The serum concentrations of EPO, G-CSF, and TPO vary inversely with red cell oxygen-carrying capacity, neutrophil count, and platelet count, respectively. However, except for EPO, the mechanisms to “sense” the need for increased synthesis of a specific cytokine *in vivo* are not well understood. In the case of bacterial infections, certain bacterial cell wall products, such as lipopolysaccharides, are potent inducers of G-CSF synthesis by macrophages and other cells. In addition, a number of cytokines associated with an acute immune response, such as interferon- $\gamma$  and tumor necrosis factor, will induce secretion of G-CSF and GM-CSF by a variety of other cells. Other factors, such as GM-CSF and IL-3, rarely circulate in detectable levels even during severe neutropenia.

New insights into cytokine biology have been recently obtained by studying mice engineered to lack one or more cytokines. These knockout mice have provided information in some cases that challenges hypotheses of cytokine function based on many years of tissue culture studies.<sup>8,10,11</sup> For example, mice deficient in GM-CSF production are not leukopenic and, in fact, have so far been found to have only a pulmonary defect that resembles pulmonary alveolar proteinosis.<sup>12</sup> Similarly, mice deficient in IL-3 have normal production of granulocytes, red cells, and platelets but have defects in mast cells and certain immune responses.<sup>13,14</sup> Mice with natural mutations in the macrophage colony-stimulating factor or colony-stimulating factor-1 (CSF-1) gene have reduced macrophage number and severe osteopetrosis. Other cytokine-deficient mice also have significant hematopoietic defects. Mice that are deficient in G-CSF,<sup>15</sup> EPO,<sup>16</sup> and TPO<sup>17</sup> are selectively neutropenic, anemic, and thrombocytopenic, respectively. Steel factor-deficient mice may be severely anemic, depending on the exact mutation.<sup>18,19</sup> Overall, these emerging results further suggest that the cytokine network that regulates hematopoiesis is complex, with overlapping and redundant functions for some factors and unclear functions for other factors. To investigate these possibilities, mice deficient in multiple factors are now being studied. These mice will likely provide further insights into the critical events of hematopoietic regulation.<sup>20</sup>

## BIOLOGIC FEATURES OF THE MAJOR HEMATOPOIETIC GROWTH FACTORS IN CLINICAL USE

### ERYTHROPOIETIN

EPO is the primary regulator of the late stages of red cell production, and both humans and mice deficient in EPO production develop severe anemia. The biology and pharmacology of EPO have been reviewed extensively.<sup>21,22,23,24</sup> and <sup>25</sup> The EPO gene is located on human chromosome 7q11-22, and the cDNA was cloned in 1984.<sup>26,27</sup> and <sup>28</sup> The mature protein contains 165 amino acids and has a molecular weight of 30,400 daltons. EPO is produced in the kidney in response to hypoxia or decreased oxygen-carrying capacity of the blood. The mechanism is still not completely understood, but it is clear that transcription of the EPO gene is regulated in part by a pathway that involves an oxygen-binding heme protein.<sup>29</sup> Occasional patients present with erythrocytosis secondary to either a renal tumor causing local hypoxia related to compression or, more rarely, secondary to secretion of EPO by the tumor.

EPO binds to bone marrow cells expressing the EPO receptor and stimulates proliferation of erythroid colony-forming cells and a subset of less mature burst-forming units. Cloning of the EPO receptor was reported in 1989,<sup>30</sup> and it was shown to be a single-chain transmembrane protein that is believed to function as either a monomer or homodimer. The receptor is a member of the HGF receptor superfamily and shares homology with the receptors for G-CSF, GM-CSF, IL-2, TPO, and other cytokines.<sup>31,32</sup> Interestingly, the receptor interacts with the gp55 protein of the Friend erythroleukemia virus, and the resulting activation of the EPO receptor is involved in causing erythroleukemias of mice.<sup>33,34</sup> and <sup>35</sup> In addition, other recent studies with the Friend erythroleukemia virus suggest that the EPO receptor may also interact with a transmembrane tyrosine kinase termed *Ron/stk*. Mutations in the distal end of the EPO receptor are associated with familial erythrocytosis<sup>36,37</sup> and <sup>38</sup> but have not yet been associated with human erythroleukemias.

The serum concentration of EPO in normal individuals is approximately 4 to 30 U/L, and the half-life of recombinant EPO administered intravenously in humans is 9 to 13 hours. Serum EPO levels reproducibly start to rise as the hematocrit drops below approximately 35% and can increase 100- to 1000-fold with severe anemia. In cancer patients with chronic anemias, the EPO level is often inappropriately low.<sup>39,40</sup> The clinical indications for EPO treatment are described in detail later in the section [Treatment of Anemia in Cancer Patients](#). In cancer patients, EPO treatment is indicated for chemotherapy-associated anemia not due to other causes (iron deficiency, marrow involvement with tumor, etc.) and is most likely to have benefit if the serum EPO level is abnormally low.

Toxic effects of EPO in cancer patients are generally minimal. The hypertension and thrombotic events seen in patients with chronic renal failure treated with EPO are rarely seen in cancer patients with normal renal function. Monitoring of hematocrit is required to avoid erythrocytosis.

### GRANULOCYTE COLONY-STIMULATING FACTOR

G-CSF (filgrastim, lenograstim) regulates the production, maturation, and function of cells of the neutrophil lineage.<sup>8,41,42</sup> and <sup>43</sup> G-CSF was initially investigated in the mouse as a factor with potent capacity to differentiate myeloid leukemia cell lines and was later purified from mouse lung-conditioned medium.<sup>44</sup> Human G-CSF was purified from medium conditioned by bladder and head and neck cancer cell lines, and the gene was then cloned.<sup>45,46</sup> The human gene is located on chromosome 17q11-21 and encodes a mature polypeptide of 175 amino acids with a molecular weight of 18,800 daltons. In tissue culture studies, G-CSF induces proliferation and differentiation of cells of the neutrophil lineage. In the mouse, knockout of the G-CSF gene produces severe neutropenia but has minimal effect on other lineages.<sup>15</sup> Hammond et al.<sup>47</sup> have also shown that dogs induced to form neutralizing anti-antibodies to G-CSF become profoundly neutropenic.<sup>47</sup> G-CSF may also enhance several functions of neutrophils, but the significance of this observation is unknown. Overall, it is clear that G-CSF is critically involved in regulating neutrophil production.

G-CSF is produced by many different cell types, and expression of G-CSF can be rapidly induced by exposure of epithelial cells, macrophages, endothelial cells, and marrow stromal cells to inflammatory stimuli, particularly endotoxin. Unlike many other hemopoietins, there is readily detectable G-CSF in the serum of normal individuals, with a typical range of 20 to 100 pg/mL. The serum level varies inversely with neutrophil concentration in the blood, and in bacteremic, neutropenic patients, serum levels can exceed 2000 pg/mL.

The receptor for G-CSF is widely expressed, not only on myeloid lineage cells but on endothelial cells and epithelial cancer cell lines. The function of nonhematopoietic G-CSF receptors is not clear, however. The receptor for G-CSF is a member of the cytokine receptor superfamily<sup>48,49</sup> and is composed of a single known transmembrane protein of approximately 100 kD molecular weight. Mutations in the cytoplasmic domain of the receptor have recently been demonstrated in a small number of patients with congenital neutropenia and acute myeloblastic leukemia.<sup>50</sup> The mutations truncate the receptor, possibly removing a domain involved in the differentiation-inducing function of G-CSF.<sup>50</sup> Function of the truncated receptor in murine models suggests that the receptor may be activated to an excessive level by G-CSF.<sup>51</sup>

Administration of G-CSF to humans results in a dose-dependent increase in circulating neutrophils accompanied by expansion of the myeloid components in the marrow and accelerated production of neutrophils due to reduced transit time from stem cell to mature neutrophil. The fraction of myeloid progenitor cells in S-phase in the marrow is increased, and there is some suggestion that G-CSF enhances entry of quiescent stem and progenitor cells into the cell cycle. Neutrophils produced in response to G-CSF therapy have been shown to be functionally normal in terms of standard assays for phagocytosis and activation of the respiratory burst and further appear to have normal function *in vivo*. Marrow aspirates performed on patients receiving G-CSF or other myeloid growth factors may show a striking left shift, and circulating neutrophils have interesting morphologic changes consistent with activation, including Döhle's inclusion bodies, toxic granulation, and an increase in band forms. The elimination half-life of G-CSF in the serum is in the range of 1.3 to 4.2 hours but appears to vary with neutrophil mass, suggesting that neutrophils may contribute to metabolizing the cytokine.<sup>52</sup>

Toxic side effects of G-CSF in humans have been generally mild. Some patients experience bone pain during administration, but fever and weight gain are rare. Chronic administration of G-CSF has been associated with benign splenomegaly,<sup>53</sup> presumably due to extramedullary hematopoiesis. Bone scan abnormalities have also been reported, including an apparent “flare” of metastatic bone lesions and increased uptake in the axial skeleton or juxtaarticular regions.<sup>54</sup> In many patients, there is an acute response to intravenous injections of G-CSF characterized by abrupt, but transient, neutropenia.<sup>55</sup> Occasionally, patients will have transient dyspnea

and pulmonary infiltrates on chest radiography. In patients with underlying severe pulmonary disease, these effects can be clinically significant.<sup>56</sup> The acute neutropenia is believed to be due to up-regulation of neutrophil adhesion receptors followed by either intravascular aggregation or margination, and is generally not seen with subcutaneous administration.<sup>55,57</sup> In patients with normal marrow function, prolonged administration of G-CSF can lead to very high neutrophil counts, and it is recommended that in most cases, G-CSF should be discontinued or dose-reduced when the neutrophil count exceeds 10,000 cells/mL. Once G-CSF is discontinued, the absolute neutrophil count typically falls by approximately 50% per day and will return to baseline in 4 to 6 days. Careful studies in normal volunteers have also shown that some alterations of blood chemistries are common but of no apparent clinical consequence.<sup>58</sup>

## GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR

GM-CSF (sargramostim, molgramostim) is a potent growth factor for the myeloid lineage in tissue culture and was cloned by Wong et al.<sup>59</sup> GM-CSF is a glycoprotein with an approximate molecular weight of 22,000 daltons, and the gene has been localized to chromosome 5q31 in close proximity to the gene for IL-3.<sup>60</sup> GM-CSF can be produced by many cells in the body, particularly by activated T cells. Recombinant or purified natural GM-CSF stimulates granulocyte-macrophage and eosinophil colony formation and cooperates with EPO to stimulate growth of erythroid bursts. GM-CSF also stimulates the activity of multiple neutrophil functions and primes these cells to respond more vigorously to other stimuli.<sup>61,62</sup> Changes in expression of neutrophil adhesion molecules are particularly prominent, including up-regulation of the beta-2 integrin CD11/CD18 both *in vitro* and *in vivo*.<sup>63</sup>

A mouse in which the GM-CSF gene has been knocked out does not have demonstrable defects in hematopoiesis but develops a severe lung disorder similar to pulmonary alveolar proteinosis.<sup>12,64</sup> Interestingly, patients with this disorder have been shown to have defects in expression, function, or mutations in the beta chain of the receptor for GM-CSF.<sup>65,66</sup> Receptors for GM-CSF are normally found on both hematopoietic and nonhematopoietic cells, including endothelial cells and some tumor cell lines, such as melanoma and lung cancer cells. The function of these receptors, if any, on nonhematopoietic cells is unclear. The receptor is a heterodimer, composed of a ligand-binding alpha chain and a beta chain necessary for high-affinity binding and signal transduction. The alpha chain uniquely binds GM-CSF, but the same beta chain is also used by the receptors for IL-3 and -5.

Administration of GM-CSF to humans results in a dose-dependent increase in blood neutrophils, eosinophils and, to a lesser extent, macrophages and sometimes lymphocytes. This is accompanied by a dramatic left shift in the myeloid series in the marrow. There is no significant effect on the red cell or platelet lineages. The toxic effects of GM-CSF have been evaluated extensively. If given intravenously in particular, the first dose of GM-CSF may be accompanied by acute but self-limited neutropenia thought to be due to up-regulation of adhesion receptors on neutrophils.<sup>55</sup> Occasional patients may experience brief dyspnea. Many patients experience a low-grade fever, myalgias, and fatigue. At high doses, weight gain, pericarditis, pleuritis, and a capillary leak syndrome may develop,<sup>67</sup> but this is rare at doses in current use. The activities and toxicities of GM-CSF and G-CSF have been directly compared in very few studies. In a randomized study after autologous stem cell transplantation for breast cancer, the efficacy and toxicities of the two factors were equivalent.<sup>68</sup>

There are several formulations of recombinant GM-CSF available, including yeast-derived (sargramostim) and *Escherichia coli*-derived (molgramostim) versions. At present, various formulations of GM-CSF seem to have similar biologic effects. Sargramostim is glycosylated and therefore has a lower specific activity than Molgramostim (because of its higher molecular weight). Manufacturer's directions should be read carefully when changing between formulations of GM-CSF. The recommended dosing for sargramostim is 250 mg/m<sup>2</sup>/d in patients receiving chemotherapy. Subcutaneous administration is generally preferred over short-term intravenous administration, due to reduced toxicity and equivalent efficacy. However, if clinically indicated, intravenous administration of GM-CSF is acceptable.

## CLINICAL APPLICATIONS OF HEMATOPOIETIC GROWTH FACTORS IN CANCER THERAPY

### TREATMENT OF ANEMIA IN CANCER PATIENTS

#### Pathophysiology

Anemia in cancer patients is common and may contribute significantly to quality of life. Anemia can be multifactorial in the cancer patient and can be caused by blood loss, iron or vitamin deficiency, chemotherapy, radiation to the marrow, stem cell damage, hemolysis, hypersplenism, drug toxicity, or tumor involvement of the marrow. An entity known as *anemia of cancer* has been described but may be multifactorial and is likely related to anemia of chronic disease. In both anemias, EPO production is inadequate for the degree of anemia.<sup>69</sup> There may also be an impaired response to EPO by marrow progenitor cells. Stem cell depletion may be more common than generally appreciated because of increasing use of higher doses and repeated courses of chemotherapy and radiation. Radiation involving the pelvis or spine is particularly problematic because of the large volume of marrow in those bones.

#### Clinical Trials with Erythropoietin

Use of EPO in anemia associated with cancer has been extensively investigated.<sup>70,71</sup> and <sup>72</sup> Trials have been conducted in patients with anemia due to marrow involvement with lymphoproliferative disorders<sup>73</sup>; in those with myelodysplastic syndromes (MDSs) or solid tumors; in those developing anemia after chemotherapy,<sup>74,75</sup> and <sup>76</sup> autologous transplantation,<sup>77</sup> allogeneic transplantation,<sup>78</sup> or radiation therapy<sup>79</sup>; and in those with anemia of cancer. The rates of response, generally defined as an increase in hemoglobin or a decrease in transfusion requirements (or both), are fairly high in most groups of patients, typically in the range of 50%.<sup>76,80,81,82</sup> and <sup>83</sup> Lack of response correlates with high pretreatment serum level of endogenous EPO. Patients who have an increase in hemoglobin of more than 0.5 g/dL within 2 weeks have a high likelihood of a sustained response.<sup>84</sup> The benefit of EPO treatment with cyclical chemotherapy has been confirmed in several randomized, placebo-controlled multicenter trials, and response has been associated with improved performance status and quality of life.<sup>85</sup> However, despite the high response rate and the apparent reduction in transfusions, EPO therapy is expensive, and careful selection of patients most likely to benefit is warranted.<sup>86</sup>

Subcutaneous EPO administration three times weekly appears to be at least as effective as daily intravenous administration. Higher doses are not clearly better than lower doses, but there is a threshold effect, and intravenous doses less than 100 U/kg and subcutaneous doses less than 50 U/kg may be associated with lower response rates. A reasonable approach would be 50 to 150 U/kg three times weekly by subcutaneous injection, which could be increased to 300 U/kg after 6 weeks without response. Interestingly, late responses are fairly common, and nine weeks of therapy or more may be required in some responding patients. Since many patients fail to respond even to higher levels of EPO, there has been considerable interest in predicting early in the course of treatment which patients are not likely to respond. Several algorithms have been generated and suggest that failure to increase hemoglobin by more than 0.5 g/dL or serum ferritin by more than 400 ng/mL after 2 weeks of treatment predicts for failure.<sup>84,87</sup> Iron deficiency will prevent response to EPO and should be considered in selected nonresponsive patients.<sup>88</sup> Finally, most studies so far have involved concurrent administration of EPO with chemotherapy. Other schedules in which EPO is given before or at the end of chemotherapy are being investigated.

**CISPLATIN -ASSOCIATED ANEMIA.** Approximately 40% of patients receiving cisplatin chemotherapy develop anemia, and many will require transfusion. Studies of EPO administration to treat cisplatin-induced anemia have generally been positive, even in elderly patients.<sup>81,82,89</sup> Henry and Abels<sup>76</sup> performed three randomized double-blind, placebo-controlled trials of EPO for anemic cancer patients not receiving concomitant chemotherapy, patients receiving chemotherapy that did not include cisplatin, and patients receiving cisplatin-containing chemotherapy. Patients not receiving chemotherapy received 100 U/kg three times weekly, while those on chemotherapy received 150 U/kg three times weekly. Overall, the trials involved 413 patients. Patients receiving EPO in all three trials had a statistically significant increase in hematocrit as compared to placebo-treated patients.<sup>76</sup> Quality of life improved significantly for EPO-treated patients, with an overall response rate of approximately 50% in all three groups. Similar results were reported by Cascinu et al.,<sup>74</sup> who performed a randomized, double-blind trial with EPO versus placebo in 100 patients with cisplatin-associated anemia (hemoglobin <90 g/L), administering EPO at 100 U/kg subcutaneously thrice weekly. After 9 weeks of therapy, the mean hemoglobin levels of the EPO-treated group were statistically different from placebo patients: EPO patients went from a baseline of 86.3 ± 6.2 g/dL to 105.1 ± 9.4 g/dL at 9 weeks, while placebo patients went from a baseline of 87.3 ± 5.2 g/dL to 81.2 ± 11 g/dL at 9 weeks. Also, only 20% of EPO-treated patients required blood transfusion versus 56% of placebo-treated patients. No significant side effects of EPO treatment were encountered. Another multicenter, double-blind, placebo-controlled trial was conducted by Case et al.,<sup>75</sup> who randomly assigned 153 anemic cancer patients receiving cyclic chemotherapy to EPO, 150 U/kg three times weekly, or placebo. EPO-treated patients had a statistically significant increase in hematocrit and a trend toward lower transfusion requirements. Again, no significant side effects were encountered. Also, ten Bokkel Huinink et al.<sup>90</sup> randomly chose 122 ovarian cancer patients receiving platinum-based chemotherapy to EPO or control arms, and demonstrated a significant reduction in transfusion requirement. Overall, these multiple, randomized, controlled trials indicate that EPO is safe and effective for therapy of both chemotherapy-associated and non-chemotherapy-associated chronic anemias in patients with solid tumors. Treatment reduces need for transfusion and improves quality of life for many patients.<sup>91</sup> Recently, EPO therapy in children receiving cisplatin-based therapy has also been shown to

reduce the need for transfusions.<sup>92</sup>

**ANEMIAS ASSOCIATED WITH MYELODYSPLASTIC SYNDROMES.** The role of EPO in treating anemia associated with hematologic malignancies is somewhat less clear, particularly for the anemia of MDS. Most studies reported to date are uncontrolled and have included only small numbers of patients.<sup>93,94,95,96,97,98,99</sup> and <sup>100</sup> The response rates tend to be more than 25%, although a few patients will respond to higher doses of EPO.<sup>101</sup> A metaanalysis of 205 patients with an MDS from 17 different studies found an overall response rate of only 16%, with a particularly low response rate—7.5%—in patients with refractory anemia with ringed sideroblasts. Factors that predicted for a low response rate were transfusion dependence, high serum EPO, and refractory anemia with ringed sideroblasts. Several studies have looked at sequential or combined use of a myeloid growth factor with EPO,<sup>101,102,103</sup> and <sup>104</sup> but responses are not clearly higher with the doses and schedules studied so far. As is the case for the anemia of cancer, late EPO responses may be observed,<sup>105</sup> necessitating long courses of therapy in clinical trials. At present, EPO appears to benefit only a small number of patients with MDS, primarily patients with low serum EPO levels and minimal transfusion requirement. In recent studies, the combined use of EPO with G-CSF has been encouraging, with a higher fraction of patients responding to the combination.<sup>106,107</sup>

**BONE MARROW TRANSPLANTATION.** The available data suggest that EPO treatment may be useful for treatment of anemia associated with allogeneic bone marrow transplantation, but is not clearly useful as an adjunct for autologous transplantation.<sup>108</sup> Several randomized, controlled studies have compared EPO versus placebo after autologous or allogeneic transplantation.<sup>78,109,110</sup> Biggs et al.<sup>78</sup> gave EPO (300 U/kg intravenously three times weekly) or placebo to 91 patients undergoing allotransplantation. There was no reduction in red blood cell or platelet transfusion requirement and no reduction in hospital stay.<sup>78</sup> Link et al.<sup>109</sup> randomly selected 107 patients undergoing allotransplantation to EPO (150 U/kg/d by continuous intravenous infusion) or placebo until patients reached 7 days of transfusion independence or day 41.<sup>109</sup> The time to transfusion independence was reduced by EPO from 27 days to 19 days, but the number of transfusions required in the pertransplantation period was similar. EPO-treated patients had a somewhat smaller transfusion requirement from days 42 to 100. The same authors conducted a randomized trial of identical design with 57 patients undergoing autologous transplantation.<sup>109</sup> No difference in transfusion requirement was observed. Chao et al.<sup>110</sup> conducted a placebo-controlled trial of EPO (600 U/kg three times weekly) starting 3 weeks before autologous bone marrow transplantation in 35 patients with lymphoma.<sup>110</sup> All patients also received G-CSF after marrow reinfusion. No differences were observed in transfusion requirement or hematopoietic recovery. Similar results were reported when EPO was combined with GM-CSF in a nonrandomized study of autologous marrow transplantation with historical controls.<sup>111</sup> However, other recent studies have suggested a benefit in combining EPO with G-CSF after transplantation.<sup>112</sup> Another potential use of EPO is in the treatment of late-onset anemia after transplantation, concerning which encouraging pilot studies have been presented.<sup>113</sup> Overall, EPO has been of modest benefit in the allogeneic marrow transplantation setting.

Overall, EPO has an important role in the therapy of anemia in some cancer patients. In the individual cancer patient, the clinician needs to look carefully for treatable causes of anemia, such as iron deficiency or blood loss and to consider the underlying illness and other factors, such as the serum EPO level, to determine whether a course of EPO treatment is warranted.

## REDUCTION OF CHEMOTHERAPY-ASSOCIATED NEUTROPENIA

### *Myelosuppression Associated with Standard-Dose Chemotherapy*

Neutropenia and infection are major causes of morbidity and mortality in cancer patients and are dose-limiting for many types of chemotherapy. It is standard practice to treat all neutropenic, febrile patients with broad-spectrum antibiotics, even though many patients do not have documented infections. This adversely affects quality of life, increases hospital costs, and often results in reduction of chemotherapy doses for subsequent cycles. Reducing the incidence of febrile neutropenia and infection are major goals of CSF therapy in this setting.

**GRANULOCYTE COLONY-STIMULATING FACTOR.** G-CSF has been extensively investigated in clinical trials as an adjunct to cancer chemotherapy, and its use in this setting has been extensively reviewed.<sup>114,115,116</sup> and <sup>117</sup> The initial phase I and phase II studies in bladder cancer and small cell lung cancer patients established that G-CSF administration by either subcutaneous or intravenous routes caused a dramatic, dose-dependent increase in blood neutrophil counts. Data from numerous phase I and phase II studies predicted that administration of G-CSF after standard-dose, myelosuppressive chemotherapy would shorten the duration of neutropenia, but it was not clear from these early trials whether this would translate into clinical benefit. The efficacy of G-CSF has now been established in a series of randomized, controlled clinical trials in which the chemotherapy was sufficient to cause febrile neutropenia in more than 40% of the control group. A pivotal trial was conducted by Crawford et al.,<sup>118</sup> who randomly chose patients with small cell lung cancer to receive G-CSF or placebo after a myelosuppressive regimen containing cyclophosphamide, doxorubicin, and etoposide (CAE). The incidence of febrile neutropenia was significantly reduced in patients receiving G-CSF. Further, length of hospital stay, incidence of confirmed infections, and days of antibiotic use were reduced by approximately 50%.<sup>118</sup> The results of this study have been confirmed by several additional randomized, controlled phase III studies (small cell lung cancer patients receiving CAE chemotherapy<sup>119</sup>; non-Hodgkin's lymphoma patients receiving vincristine, doxorubicin, prednisolone, etoposide, cyclophosphamide, and bleomycin<sup>120</sup>; and patients with various types of cancer receiving several different chemotherapy regimens<sup>121</sup>). In none of these randomized studies was there a clear difference in mortality, tumor response rate, or survival. Thus, despite the fact that some epithelial tumor cells express G-CSF receptors, there does not appear to be any adverse effect of G-CSF on tumor growth when given with chemotherapy. In these randomized studies, the toxicity of G-CSF has been minimal and was generally limited to medullary bone pain that can usually be relieved with analgesics.

The timing of G-CSF after chemotherapy has been investigated in patients receiving melphalan (25 mg/m<sup>2</sup>).<sup>57</sup> Delaying administration to 8 days after completion of chemotherapy appeared to be somewhat less effective than immediate administration, and it is now general practice to start G-CSF 24 to 48 hours after completing chemotherapy administration, typically continuing until the neutrophil count has recovered to 10,000/mL. However, administration of G-CSF for a defined period of only 7 days had benefit.<sup>57</sup> Also, there is considerable interest in evaluating G-CSF schedules with lower doses than the standard 5 mg/kg/d. In a randomized trial, Toner et al.<sup>122</sup> found that 2 mg/kg/d was as effective as 5 mg/kg/d in reducing the duration and severity of chemotherapy-related neutropenia. Also, shorter courses of G-CSF therapy are being investigated.<sup>123</sup>

**GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR.** Administration of GM-CSF after standard-dose chemotherapy has also been extensively evaluated. In phase I and phase II studies where GM-CSF was administered in alternate cycles, shortening of the duration of neutropenia has been observed.<sup>67</sup> In larger, randomized, placebo-controlled studies, however, benefit has in some cases been limited to subsets of patients.<sup>124,125</sup> and <sup>126</sup> In one randomized study in patients with small cell lung cancer receiving CAE chemotherapy, GM-CSF reduced the duration of neutropenia but not the incidence of febrile neutropenia, days in hospital, or antibiotic use. Similarly, in a randomized trial of GM-CSF in patients with germ cell cancer receiving vinblastine, ifosfamide, and platinum, no significant beneficial effects were seen.<sup>124</sup> When given with 21 days of oral etoposide, GM-CSF did not significantly reduce neutropenia or neutropenic complications in a randomized study in patients with advanced cancers.<sup>127</sup> However, in a randomized study of fluorouracil, doxorubicin, and cyclophosphamide therapy in 142 patients with breast cancer, GM-CSF reduced the median duration of severe neutropenia (absolute neutrophil count <500/mL) to 2.8 days as compared to 6.8 days with placebo ( $P < .001$ ) and reduced the duration of an absolute neutrophil count less than 1000/mL to 6.0 versus 9.1 days, respectively.<sup>128</sup> In children with solid tumors, GM-CSF reduced the duration of neutropenia but not the rate of febrile neutropenia.

There are very few studies in which the activities of GM-CSF and G-CSF have been directly compared. In one randomized study comparing these two growth factors after cyclophosphamide (7 g/m<sup>2</sup>), patients treated with G-CSF recovered neutrophils slightly more rapidly, but patients treated with GM-CSF recovered platelets more rapidly; overall, both GM-CSF and G-CSF were thought to be effective.<sup>129</sup>

### *Concurrent Administration of Growth Factors with Chemotherapy or Radiation Therapy*

Although the number of relevant studies is small, there is concern that simultaneous administration of GM-CSF or G-CSF with chemotherapy or radiation may lead to serious toxicity.<sup>130</sup> In a randomized trial in limited-stage small cell lung cancer patients receiving platinum, etoposide, and chest radiation, patients receiving GM-CSF had more thrombocytopenia, more toxic deaths, more antibiotic use, and longer hospital stays.<sup>131</sup> Similarly, patients with non-small cell lung cancer given G-CSF with cisplatin, etoposide, and radiation therapy had worse thrombocytopenia than controls.<sup>132</sup> Concern has also been raised about continuing G-CSF up to less than 48 hours before the next cycle of chemotherapy.<sup>133</sup> In contrast, concurrent administration of G-CSF with weekly cycles of dose-intensive vinorelbine did not lead to an apparent increase in myelosuppression.<sup>134</sup> However, until more information is available, concurrent administration of myelosuppressive chemotherapy with growth factors should remain investigational, and the special situation where both chemotherapy and radiation therapy are given concurrently with a growth factor should be avoided.

In some, but not all, of these studies, hospital stay, antibiotic use, infections, or platelet transfusions were also reduced. There has been no evidence of reduced mortality or increase in tumor response rates. In studies with autologous, mobilized blood stem cells, G-CSF also reduces the duration of neutropenia, but the overall impact on the transplant procedure may be less than when marrow stem cells are used for the transplantation.<sup>160,161</sup> Interestingly, administration of G-CSF after blood stem cell autologous transplant can be delayed for several days without loss of efficacy.<sup>162</sup> In children, the use of G-CSF after autologous blood transplantation is controversial.<sup>163</sup> In studies with allogeneic marrow transplantation, addition of a CSF tended to reduce neutropenia, but infection rate and hospital stay have not been consistently reduced.<sup>117,164,165,166,167,168,169,170 and 171</sup> The use of GM-CSF after blood stem cell transplantation has shown only marginal benefit.<sup>172</sup>

The potential use of growth factors for treatment of graft failure or delayed engraftment after either autologous or allogeneic transplantation has been explored to a limited extent, and results are encouraging for both GM-CSF and G-CSF.<sup>173,174,175,176,177,178 and 179</sup> It is clear that while not all patients will respond, neutrophil counts can be rapidly increased in many cases. Combining GM-CSF and G-CSF in a sequential manner did not improve results over GM-CSF alone.<sup>174</sup> In many cases, retransplantation with growth factor–mobilized blood stem cells has been of great value.<sup>180</sup>

### **Mobilization of Peripheral Blood Progenitor Cells by Hematopoietic Growth Factors**

One of the most remarkable effects of G-CSF and GM-CSF is transient mobilization of hematopoietic progenitor and stem cells into the peripheral blood. This unexpected phenomenon was first noted during early phase I studies with GM-CSF<sup>181</sup> and G-CSF<sup>182</sup> and has now been observed with several other cytokines, such as IL-3<sup>183</sup> and even EPO.<sup>184</sup> The effects of either GM-CSF or G-CSF appear to be independent and additive to the effects of myelosuppressive chemotherapy<sup>181</sup> and, in some circumstances, mobilization with growth factor is as good as with a combination of growth factor and cyclophosphamide.<sup>185</sup> The concentration of progenitor cells in the blood of normal individuals is too low to render harvesting of these cells practical. GM-CSF or G-CSF increases progenitor cell concentration approximately tenfold and, when administered after some types of chemotherapy, such as high-dose cyclophosphamide,<sup>186</sup> the increase in blood progenitor cell concentration can be 100-fold or more. However, interpatient variability is substantial, and mobilization is generally reduced in patients with extensive prior exposure to chemotherapy or radiation, particularly to the pelvis. Nonetheless, GM-CSF-mobilized or G-CSF-mobilized progenitor cells can be collected from most cancer patients by leukapheresis in sufficient quantity to replace marrow harvests for autologous transplantation protocols. The mobilized cells may be more immature than the progenitor cells that are resident in the blood of untreated individuals.<sup>187</sup> Patients receiving peripheral blood progenitor cells tend to reconstitute earlier and to require fewer platelet transfusions than patients receiving autologous marrow.<sup>188</sup> As a result, using GM-CSF or G-CSF to assist in mobilizing progenitor cells has become used in autologous transplantation protocols for many different tumors.<sup>186,189,190,191,192 and 193</sup> G-CSF–mobilized or GM-CSF–mobilized peripheral blood progenitor cells also offer advantages in allogeneic transplantation.<sup>194</sup> In this situation, no chemotherapy is administered, but collection of adequate amounts of progenitor cells with several episodes of leukapheresis is well tolerated by normal donors.<sup>195</sup> Reconstitution is prompt and durable,<sup>196,197 and 198</sup> and preliminary results of a randomized trial comparing allogeneic marrow with blood stem cells favors the blood source.<sup>199</sup> Recent studies suggest that combinations of cytokines may be more effective than single cytokines. Winter et al.<sup>200</sup> compared the mobilizing effects of GM-CSF and G-CSF, either alone or in various combinations, including adding G-CSF for 5 days after 7 days of GM-CSF and adding GM-CSF after 7 days of G-CSF. When used individually, GM-CSF and G-CSF administration resulted in mobilization of approximately the same number of progenitor cells, approximately a 35-fold increase over pretreatment values.<sup>200</sup> Administration of G-CSF to patients already receiving GM-CSF resulted in an increase to approximately 80-fold over baseline. Interestingly, the combination of G-CSF and stem cell factor may have particularly good ability to mobilize stem cells, and a number of studies are ongoing with this combination.<sup>201,202</sup> Thus, cytokine combinations may be more efficacious than single cytokines for mobilization, and other combinations and schedules should be tested.

Most studies using cytokine-mobilized peripheral blood progenitor cells have also given G-CSF or GM-CSF after transplant to accelerate reconstitution. This approach seems reasonable at present in autologous transplantation, but additional studies are needed in allogeneic transplants of blood stem cells. The hematopoietic reconstitution observed after peripheral blood progenitor cell transplantations may be sufficiently fast so that the cost-effectiveness of G-CSF or GM-CSF will need to be carefully evaluated.

Tumor cell contamination of progenitor cells collected from the blood could limit the success of these products for autologous transplantation, as is the case for autologous marrow transplantation.<sup>203,204,205 and 206</sup> Recent efforts to reduce tumor cell contamination have focused on either immunologic purging of contaminating tumor cells or positive selection of progenitor cells using the CD34 cell surface marker.<sup>205,207,208</sup> In general, mobilized stem cell products have a high likelihood of containing tumor cells.<sup>209</sup>

### **Ex Vivo Expansion of Hematopoietic Progenitor Cells**

One area of active research is the potential use of growth factors to permit *ex vivo* expansion of either marrow or blood stem cells. When partially purified stem cells are cultured with mixtures of growth factors, typically containing Steel factor and a variety of HGFs, substantial expansion of progenitor cells has been observed. However, currently only limited expansion of hematopoietic stem cells has been achieved, and there is the potential that there will not be enough true hematopoietic stem cells to effect long-term permanent reconstitution if these expanded populations are used in transplantation settings. It is possible that there are yet unknown cytokines that will induce stem cell proliferation while inhibiting differentiation, and such cytokines might be ideal for this process. Alternatively, expanded progenitor cells may have some uses, even if the stem cell content is decreased. For example, progenitor cells may be useful to accelerate hematopoietic recovery after myelosuppressive, but not myeloablative, chemotherapy regimens.

## **TREATMENT OF LEUKEMIAS**

### **Acute Myelogenous Leukemia**

Infection related to neutropenia remains a major cause of morbidity and mortality during all phases of the treatment of acute myelogenous leukemia (AML), and any reduction of chemotherapy- or disease-associated neutropenia could be beneficial. The use of GM-CSF and G-CSF in AML therapy has been approached with justifiable caution, however, since both of these cytokines are excellent growth factors for leukemia cells *in vitro*, and there remains concern that these factors could either accelerate leukemic cell growth, reduce chemotherapy response, or enhance toxicity. AML cells from most patients have receptors for both GM-CSF and G-CSF,<sup>210,211 and 212</sup> and both factors induce rapid proliferation of leukemic cells without any evidence of terminal differentiation. Thus, administration of either factor carries the risk of promoting leukemic cell proliferation. In the small number of clinical trials conducted so far, however, administration of G-CSF or GM-CSF immediately after standard chemotherapy has not been associated with leukemic cell regrowth or early relapse. Ohno et al.<sup>213</sup> randomly assigned a heterogeneous group of patients with acute leukemia to G-CSF or no treatment during induction therapy. There was a 1-week reduction in the duration of severe neutropenia but no decrease in antibiotic use or hospital stay. The complete remission rate was not decreased by G-CSF, and long-term outcome was unchanged.<sup>213</sup> The results of this study were confirmed in a large study conducted in 31 centers in Europe and Australia in which 521 adult patients with AML were randomly chosen to receive G-CSF or placebo after induction and consolidation therapy.<sup>214</sup> Patients in the G-CSF arm had a statistically significant improvement in duration of neutropenia, a 5-day reduction in the median duration of hospital stay, and a reduction in duration of antibiotic use. There was no significant difference reported in rate of complete remission or overall survival.<sup>214</sup> The Southwest Oncology Group randomly selected 234 patients older than age 55 and having *de novo* or secondary AML to receive G-CSF or placebo.<sup>215</sup> Patients on the G-CSF arm had a 3- to 4-day reduction in the duration of severe neutropenia after induction therapy and also reduced antibiotic use and days of fever. However, there was no reduction in the incidence of severe infections or any difference in complete remission rate or overall survival.<sup>215</sup>

**ACUTE MYELOID LEUKEMIA IN THE ELDERLY.** GM-CSF has been investigated in two large randomized group trials in induction therapy of AML in older patients.<sup>216,217</sup> An Eastern Cooperative Group Study randomly chose 124 AML patients ages 55 to 70 to receive GM-CSF or placebo after induction therapy.<sup>217</sup> The study drug was started on day 11 if a day-10 marrow was hypoplastic, and patients who entered complete remission received the study drug after consolidation therapy as well. Patients receiving GM-CSF experienced a significant reduction of infectious toxicity and a marginal improvement in median survival. Ten percent of GM-CSF–treated patients experienced severe infections, as compared to 36% of placebo patients. Mortality of patients who developed fungal infections was also lower with GM-CSF treatment, and overall early mortality (within 30 days) was significantly reduced in the GM-CSF arm. However, the beneficial effects of GM-CSF in an elderly population with AML were not confirmed in a larger Cancer and Leukemia Group B study reported by Stone et al.<sup>216</sup> In that study, 388 patients older than age 60 were randomly assigned to GM-CSF or placebo. There was no difference in remission rate, incidence of severe infections, or early deaths. There was a significant decrease in median duration of neutropenia for patients receiving GM-CSF, but the absolute difference was small (15 vs. 17 days).

Considering all the studies in which patients with AML have been randomly chosen to receive growth factor (G-CSF or GM-CSF) or placebo, it appears that although there may be some reduction in duration of neutropenia during induction therapy, this has not resulted in any significant reduction of severe infections or improvement

in remission rate and survival.<sup>218,219</sup> At this time, the use of growth factors in myeloid leukemias, particularly in the elderly, requires additional study.

**“PRIMING” OF ACUTE MYELOID LEUKEMIA CELLS AND DIFFERENTIATION THERAPY WITH GROWTH FACTORS.** Several investigators have tried to take advantage of the fact that GM-CSF or G-CSF induces proliferation of myeloid leukemic cells<sup>212</sup> by using these cytokines to induce leukemic cells to initiate or increase DNA synthesis, followed immediately by administration of chemotherapy with drugs such as cytosine arabinoside, which are most effective against cells actively synthesizing DNA. This approach, termed *priming*, is remarkably effective in the laboratory.<sup>220</sup> However, although pilot studies suggested that GM-CSF and cytosine arabinoside could be coadministered without undue toxicity,<sup>221</sup> larger studies did not suggest that this approach had any benefit in terms of increased complete remission rate or increased survival.<sup>222,223</sup> One explanation is that the CSFs promote viability as well as proliferation of leukemic cells, and they may be paradoxically reducing cell death due to cytotoxic chemotherapy. At present, there is no indication for using CSFs as priming agents outside of a clinical trial.

### **Acute Lymphoblastic Leukemia**

The use of cytokines during induction therapy of adult acute lymphoblastic leukemia (ALL) has not been extensively investigated. A prospective, multicenter trial reported by Ottmann et al.<sup>224</sup> randomly chose 76 patients to receive G-CSF or no growth factor during induction therapy. Patients in the G-CSF arm had a statistically significant reduction in the duration of severe neutropenia (8 days vs. 12.5 days), a lower incidence of nonviral infections, and fewer interruptions of scheduled chemotherapy.<sup>224</sup> The complete remission rates in the G-CSF and control groups were the same (95%), and the probability of disease-free survival at 20 months was also identical. A randomized Cancer and Leukemia Group B trial arrived at similar conclusions.<sup>225</sup> Adults who received intensive chemotherapy for ALL benefited from G-CSF treatment in terms of more rapid recovery of neutrophils, but overall outcome was unchanged. Thus, as is the case for adults with AML, adults with ALL treated with G-CSF have less neutropenia and probably fewer infections but no real improvement in disease outcome.

### **Myelodysplastic Syndromes**

Anemia, neutropenia, and thrombocytopenia are common and chronic problems for patients with MDSs and, as a result, MDS patients have been among the first groups to receive HGFs.<sup>226,227</sup> and <sup>228</sup> The use of EPO to treat anemias of MDS patients was described earlier in the section [Treatment of Anemia in Cancer Patients](#). In phase I and phase II trials, both GM-CSF<sup>229,230,231</sup> and <sup>232</sup> and G-CSF<sup>229,230,231</sup> and <sup>232</sup> have been shown to increase the neutrophil count by at least twofold in a variable number of patients (but generally less than 50%) and inevitably for only as long as the cytokine was administered. Even minimal red cell and platelet responses have been uncommon with both GM-CSF and G-CSF. A randomized trial of GM-CSF or observation was conducted in which 133 neutropenic patients with MDS were entered and followed up for 90 days.<sup>233</sup> Patients treated with GM-CSF had a statistically significant increase in neutrophils after 30, 60, and 90 days of treatment<sup>233</sup> and a significant reduction in major infections during the treatment period (15%, GM-CSF; 33%, observation). However, GM-CSF did not increase in hemoglobin or platelets, change transfusion requirement, or reduce the incidence of conversion to AML. The increase in neutrophil counts has been confirmed in other large studies of MDS patients treated with GM-CSF by Willemze et al.,<sup>231</sup> who treated 101 cases with two different daily doses of GM-CSF for 8 weeks. Of 82 evaluable patients, 66% had an increase in neutrophil count of twofold or more during the study, but sustained neutrophil responses, red cell responses, and platelet responses were rare. Interestingly, neutrophil responses in MDS patients may require only very low doses of GM-CSF.<sup>234</sup> There is no evidence so far that GM-CSF preferentially stimulates proliferation of normal progenitor cells rather than MDS progenitor cells. Serial karyotype analysis in one study showed that karyotypes of patients on GM-CSF remained abnormal or became increasingly abnormal over the study duration.<sup>235</sup> There is no clear evidence that GM-CSF administration accelerates development of acute leukemia, although some patients with advanced MDS may have an increase in blood or marrow blasts that may decrease after withdrawal of cytokine. Combinations of GM-CSF and EPO may have increased activity as compared to either agent alone.<sup>106</sup>

G-CSF is also effective at increasing neutrophil counts of patients with MDS.<sup>236,237</sup> In a randomized phase III trial of G-CSF versus observation, the G-CSF–treated arm had a statistically significant increase in neutrophil count.<sup>238</sup> However, the survival for patients with refractory anemia with excess blasts was significantly shorter in the G-CSF arm at the time of the initial analysis of the study.<sup>238</sup> It is not clear whether this is possibly due to an increased number of poor prognosis patients having been randomly assigned to the G-CSF arm or whether this is an effect of G-CSF. The combination of G-CSF with EPO may have significant advantages and deserves further study.<sup>107,112,239</sup>

Both GM-CSF<sup>232,240</sup> and G-CSF<sup>241</sup> have been used as adjuncts to chemotherapy in patients with MDS to reduce myelosuppression. Both factors appear to reduce myelosuppression, but there is no clear effect on response rates or rates of infection.<sup>232,241</sup> The beneficial effects of G-CSF on recovery from neutropenia have been confirmed in recent randomized trials.<sup>242,243</sup>

Overall, the use of GM-CSF and G-CSF remains experimental in MDS, with no clear demonstration of benefit in large patient populations. However, in the individual neutropenic patient with repeated infections, a trial of G-CSF or GM-CSF is reasonable.

## **REDUCTION OF CHEMOTHERAPY-RELATED THROMBOCYTOPENIA**

### **Interleukin-11**

IL-11 (Neumega) is a growth factor produced by stromal cells and has activity on progenitor cells, B cells, intestinal crypt cells, and osteoclasts, but not on stem cells.<sup>244,245,246,247,248</sup> and <sup>249</sup> Preliminary studies in both animals and humans suggested that IL-11 increased platelet counts, presumably through an effect on megakaryocytes.<sup>250,251</sup> Side effects in a phase I clinical study in breast cancer patients included fatigue, myalgia, and arthralgia and a grade 3 central nervous system event in one patient but no fever or capillary leak syndrome.<sup>251</sup> The incidence of severe thrombocytopenia after cyclophosphamide and doxorubicin appeared to be reduced.<sup>251</sup> Several randomized placebo controlled clinical trials have shown a reduction in the need for platelet transfusions in the setting of intensive chemotherapy.<sup>252,253</sup> In autologous transplantation, IL-11 did not reduce platelet transfusion requirement.<sup>254</sup> *In vitro*, IL-11 acts synergistically with several other HGFs to support proliferation of hematopoietic progenitor cells,<sup>245,246</sup> suggesting that combinations of IL-11 with other growth factors will be worth exploring in clinical trials. Interestingly, IL-11 reduces chemotherapy- or radiation therapy–induced damage to the intestine in animal models,<sup>255,256</sup> and it is possible that this factor will reduce therapy-associated gastrointestinal toxicity in humans.<sup>257</sup> IL-11 is currently approved for use in treating chemotherapy-associated thrombocytopenia.

### **Thrombopoietin (Megakaryocyte Growth and Development Factor)**

TPO was cloned by several groups after either purification of the protein from plasma of thrombocytopenic animals, by using the receptor for ligand affinity purification, or by clever expression cloning strategies.<sup>258,259,260</sup> and <sup>261</sup> The receptor for TPO has been identified as c-MPL, the cellular homologue of a viral oncogene that causes a myeloproliferative syndrome in mice. TPO levels vary inversely with the platelet count,<sup>262</sup> suggesting that TPO secretion can be directly induced by thrombocytopenia. TPO induces proliferation of megakaryocyte progenitor cells,<sup>263</sup> expansion of megakaryocytes *in vivo*, and production and release of platelets.<sup>264</sup> Further, TPO acts synergistically with several other growth factors to enhance megakaryocyte differentiation and proliferation.<sup>265</sup> Randomized, placebo-controlled clinical trials in cancer patients have shown a benefit for TPO administration,<sup>266,267</sup> but development has been slowed by rare instances of thrombocytopenia. This cytokine has not yet been approved for use in cancer patients, and its final role in cancer chemotherapy is still to be determined.

## **LONG-TERM EFFECTS OF GROWTH FACTOR ADMINISTRATION**

The long-term consequences of administration of HGFs are not yet known. In children with congenital neutropenias responsive to G-CSF, some have now received this cytokine for several years. Although splenomegaly, apparently related to extramedullary hematopoiesis, has been observed, few serious side effects have been reported.<sup>53</sup> One interesting case has been described in which G-CSF–related extramedullary hematopoiesis was confused with recurrent lymphoma.<sup>268</sup> However, there is no evidence to date that CSF administration by itself predisposes patients to develop leukemia or myelodysplasia. Concern has been raised that administration of CSFs with chemotherapy may increase the cumulative stem cell damage that can occur with some types of chemotherapy drugs or radiation. In fact, in a mouse model, repeated sequential administration of cyclophosphamide and G-CSF was more toxic to stem cells than cyclophosphamide alone.<sup>269</sup> It is possible that CSFs will induce more stem cells to enter the cell cycle and, therefore, potentially become more sensitive to chemotherapy-induced DNA damage. Careful follow-up of patients receiving aggressive chemotherapy with growth factor support is warranted, particularly if these patients later undergo autologous progenitor cell transplantation, or during other situations in which the marrow is stressed, such as during serious bacterial or viral infections.

## CONCLUSIONS

There is little doubt that the use of HGFs represents a significant advance in the supportive care available to cancer patients. At present, there are a number of clinical situations wherein administration of a growth factor is warranted, such as after myelosuppressive chemotherapy where there is a high likelihood of febrile neutropenia and after autologous progenitor cell transplantation. Patients who have already had an episode of febrile neutropenia should receive a growth factor if there are good reasons to maintain dose intensity. Ultimately, however, the utility of high-dose chemotherapy needs to be established in each tumor in terms of survival or improved quality of life. Finally, cytokines are expensive, and further efforts to define cost-effectiveness in useful terms are needed. However, despite these cautions, the remarkable ability to manipulate hematopoiesis with growth factors is likely to be beneficial to cancer patients in many different situations.

## INTRODUCTION

Infections are major causes of morbidity and mortality in patients with cancer. The risk of infection is principally related to the intensity and duration of immunosuppressive chemotherapy. It is essential to know the patient's quantitative and qualitative immune defects and to stratify the risk for specific pathogens in the context of the history, physical examination, and radiologic and laboratory data.

In the 1980s, there was a shift in the relative prevalence of specific pathogens afflicting patients with cancer. Whereas in the 1960s and 1970s, gram-negative bacterial pathogens (*Enterobacteriaceae* and *Pseudomonas aeruginosa*) were the principal causes of bacteremia, in the 1990s and 1980s, gram-positive bacterial pathogens became predominant.<sup>1</sup> Today, filamentous fungi are a major cause of mortality in allogeneic bone marrow transplant (BMT) recipients and in patients with prolonged neutropenia. The spectrum of invasive fungal infections has dramatically increased. Examples of such emerging pathogens include *Fusarium*, *Acremonium*, *Scedosporium*, and dematiaceous (dark-walled fungi) species, and the yeast *Trichosporon beigeli*. This population is also at risk for a broad spectrum of viral and protozoal infections.

We describe the clinical manifestations and treatment of the major pathogens encountered in an oncology population. Specific infectious syndromes, such as fever without a documented source, pneumonia, skin infection, gastrointestinal infection, and sepsis, are reviewed. We also discuss novel approaches aimed at prevention

and early diagnosis of infections and immune augmentation strategies.

## FACTORS PREDISPOSING TO INFECTION IN PATIENTS WITH CANCER

Patients with cancer are a highly varied population, both in terms of the underlying malignancy and the level of immunosuppression. We describe specific categories of immunosuppression and the pathogens to which these patients are most susceptible. Multiple predisposing factors may exist in a single patient, thus increasing the spectrum of likely pathogens. The major categories of immunologic deficits in persons with cancer and the pathogens to which they are susceptible are summarized in [Table 54-1](#).

Immunity	Bacterial	Fungal	Parasitic	Viral
Defective ability of phagocytes (leukocytes or macrophages)	Gram positive Staphylococcus aureus Streptococcus pneumoniae Klebsiella pneumoniae Gram negative Pseudomonas aeruginosa Serratia marcescens Enterobacteriaceae Meningococcus meningitidis Neisseria meningitidis	Candida sp. Aspergillus Cryptococcus neoformans Histoplasma capsulatum Blastomyces dermatitidis Coccidioides immitis Other filamentous fungi		
Defective subcellular immunity	Staphylococcus aureus Streptococcus pneumoniae Listeria monocytogenes Salmonella Cryptosporidium parvum	Candida sp. Aspergillus spp. Histoplasma capsulatum Cryptosporidium parvum Toxoplasma gondii Strongyloides stercoralis	Parasitic (not) Toxoplasma gondii Strongyloides stercoralis	Cytomegalovirus Epstein-Barr virus Herpesvirus Varicella-zoster virus
Defective humoral immunity	Streptococcus pneumoniae Staphylococcus aureus	Aspergillus spp. Candida spp.		Cytomegalovirus Epstein-Barr virus Herpesvirus Varicella-zoster virus
Splenic	Streptococcus pneumoniae Staphylococcus aureus Mycobacterium tuberculosis Mycobacterium avium Mycobacterium kansasii Coccidioides immitis			Cytomegalovirus Epstein-Barr virus Herpesvirus Varicella-zoster virus

**TABLE 54-1.** Predominant Immunologic Defects and Associated Pathogens in Patients with Cancer

### ABSOLUTE NEUTROPHIL COUNT GREATER THAN 500/mL AND NO IMMUNOSUPPRESSIVE THERAPY

The group with absolute neutrophil count greater than 500/ $\mu$ L and no immunosuppressive therapy represents the least immunosuppressed patients with cancer, but some level of risk of infection may still exist. The malignancy itself may be associated with an immune defect. Malignancies associated with defective immunoglobulin production lead to increased susceptibility to encapsulated bacteria, principally *Streptococcus pneumoniae*. Such patients may have recurrent sinopulmonary infections, septicemia, and disseminated infection. Patients with chronic lymphocytic leukemia frequently have hypogammaglobulinemia or dysglobulinemia.<sup>2</sup> Low levels of both total immunoglobulin G (IgG) and specific antibodies to pneumococcal polysaccharide capsule are associated with an increased rate of infections in these patients.<sup>2</sup> A decision analysis suggested that routine administration of immunoglobulin to patients with chronic lymphocytic leukemia and hypogammaglobulinemia reduces the frequency of bacterial infections, but is not cost-effective.<sup>3</sup>

Patients with multiple myeloma and other related gammaglobulinopathies also are often functionally hypogammaglobulinemic; the total level of immunoglobulin production is elevated, but the repertoire of antibody production is restricted. Savage et al.<sup>4</sup> noted a biphasic pattern of infection among patients with multiple myeloma. Infections by *S pneumoniae* and *Haemophilus influenzae* occurred early in the disease and in patients responding to chemotherapy, whereas infections by *Staphylococcus aureus* and gram-negative pathogens occurred more commonly in advanced disease and during neutropenia. Serum from patients with multiple myeloma may be defective in the activation of C3, the major opsonin of the complement system, which likely further contributes to susceptibility to pneumococcal infection.<sup>5</sup> One randomized study showed that prophylactic intravenous immunoglobulin protected against life-threatening and recurrent infections in patients with multiple myeloma.<sup>6</sup> The patients who benefited most from immunoglobulin therapy were those with poor IgG antibody responses to pneumococcal vaccination.

Patients with hairy cell leukemia appear to have a defect in cell-mediated immunity, leaving them prone to develop an unusually high frequency of opportunistic atypical mycobacterial infections.<sup>7</sup> Patients with untreated Hodgkin's disease have significant abnormalities in T-cell number and function, which persist in the majority of long-term survivors.<sup>8</sup> Such patients are at increased risk for toxoplasmosis, nocardiosis, pneumocystosis, cryptococcosis, mycobacterial infections, and herpes zoster. Most opportunistic infections occurred during poorly controlled malignancy when patients were receiving corticosteroids, myeloablative chemotherapy, or both.<sup>9</sup>

Adrenal tumors and ectopic adrenocorticotropic hormone–secreting tumors resulting in high levels of cortisol<sup>10,11</sup> and T-cell leukemias<sup>12</sup> are associated with defects in cellular immunity resulting in an increased risk of mucosal candidiasis, *Pneumocystis carini* pneumonia (PCP), and invasive aspergillosis.

Solid tumors may predispose patients to infection because of anatomic factors. Tumors that overgrow their blood supply become necrotic, thus forming a nidus for infection. Head and neck tumors may cause erosion through the fascial planes of the neck and floor of the mouth, predisposing patients to serious infections caused by mouth flora. Lemierre's syndrome, a septic thrombophlebitis of the neck with possible embolization to the tricuspid valve and lung and dissemination to other organs, is usually caused by *Fusobacterium* species, which are anaerobic oral commensal organisms.<sup>13</sup> This infection may develop during the course of uncontrolled head and neck cancer. Head and neck cancers may also increase the risk of aspiration pneumonia. Endobronchial lung tumors are associated with recurrent postobstructive pneumonias. Abdominal tumors may obstruct hollow viscera, such as the genitourinary or hepatobiliary tracts, predisposing to pyelonephritis and cholangitis, respectively. Direct invasion through the colonic mucosa is associated with local abscess formation and sepsis by enteric flora. *Streptococcus bovis* bacteremia is highly associated with colon cancer. Breast tumors increase the risk of mastitis and abscess formation, usually by *Staphylococcus aureus*.

Therapy for the underlying malignancy, independent of the immunosuppression, may be associated with an increased risk of infection. Local radiation therapy is associated with loss of epithelial integrity, necrosis, loss of blood supply, and consequent poor ability to repair wounds. Visceral complications include radiation pneumonitis, esophagitis, and enteritis. Implantable hardware necessary for administration of chemotherapy, such as cuffed intravenous catheters and Ommaya reservoirs, are potential niduses of infection.

Patients with malignancy commonly experience malnutrition, which increases the risk of infection. Weight loss frequently precedes the diagnosis of cancer, and the nausea, mucositis, and enteritis that follow antineoplastic chemotherapy worsen malnutrition.

### NEUTROPENIA

Neutropenia may develop independently of chemotherapy in certain patients with cancer. In acute leukemia, the marrow may be replaced with malignant cells so that virtually no normal circulating neutrophils exist. Similarly, patients with premalignant hematologic disease, such as myelodysplastic syndrome, may have associated bone marrow failure. Patients also may develop neutropenia due to tumor-related autoimmune neutrophil destruction.<sup>14</sup> Persons rendered neutropenic by myeloablative chemotherapy are likely to be at greater risk for life-threatening infections due to the concomitant disruption of epithelial mucosal barriers by such agents.

The relationship between circulating leukocytes and risk of infection was established by Bodey et al.<sup>15</sup> in a classic early study of 52 patients with acute lymphocytic leukemia or acute myelogenous leukemia. The frequency of severe infections was highest when the absolute neutrophil count (ANC) was less than 100/ $\mu$ L and proportionately less frequent at 100 to 500/ $\mu$ L and 500 to 1000/ $\mu$ L, respectively. This relationship was sustained whether the patient was in relapse or remission, although the overall risk of infection was greater during relapse. Ninety percent of disseminated fungal infections and 78% of septicemias occurred when the ANC was less than 500/ $\mu$ L. No further reduction in the rate of serious infections occurred at ANC greater than 1000 to 1500/ $\mu$ L. In addition to the depth of neutropenia, the risk of infection was strongly related to the duration of neutropenia. A neutrophil count of less than 100/ $\mu$ L resulted in infections in all patients within 3 weeks and in severe infections within 6 weeks. The likelihood of survival from severe infections was related to both the initial granulocyte level and whether an increase in the neutrophil count occurred within the first week. With an initial ANC of less than 100/ $\mu$ L and no increase within the first week, mortality was 80%.

The risk of invasive aspergillosis is also directly related to the period of neutropenia. In patients with leukemia, Gerson et al.<sup>16</sup> showed that aspergillosis was uncommon when neutropenia lasted for less than 14 days. However, after 14 days, the risk of aspergillosis increased in direct proportion to the length of neutropenia. Invasive aspergillosis is also a major cause of mortality in patients with persistent neutropenia secondary to aplastic anemia.<sup>17</sup> Since the mid-1980s, an increasing

spectrum of fungal pathogens has been encountered in patients with prolonged neutropenia, including *Fusarium* species, dark-walled molds, and *Trichosporon* species.<sup>18,19</sup>

Diagnosis of infection in granulocytopenic patients may be hampered by the lack of typical symptoms and signs. Sickles et al.<sup>20</sup> compared the clinical manifestations of infections in neutropenic and nonneutropenic patients with cancer. Fever was present in virtually all patients with an ANC less than 100/ $\mu$ L and in 90% of patients with 101 to 1000/ $\mu$ L. However, physical findings of infection, including fluctuance, exudate, local heat and swelling, ulceration, and local adenopathy, were less frequent in neutropenic than in nonneutropenic patients with similar infections. Local erythema and tenderness were sensitive indicators of infection in neutropenic patients. In neutropenic patients with pneumonia, sputum and physical examination signs of consolidation were less frequent than in nonneutropenic patients as were localizing symptoms and pyuria in cases of urinary tract infection. Local infections more commonly led to bacteremia with an ANC less than 100/ $\mu$ L. Thus, fever is a relatively sensitive sign of infection in the neutropenic patient, whereas other findings of infection are often lacking. The high likelihood of systemic infection and mortality in febrile neutropenic patients constitutes the rationale for initiating empiric antibacterial therapy before a documented source of infection or culture data are available.

## MUCOSAL IMMUNITY

The mucosal linings in the gastrointestinal, sinopulmonary, and genitourinary tracts constitute the first line of host defense against a variety of pathogens. Chemotherapy and radiation therapy cause defects in mucosal immunity at several different levels. The physical protective barrier conferred by the epithelial lining is compromised, thus allowing access to colonizing microflora. In BMT patients, chronic graft-versus-host disease (GVHD) further compromises mucosal immunity. These patients have defective salivary immunoglobulin secretion,<sup>21</sup> and corticosteroids profoundly compromise mucosa-associated lymphoid tissue by inducing apoptosis of M cells and depleting lymphoid follicles of T and B cells.<sup>22</sup>

Mucosal epithelial cells secrete a variety of antimicrobial peptides, including lactoferrin (iron sequestration), lysozyme (hydrolysis of peptidoglycan of gram-positive bacteria), and phospholipase A2 (cleavage of structural phospholipids of bacteria).<sup>23</sup> Defensins are a group of small cysteine-rich antibacterial peptides (molecular weight, approximately 4 kD) located abundantly in the primary (azurophilic) granules of neutrophils and in a variety of mucosal epithelial cells, including bronchial epithelium and Paneth's cells within small intestinal crypts.<sup>23</sup> Neutropenia and loss of the epithelial cell anatomic barrier and local production of antimicrobial proteins likely predispose to typhlitis (neutropenic enterocolitis). Synthetically produced antimicrobial peptides are potential therapeutic candidates for augmenting mucosal immunity.<sup>24</sup>

## IMMUNOSUPPRESSIVE AGENTS NOT RELATED TO NEUTROPENIA

### Corticosteroids

Corticosteroids have profound effects on the distribution and function of neutrophils, monocytes, and lymphocytes. They induce a neutrophilic leukocytosis by accelerating the release of neutrophils from the bone marrow and by inhibiting the egress of neutrophils from the circulation. Corticosteroids reduce adherence of neutrophils to the endothelium, thus inhibiting migration to inflammatory sites, and inhibit neutrophil fungicidal activity.<sup>25</sup>

Corticosteroids elicit a peripheral blood monocytopenia that lasts for 24 hours. In addition, a number of monocyte functions are impaired, including chemotaxis, bactericidal activity, and production of interleukin-1 (IL-1) and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ).<sup>26</sup>

Corticosteroids inhibit T-cell activation, leading to reduced proliferative responses and cytokine production, and also induce a redistribution of lymphocytes out of the circulation, leading to peripheral lymphocytopenia. This redistribution predominantly involves T cells.<sup>27</sup> At high doses, corticosteroids also inhibit immunoglobulin generation by B cells.<sup>28</sup>

In patients with cancer, corticosteroids are seldom the only immunosuppressive agents being administered, and it is therefore difficult to delineate the degree of impairment in host defense elicited by the corticosteroid regimen alone. Infections that occur in patients with collagen vascular diseases treated with corticosteroids are associated with both impaired phagocytic function (such as *S aureus* and Enterobacteriaceae) and cell-mediated immunity (such as herpes zoster, and *P carinii*).<sup>26</sup> In this population, the incidence of infectious complications increases when the adult equivalent of prednisone, 20 to 40 mg/d, is administered for longer than 4 to 6 weeks.<sup>27,29</sup> In patients with cancer, the most intensive corticosteroid regimens (usually the equivalent of prednisone, 1 g daily) are used to treat BMT recipients with GVHD, leading to a global suppression of phagocytic and cell-mediated activity and rendering these patients highly susceptible to a broad spectrum of bacterial, fungal, viral, and protozoal pathogens. In addition to immunosuppression, corticosteroids directly stimulate the growth of *Aspergillus fumigatus in vitro*,<sup>30</sup> possibly via sterol-binding proteins in the fungus.

### Methotrexate

Methotrexate inhibits dihydrofolate reductase, an enzyme required for the synthesis of DNA and certain amino acids. At the high doses used in antineoplastic chemotherapy, methotrexate is highly immunosuppressive. As with other cytotoxic agents, methotrexate causes bone marrow suppression and mucositis. Trimethoprim-sulfamethoxazole, an antifolate drug commonly used as prophylaxis against *P carinii* infection in this population, may aggravate the hematologic toxicity of methotrexate.<sup>31</sup>

In patients with collagen vascular disease treated with low-dose methotrexate, the infection rate was low. The most common opportunistic pathogens were *P carinii* and herpes zoster.<sup>26</sup> Other reported infections included aspergillosis, histoplasmosis, nocardiosis, mycobacterial infections, and *Listeria monocytogenes* meningitis.<sup>26</sup> Epstein-Barr virus (EBV)-associated B-cell lymphoproliferative disease has been identified in a few patients with collagen vascular diseases treated with methotrexate.<sup>32</sup> Thus, long-term use of low-dose methotrexate can lead to significant depression of cell-mediated immunity, independent of its myeloid toxicity.

### Cyclosporin A

Cyclosporin A (CSA) is a potent inhibitor of T-cell activation that is commonly used in the postengraftment period after BMT. CSA is a prodrug that binds to the intracellular protein, cyclophilin. The resulting complex in turn inhibits the calcium-regulated protein phosphatase, calcineurin, a protein required for signal transduction after activation of the T-cell receptor. Calcium-dependent production of the potent neutrophil chemoattractant, IL-8, is inhibited by CSA.<sup>33</sup> Compared with methotrexate, CSA is associated with less mucositis, and in some studies, more rapid myeloid recovery in BMT recipients.<sup>34,35</sup>

### Fludarabine

Fludarabine is a fluorinated analog of adenine that has been used in a variety of hematologic malignancies, including chronic lymphocytic leukemia, hairy cell leukemia, and low-grade lymphomas. Fludarabine is a lymphotoxic compound, primarily affecting CD4+ lymphocytes. The combination of fludarabine and corticosteroids is more immunosuppressive than either agent alone.<sup>36</sup> Fludarabine plus prednisone results in a uniform depression of CD4+ cells that may persist for several months after completion of therapy.<sup>37</sup> In one series, 14 of 264 patients (5%) with chronic lymphocytic leukemia developed either PCP or listeriosis, and three cases occurred more than 1 year after therapy in patients who were in remission. Other opportunistic pathogens reflecting T-cell depression include disseminated varicella, mycobacteria, and fungi.<sup>38</sup> Prophylaxis with trimethoprim-sulfamethoxazole (which has activity against both *P carinii* and *L monocytogenes*) appears to be warranted.

### Interleukin-2

Patients receiving high-dose IL-2 for malignancy have an increased risk of bacterial infections. Among 345 patients with cancer enrolled in a multicenter study of IL-2, 88 (26%) had bacteremia.<sup>39</sup> *S aureus* followed by coagulase-negative staphylococci were the most common pathogens. The frequency of sepsis in IL-2 recipients was several-fold greater than in nonneutropenic patients with indwelling central catheters. IL-2 causes a profound but reversible defect in neutrophil chemotaxis that may account for the increased frequency of infections.<sup>39</sup>

## SPLENECTOMY

The spleen is a reservoir in which rapid antigen presentation occurs, leading to the production of opsonizing antibodies by B cells. Splenic macrophages remove both opsonized and nonopsonized particles from the blood stream. The removal of nonopsonized bacteria is a particularly important function to protect against encapsulated bacteria to which the patient is not immune.

Asplenic patients are principally at risk for overwhelming sepsis by encapsulated bacteria. The most common pathogen is *S pneumoniae*, but other pathogens include *Haemophilus influenzae* and *Neisseria meningitidis*. It is best to immunize individuals against encapsulated bacteria in advance of splenectomy. If this is not feasible, immunization is still advisable after splenectomy, because such patients are still capable of mounting a protective antibody response. In a study of asplenic patients, IgG responses to immunization with pneumococcal, *H influenzae* type b, and meningococcal vaccines were normal by day 28.<sup>40</sup> Patients with Hodgkin's disease, most of whom were asplenic, had normal IgG responses to pneumococcal polysaccharide vaccine. Molrine et al.<sup>40</sup> suggest reimmunization of asplenic persons every 5 years with the pneumococcal polysaccharide vaccine based on a potential increased risk for disease as protective antibody levels wane over time.

Asplenic patients should be advised to seek medical attention when fever occurs. Prophylaxis with penicillin has been traditionally used after splenectomy. However, the growing frequency of antimicrobial resistance among *S pneumoniae* isolates raises a note of caution. In a surveillance study, the overall percentages of respiratory pneumococcal isolates from the United States with intermediate and high-level resistance to penicillin were 28% and 16%, respectively.<sup>41</sup> A significant minority of penicillin-resistant isolates are cross-resistant to cephalosporins, macrolides, and trimethoprim-sulfamethoxazole.<sup>41</sup> Newer generation quinolones have reliable activity against penicillin-resistant pneumococci, though a Canadian study documented an increased frequency of quinolone-resistant pneumococcal isolates in association with increased use of these agents.<sup>42</sup> Physicians should be aware of local patterns of resistance to guide prophylactic and empiric antibiotic therapy.

Other pathogens associated with a more fulminant course in asplenic individuals include *Capnocytophaga* species,<sup>43,44</sup> babesiosis,<sup>45</sup> malaria, and *Salmonella* species. *Capnocytophaga canimorsus* infection is typically associated with dog bites and can lead to sepsis with or without evidence of cellulitis. *Babesia microti* is transmitted by the *Ixodes* tick, which is also the vector for Lyme disease. When in Lyme-endemic regions in the spring to autumn periods, patients should follow basic precautions to avoid tick bites (long sleeves, tick repellants) and be vigilant about fever. The diagnosis of babesiosis is confirmed by a peripheral blood smear showing characteristic intraerythrocytic inclusions.

## BONE MARROW TRANSPLANTATION

The spectrum of pathogens to which BMT recipients are most susceptible follows a time line corresponding to the predominant immune defects observed at different periods (Table 54-2). In the early stage of BMT, neutropenia is the principal host defense defect. These patients are at risk for the same spectrum of bacterial and fungal infections that afflict nontransplant patients who have been treated with potent myeloablative therapy (see [Neutropenia](#), earlier in this chapter). Severe mucocutaneous herpes simplex virus (HSV) infection is also commonly observed in the first month of transplantation in association with chemotherapy-induced mucositis. After myeloid engraftment, fever and mucositis typically resolve, and the risk of serious bacterial and fungal infections decreases.

Principal immune defect	Months Posttransplant		
	<1	1-6	>6
Neutropenia	Neutropenia	T-cell, humoral Thymic (epithelial)	Humoral
Pathogen	Staphylococci Serratia Serratia Serratia Pseudomonas aeruginosa Fungi Candida Aspergillus Serratia marcescens	Staphylococci Fungi Candida Cryptococcus neoformans Disseminated fungi Pneumocystis carinii Toxoplasma Coccidioides Sporothrix Histoplasma Respiratory virus	Respiratory virus Varicella zoster virus Disseminated bacteria

Note: The predominant disease etiology in the late transplant period is due to the presence of phagocytic (granulocyte and/or neutrophil) defects, the presence of the period of risk for both common bacterial and opportunistic infections.

**TABLE 54-2.** Time Line of Principal Immune Defects and Infectious Complications in Bone Marrow Transplant Recipients

After myeloid engraftment, a qualitative dysfunction of phagocytes persists due to corticosteroid therapy and other immunosuppressive agents (see [Immunosuppressive Agents Not Related to Neutropenia](#), earlier in this chapter). The risk of infection by filamentous fungi during this period is strongly associated with the severity of GVHD and requirement for potent immunosuppressive regimens. Impairment in neutrophil chemotaxis has been noted in some patients and may increase the risk of infection.<sup>46,47</sup> Alveolar macrophage function in patients studied within 4 months of allogeneic BMT was impaired based on chemotaxis, phagocytosis, and killing of bacterial and candidal species.<sup>48</sup> These observations may, in part, account for the increased risk of pneumonia during this period.

Defects in cell-mediated immunity persist for several months even in uncomplicated allogeneic transplant recipients, thus predisposing these patients to a variety of opportunistic infections, such as candidiasis, *P carinii*, cytomegalovirus (CMV), and herpes zoster (see [Table 54-2](#)). Repopulation of specific T-cell subsets occurs at different rates, resulting in a lower than normal CD4+ (helper T cell) to CD8+ (suppressor-cytotoxic T cell) ratio for the first 6 months after engraftment.<sup>49</sup> In addition to quantitative T-cell deficiencies, loss of T-cell receptor diversity is observed.<sup>50</sup> During the first 100 days of transplantation, delayed hypersensitivity responses, proliferative responses to mitogens and antigens, and T-cell-mediated activation of B cells to produce immunoglobulin are impaired.<sup>51</sup> By 1 year after engraftment, BMT recipients without chronic GVHD have normalized CD4+/CD8+ ratios, and in general, have normal *in vivo* and *in vitro* T-cell responses.

Defective reconstitution of humoral immunity is a major factor contributing to increased infection susceptibility in the late transplant period. Winston et al.<sup>52</sup> noted an unusually high frequency of pneumococcal infections between 7 and 36 months after transplantation. All infections occurred after trimethoprim-sulfamethoxazole prophylaxis for *P carinii* was halted. The risk of pneumococcal infection was associated with serum opsonic deficiency for *S pneumoniae*. Kalhs et al.<sup>53,54</sup> showed that functional asplenia, as determined by the presence of Howell-Jolly bodies in peripheral blood smears, was a late complication of allogeneic BMT only in patients with severe GVHD. Thus, even in BMT recipients who have had an uncomplicated course, fever in the late transplant period must be evaluated promptly (similar to patients with asplenia) because of the risk of overwhelming infection by one of these pathogens (see [Table 54-2](#)).

During periods of severe GVHD, the immunosuppressive regimen is intensified to include high-dose corticosteroids in combination with CSA and possibly an antilymphocyte globulin preparation. CD4+ lymphocytopenia may, in part, result from GVHD-induced injury of thymic epithelial cells.<sup>55</sup> Whereas mature and cooperative T- and B-cell functions are generally reconstituted by 1 year after engraftment in uncomplicated allogeneic BMT, chronic GVHD is associated with persistently depressed cell-mediated and humoral immunity.

Autologous transplants are associated with less infectious complications than allogeneic transplants due to reduced severity of GVHD and earlier reconstitution of T-cell immunity. Allogeneic transplantation using alternative donors (such as HLA-matched unrelated donors, partially mismatched related donors, and mismatched cord blood) has a higher risk of GVHD and usually requires depletion of mature donor T cells, leading to delayed immune reconstitution and, consequently, a greater risk of infectious complications.

## ALTERATIONS IN MICROFLORA COLONIZATION

A shift in the normal respiratory flora toward colonization with aerobic gram-negative bacilli occurs in sick hospitalized patients.<sup>56</sup> This may be due to changes in the fibronectin content of cell surfaces in debilitated persons, leading to reduced adherence by the normal anaerobic flora, thus favoring colonization by aerobic gram-negative bacilli.<sup>57</sup> In immunocompromised patients with cancer, alterations in bowel flora leading to acquisition of more virulent bacteria are well documented. This change is exacerbated by the use of broad-spectrum antibiotics that may suppress the normal anaerobic bowel flora. Patients with acute leukemia are frequent

stool carriers of *P aeruginosa*, and nosocomial infections are often preceded by enteric colonization by the infecting strain.

In a classic study, Schimpff et al.<sup>58</sup> collected surveillance cultures from the nose, gingiva, axilla, and rectum of hospitalized patients with acute nonlymphocytic leukemia. Infection nearly always occurred during neutropenia, and in approximately 85% of cases, the infecting organism had been isolated in surveillance cultures before the onset of disease. In almost one-half of the cases, the pathogen was acquired after hospital admission.

## BACTERIAL PATHOGENS IN CANCER PATIENTS

### STAPHYLOCOCCUS SPECIES

Since the 1980s, there has been a marked increase in the proportion of bacterial infections and bacteremia caused by *Staphylococcus* species. The frequency of *S aureus* infections has remained stable, whereas the incidence of infections caused by coagulase-negative staphylococci has increased, almost certainly due to widespread use of broad-spectrum antibiotics and surgically implantable central venous catheters. Coagulase-negative staphylococci are considered to be low pathogens of low virulence, and their isolation from blood is frequently dismissed as a skin contaminant. In patients with cancer, coagulase-negative staphylococci may produce a localized catheter-associated infection, bacteremia, or, less frequently, metastatic infection. The majority of nosocomial coagulase-negative staphylococci are resistant to antistaphylococcal penicillins, making vancomycin the initial drug of choice for such infections. However, given the increased prevalence of serious infections due to vancomycin-resistant enterococci (VRE), an antistaphylococcal penicillin should be used for staphylococci sensitive to one of these agents.

*S aureus* is the most common cause of surgical wound infections and can cause both local and systemic disease. In some instances a toxic shock syndrome occurs, manifesting as fever, hypotension, gastrointestinal toxicity, rash, and skin exfoliation. Prompt initiation of antibiotics, fluid resuscitation, removal of surgical packing, and wound débridement are required. In patients with cancer, disruptions of the skin barrier from indwelling intravenous catheters or biopsy sites are additional portals of entry.

The incidence of methicillin-resistant *S aureus* (MRSA) isolates causing nosocomial blood stream infections in the United States is increasing. In a 3-year surveillance study of more than 10,000 cases of nosocomial bacteremia, almost 30% of *S aureus* isolates were methicillin resistant.<sup>59</sup> Among hematology and oncology patients, the rate was 25%. These observations highlight the need to be familiar with the resistance patterns of bacterial pathogens at one's institution to guide empiric antibiotic therapy before the availability of culture results (see [Evaluation and Management of Febrile Neutropenia without an Apparent Source](#), later in this chapter).

MRSA isolates are typically broadly resistant to all antibiotics, except vancomycin. Clinical *S aureus* isolates have been isolated with intermediate resistance to vancomycin.<sup>60,61</sup> Preventing emergence and spread of these organisms requires careful attention to infection control guidelines and judicious use of antibiotics.

Patients with MRSA infection should be kept in private rooms, under contact precautions. Gown and gloves should be worn by hospital staff in cases of a draining wound or other situations in which spread to hands and clothing is likely to occur. Attempts at eradication of nasal carriage of *S aureus* with topical mupirocin and other agents have produced mixed results, and MRSA may develop resistance to mupirocin.<sup>62</sup>

### ENTEROCOCCUS SPECIES

An increased incidence of nosocomial infections caused by multidrug-resistant enterococcal species has been observed. Approximately 50% of *Enterococcus faecium* and the minority of *Enterococcus faecalis* isolates are resistant to vancomycin<sup>59</sup> and are typically multiply resistant to penicillin, ampicillin, and aminoglycosides. Patients with cancer who spend a significant time in the hospital are at high risk for being colonized by drug-resistant *Enterococcus* species. The portal of entry for enterococcal bacteremia may be an indwelling central catheter or defects in the gut mucosa from chemotherapy or radiation toxicity. Tumor invasion of the gut may predispose to bacteremia by *Enterococcus* species, as well as *Streptococcus bovis*.

Ampicillin is the drug of choice for sensitive *Enterococcus* isolates. For serious infections (e.g., bacteremia), addition of an aminoglycoside for synergy is reasonable because even sensitive strains are intrinsically tolerant to the bactericidal activity of penicillins and vancomycin. The newly licensed streptogramin antibiotic, quinupristin/dalfopristin (Synercid), is active against most strains of *E faecium* but not *E faecalis*.<sup>63</sup> Linezolid, a prototype of the oxazolidinone group of antimicrobial agents, has broad activity against gram-positive pathogens, including MRSA and VRE, and is being evaluated in clinical trials.<sup>64</sup> Chloramphenicol, fluoroquinolones, tetracyclines, and rifampin may also have activity against VRE. Prevention and infection control methods, including prudent use of antibiotics (restriction of vancomycin usage), isolation of colonized and infected patients, surveillance, hand washing, and use of appropriate barrier protections, are critical for reducing rates of VRE infection.

### VIRIDANS STREPTOCOCCI

Viridans streptococci, also called *a-hemolytic streptococci*, are oral commensal organisms. In the nonimmunocompromised population, they are the most common cause of native valve endocarditis, which usually has a subacute course. In neutropenic patients, viridans streptococci are more virulent. Cytosine arabinoside (Ara-C), a highly mucotoxic agent, and prophylaxis with ciprofloxacin or trimethoprim-sulfamethoxazole (presumably, by selecting for resistant streptococci) are the major risk factors for bacteremia by viridans streptococci.<sup>65,66</sup> and <sup>67</sup>

Neutropenic patients with viridans streptococcal bacteremia may have a 24- to 48-hour prodrome of low-grade fever and facial flushing, followed by a high fever and chills. In approximately 25% of patients, bacteremia is complicated by a shock syndrome, characterized by hypotension, respiratory distress syndrome, renal failure, and a maculopapular rash usually starting at the trunk and spreading centrifugally to the face and extremities.<sup>65</sup> Desquamation of the palms and soles may subsequently occur. Endocarditis is observed in a minority of patients. Septic shock may be more common in children than in adults.<sup>68,69</sup>

In a secondary analysis of 909 bacteremias in patients previously enrolled in trials of neutropenic fever, 13% were caused by viridans streptococci.<sup>70</sup> All 52 patients with viridans streptococcal bacteremia who received initial vancomycin survived, compared with an 86% survival rate in patients whose vancomycin therapy was delayed 2 to 3 days ( $P = .004$ ). Of the empiric monotherapy regimens used for febrile neutropenia, ceftazidime has the poorest activity against viridans streptococci, thus prompting some investigators to add vancomycin empirically in patients with neutropenic fever and significant chemotherapy-induced mucositis (see [Evaluation and Management of Febrile Neutropenia without an Apparent Source](#), later in this chapter).<sup>71</sup>

### MISCELLANEOUS GRAM-POSITIVE BACTERIA

In the 1990s, there has been an emerging spectrum of gram-positive bacterial infections in patients with cancer. The widespread use of surgically implanted central venous catheters and fluoroquinolone prophylaxis may be contributing to the more frequent isolation of these bacteria. They include *Corynebacterium jeikeium*, *Bacillus cereus*, *Stomatococcus mucilaginosus*, and *Leuconostoc* species.<sup>1</sup> These bacteria are associated with localized catheter and wound infections, bacteremia, and disseminated infection.

*C jeikeium* is a common cutaneous commensal organism that has been associated with infection of prosthetic devices, such as vascular catheters, peritoneal dialysis catheters, prosthetic valves, and ventricular shunts. *C jeikeium* is highly resistant to antibiotics, except vancomycin.

In a review of *C jeikeium* infections in patients with hematologic malignancies, skin lesions were present in one-half of the cases, pulmonary lesions occurred in approximately one-third of cases, and one-third of the patients died.<sup>72</sup> In neutropenic patients, survival was strongly associated with resolution of neutropenia. Virtually all of these patients had an indwelling central venous catheter, which was likely to be the principal portal of entry. In a series of BMT recipients with *C jeikeium* bacteremia, all eight patients who received appropriate antibiotic therapy and who had their central intravenous catheters removed survived regardless of persistent neutropenia.<sup>73</sup> Mortality was greater than 50% in those patients who received no antibiotics and in those who received antibiotics without removal of the central venous catheter. Current treatment consists of prompt initiation of vancomycin and consideration of removal of the infected intravenous catheters.

In neutropenic children, *Bacillus cereus* was associated with a primary cutaneous infection involving vesicular and pustular lesions.<sup>74</sup> *Stomatococcus mucilaginosus* appears to be particularly virulent in neutropenic patients and has been associated with septic shock, respiratory distress syndrome, and meningitis.<sup>75</sup> *Leuconostoc*,

*Lactobacillus*, and *Pediococcus* species are often resistant to vancomycin,<sup>76</sup> but most isolates are susceptible to penicillin.

## ENTEROBACTERIACEAE

The Enterobacteriaceae include several pathogenic species, including *Escherichia coli*, *Klebsiella*, *Proteus*, *Enterobacter*, *Serratia*, and *Citrobacter* species. Patients with neutropenia are at highest risk for bacteremia and life-threatening infections by these pathogens. The principal portal of entry appears to be translocation of bacteria from the alimentary tract.

There has been an increasing frequency of infection due to Enterobacteriaceae and other gram-negative bacteria (such as *Stenotrophomonas maltophilia* and *Acinetobacter* species), which are highly resistant to b-lactam antibiotics. Bush et al.<sup>77</sup> presented an updated classification of b-lactamases, which include three groups of enzymes: (1) group 1 cephalosporinases (also referred to as *Bush group 1* b-lactamases) are not well inhibited by clavulanic acid; (2) group 2 penicillinases, cephalosporinases, and extended spectrum b-lactamases are generally inhibited by b-lactamase inhibitors; and (3) group 3 metallo-b-lactamases that hydrolyze penicillins, cephalosporins, and carbapenems and confer broad resistance to almost all b-lactam antibiotics. [Table 54-3](#) summarizes commonly used antibacterial agents in patients with cancer.

Antibiotic	Class	Dose (mg/kg)	Comments
Amoxicillin	B-lactamase inhibitor combination	10-15 qd	For respiratory tract infections
Ampicillin	B-lactamase inhibitor combination	10-15 qd	For respiratory tract infections
Cefazolin	1st generation cephalosporin	10-15 qd	For respiratory tract infections
Cefepime	4th generation cephalosporin	100-150 qd	For severe infections
Ceftazidime	3rd generation cephalosporin	100-150 qd	For severe infections
Meropenem	Carbapenem	100-150 qd	For severe infections
Imipenem	Carbapenem	100-150 qd	For severe infections
Vancomycin	Glycopeptide	15-20 qd	For gram-positive infections
Linezolid	Oxazolidinone	600-900 bid	For gram-positive infections
Daptomycin	Lipopeptide	6-10 qd	For gram-positive infections
Tigecycline	Glycylcycline	100-150 qd	For gram-positive and gram-negative infections
Colistin	Polymyxin	9-12 qd	For gram-negative infections
Chloramphenicol	Chloramphenicol	25-35 qd	For gram-positive and gram-negative infections
Trimethoprim-sulfamethoxazole	Trimethoprim-sulfamethoxazole	10-15 qd	For gram-positive and gram-negative infections
Fluoroquinolones	Fluoroquinolones	400-800 bid	For gram-negative infections
Fluconazole	Triazole	400-800 qd	For fungal infections
Isavuconazole	Triazole	400-800 qd	For fungal infections
Voriconazole	Triazole	6-12 qd	For fungal infections
Posaconazole	Triazole	800-1200 qd	For fungal infections
Isavuconazole	Triazole	400-800 qd	For fungal infections

**TABLE 54-3.** Commonly Used Antibacterial Agents in Patients with Cancer

Extended spectrum b-lactamase-producing pathogens (most common in *E coli* and *Klebsiella* species) may not be detected with standard susceptibility testing because of different susceptibility patterns among third-generation cephalosporins. In one study of a nosocomial outbreak of extended spectrum b-lactamases producing *Klebsiella* strain (as indicated by ceftazidime resistance), use of other third-generation cephalosporins was associated with a poorer outcome.<sup>78</sup> Carbapenems (imipenem and meropenem) have consistent bactericidal activity against extended spectrum b-lactamase-producing strains and should be considered drugs of choice in serious infections by these pathogens.

The Bush group 1 b-lactamases may not be initially expressed (repressed), but are induced (de-repressed) after exposure to broad-spectrum cephalosporins, and confer resistance to virtually all b-lactam antibiotics with the exception of the carbapenems and cefepime. This group of b-lactamases is characteristic of *Enterobacter* species, but is also observed in *P aeruginosa*, *Citrobacter*, *Serratia*, and indole-positive *Proteus* species. Thus, if an *Enterobacter* species is isolated from a blood culture, it is reasonable to change the initial antibiotic regimen to a carbapenem, knowing the potential for induction of a cephalosporinase if third-generation cephalosporin therapy is continued.

## PSEUDOMONAS AERUGINOSA

Infections caused by *P aeruginosa* in patients with cancer have diminished since the 1960s and 1970s. Currently, approximately 5% to 10% of bacteremias are caused by this organism in patients with neutropenia. This reduction may reflect the widespread use of fluoroquinolones as prophylaxis as well as the availability of agents with potent antipseudomonal activity, such as ceftazidime, that are used as initial empiric therapy for febrile neutropenia.

Bodey et al.<sup>79</sup> retrospectively analyzed 410 cases of *P aeruginosa* bacteremia in patients with cancer. The overall rate was 4.7 cases per 1000 admissions and was most common among patients with leukemia. Neutropenia was the dominant risk factor. The infections were highly virulent, with 33% of patients developing septic shock and 32% having pneumonia. Other sites of infection included soft tissue, urinary tract, perirectal region, and central venous catheters. Patients who received an antipseudomonal b-lactam antibiotic, with or without an aminoglycoside, had survival rates of 72% and 71%, respectively, compared with 29% survival in patients who received only an aminoglycoside.

The site of disease often reflects where colonization has occurred.<sup>58</sup> Colonization of the upper airway may lead to pneumonia after aspiration of infected droplets. Typhilitis (neutropenic enterocolitis) and perineal cellulitis may follow colonization of the gut by *P aeruginosa*. Pathologically, *P aeruginosa* invades small arteries and veins, leading to thrombosis, hemorrhage, and infarction. This angioinvasion is most evident in cases of ecthyma gangrenosum in which *P aeruginosa* invades cutaneous blood vessels and perivascular connective tissue, leading to coagulative necrosis of the dermis ( [Fig. 54-1](#)). The lesions of ecthyma gangrenosum usually evolve from erythematous macules to papules, and ultimately necrotic nodules and bullae. The lesions may present in any stage with minimal or absent inflammatory infiltrate.

**FIGURE 54-1.** Lesions of ecthyma gangrenosum in a neutropenic patient with bacteremia due to *Pseudomonas aeruginosa*. The ecthyma lesions are in the necrotic ulcerative edge.

Initial optimal antibiotic therapy for *P aeruginosa* bacteremia consists of an antipseudomonal b-lactam antibiotic and an aminoglycoside. It is reasonable to continue aminoglycoside therapy until clinical stability and sterilization of blood have been achieved. Emergence of resistance to cephalosporins and carbapenems during monotherapy for *P aeruginosa* infections may occur. Carbapenem resistance results from an alteration of a porin protein on the outer membrane of the bacteria, preventing penetration of the antibiotic and b-lactamase production.<sup>80</sup> Emergence of resistance to carbapenems during therapy for *P aeruginosa* is well documented and may result in treatment failure. Quinolone-resistant *P aeruginosa* isolates are being observed with increasing frequency. See sections on [Neutropenic Fever](#) and [Manifestations and Therapy of Infections](#), later in this chapter.

## STENOTROPHOMONAS (XANTHOMONAS) MALTOPHILIA

*Stenotrophomonas maltophilia* colonizes hospital environments and establishes carriage generally in patients who have been treated with broad-spectrum antimicrobial agents. This organism has become an increasingly important cause of nosocomial infections in patients with cancer.<sup>81</sup> Clinical manifestations include bacteremia, pneumonia, endocarditis, mastoiditis, and meningitis. Vartivarian et al.<sup>82</sup> reviewed 17 cases of mucocutaneous and soft tissue infections caused by *S. maltophilia* in patients with cancer. These infections manifested as mucocutaneous ulcerations, primary cellulitis (usually catheter related), and metastatic cellulitis consisting of multiple hard, tender nodules with surrounding or distant cellulitic areas resembling disseminated fungal infection, and one case of ecthyma gangrenosum, resembling *P. aeruginosa*. Disseminated cellulitic lesions were most common in patients with refractory leukemia and were frequently associated with septic shock, multiorgan failure, and pneumonia.

*Stenotrophomonas maltophilia* is resistant to imipenem, and isolates are often broadly resistant to other agents. The organism elaborates a metallo- $\beta$ -lactamase, which hydrolyzes carbapenems. The majority of strains are susceptible to trimethoprim-sulfamethoxazole, which is the preferred initial antibiotic for this organism, pending susceptibility data.

## ACINETOBACTER SPECIES

*Acinetobacter calcoaceticus* and *Acinetobacter baumannii* are the principal pathogenic species within this genus. These gram-negative coccobacilli are ubiquitous, easily colonize hospital environments, and have been associated with nosocomial outbreaks. *Acinetobacter* species are frequently multidrug resistant, and the risk of infection in one nosocomial outbreak was associated with quinolones.<sup>83</sup> In the largest series of *Acinetobacter* septicemia in patients with cancer (95 cases), 80% of cases were thought to be catheter related and responded to catheter removal and antimicrobial therapy.<sup>84</sup> Infection was polymicrobial in 25% of cases.<sup>84</sup>

## CLOSTRIDIUM SPECIES

*Clostridium* species include highly virulent toxin-producing species as well as relatively avirulent saprophytes. Toxin-producing species can cause invasive disease such as myonecrosis (gas gangrene), emphysematous cholecystitis and pyelonephritis, necrotizing enterocolitis (typhlitis), and septic shock (see [Intraabdominal Infections](#), later in this chapter). *Clostridium perfringens* and *Clostridium septicum* are the most common clostridial species to cause bacteremia in patients with cancer. *Clostridium tertium* sepsis is less commonly observed, but is highly virulent.<sup>85</sup> Cases of infection due to clostridial species other than *C. perfringens*, *C. septicum*, and *C. tertium* are usually only associated with fever, without evidence of organ involvement, and a low mortality.

Extraintestinal clostridial infections can be devastating. The morbidity and mortality associated with clostridial bacteremia depends on the virulence of the species and the immune status of the host. Clostridial bacteremia after septic abortion is usually self-limited, but clostridial bacteremia with septic shock and myonecrosis requires emergent surgical débridement.

Bodey et al.<sup>86</sup> evaluated 136 episodes of bacteremia due to clostridial species in patients with cancer. Most cases were associated with leukemia, gastrointestinal, and genitourinary malignancies. Eighty-three cases were monomicrobial and 53 were polymicrobial. In 45% of cases of polymicrobial bacteremia, three or more organisms were isolated from the blood. Isolates associated with clostridial sepsis consisted predominantly of enteric flora: *E. coli*, *Klebsiella* species, and *Bacteroides* species. Polymicrobial bacteremias were more likely to result in septic shock and death. The overall survival rate from clostridial bacteremia was 58%, a dramatically poorer prognosis than monomicrobial bacteremias caused by aerobic gram-positive and gram-negative species.

Local and systemic clostridial infections are associated with gastrointestinal and genitourinary neoplasms. They are normally commensals, but proliferate in tissues with a low redox potential, such as necrotic tumors. Damage to the mucosa by chemotherapy or radiation therapy likely further predisposes to local invasion and dissemination. Local bowel invasion by clostridial species can result in necrotizing colitis (typhlitis), which typically involves the cecum but can extend to other regions of the bowel.

Clostridial infections often have a fulminant course. Acute hemolysis, myonecrosis, diffuse spreading cellulitis, and septic shock have a high mortality. Clostridial myonecrosis may respond to rapid surgical débridement. A needle aspiration or biopsy of the infected tissue showing large, thick gram-positive rods is highly suggestive of the diagnosis. However, staining of the organism in clinical material may be variable or appear to be gram negative. In patients with leukemia, clostridial soft tissue infection and septic shock may be particularly rapid, precluding surgical intervention.

Clindamycin and metronidazole are both active against *Clostridia*. Clindamycin, in addition to its antianaerobic activity, may have a theoretical value of reducing toxin production. In a mouse model of myonecrosis by *C. perfringens*, clindamycin and metronidazole were each more effective than penicillin.<sup>87</sup> The initial antibiotic regimen should also include an agent active against aerobic enteric flora, such as ceftriaxone, since deep soft tissue infections are often polymicrobial. In neutropenic patients, metronidazole or clindamycin plus an antipseudomonal  $\beta$ -lactam (such as ceftazidime or cefepime), with or without an aminoglycoside, are reasonable regimens.

## MYCOBACTERIA

Host defense against *Mycobacterium* species relies principally on functional T lymphocytes. It is therefore surprising that the incidence of *Mycobacterium tuberculosis* (MTB) infection in BMT recipients is relatively low. In two large BMT centers in the United States, MTB infection occurred in approximately 1 per 1000 patients.<sup>88,89</sup> In a Saudi Arabian study, the incidence of tuberculosis was 0.6% among BMT recipients.<sup>90</sup> In contrast, a study in Hong Kong, a highly endemic area for MTB, reported a 5.5% incidence of MTB in BMT recipients.<sup>91</sup> Therefore, an extra level of vigilance for MTB is necessary among patients who have resided in endemic countries.

In patients with compromised T-cell immunity, the clinical manifestations of infection due to MTB may be atypical, and disseminated disease is more common than in immunocompetent patients.<sup>92</sup> The chest radiographic appearance is highly variable and may include an isolated nodule, an infiltrate, or a diffuse reticulonodular pattern indicative of hematogenous dissemination. The chest radiographic result may be negative in patients with disseminated extrapulmonary tuberculosis. Cavitory lung disease is less commonly observed in immunocompromised hosts. Extrapulmonary manifestations may include meningitis, brain abscess, vertebral or paravertebral abscess, septic joint, hepatic and splenic disease, and bone marrow involvement. Patients who consume unpasteurized dairy products are at increased risk of gastrointestinal tuberculosis caused by *Mycobacterium bovis*. In addition, systemic iatrogenic *M. bovis* infection may rarely occur after intravesicular therapy with bacille Calmette-Guérin for bladder cancer.<sup>93</sup>

Because of the varied manifestations of MTB, a high index of suspicion may be required to make the diagnosis. For example, a new pulmonary nodule or infiltrate may be mistaken for aspergillosis, and gastrointestinal tuberculosis may be mistaken for GVHD. A definitive diagnosis should be pursued aggressively and early. Detection of mycobacterial DNA in clinical specimens by polymerase chain reaction (PCR) may facilitate a more rapid diagnosis, although cultures are required for drug susceptibility testing.

Due to the increased frequency of drug-resistant isolates, initial therapy for tuberculosis consists of a four-drug regimen (isoniazid, rifampin, pyrazinamide, and ethambutol) for the first 2 months. If a positive clinical response is seen, an additional 4 months of isoniazid and rifampin (if the isolate is sensitive to these agents) is administered. In patients with profound immunosuppression, it is reasonable to extend the course of therapy to 9 months, given the potential increased risk for recrudescence. Rifampin is both metabolized by, and is a potent inducer of, the hepatic cytochrome P-4503A isozyme, creating the potential for adverse drug-drug interactions with other drugs (such as CSA and antifungal azoles) used in this patient group that are also metabolized through this pathway. Consultation with MTB specialists is advised for suspected or confirmed multidrug-resistant tuberculosis.

Prevention of infection relies on compliance with established infection control measures, including respiratory isolation of persons with presumed or known active tuberculosis in negative pressure rooms. Given the low prevalence of tuberculosis in cancer centers in the United States, we suggest that skin testing be reserved for patients with some additional risk factor for tuberculosis (such as residence in an endemic country or human immunodeficiency virus infection).

Infection with nontuberculous mycobacteria (atypical mycobacteria) is well described among patients with cancer. Pathogenic species include *Mycobacterium avium* complex, *Mycobacterium kansasii*, *Mycobacterium haemophilum*, and the *Mycobacterium fortuitum-chelonae* complex. Clinical manifestations include pneumonia, soft tissue or wound infections, and central catheter infections that may require surgical excision of the infected tunnel site<sup>94</sup> (see [Implanted Vascular Catheters](#), later in this chapter). Patients with hairy cell leukemia appear to be particularly susceptible to *M. kansasii* infection.<sup>95</sup> Sites of involvement include the lungs, lymph nodes, liver, and spleen, and disseminated disease. *M. haemophilum* may cause fatal pneumonia and disseminated cutaneous lesions.<sup>96</sup> This organism has a unique

requirement for iron supplementation for growth, and therefore the microbiology laboratory should be alerted that this diagnosis is being considered. Speciation of mycobacterial isolates is essential because atypical mycobacteria are typically resistant to regimens for MTB. DNA probes are used to rapidly identify isolates at the species level.

## **NOCARDIA**

*Nocardia* infections are most frequent in patients with impaired T-cell immunity. Patients with Hodgkin's and non-Hodgkin's lymphoma receiving immunosuppressive therapy appear to be at particularly high risk for nocardiosis. <sup>97,98</sup> and <sup>99</sup> Nocardiosis is relatively uncommon in BMT recipients, with an incidence of 0.3% to 0.7%. <sup>100,101</sup> In the largest series, nocardiosis occurred exclusively in allogeneic transplant recipients and developed in both the early and late transplant period (median time, 210 days). <sup>100</sup>

The lungs are the most common site of infection for bronchopneumonia, lobar pneumonia, nodules, and necrotizing abscesses with cavitation observed. Empyema and extension to the chest wall occur. The lesion may be mistaken for a tumor. Extrapulmonary nocardiosis may occur in the presence or absence of pulmonary disease. Brain abscess, meningitis, osteomyelitis, soft tissue mass, cutaneous abscess, catheter exit site infection, liver abscess, bacteremia, and disseminated disease are seen.

*Nocardia* species are slender, filamentous, beaded, branching gram-positive rods. When nocardiosis is considered, a modified acid fast smear should be ordered because *Nocardia* species stain variably when the conventional acid fast smear is used. Visualization of *Nocardia* species in histologic specimens may also be variable due to weak uptake of stains. A combination of Gram's staining and staining using the Ziehl-Neelsen (acid alcohol decolorizing agent) and Fite (sulfuric acid used instead of alcohol) methods may increase the diagnostic yield. <sup>100</sup> Although *Nocardia* species grow on a variety of media, it is important to alert the microbiology laboratory so that appropriate culture conditions are used.

Therapy consists of high-dose trimethoprim-sulfamethoxazole (15 to 20 mg of trimethoprim/kg daily in three to four divided doses). Combination therapy consisting of a sulfonamide plus an agent with presumed synergy, such as amikacin, imipenem, minocycline, or ceftriaxone, also is frequently used. <sup>100</sup> Surgical drainage or resection should be considered in cases refractory to medical therapy. However, the time course of resolution is slow, and the therapy must be continued for months.

## **FUNGAL INFECTIONS**

### **CANDIDIASIS**

#### ***Oropharyngeal and Esophageal Candidiasis***

Oral mucosal candidiasis, also called *thrush*, indicates T-cell immunodeficiency. In patients with cancer, conditions that predispose to oral candidiasis include cytotoxic chemotherapy causing mucosal disruption, high-dose corticosteroids, and use of broad-spectrum antibiotics.

The diagnosis of oral candidiasis is usually made visually. White adherent plaques develop on the palate, buccal mucosa, tongue, or gingiva. The differential diagnosis includes chemotherapy-induced mucositis, bacterial infections, and HSV infection. A wet mount or Gram's stain showing pseudohyphae establishes the diagnosis. A culture of the oral mucosa that grows *Candida* species is not by itself diagnostic as these species commonly colonize the mouth. Therapy for oropharyngeal candidiasis includes local treatments such as nystatin or clotrimazole troches or oral fluconazole.

Esophageal candidiasis is a more severe mucosal disease that typically manifests with odynophagia. The differential diagnosis includes esophageal infection by HSV, CMV (in BMT recipients), and bacterial infections (see [Esophagitis](#), later in this chapter). Systemic antifungal therapy (fluconazole or amphotericin B) is required.

#### ***Candidemia***

*Candida* species are the fourth most common nosocomial blood culture isolates in the United States. <sup>102</sup> In some series, the attributable mortality to candidemia was 40% to 60%. <sup>103</sup> This high mortality may reflect the fact that these patients often have serious comorbidities, such as malignancy, neutropenia, and illness requiring prolonged periods in the intensive care unit. In a European surveillance study of candidemia in cancer patients, the overall 30-day mortality was 39%, with increased mortality occurring in older patients, in those with poorly controlled malignancy, and in cases in which *Candida (Torulopsis) glabrata* was isolated. <sup>104</sup> In a retrospective study of 476 cases of candidemia at M. D. Anderson Cancer Center, the mortality was 52%. Neutropenia, a high APACHE (Acute Physiology and Chronic Health Education) score, and disseminated disease were associated with poorer outcomes. <sup>105</sup>

*Candida albicans* is the most common species isolated from the blood. The proportion of non-*albicans* *Candida* species varies among different centers. Among patients with cancer, non-*albicans* *Candida* species account for approximately 45% of cases of systemic candidiasis. <sup>106</sup> Among non-*albicans* *Candida* species, *Candida tropicalis* was the most common isolate followed by *C glabrata*, *C parapsilosis*, and *C krusei*. <sup>106</sup> The proportion of non-*albicans* *Candida* isolates has direct clinical significance. *C krusei* is always resistant to fluconazole, and *C glabrata* is variably resistant. When either of these two species are isolated from the blood, amphotericin B therapy is necessary. *C tropicalis* is more virulent than *C albicans* in immunocompromised animal models <sup>107</sup> and often has a more severe clinical course in patients. <sup>108</sup> Cutaneous dissemination, arthralgias, myalgias, and renal failure appear to be more common in *C tropicalis* infection. <sup>108</sup> *C parapsilosis* is mostly associated with vascular catheters and lipid formulations used for total parenteral nutrition. Some *C guilliermondi* and *C lusitanae* isolates are resistant to amphotericin B.

Antifungal susceptibility testing is becoming more common and gaining acceptance. Standard guidelines and interpretive breakpoints for susceptibility testing of fluconazole, itraconazole, and 5-flucytosine against yeasts have been proposed by the National Committee for Clinical Laboratory Standards. These may be useful in select cases in which resistance is suspected and in epidemiologic studies.

Isolation of *Candida* species from blood remains unreliable even with modern blood culture isolation systems. The sensitivity for detecting candidemia has been significantly improved by the lysis centrifugation system (Isolator, Wampole Laboratories, Cranbury, NJ) and the BacTAlert system (Organon Teknika, Durham, NC), which detect candidemia earlier and more reliably than conventional broth systems. <sup>18</sup> However, in single organ infection and in early disseminated candidiasis, even lysis centrifugation culture has limited sensitivity. <sup>109</sup> Nonculture methods, such as amplification by PCR, antigen detection, and detection of metabolites, are investigational and may prove useful in complementing culture methods. <sup>110</sup>

All candidemic patients, both neutropenic and nonneutropenic, should be treated with fluconazole or amphotericin B. Isolation of a *Candida* species from only a single blood culture (whether drawn from a catheter or peripheral vein), should be considered indicative of hematogenously disseminated disease. The rationale for early antifungal therapy is to avoid sequelae, such as endophthalmitis and hepatosplenic candidiasis. In a retrospective study of 155 cases of catheter-associated fungemia in patients with cancer, a significant proportion of patients who did not receive antifungal therapy after isolation of a *Candida* species from the blood (possibly because the isolate was considered to be a contaminant or candidemia was considered to be transient) subsequently developed disseminated candidiasis. <sup>111</sup> The site of blood collection, either from a central catheter or peripheral site, had no predictive value in defining the risk of subsequent disseminated disease. <sup>111</sup>

A large randomized study comparing intravenous fluconazole (400 mg daily) with amphotericin B (0.5 mg/kg daily) as therapy for candidemia in nonneutropenic patients found both regimens equally effective. <sup>112</sup> In uncomplicated candidemia, at least 2 weeks of antifungal therapy after the last positive culture result should be administered. Due to the increased frequency of *Candida* isolates with intermediate or complete resistance to fluconazole, a National Institute of Allergy and Infectious Disease Mycosis Study Group trial is underway to compare fluconazole plus amphotericin B versus fluconazole alone in nonneutropenic patients with candidemia.

Management of candidemia in neutropenic patients is more controversial. Amphotericin B has been the standard therapy, but use of fluconazole in this population has increased. In a consensus conference dealing with the management of candidal infections, 17 of 20 investigators chose fluconazole for treatment of uncomplicated candidemia in stable neutropenic patients if no prior azole prophylaxis was administered and no evidence of hematogenous seeding or deep organ involvement existed. <sup>103</sup> A randomized multicenter study <sup>113</sup> and a matched cohort study <sup>114</sup> showed that fluconazole and amphotericin B had comparable efficacy in invasive candidiasis in neutropenic and nonneutropenic patients. In centers in which non-*albicans* *Candida* species (most notably, *C krusei* and *C glabrata*) are frequently isolated, we believe that it is prudent to use amphotericin B initially. Candiduria in the neutropenic patient should be treated with systemic antifungal therapy because

with hemorrhage, perforation, and polymicrobial sepsis. Early diagnosis of isolated gastrointestinal aspergillosis followed by resection of the involved bowel and systemic antifungal therapy may be life saving. Other sites of disseminated aspergillosis include the skin, heart, eye, bone, kidney, liver, and thyroid.

Isolation of an *Aspergillus* species from a sputum or bronchoalveolar lavage specimen should be presumed to represent invasive disease in neutropenic patients.<sup>124</sup> In the study by Wald et al.<sup>120</sup> a mucosal isolate of an *Aspergillus* species had a positive predictive value of 60% for invasive disease among BMT recipients; during the neutropenic period, the positive predictive value was 94%.

Early diagnosis of aspergillosis in highly immunocompromised patients remains difficult. Blood cultures are rarely positive, sputum and bronchoalveolar cultures have approximately 50% sensitivity in focal pulmonary lesions, and definitive diagnosis often requires an invasive procedure and is usually only made when the disease is advanced.

CT scanning of the chest may facilitate early detection of aspergillosis. A CT scan may show peripheral or subpleural nodules inapparent on plain chest radiographs. The *halo sign* is a characteristic chest CT feature of angioinvasive organisms.<sup>125</sup> The hazy alveolar infiltrates appear to correspond to regions of ischemia and are highly suggestive of invasive aspergillosis.<sup>125</sup> Ultrafast CT technology reduces the scanning time to as little as 5 minutes, thus permitting wider application to seriously ill patients. Early recognition of pulmonary aspergillosis followed by intensive antifungal therapy and surgical resection of localized disease (see discussion later in this section) has led to improved survival.<sup>126</sup>

PCR-based detection of subclinical aspergillosis is a promising tool for early diagnosis. In a European study, 134 patients underwent at least two bronchoalveolar lavages at the time of BMT, and PCR for *Aspergillus* species was performed.<sup>127</sup> Of seven patients whose bronchoalveolar lavage was PCR positive and culture and cytology were negative, five developed invasive pulmonary aspergillosis within the first 100 days of transplant. A larger study to prospectively evaluate the predictive value of PCR screening of whole blood for *Aspergillus* species DNA among allogeneic BMT recipients is underway. A sensitive double-sandwich enzyme-linked immunosorbent assay for detection of the fungal cell wall constituent galactomannan has been developed.<sup>128</sup> Clinical trials are now essential to delineate which of these diagnostic methods, or which combination, provides the optimal positive and negative predictive value for invasive disease among high-risk patients, and how this information should be translated into a rational therapeutic algorithm.

*Aspergillus fumigatus* followed by *Aspergillus flavus* are the most common species causing invasive disease in neutropenic patients and after BMT. Therapy for invasive aspergillosis in neutropenic patients and in BMT recipients involves high-dose conventional amphotericin B (1.0 to 1.5 mg/kg daily) or a lipid formulation of amphotericin B. *Aspergillus terreus* is an emerging pathogen in this population that is notable for being resistant to amphotericin B.<sup>129</sup> In cases of invasive *A terreus* infection, the third-generation triazole, voriconazole, may be of value based on *in vitro* sensitivity data.<sup>129</sup>

Surgical excision of locally invasive disease, such as sinusitis, primary cutaneous lesions, intravitreal disease, or bone lesions should be performed. Removal of infected intravenous and peritoneal dialysis catheters and silk sutures in bronchial stumps are also necessary components of therapy. In neutropenic patients and in allogeneic BMT recipients, combined surgery and systemic antifungal therapy should be used in cases of apparent localized disease because of the risk of subclinical dissemination.

The indications for and timing of thoracic surgery for aspergillosis are controversial. In postpneumonectomy patients, infection of the bronchial stump should be débrided and sutures removed. Invasive pleural and pericardial aspergillosis should be treated with decortication and stripping. When possible, pulmonary aspergillosis adjacent to major vessels should be surgically removed to avoid exsanguinating hemoptysis. In a retrospective series of patients with acute leukemia and pulmonary filamentous mycosis (mostly caused by *Aspergillus* species), hemoptysis most commonly occurred shortly after resolution of neutropenia.<sup>130</sup>

Patients who recover from an episode of invasive aspergillosis are at risk for relapse during a subsequent course of myeloablative chemotherapy. In the largest series, a retrospective analysis was performed on 48 patients with definite or probable aspergillosis who subsequently were treated with BMT (77% allogeneic).<sup>131</sup> All patients received systemic antifungal therapy, and approximately 40% underwent surgical resection as initial therapy. Forty-one of 48 (85%) patients received secondary prophylaxis at the time of BMT; the regimens included itraconazole, amphotericin B (conventional and lipid formulations), and combinations of agents with wide variability in dosage and duration. The overall incidence of relapse was 29% among patients receiving secondary prophylaxis and 57% among those who did not. Fourteen of 16 (88%) patients who had relapses died. Other smaller series have also shown that systemic antifungal therapy (with and without surgical resection) of primary fungal infection followed by secondary prophylaxis can suppress reactivation in the majority of patients subsequently undergoing additional myeloablative chemotherapy or BMT.<sup>132,133</sup>

We advise using high-dose amphotericin B (1.0 to 1.5 mg/kg daily) or a lipid formulation of amphotericin B for secondary prophylaxis of invasive aspergillosis during neutropenia after intensive chemotherapy for leukemia or preparative regimens for BMT. Oral itraconazole is more suitable as a maintenance regimen after resolution of neutropenia and mucositis. Antifungal prophylaxis should be reinitiated preemptively during GVHD. Surgical resection does not obviate the need for secondary antifungal prophylaxis during subsequent chemotherapy given the likelihood of residual foci of disease not apparent on diagnostic imaging.

An additional component in treating aspergillosis is reversal or amelioration of immunosuppression. In patients with neutropenia and disseminated aspergillosis, resolution of neutropenia is critical for survival. Granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) may accelerate myelopoiesis and reduce the neutropenic period as well as augment neutrophil activity. Use of these agents for treatment of serious fungal infections is limited so far to case reports. Corticosteroid therapy should be reduced or discontinued if at all feasible. Granulocyte transfusions may stabilize progressive invasive aspergillosis refractory to antifungal chemotherapy and allow more time until recovery from neutropenia (see [Granulocyte Transfusions](#), later in this chapter).

## ZYGOMYCOSIS

Risk factors for zygomycosis (also termed  *mucormycosis*) include diabetic ketoacidosis, protein-calorie malnutrition, iron overload, and prolonged neutropenia.<sup>134</sup> Patients receiving potent myeloablative chemotherapy for leukemia are at risk for locally invasive as well as disseminated disease.

Zygomycosis typically manifests as rhinocerebral or pulmonary disease after inhalation of spores. In rhinocerebral disease, fever, facial pain, and headache are common findings. Contiguous extension may lead to orbital involvement with proptosis and extraocular muscle paresis, involvement of hard palate, and spread to the brain. An eschar over the palate is suggestive of zygomycosis, but other filamentous fungi can produce similar findings in highly immunocompromised persons. Occasionally, isolated primary cutaneous disease may follow minor trauma. Injection drug users may inject contaminating spores directly into the blood stream and may present with isolated space-occupying lesions of the brain or other organs. Therapy for zygomycosis involves high-dose amphotericin B (conventional or lipid formulations) plus early and aggressive surgical débridement. Itraconazole is not active against *Zygomycetes* species.

## CRYPTOCOCCUS NEOFORMANS

Among patients with cancer, lymphoreticular malignancy and corticosteroid therapy appear to be major risk factors.<sup>135</sup> Host defense against cryptococcal infection is dependent on T-cell immunity. Isolated neutropenia is rarely associated with cryptococcal infection. Immunoglobulins directed against capsular epitopes and complement facilitate phagocytosis of the organism and likely play a role in host defense.<sup>136,137</sup> The principal portal of entry of this organism is via inhalation. Spread to the blood and then to the CNS is a prerequisite for subsequent development of cryptococcal meningitis.

Although meningitis is the most common presentation of cryptococcal infection, other manifestations include primary pneumonia, fungemia, and cutaneous and visceral dissemination. In the pre-acquired immunodeficiency syndrome (AIDS) era, patients who died early during therapy were more likely to have rapidly progressive infection, cerebrospinal fluid with high opening pressure, a low glucose level, less than 20 leukocytes/ $\mu$ L, a positive india ink preparation, culture of cryptococci from extraneural sites, and high titers of cryptococcal antigen in serum and cerebrospinal fluid.<sup>135</sup> A more recent study of non-AIDS-associated cryptococcal disease showed that mortality was highest among persons with malignancy.<sup>138</sup> Additional CNS complications include development of a mass lesion, obstructive hydrocephalus requiring shunting,<sup>139</sup> and vision loss. Vision loss may be a consequence of endophthalmitis, a space-occupying lesion in the visual pathway, direct invasion of the optic nerve (which may cause vision loss over several hours), and as a consequence of elevated intracranial pressure.<sup>140</sup>

Optimal therapy for non-AIDS-associated cryptococcal disease is not well defined. In a classic study, Bennett et al.<sup>141</sup> showed that the combination of amphotericin B plus 5-flucytosine for 6 weeks was superior to amphotericin B alone administered for 10 weeks in non-AIDS-associated cryptococcal meningitis. In AIDS-associated

cryptococcal meningitis, the optimal regimen currently is amphotericin B (0.7 mg/kg daily) plus 5-flucytosine (100 mg/kg daily) for the first 2 weeks, followed by life-long maintenance fluconazole therapy (400 mg daily).<sup>142,143</sup> This is an appropriate regimen to use in non-AIDS-associated cryptococcal infection in the absence of modern randomized trials. In neutropenic patients, reduction of the dosage of 5-flucytosine may be considered to avoid delay in myeloid recovery. Because fluconazole is well tolerated, continuing therapy with this agent for several months (or longer if intensive immunosuppressive therapy is continued) is reasonable. In a retrospective series, fluconazole was as efficacious as amphotericin B as initial therapy for non-AIDS-associated cryptococcal disease.<sup>138</sup> Further studies are required to evaluate initial therapy with fluconazole in different populations with cryptococcal disease.

## EMERGING OPPORTUNISTIC FUNGAL PATHOGENS

### *Trichosporon* Species

*Trichosporon* species typically infect profoundly neutropenic patients and those receiving corticosteroid therapy. Acute disseminated trichosporonosis typically manifests with refractory fungemia, funguria, cutaneous lesions, renal failure, pulmonary lesions, and chorioretinitis.<sup>144,145</sup> Disseminated trichosporonosis may yield a false-positive cryptococcal latex antigen test result because of cross-reactivity with the polysaccharide capsule of *C. neoformans*.<sup>146</sup> This cross-reactivity may be clinically important because patients treated with high-dose corticosteroid therapy are at risk for both infections, and *C. neoformans* typically responds to amphotericin B therapy, whereas *Trichosporon* species are usually resistant.

*In vitro* and experimental infections indicate that most *Trichosporon* species are inhibited, but not killed, by achievable serum levels of conventional amphotericin B.<sup>147</sup> Fluconazole has superior activity in experimental infections and is recommended as the preferred antifungal agent.<sup>148,149</sup> Combination therapy with high-dose amphotericin B (1.0 to 1.5 mg/kg daily) and fluconazole (800 mg daily or 12 mg/kg daily in children) may have synergy against some strains based on murine models of trichosporonosis.<sup>148</sup>

*Blastoschizomyces capitatus* (formerly *Trichosporon capitatus*) usually presents as a chronic disseminated infection, resembling chronic candidiasis.<sup>150</sup> A CT scan may show lesions suggestive of hepatosplenic candidiasis, and definitive diagnosis requires either a positive blood culture result or biopsy. CNS involvement is also observed. *B. capitatus* does not cross-react with the cryptococcal latex agglutination test.

### *Malassezia* Species

*Malassezia furfur* is often associated with lipid parenteral nutrition administered through a central venous catheter in immunocompromised patients or premature infants.<sup>151</sup> Clinical manifestations, including persistent fungemia, pulmonary infiltrates, and thrombocytopenia, occur in premature infants but not in adults. Blood culture recovery is enhanced by addition of olive oil or other long-chain fatty acids to the culture plates.

*M. furfur* is often refractory to amphotericin B therapy. Fluconazole therapy is probably the drug of choice, but discontinuation of lipid infusions and removal of the central catheter are important for successful resolution of fungemia. In neutropenic patients and patients treated with corticosteroids, a folliculitis resembling disseminated candidiasis may occur. This infection is a localized process and does not imply disseminated infection. *Malassezia pachydermatis* is a less common cause of infection than *M. furfur* and has similar clinical manifestations.

### Dematiaceous (Dark-Walled) Molds

Dark-walled molds contain melanin in their cell walls that imparts a brown or olive-green pigment in culture. In immunocompromised patients, soft tissue infection, sinusitis, CNS infection, pneumonia, fungemia, and disseminated disease are observed. Subcutaneous infection is most frequently caused by *Alternaria* species.<sup>152</sup> *Bipolaris*, *Cladophialophora* (*Xylohypha* or *Cladosporium*) *bantiana*, *Wangiella*, and *Dactylaria* species have strong predispositions to cause CNS disease.<sup>153</sup>

Definitive diagnosis of phaeohyphomycosis requires documentation of fungal invasion and recovery of the mold from culture of tissue specimens. Positive results of Fontana-Masson staining of tissue specimens, which detects phenolic compounds, including melanin, are suggestive, but not diagnostic, of phaeohyphomycosis.<sup>154</sup> Disseminated infection by *Bipolaris* species may yield a positive blood culture result.

Therapy in immunocompromised patients involves surgical excision of localized disease when feasible and systemic antifungal therapy. Amphotericin B (1.0 to 1.5 mg/kg daily) is standard initial therapy. Sensitivity to amphotericin B is variable, and clinical failures have been reported. Itraconazole has been shown to be effective in cases of phaeohyphomycosis refractory to amphotericin B.<sup>249</sup> Our practice has been to use amphotericin B plus itraconazole as initial therapy for phaeohyphomycosis in severely immunosuppressed patients, followed by prolonged itraconazole maintenance therapy once stabilization has been achieved. Monitoring of serum itraconazole levels is necessary to document oral absorption.

### *Fusarium* Species

*Fusarium* species are soil saprophytes that have been associated with soft tissue infection, onychomycosis, and keratitis in immunocompetent hosts. With the widespread use of intensive antineoplastic therapy and BMT, more than 150 cases of invasive and disseminated fusariosis have been reported, most within the 1990s.<sup>155</sup> The clinical findings and histologic appearance may be indistinguishable from aspergillosis. In the absence of a definitive culture diagnosis, the likelihood of infection by a *Fusarium* species is substantially increased by the presence of disseminated cutaneous lesions and isolation of a mold from blood culture.

Boutati and Anaissie<sup>155</sup> made important observations about invasive and disseminated fusariosis in a retrospective review of 43 cases occurring in patients with hematologic malignancies at M. D. Anderson Cancer Center. Most cases of disseminated fusariosis were diagnosed during neutropenia, and a high risk of relapse was associated with subsequent myelosuppression. Similar to aspergillosis, a bimodal distribution of fusariosis occurred in BMT recipients (before and after myeloid engraftment). The skin was identified as an important portal of entry. Initial localized manifestations included onychomycosis, paronychia, and cellulitis. Early identification of localized skin disease and surgical débridement may be life saving. Inhalation of spores is another major portal of entry, leading to fungal sinusitis and pneumonia.

Survival from disseminated fusariosis is critically dependent on resolution of neutropenia. Despite the poor response, amphotericin B (1.0 to 1.5 mg/kg daily) or a lipid formulation (greater than or equal to 5 mg/kg/d) is standard therapy. We use G-CSF and granulocyte transfusions in combination with antifungal therapy to try to control the infection until myeloid recovery occurs.

### *Scedosporium* Species

*Scedosporium apiospermum* (*Pseudallescheria boydii*) and *Scedosporium prolificans* are the principal pathogenic species in the genus *Scedosporium*. In neutropenic patients, *P. boydii* is a virulent pathogen, which clinically and histologically resembles aspergillosis. Invasion of blood vessels leading to infarction is common. *P. boydii* causes sinopulmonary disease, endophthalmitis, and dissemination to the CNS. The infection can also spread directly from the skin to bone and joint. Establishing a culture diagnosis of *P. boydii* is important because of its frequent resistance to amphotericin B. *P. boydii* is usually susceptible to azoles, and *in vitro* studies and some clinical experience suggest that the combination of amphotericin B plus an azole (e.g., fluconazole, itraconazole, or miconazole) may provide enhanced activity.<sup>156</sup> Surgical resection of localized lesions is strongly advised. *S. prolificans* causes a similar spectrum of disease as *P. boydii* and is generally resistant to all antifungal agents.

## ENDEMIC DIMORPHIC FUNGI

Endemic dimorphic fungi are so named because of their characteristic geographic distribution. These organisms include *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*, and *Penicillium marneffe* (*P. marneffe* is endemic in Southeast Asia). These fungi are dimorphic, existing in nature in the mycelial stage, and convert to yeast stage at body temperature. Because some of these pathogens may be quiescent during the initial infection and only manifest clinically during a subsequent period of severe depression or cell-mediated immunity, a detailed travel history is essential.

Endemic mycoses in the central United States include histoplasmosis and blastomycosis. In the immunocompetent host, inhalation of *Histoplasma* microconidia is

typically asymptomatic, but may manifest with acute fever, pulmonary infiltrates, and hypoxia. Immunocompromised patients have a higher risk of disseminated histoplasmosis involving the liver, spleen, lymph nodes, bone marrow, adrenal glands, mucocutaneous tissues, gastrointestinal tract, and CNS. The chest radiograph may show a miliary reticulonodular appearance, suggestive of tuberculosis. An acute sepsis syndrome with hypotension and disseminated intravascular coagulation, adrenal crisis, and meningitis are additional potentially lethal complications.

A rapid diagnosis of histoplasmosis can be made by Giemsa staining of a peripheral blood smear of bone marrow aspirate demonstrating characteristic intracellular yeast forms. Lysis centrifugation is the preferred blood culture system. Antigen detection from blood and urine is a sensitive and specific method in disseminated disease.<sup>157</sup> Antibody detection may also be useful, but false-negative results may occur in immunocompromised patients. Biopsy of specimens may show intracellular or narrow budding yeasts suggestive of the diagnosis, which should be confirmed by culture. In the immunocompromised patient, histoplasmosis should be treated with high-dose amphotericin B (1.0 to 1.5 mg/kg of body weight daily). Prolonged therapy with itraconazole may be initiated after stabilization of disease and should probably be continued for the duration of immunosuppression.

*Blastomyces dermatitidis* may present as an acute pulmonary infection resembling bacterial pneumonia, or as a chronic infection resembling tuberculosis or lung cancer. Extrapulmonary manifestations include involvement of bone, prostate, and CNS. Skin disease resulting from direct inoculation includes large ulcerative and verrucous lesions.

*Coccidioides immitis* is endemic in the southwestern United States. In normal persons, infection is usually symptomatic or self-limited. In patients with compromised cell-mediated immunity, *C immitis* is likely to be more virulent. In an early review of *C immitis* infection in immunocompromised patients, disseminated disease occurred in almost one-half of the cases and was associated with a high mortality.<sup>158</sup> Progression of infection was often fulminant, and evidence of pulmonary disease frequently occurred after signs of dissemination manifested.<sup>158</sup> Diagnosis is most easily established by serology (in systemic disease) or demonstration of pathognomonic spherules in sputum or tissue samples. Coccidioidomycosis can involve virtually any organ in disseminated disease, but has a particular tropism for bone and the CNS. Therapy for disseminated disease generally requires amphotericin B followed by maintenance fluconazole. Intracisternal amphotericin B should be added in cases of meningitis.

## ANTIFUNGAL AGENTS

### Azoles

The antifungal activity of azoles principally results from inhibition of the enzyme, lanosterol 14- $\alpha$ -demethylase, which converts lanosterol to ergosterol, a critical component of the fungal cell membrane. These agents also inhibit the cytochrome P-450-dependent enzymes of the fungal respiratory chain. One of the potential toxicities of these compounds is that, to varying degrees, they inhibit mammalian hepatic cytochrome P-450 mixed function oxidases (e.g., 3A4, 3C9, and 3C19), which are involved in the metabolism of numerous drugs. Thus, the potential exists for serious and even life-threatening drug-drug interactions resulting from toxic levels of drugs metabolized by cytochrome P-450 system when they are administered concurrently with the antifungal azoles. The triazoles fluconazole and itraconazole are the most commonly used azoles in patients with cancer (see [Table 54-4](#)).

### Fluconazole

Fluconazole has activity against yeasts, dermatophytes, and dimorphic fungi, but not against *Aspergillus* species and other filamentous fungi. It has a favorable pharmacokinetic profile. The oral bioavailability of fluconazole exceeds 90%, and absorption is not affected by food or gastric pH. Fluconazole effectively penetrates the CNS, making it a valuable drug for maintenance therapy for cryptococcal and coccidioid meningitis. The elimination half-life is approximately 30 hours. Drug-drug interactions with fluconazole appear to be less severe than with itraconazole and ketoconazole.

The minimum dose of fluconazole for candidemia or invasive candidiasis is 400 mg daily in adults or 8 to 10 mg/kg/d in children. Dosage reduction is required in patients with renal impairment (creatinine clearance less than 50 mL/min). Clinical experience has been gained using dosages of 800 mg or greater,<sup>159</sup> and several investigators recommend using such a dosage in patients with invasive candidiasis until control of infection is achieved.<sup>103</sup>

One of the major uses of fluconazole in patients with cancer is as a prophylactic agent. In BMT recipients, two double-blind, placebo-controlled trials have shown that prophylactic fluconazole controlled yeast colonization and reduced the rate of mucosal candidiasis and invasive *Candida* infections.<sup>160,161</sup> The use of empiric amphotericin B for prolonged neutropenic fever also was delayed. A reduction in mortality was noted in one of the studies.<sup>161</sup> In an autopsy series of BMT recipients performed at the Fred Hutchinson Cancer Research Center, fluconazole prophylaxis was associated with a reduction in candidal infections, most notably in hepatic candidiasis, but infections by *Aspergillus* species were increased.<sup>162</sup>

Fluconazole prophylaxis has produced mixed results in patients with leukemia receiving chemotherapy. In one randomized study, fluconazole prophylaxis was associated with a reduction in skin and mucosal infection and delay in empiric amphotericin B, but with no significant difference in invasive candidiasis or mortality in comparison with the placebo arm.<sup>163</sup> In another study, fluconazole prophylaxis reduced fungal colonization, invasive infection, and fungal infection-related mortality in patients with leukemia receiving intensive cytotoxic chemotherapy.<sup>164</sup> The major concern with prophylactic fluconazole is the emergence of resistant *Candida* species<sup>165</sup> (see [Candidemia](#), earlier in this chapter).

### Itraconazole

Itraconazole has antifungal activity against yeasts, dermatophytes, and dimorphic fungi, and in contrast to fluconazole, is also active against *Aspergillus* species and dark-walled molds. Itraconazole is not active against *Fusarium* species or the agents of zygomycosis.

Itraconazole is available in oral form (capsules and solution) but its oral bioavailability can be erratic. The parenteral solution of itraconazole has been made available in the United States. However, little is known about its use in neutropenic hosts or BMT recipients. Itraconazole is soluble only at an acidic pH, and thus absorption is compromised in patients with achlorhydria and in those patients taking antacids or H<sub>2</sub>-receptor antagonists. Absorption is enhanced when itraconazole is taken with food or an acidic beverage. The cyclodextrin preparation of itraconazole is in solution form and has approximately a twofold increased bioavailability compared with that of itraconazole capsules. Because of the inconsistent absorption, plasma itraconazole levels should be monitored. There is no established target plasma itraconazole level that has been clearly associated with clinical response. In a cyclosporin-methylprednisolone animal model, plasma itraconazole levels were shown to correlate with microbiologic clearance of experimental aspergillosis.<sup>166</sup> Based on such studies, we recommend that the plasma itraconazole level should be at least 4  $\mu$ g/mL by bioassay or 1  $\mu$ g/mL by high-pressure liquid chromatography in the setting of invasive fungal infection.

Itraconazole is approved as a second-line agent for treatment of aspergillosis in patients intolerant of amphotericin B. In a nonrandomized, compassionate use protocol, itraconazole had comparable efficacy compared with amphotericin B in the treatment of invasive aspergillosis in a variety of patient populations.<sup>167,168</sup> We advise that amphotericin B (conventional or lipid formulation) be the initial agent of choice for invasive mold infections in neutropenic or otherwise severely immunosuppressed patients with cancer. The bioavailability of the oral preparation of itraconazole is unreliable, making it more suitable as a maintenance regimen after control of infection has been achieved. Randomized, prospective studies are required to delineate the optimal role of parenteral itraconazole in neutropenic patients and BMT recipients.

### Third-Generation Azoles

In view of the lack of antifungal activity of fluconazole against filamentous fungi, the increasing frequency of fluconazole-resistant *Candida* species, and the inconsistent oral absorption of itraconazole, newer azoles have been developed to overcome some of these limitations. Voriconazole, posaconazole (SCH 56592), and ravuconazole (BMS 207147) are third-generation triazoles that are currently being evaluated in clinical trials. These agents can be administered orally or intravenously and have activity against *Candida* species (including species that are resistant to fluconazole), *Aspergillus* species, dematiaceous molds, *Fusarium* species, and dimorphic fungi.<sup>169</sup>

**AMPHOTERICIN B.** Amphotericin B is a member of the polyene group of antifungal agents whose principal mechanism of action is binding to ergosterol, a sterol present in fungal cell membranes. Amphotericin B is active against the majority of fungal pathogens. However, *in vitro* and clinical resistance to amphotericin B has been encountered in a variety of pathogenic fungi afflicting patients with cancer, including isolates of *Candida lusitanae*, *Trichosporon beigeli*, *Pseudallescheria boydi*,

*Fusarium* species, and *Aspergillus terreus*. High dosages (1.0 to 1.5 mg/kg daily) of conventional amphotericin B are required for invasive filamentous fungal infections.

Multiple toxicities are observed with conventional amphotericin B. Acute infusion-related events include fever, rigors, myalgias, nausea, and, less commonly, hypotension, flushing, and bronchospasm. Fever and rigors may result from release of IL-1 and TNF- $\alpha$  from monocytes<sup>170,171</sup> and tend to be most severe during the initial infusions and abate with subsequent administrations. Infusion-related reactions can be lessened with slowing the infusion rate and premedication with acetaminophen, antiemetics, low-dose hydrocortisone (25 to 50 mg in adults), and meperidine (reduces rigors).

The principal long-term adverse effect of amphotericin B is nephrotoxicity. Azotemia occurs in a large proportion of patients receiving amphotericin B, and nephrotoxicity may be compounded by concomitant administration of other nephrotoxic agents such as CSA and aminoglycosides. The azotemia in part results from an increase in tubular glomerular feedback leading to a reduction in glomerular filtration. Administration of normal saline (2 to 4 mEq/kg) before amphotericin can prevent or ameliorate this physiologic azotemia. Long-term administration of amphotericin B is almost invariably associated with renal potassium and magnesium wasting, requiring aggressive electrolyte replacement, often for weeks after the drug has been stopped. Renal tubular acidosis is also observed. Normochromic normocytic anemia likely mediated by suppression of erythropoietin synthesis is another common toxicity.<sup>172</sup>

The toxicity of amphotericin B not only contributes to patient morbidity, but also limits the maximum dosages that can be administered. Lipid formulations of amphotericin B have significantly less nephrotoxicity and, in the case of liposomal amphotericin B, reduced infusion-related toxicity. These lipid formulations (in addition to the newer broad-spectrum azoles and antifungal peptides) are therefore highly promising drugs that are evolving as important alternatives to conventional amphotericin B. Three lipid preparations of amphotericin B have been licensed: liposomal amphotericin B (LAMB or AmBisome), ABLC, and amphotericin B colloidal dispersion (ABCD). These lipid preparations have different biochemical and pharmacokinetic properties, which have been discussed in detail elsewhere.<sup>169,173</sup> All have reduced nephrotoxicity compared with that of conventional amphotericin B.

**LIPOSOMAL AMPHOTERICIN B. LAMB.** is the only true liposomal preparation of amphotericin B, consisting of unilamellar spheric vesicles. Walsh et al.<sup>174</sup> compared LAMB (343 patients) with conventional amphotericin B (344 patients) in neutropenic cancer patients with fever persisting for 5 days or more in a prospective randomized double-blind multicenter study of empiric antifungal therapy. Standard dosages of the two regimens were used (LAMB at 3 mg/kg daily and conventional amphotericin B at 0.6 mg/kg daily), and dose reductions were allowed in cases of renal insufficiency. The liposomal preparation was associated with a reduced incidence of nephrotoxicity, and infusion-related side effects, including fever, chills, hypotension, hypertension, and hypoxia. Fewer proven breakthrough invasive fungal infections (11 proven, six probable) occurred in the LAMB arm in comparison with 30 (27 proven, three probable) in the conventional amphotericin B arm ( $P = .009$ ). A significantly lower incidence of breakthrough candidemia occurred in the LAMB versus the conventional amphotericin B arm 93 versus 12 patients, respectively ( $P = .03$ ). Survival at 7 days after study drug initiation was approximately 90% in both groups. A European study of LAMB versus conventional amphotericin B found reduced nephrotoxicity in the LAMB arm.<sup>174e</sup> In a prospective, randomized trial comparing LAMB (3 or 5 mg/kg daily) with ABLC (5 mg/kg daily) as empiric therapy for persistent febrile neutropenia, patients receiving LAMB had significantly reduced infusion-related toxicity and nephrotoxicity.<sup>175</sup>

**AMPHOTERICIN B LIPID COMPLEX. ABLC** derives its name from being a complex of two phospholipids arranged in a ribbon-like structure. In the largest series, ABLC (5 mg/kg/d) was evaluated on an emergency use basis in 556 patients with definite or probable invasive mycosis in which the infection was refractory or the patient was intolerant to standard antifungal agents.<sup>176</sup> Among patients with significant azotemia at baseline, the mean serum creatinine improved over the course of ABLC therapy. Among 291 confirmed cases of fungal infection, response to ABLC occurred in 55 of 130 (42%) cases of aspergillosis, 28 of 42 (67%) cases of disseminated candidiasis, 17 of 24 (71%) cases of zygomycosis, and 9 of 11 (82%) cases of fusariosis. Open-label ABLC was also effective in an emergency use study of children with invasive fungal infections.<sup>174</sup> In a prospective study comparing ABLC with conventional amphotericin B as treatment for hematogenous and invasive candidiasis, the two agents had similar efficacy, but ABLC was associated with reduced nephrotoxicity.<sup>177</sup>

**AMPHOTERICIN B COLLOIDAL DISPERSION. ABCD.** is a complex of amphotericin B and cholesteryl sulfate forming a disc-like structure. In a dose-escalation study in BMT recipients with invasive fungal infections, infusion-related toxicities occurred in approximately 70% of patients; however, nephrotoxicity was not observed.<sup>178</sup> ABCD (4 mg/kg daily) was shown to be safe and to not exacerbate renal insufficiency in a retrospective series of 220 BMT recipients with invasive fungal infection.<sup>179,180</sup> In an open label compassionate use protocol in patients with invasive mycosis who either failed or were intolerant to conventional amphotericin B, the clinical response rate was approximately 50%, and nephrotoxicity was uncommon.<sup>179</sup> In a retrospective study, 82 patients with proven or probable aspergillosis treated with ABCD had increased survival (50% vs. 28%) and reduced nephrotoxicity compared with historical controls treated with amphotericin B.<sup>181</sup> ABCD as empiric therapy for prolonged neutropenic fever was associated with less nephrotoxicity but a greater frequency of infusion-related hypoxia and chills compared with conventional amphotericin B.<sup>182</sup>

**WHEN TO CONSIDER A LIPID FORMULATION OF AMPHOTERICIN B.** Clinical trials and a growing clinical experience suggest that lipid formulations of amphotericin B have comparable efficacy and reduced nephrotoxicity compared with conventional amphotericin B. However, the majority of treatment protocols for definite or probable invasive mycosis are limited by being open label and uncontrolled or using historical controls. The high cost of the lipid formulations of amphotericin B is an important consideration. However, in a retrospective study of 239 immunosuppressed patients receiving conventional amphotericin B for aspergillosis, serum creatinine greater than 2.5 mg/dL and BMT (autologous and allogeneic) were independently associated with subsequent requirement for dialysis and a higher mortality.<sup>183</sup> Seen in this light, lipid formulations of amphotericin B may reduce morbidity and cost in select patient groups.

A reasonable approach is to use a lipid preparation of amphotericin B as initial therapy when baseline renal insufficiency exists (e.g., creatinine clearance less than 50 mL/min) or a concomitant nephrotoxic agent is used (e.g., aminoglycoside, cyclosporin, foscarnet). Progressive deterioration of renal function despite adequate saline loading and severe infusion-related toxicities, such as high fever, rigors, and myalgias, inadequately controlled by premedication regimens clearly justify the use of a lipid preparation of amphotericin B. If maximal dosages of conventional amphotericin B do not adequately control infection, a lipid formulation may be considered as a salvage regimen. In the setting of invasive mycotic infections, the maximum recommended dosages of lipid formulations should be used.

### **Echinocandins**

A large number of naturally produced antibacterial and antifungal peptides have been characterized.<sup>24</sup> These antimicrobial peptides have been isolated from mammals, amphibians, insects, and bacterial and fungal species. Antifungal peptides have two principal modes of action: (1) direct damage to the fungal membrane structure and (2) inhibition of synthesis of cell wall constituents. The latter group can in turn be divided into inhibitors of chitin and glucan synthesis.

The echinocandins are a family of cyclic lipopeptides that are noncompetitive inhibitors of (1,3)-b-D-glucan synthase, an enzyme complex that forms glucan polymers in fungal cell walls. Echinocandins have a broad spectrum of activity against *Candida* and *Aspergillus* species and *P. carinii*. Three echinocandins are leading candidates for clinical trials: caspofungin (MK-0991), LY303366, and FK463. In a study of 400 blood stream isolates of *Candida* species, echinocandins were active against all isolates, including those that were resistant to fluconazole or itraconazole.<sup>184</sup> Echinocandins were effective in animal models of disseminated candidiasis and aspergillosis.<sup>185,186</sup>

Echinocandins have been used successfully in AIDS-associated mucosal and esophageal candidiasis.<sup>187</sup> Currently, caspofungin (Merck) and FK463 (Fujisawa Health Care) are being evaluated in phase III studies of hematogenous candidiasis and as prophylaxis in BMT recipients, respectively. Other echinocandin agents are in preclinical stages of development.

## **VIRAL INFECTIONS**

### **HERPES VIRUSES**

The herpes viruses are the most important viral pathogens in patients with cancer. Pathogens in this group include HSV 1 and 2, varicella zoster virus (VZV), CMV, EBV, and human herpesvirus 6 (HHV-6). These DNA viruses establish a latent phase after primary infection, in which the viral genome resides in target cells for the lifetime of the host, with the potential to reactivate. Host defense against these viruses is dependent on viral-specific helper and cytotoxic T lymphocytes, and thus both the likelihood of reactivation and the severity of disease are augmented during profound T-cell immunosuppression. [Table 54-5](#) summarizes common antiviral agents used in persons with cancer (see reference [188](#) for an excellent review).

Disease	Antiviral Therapy	Comments
Herpesvirus group	Acyclovir, 5 mg/kg q8h IV	
Acyclovir	Acyclovir, 10 mg/kg IV q8h	Not available in reference literature
Foscarnet	Foscarnet, 40 mg/kg IV q12h	
Valacyclovir	Valacyclovir, 10 mg/kg IV q8h	
Cytomegalovirus	Acyclovir, 10 mg/kg q8h IV	Prevention of disease
Herpes simplex virus	Acyclovir, 10 mg/kg q8h IV	
Cytomegalovirus	Acyclovir, 10 mg/kg q8h IV	
Epstein-Barr virus	Acyclovir, 10 mg/kg q8h IV	
Human herpesvirus 8	Acyclovir, 10 mg/kg q8h IV	
Human herpesvirus 6	Acyclovir, 10 mg/kg q8h IV

**TABLE 54-5.** Antiviral Agents Commonly Used in Immunocompromised Patients with Cancer

### Herpes Simplex Virus

HSV differs from other members of the herpes virus group by predominantly affecting patients during profound neutropenia. Among seropositive patients, the incidence of HSV reactivation is approximately 70% to 80% after induction chemotherapy for leukemia<sup>189</sup> or conditioning for BMT<sup>190</sup> in seropositive patients. Among BMT recipients, HSV disease is most likely to occur within the first few weeks, but may occur in later stages during intense immunosuppression. Oropharyngeal HSV (usually caused by HSV-1) during neutropenia may be severe, causing gingival disease, stomatitis, and cheilitis, clinically indistinguishable from mucositis after cytotoxic chemotherapy. An oral swab culture for HSV detects viral shedding, suggesting that HSV is contributing to the mucosal disease. Local spread of HSV may cause esophagitis, and aspiration of mucosal HSV may occasionally lead to tracheitis and pneumonia. Documentation of pulmonary involvement requires a biopsy because respiratory secretions may be contaminated by oral mucosal HSV. Disseminated HSV disease may involve the skin abdominal organs (most notably, necrotizing hepatitis) and brain. HSV-2 disease is more likely to cause genital and anal disease.

Diagnosis of HSV disease is made by culture, by biopsy material, or both showing characteristic inclusions with positive immunohistochemistry. In patients with mucosal disease, it is safest to treat with intravenous acyclovir (5 mg/kg every 8 hours), switching to an oral regimen when the disease is abating. Milder HSV disease can be treated initially with an oral regimen (famciclovir, 500 mg three times a day, or valacyclovir, 1 g three times a day) under close observation. Disseminated HSV disease should be treated with intravenous acyclovir (10 mg/kg every 8 hours). Acyclovir prophylaxis during intensive myeloablative chemotherapy for acute leukemia<sup>189</sup> and during the early period of BMT<sup>191</sup> markedly reduces the incidence of HSV.

### Cytomegalovirus and Prevention of Cytomegalovirus Disease

CMV is the most serious of the viral pathogens in BMT recipients, with seropositive recipients at the greatest risk of developing CMV disease. Before the widespread adoption of prophylaxis against CMV, approximately 50% of seropositive transplant recipients developed CMV disease. Seronegative recipients may acquire primary CMV infection from the bone marrow allograft from a seropositive donor or from infected blood products.

CMV disease most commonly occurs in the postengraftment period, between days 30 and 100 of transplantation. However, disease after day 100 is well documented. In patients with GVHD requiring intensive immunosuppressive therapy, T-cell immunity is suppressed, and the risk for CMV disease is consequently increased.<sup>192</sup> Antilymphocyte antibody preparations profoundly reduce the number of circulating T cells and likely further increase the risk of CMV reactivation. CMV disease is far less frequent in autologous BMT recipients, but can be lethal. CD34-selected autologous stem cell transplantation is associated with a greater risk of CMV disease than conventional nonselected peripheral stem cell transplantation.<sup>193</sup> The period of risk in autologous transplantation is generally confined to the first 3 months, corresponding to the period of reconstitution of T-cell immunity.<sup>193</sup>

CMV infection, either primary or reactivated, can have protean manifestations in the BMT recipient, ranging from asymptomatic viral shedding, to a self-limited mononucleosis-like syndrome, to life-threatening organ disease. Pulmonary disease typically manifests as an interstitial pneumonitis resembling PCP, associated with hypoxia and progression to respiratory failure. A definitive diagnosis of CMV pneumonitis requires a compatible clinical syndrome plus either the histologic documentation of characteristic CMV inclusions within parenchymal tissue or intracellular inclusions within epithelial cells obtained by bronchoalveolar lavage. Because CMV can be shed from pulmonary secretions without causing invasive disease, simple recovery of CMV from pulmonary secretions by culture, PCR, or antigen detection studies should not be considered evidence of CMV disease. However, in an allogeneic transplant recipient with a compatible chest radiograph, such documentation of CMV infection in the absence of cytologic or histologic evidence of disease should prompt anti-CMV therapy given the high likelihood of CMV disease in this setting. Both infectious and noninfectious processes may masquerade as, or occur in addition to, pulmonary CMV disease. In one study of late CMV pneumonia (occurring after day 100 of transplantation), approximately one-half of the cases were associated with concurrent pulmonary infections, including *P aeruginosa*, *Legionella*, *Aspergillus* species, *Mycobacteria* species, *Nocardia* species, toxoplasmosis, and respiratory viruses.<sup>194</sup> Therefore, diffuse interstitial disease in a BMT recipient should be evaluated early with bronchoalveolar lavage, and if feasible, transbronchial biopsy (see [Pulmonary Infiltrates](#), later in this chapter). Treatment of CMV pneumonia consists of ganciclovir (5 mg/kg every 12 hours) plus immunoglobulin (normal or CMV hyperimmune). The expected mortality is between 30% and 50%, which is significantly improved compared with series in which ganciclovir alone was used.<sup>195</sup>

CMV disease can occur at any location within the gastrointestinal tract, although esophagitis and colitis are the most common sites. In the esophagus, ulcerations resembling HSV or candidal esophagitis occur. Differentiation of CMV from these causes relies on biopsy or cytology. CMV colitis is associated with abdominal pain and diarrhea. CMV involvement of enteric vessels may result in hemorrhage and infarction. However, in a randomized study, treatment of CMV gastroenteritis with ganciclovir produced similar results as placebo.<sup>196</sup>

CMV hepatitis should be considered in the setting of fever and elevations of liver transaminase enzymes. Other potential viral etiologies include HSV-1 and -2, hepatitis viruses, and EBV. A liver biopsy documenting CMV inclusions definitively establishes the diagnosis.

Less common sites of CMV disease in BMT recipients include pancreas, brain, spinal cord (transverse myelitis), and adrenals. CMV retinitis, the most common complication in patients with AIDS, is rare in transplant recipients. A CMV syndrome is associated with fever, pancytopenia, and CMV viremia and may precede the development of organ disease.

Because of the high mortality associated with CMV disease, much effort has been focused on prevention. CMV-seronegative blood transplant recipients should receive only CMV-seronegative blood products or leukocyte-depleted products to avoid primary CMV infection. The incidence of CMV infection in CMV-seronegative transplant recipients who had CMV-seronegative donors and were given only CMV-seronegative blood products was approximately 5% in three separate studies.<sup>197,198 and 199</sup> Use of CMV-seronegative blood products likely reduces the frequency of CMV infection in cases of CMV-seronegative recipients and seropositive donors, although the magnitude of protection varies widely with different series.<sup>197,198 and 199</sup>

Reactivation of latent CMV infection after transplantation occurs in approximately 70% of seropositive recipients who do not receive antiviral prophylaxis. Antiviral agents have been used successfully to reduce the rate of CMV disease. The following two preventive approaches have been evaluated in allogeneic BMT recipients.<sup>195</sup>

1. Prophylaxis: antiviral agents are administered to all CMV-seropositive BMT recipients (CMV-seronegative recipients receiving seropositive bone marrow were also candidates for antiviral prophylaxis in some studies).
2. Preemptive therapy: initiation of antiviral agents after detection of asymptomatic CMV infection by screening cultures or molecular detection methods.

Offering anti-CMV prophylaxis to all seropositive allogeneic transplant recipients has important advantages and shortcomings. In two studies, acyclovir prophylaxis was associated with increased survival, but the rates of CMV reactivation and disease were fairly high.<sup>200,201</sup> *In vitro*, ganciclovir, an acyclic nucleoside analog of guanosine, is approximately 50 times more active than acyclovir against CMV.<sup>202</sup> Two randomized placebo-controlled studies of ganciclovir prophylaxis for CMV-seropositive allogeneic transplant recipients produced similar results.<sup>197,203</sup> Ganciclovir prophylaxis was highly effective at suppressing CMV during the early

transplant period, but was associated with higher rates of neutropenia, bacterial and opportunistic infections, and late CMV disease. Ganciclovir prophylaxis did not lead to an improvement in survival.

Nguyen et al.<sup>194</sup> retrospectively reviewed 541 adult allogeneic transplant recipients at the University of Texas M. D. Anderson Cancer Center who had received ganciclovir prophylaxis. Thirty-five episodes of CMV pneumonia were documented, 26 (74%) of which occurred after day 100. The mortality was approximately 75%. Almost all cases of late CMV pneumonia occurred in patients with GVHD or who had received T-cell–depleted transplants. Reconstitution of CMV-specific T-cell responses are delayed in allogeneic transplant recipients who received ganciclovir prophylaxis, thus, conceivably predisposing such patients to late CMV disease.<sup>204</sup> These observations provide a rationale for targeting patients at highest risk for CMV disease for antiviral therapy as opposed to administering prophylaxis to all seropositive patients.

Highly sensitive detection methods to identify subclinical CMV infection have been evaluated. These methods include detection of the CMV pp65 antigen from peripheral blood leukocytes and detection of CMV DNA by PCR from blood, serum, or plasma. Boeckh et al.<sup>205,206</sup> showed that preemptive ganciclovir based on detection of CMV antigenemia was associated with a similar rate of CMV disease and similar long-term survival rates as standard ganciclovir prophylaxis initiated at engraftment.

Einsele et al.<sup>207</sup> randomized allogeneic transplant recipients to receive preemptive ganciclovir therapy based on PCR detection of CMV from blood (PCR group) or a positive CMV culture from blood, urine, or throat washings (culture group). PCR screening led to earlier detection of subclinical CMV infection compared with culture. The PCR group had a reduced rate of CMV disease, duration of ganciclovir therapy, neutropenia, and nonviral infections compared with the culture group, and overall survival was superior. Discontinuing preemptive ganciclovir in patients whose blood became PCR negative appeared to be safe.

Foscarnet, an antiviral drug with activity against CMV, may have an advantage over ganciclovir in patients with delayed engraftment or with ganciclovir-associated neutropenia. Azotemia is the major toxicity associated with foscarnet. Moretti et al.<sup>208</sup> compared ganciclovir with foscarnet as preemptive therapy at the time of documentation of subclinical CMV antigenemia. There was a trend to more rapid clearance of CMV antigenemia in the foscarnet group. The major adverse effect was cytopenia in the ganciclovir group and azotemia in the foscarnet group. The study was not sufficiently powered to detect a difference in CMV disease or mortality.

Determination of optimal CMV preventive strategies will require additional prospective randomized studies. Newer, less toxic antiviral agents will need to be evaluated. Lowance et al.<sup>209</sup> showed that valacyclovir (a valine esterified analog of acyclovir with high oral bioavailability) was well tolerated and reduced CMV disease in renal transplant recipients. In addition, immune augmentation strategies (see [Immune Augmentation Strategies](#), later in this chapter) may also be useful as preventive and treatment strategies.

### **Varicella Zoster Virus**

Control of VZV infection is dependent on T-cell<sup>210,211</sup> and<sup>212</sup> and humoral immunity.<sup>213</sup> BMT recipients and patients receiving intensive corticosteroid therapy are at risk for life-threatening disseminated primary and reactivated VZV infection. Reactivated VZV disease is typically a late complication of BMT, usually occurring 3 months to more than a year after transplantation. Before the routine use of antiviral agents for prophylaxis against CMV infection, 17% of BMT recipients had an episode of reactivated VZV within the first year.<sup>214</sup> In one study of acyclovir prophylaxis for CMV, the rate of VZV at day 210 after transplantation was only 3% in patients receiving prolonged high-dose acyclovir.<sup>200</sup>

The major risk factor for developing VZV is acute and chronic GVHD requiring intensive immunosuppressive therapy.<sup>214</sup> In such immunocompromised patients, VZV infection may manifest with a multidermatomal or disseminated vesicular exanthem associated with hemorrhage and necrosis. Infection of visceral can cause hemorrhagic pneumonia, encephalitis, retinal necrosis, hepatitis, and small bowel disease. Secondary bacterial infections may occur in cutaneous VZV lesions. VZV infection can also be complicated by bleeding disorders, thrombocytopenia, vasculitis, disseminated intravascular coagulation, and fulminant purpura resembling bacterial sepsis.

The diagnosis of single dermatomal shingles can usually be made by visual inspection alone. In the immunosuppressed patient, multidermatomal or disseminated cutaneous disease may make the diagnosis on clinical grounds less certain. Immunofluorescent staining of material from an unroofed skin lesion or from a skin biopsy may establish the diagnosis within hours. A Tzanck's preparation confirms infection by a herpes virus, but is not specific for VZV. Viral culture should also be performed.

Intravenous acyclovir (10 mg/kg every 8 hours) is the established treatment for primary or reactivated VZV in immunosuppressed patients.<sup>215</sup> Early initiation of acyclovir reduces progression of disease and usually eliminates mortality in patients with reactivated disease. All BMT recipients with VZV infection should be treated initially as inpatients because of the potential for dissemination. Once clinical improvement has occurred (e.g., resolution of fever, healing of lesions), an oral regimen can be substituted and completed as an outpatient. The oral regimen may consist of acyclovir (800 mg five times per day), valacyclovir (1 g three times a day), or famciclovir (500 mg three times a day). Salicylates should not be used because of the risk of Reye's syndrome.

Lack of a clinical response to therapy should prompt reconsideration of the initial diagnosis, the possibility of a secondary infection, or VZV resistance to acyclovir. Streptococcal impetigo, dermatitis, and various noninfectious bullous diseases can mimic VZV. In such cases, a biopsy is required to establish the diagnosis. Severe streptococcal infections may occur after primary VZV infection. Resistance of VZV to acyclovir may be increased in BMT recipients who have received prolonged courses of acyclovir or ganciclovir as prophylaxis for CMV infection. However, in one study of acyclovir prophylaxis against CMV, the relatively small proportion (less than 10%) of patients who developed VZV disease were successfully treated with acyclovir, indicating that either antiviral resistance did not occur or could be overcome by intensification of the acyclovir regimen.<sup>200</sup> If VZV infection develops while receiving ganciclovir, foscarnet should be initiated because of the cross-resistance between acyclovir and ganciclovir.

Nosocomial transmission of VZV is well documented.<sup>216</sup> Patients with primary varicella (chicken pox), those with disseminated zoster, or immunocompromised patients with dermatomal zoster should be placed under contact and respiratory isolation (private negative-pressure room, air exhausted to outside, six or more air exchanges per hour). Varicella zoster immune globulin should be offered to immunosuppressed VZV-seronegative patients after exposures such as prolonged face-to-face contact, a household or playmate contact, or exposure to a roommate in a shared hospital room. Varicella zoster immune globulin is most effective when administered within 72 hours of exposure; its efficacy is unknown 96 hours after exposure.

The current varicella vaccine uses the live attenuated Oka strain (Merck). The vaccine is immunogenic and protective. The attenuated VZV can cause latent infection, and zoster caused by either the vaccine-type or wild-type VZV can occur months to years after vaccination.<sup>217</sup> This vaccine has been studied extensively in children with leukemia and has been shown to be safe and effective.<sup>217,218</sup>

The American Academy of Pediatrics states that the Oka vaccine is contraindicated in immunocompromised individuals, except for children with acute lymphoblastic leukemia to whom the vaccine may be administered in study conditions.<sup>219</sup> In families with immunocompromised persons, no precautions are required after vaccination of healthy children in whom a rash has not developed. If a rash does occur, direct contact with immunocompromised persons should be avoided. If inadvertent contact occurs, the use of varicella zoster immune globulin is not recommended because of the low transmission rate and the expectation that disease will be mild if it occurs.

### **Epstein-Barr Virus**

In the United States, most adults have been infected by EBV. Primary infection is usually asymptomatic, but may cause a mononucleosis syndrome. Latent infection persists in B cells and produces no disease in the vast majority of people. EBV-specific cytotoxic T lymphocytes are the principal controllers of the replication of EBV-infected B cells.<sup>220,221</sup> EBV lymphoproliferative disorders are encountered in patients with severely impaired T-cell immunity,<sup>222</sup> such as AIDS or intensive and prolonged immunosuppressive therapy. EBV-induced posttransplant lymphoproliferative disorder (PTLD) is defined as an abnormal proliferation of B-lymphoid cells in transplant recipients. The lesions may be composed of a polyclonal or monoclonal population of transformed B cells. PTLD is most common during the first year of transplantation. Patients with GVHD treated with antilymphocyte immunoglobulins<sup>223</sup> and recipients of T-cell–depleted marrow from HLA-mismatched donors<sup>224</sup> are at highest risk for PTLD.

Clinical manifestations of PTLD are varied, and a high index of suspicion is required to make the diagnosis. Patients may have a mononucleosis-like syndrome with fever and localized adenopathy. Disseminated disease may manifest with generalized adenopathy and extranodal organ involvement, including the bowel, liver, bone marrow, and CNS. A CT scan of the head, chest, abdomen, and pelvis is useful in evaluating a high-risk patient with unexplained fever. Diagnosis of PTLD requires biopsy of an affected area showing a characteristic histologic appearance and evidence of EBV infection using immunohistochemical methods or by detecting EBV DNA.

In organ transplant recipients, most PTLD is of recipient origin. In BMT-associated PTLD, the abnormal clones are typically of donor origin.<sup>223,224</sup> Thus, in allogeneic BMT recipients, a balance is created between donor-derived B-cell clonal proliferation and the establishment of donor-derived cytotoxic T-cell immunity, which contain these proliferative responses. Whereas PTLD in organ transplant recipients typically responds to a reduction in the intensity of immunosuppression, PTLD in BMT recipients may not respond to such conservative measures. Adoptive immunotherapy is a promising strategy (see [Immune Augmentation Strategies](#), later in this chapter).

### **Human Herpesvirus 6**

HHV-6 was first isolated from peripheral blood from patients with lymphoproliferative disorders.<sup>225</sup> This virus was initially called *human B-lymphotropic virus*, but it was later discovered that the virus is predominantly T-cell trophic.<sup>226</sup> HHV-6 has been recognized as an opportunistic pathogen in solid organ and BMT recipients. In BMT recipients, HHV-6 has been associated with a variety of syndromes: (1) fever and rash clinically resembling cutaneous GVHD; (2) an increased risk of GVHD; (3) bone marrow suppression; (4) encephalitis; and (5) pneumonitis. However, establishing a causal relationship between HHV-6 and these syndromes is made difficult by the fact that HHV-6 can be documented in approximately 50% of BMT recipients, usually between 2 and 4 weeks after transplantation.<sup>227,228</sup> and <sup>229</sup> The evidence supporting a link between HHV-6 infection and encephalitis<sup>230</sup> and interstitial pneumonitis<sup>231</sup> is the most persuasive, based on the *in situ* documentation of HHV-6 in the respective organs using immunohistochemistry, molecular detection methods, and culture.

Singh and Carrigan<sup>232</sup> proposed the following two criteria for the diagnosis of HHV-6 disease: (1) presence of bone marrow suppression, encephalitis, or pneumonitis and (2) documentation of active infection by culture, PCR from an acellular specimen (a positive PCR result from blood cannot distinguish active from latent infection), or immunohistochemistry. Comparative studies evaluating therapy for HHV-6 have not been performed, and it is therefore not possible to make definitive recommendations about therapy. HHV-6 is sensitive *in vitro* to ganciclovir and foscarnet, and it is reasonable to initiate therapy with either of these agents when HHV-6 disease is proven or strongly suspected. The role of screening for asymptomatic HHV-6 infection and prophylaxis with antiviral agents is uncertain.

## **COMMUNITY RESPIRATORY VIRUSES**

Community respiratory viruses include members of the Orthomyxoviridae (influenza A, B, and C) and Paramyxoviridae [parainfluenza 1 through 4, respiratory syncytial virus (RSV), and measles] families, adenoviruses, and picornaviruses. These viruses are important causes of morbidity and mortality in immunocompromised patients.<sup>233,234</sup> With the progress in prophylaxis and treatment of CMV disease in BMT recipients, the relative proportion of pulmonary infections caused by community respiratory viruses is likely to grow. In contrast to CMV, these viruses are seasonal and are rapidly transmitted from one person to another by respiratory secretions, thus having the potential for nosocomial outbreaks.

Respiratory viruses may account for a significant proportion of undiagnosed or idiopathic pneumonias in BMT recipients in older series.<sup>234</sup> Their importance as pathogens in this population has been documented more recently by centers that routinely screen for community viral pathogens in patients with respiratory illnesses.

### **Respiratory Syncytial Virus**

RSV infection is highly virulent in patients with leukemia and in BMT recipients. In patients with leukemia, progression to pneumonia and mortality are more common in the setting of neutropenia.<sup>235</sup> RSV infection can occur throughout the transplantation period, from the preengraftment stage to more than a year after transplantation. Upper respiratory symptoms (sinusitis, coryza, rhinorrhea) usually precede lower respiratory tract involvement (dyspnea, wheezing) and pneumonia, although upper airway symptoms may be absent. The historic mortality from RSV pneumonia in BMT recipients is approximately 80%.<sup>236</sup> At the University of Texas M. D. Anderson Cancer Center, patients who received aerosolized ribavirin and intravenous immunoglobulin containing high RSV-neutralizing titers at least 24 hours before respiratory failure had a 22% mortality compared with 100% mortality in patients who either did not receive therapy or in whom treatment was initiated after respiratory failure had occurred.<sup>237</sup>

Rapid diagnosis of RSV has been made possible by antigen detection methods. Englund et al.<sup>238</sup> showed that compared with culture, antigen detection had a sensitivity of 89% in bronchoalveolar lavage, 15% in nasal and throat washings, and 71% in endotracheal aspirates in symptomatic adult leukemia or BMT patients. The specificity was 97% to 100% from these sources. The lower sensitivity of antigen detection from the upper airway of adults is attributed to a lower viral burden. The low yield of upper airway cultures severely limits the value of these noninvasive tests in adults with respiratory disease.

A preliminary study of intravenous ribavirin for RSV pneumonia in BMT recipients who at enrollment did not require mechanical ventilation, was associated with an eventual 80% mortality.<sup>239</sup> In a second strategy, aerosolized ribavirin was administered to patients in whom RSV was isolated from nasopharyngeal washes without signs of lower respiratory tract involvement. Pneumonia developed in 8 of 25 (32%) patients, with a mortality of 29%.<sup>236</sup> These studies suggest that early diagnosis and treatment of RSV in this population may be life saving.

### **Parainfluenza**

Parainfluenza viruses are important community respiratory viruses in leukemia and BMT patients. In a review of 45 cases of parainfluenza virus infection in BMT recipients, 26 (58%) patients had pneumonia, of whom 39% died.<sup>240</sup>

Therapy for parainfluenza infection has not been established. An uncontrolled retrospective series from the University of Minnesota showed that survival with and without aerosolized ribavirin was approximately 80% in BMT recipients with parainfluenza infection.<sup>241</sup> Ribavirin was generally begun late after onset of respiratory symptoms, which may have reduced its efficacy. The role of intravenous immunoglobulin against this organism merits further exploration.

### **Influenza Virus**

Influenza virus is the most important respiratory virus globally and the most common cause of excess seasonal mortality in North America, accounting for approximately 20,000 deaths in the United States annually. During a winter outbreak period, influenza was diagnosed in approximately 30% of adult patients hospitalized for a respiratory illness at the M. D. Anderson Cancer Center.<sup>240</sup> Pneumonia occurred in 12 of 15 (80%) of patients with influenza, and four of these patients died. In other centers, the incidence of pneumonia and mortality associated with influenza virus infection was substantially lower.<sup>236</sup>

Amantadine and rimantadine are the most common agents used in treating influenza. These agents are only active against influenza A, not influenza B. In one center, resistance to these agents rapidly developed during therapy for influenza A among patients with leukemia and BMT recipients.<sup>242</sup> Ribavirin has activity against influenza A and B and has been used in patients with influenza virus infection.<sup>243</sup>

Two agents (zanamivir and oseltamivir) that inhibit the influenza virus neuraminidase have been licensed. These drugs are active against both influenza A and B and have been shown to be effective in reducing the duration of influenza illness<sup>244</sup> and to have a prophylactic benefit during community outbreaks.<sup>245,246</sup> The role of these agents as treatment or prophylaxis in immunocompromised patients with cancer has not been evaluated.

The Centers for Disease Control and Prevention recommend annual administration of the inactivated influenza vaccine to immunocompromised persons and their close contacts (e.g., health care workers and household members).<sup>247</sup> Immunocompromised persons are less likely to mount an adequate antibody response to immunization.<sup>248</sup> Immunization should be provided ideally 2 weeks before chemotherapy, or if given during chemotherapy, immunization is preferably administered

between cycles. In one study, a two-step vaccination regimen enhanced the immune response in patients receiving chemotherapy for lymphoma. <sup>249</sup>

### **Adenovirus**

The clinical manifestations of adenoviruses in BMT recipients include pneumonia, bronchiolitis, upper respiratory tract infection, renal parenchymal disease, hemorrhagic cystitis, hepatitis, small and large bowel disease, encephalitis, and disseminated infection. <sup>250,251</sup> Viral shedding from throat secretions, urine, and stool is common, occurring in approximately 5% to 20% of BMT recipients, and should not be equated with disease. In patients with definite invasive disease, long-term survival was poor. GVHD was the only significant risk factor in both studies.

Adenoviruses were cultured from 28 adult BMT recipients at the M. D. Anderson Cancer Center. <sup>240</sup> Seven of 12 patients with pneumonia and all six patients with disseminated disease died, whereas ten patients with upper respiratory tract infection survived. Risk factors for mortality included isolation of adenovirus from multiple sites and prolonged shedding. Ribavirin was not associated with benefit in this retrospective series. The role of intravenous immunoglobulin for management of adenovirus infection has not been established.

### **Measles**

Kaplan et al. <sup>252</sup> conducted an extensive review of measles in immunocompromised patients. Of 40 patients (aged 3 months to 22 years) with malignancy, 16 (40%) had no rash whereas the remainder had either typical or atypical exanthemas. Twenty-three (58%) had pneumonitis, eight (20%) had encephalitis, six (20%) had both, and six (20%) had no complications. The overall fatality rate was 55%. The benefit of ribavirin could not be assessed.

### **Diagnosis of Respiratory Viruses**

Rapid immunodiagnostic methods for common respiratory viruses have become widely used, and have resulted in reduced hospital stays, antibiotic use, and microbiologic investigations. <sup>253</sup> Such rapid methods also have additional potential benefits for early initiation of antiviral agents and implementation of appropriate infection control precautions. Cell culture is generally more sensitive than antigen detection methods, with the exception of RSV in children, in whom antigen detection is highly sensitive. Rapid antigen detection methods and cell culture are therefore complementary. PCR amplification methods are being evaluated and show promise. <sup>254</sup>

## **HEPATITIS VIRUSES**

Liver test abnormalities are common in patients with cancer. Among BMT recipients, the differential diagnosis is broad and includes drug toxicity, GVHD, venoocclusive disease, recurrent malignancy, and infectious hepatitis. Patients who receive multiple transfusions of blood and pooled plasma products are at a higher risk for transfusion-associated viral hepatitis, despite the highly effective screening methods of blood products currently used. In addition, such patients are likely to be at higher risk for reactivation of latent viral infection during intensive immunosuppressive therapy and for developing life-threatening complications.

### **Hepatitis B**

Reactivation of latent hepatitis B virus (HBV) infection in BMT recipients is an unpredictable but rare event. Although the hepatitis B surface antigen carrier state is not a contraindication to BMT, such patients appear to be at a higher risk for fulminant hepatitis as a result of reactivation. <sup>255,256 and 257</sup> In a prospective study of 100 Chinese patients who received induction chemotherapy for lymphoma, hepatitis developed in 67% of HBsAg-positive patients compared with 14% of HBsAg-negative patients. <sup>258</sup> Reactivation of HBV (as determined by serum levels of HBV DNA and HBeAg) was associated with icteric hepatitis, but infrequently with liver failure and mortality. Symptomatic hepatitis may manifest after withdrawal of immunosuppressive agents or between cycles of chemotherapy when recovery of immune responses occurs. <sup>259,260</sup>

Precore mutant HBV has been associated with cases of fulminant hepatic failure after cytotoxic chemotherapy and fibrosing cholestatic hepatitis. <sup>261,262</sup> This mutation results in failure to secrete HBeAg, and, therefore, this marker can not be used as an indicator of active viral replication.

Chronic HBV hepatitis has been reported in patients with negative serologic study results. Vergani et al. <sup>263</sup> reported 23 cases of histologically proven HBV infection in 23 children with leukemia and liver disease, none of whom had detectable HBV serum antigens or antibodies. In eight of the children, HBV markers subsequently appeared in the serum within 15 months of stopping chemotherapy. Bréchet et al. <sup>264</sup> documented HBV DNA in 59% of liver samples but in only 10% of serum samples among patients with chronic liver disease and negative test results for HBsAg.

Treatment of chronic HBV involves either the antiviral nucleoside analog lamivudine <sup>265,266</sup> or interferon- $\alpha$  (IFN- $\alpha$ ). <sup>267</sup> The advantages of lamivudine include limited side effects and the fact that histologic improvement was documented in the majority of patients. <sup>265</sup> Favoring IFN- $\alpha$  is the limited duration of therapy and the absence of viral mutations that lead to resistance to therapy. <sup>265</sup>

Vaccination against HBV should be considered in seronegative patients with cancer. However, among BMT recipients, active immunization in the immediate pretransplant and posttransplant periods is often ineffective, most likely as a result of defective T-cell and B-cell function. Adoptive transfer of immunity to HBV can be achieved after allogeneic BMT from immune donors. <sup>268</sup>

### **Hepatitis C**

Before routine blood screening began in 1991, BMT recipients were at significant risk for hepatitis C virus (HCV) infection. HCV infection can cause both early and late complications in BMT recipients. In a cohort study from Fred Hutchinson Cancer Research Center, pretransplant HCV infection plus an elevated serum aspartate transaminase level was predictive of severe venoocclusive disease (VOD) (relative risk, 9.6) <sup>269</sup>; HCV infection without elevated transaminases was not a significant risk factor for VOD. An acute flare of hepatitis occurred in about one-third of HCV-positive patients at a mean of 4 to 5 months after transplant and was usually self limited. <sup>269</sup> Frickhofen et al. also noted an association between pretransplant HCV infection and severe VOD in the early transplant period. <sup>270</sup>

Approximately one-half of HCV-positive transplant recipients at Fred Hutchinson continued to have mild to moderate elevations in liver enzymes 5 to 10 years following transplant. <sup>269</sup> However, HCV was not associated with increased mortality. <sup>269</sup> Cirrhosis was identified in 31 of 3721 patients surviving 1 or more years after BMT. <sup>271</sup> HCV infection was documented in 25 of the 31 (81%) patients, and cirrhosis was attributed to HCV infection in 15 of 16 (93%) patients presenting more than 10 years after transplantation. <sup>271</sup> To try to avoid cirrhosis, interferon- $\alpha$  and ribavirin therapy should be considered in transplant recipients with chronic HCV infection who have been off immunosuppressive agents for at least 6 months, have normal marrow recovery, and have no GVHD. <sup>271a</sup>

HCV is universally transmitted from HCV RNA-positive donors to their recipients. <sup>271a</sup> If an HCV-positive donor is the best available match, treatment of the donor with interferon- $\alpha$  and ribavirin before marrow or stem cell harvest may be considered to try to eliminate viremia (which can be monitored by PCR). Interferon should be stopped at least 1 week before harvest to avoid problems with engraftment in the recipient. <sup>271a</sup>

Significant hepatic dysfunction is uncommon in nontransplant HCV-positive patients receiving chemotherapy for hematologic malignancies. <sup>271b</sup> In a prospective study of 305 patients with lymphoma, the prevalence of HCV and HBV infection was 16% and 3.2%, respectively. <sup>271c</sup> No reactivation in HCV-positive patients occurred during chemotherapy. In contrast, HBV reactivation occurred in approximately 80% of HBV-infected patients, and was associated with a 37% mortality rate. Thus, HBV should be considered to be an opportunistic pathogen in heavily immunosuppressed persons with hematologic malignancies, whereas HCV is not.

### **Other Transfusion-Associated Hepatitis Viruses**

Hepatitis G is a newly discovered transfusion-associated virus that can establish persistent infection in asymptomatic individuals. Surveillance studies have not established a role for this virus in non-A through E acute transfusion-related hepatitis or chronic liver disease. <sup>273,274</sup> TT virus is another virus capable of establishing persistent infection whose pathogenicity remains questionable. <sup>275</sup> In a Japanese study, TT virus DNA was detected with far greater frequency in BMT recipients than

in blood donors, and, in one patient, was temporally associated with elevated serum hepatic enzymes.<sup>276</sup> Conceivably, these other transfusion-associated viruses yet to be discovered, may be agents of non-A through E hepatitis in heavily transfused persons with cancer.

## PARASITIC INFECTIONS

### *PNEUMOCYSTIS CARINII*

*Pneumocystis carinii* is more appropriately classified as a fungus than a protozoan based on gene sequence data and cell wall constituents. Defective T-cell immunity is the principal risk factor for PCP. Sepkowitz et al.<sup>277,278</sup> and<sup>279</sup> reported that corticosteroid use was associated with 204 of 227 (90%) cases of PCP in patients without AIDS at Memorial Sloan-Kettering Cancer Center between 1963 and 1992. The median time that patients received corticosteroids was 2 months, although a minority of patients had received corticosteroids for less than 1 month. Approximately 60% of patients had hematologic malignancies, 25% had solid tumors, 10% were BMT recipients, and 5% were receiving relatively mild immunosuppressive regimens.

The risk of PCP increases with the intensity of the immunosuppressive regimen. In a study of pediatric patients with acute lymphocytic leukemia, the risk of PCP was strikingly increased from less than 5% to 22% when cytosine arabinoside (Ara-C) was used.<sup>280</sup> Browne et al.<sup>281</sup> reported a 32% rate of PCP (probable plus definite) in patients with non-Hodgkin's lymphoma treated with an intensive regimen consisting of corticosteroids and multiple cytotoxic agents (methotrexate, doxorubicin, cyclophosphamide, etoposide, Ara-C, bleomycin, vincristine) as compared with no cases of PCP in patients who did not receive Ara-C and bleomycin.

*Pneumocystis carinii* can have a fulminant course, resembling a bacterial pneumonia with rapid progression to respiratory failure, or can be indolent.<sup>282</sup> Patients treated with corticosteroids may develop initial clinical manifestations of PCP only during corticosteroid taper. Bilateral interstitial infiltrates are most common in PCP, although unilateral or patchy infiltrates are also observed. Nodules, cavitary lesions, and pleural effusions are less common. In a minority of patients, the chest radiograph is normal. Extrapulmonary *P carinii* infection is rare in patients with cancer and has for the most part been reported only in patients with AIDS.

Diagnosis of PCP relies on visualization of the organism microscopically. Immunofluorescent staining using monoclonal antibodies is more sensitive than older staining methods, such as silver staining or Wright-Giemsa.<sup>283</sup> PCR-based detection of *P carinii* from induced sputum or blood is a promising experimental diagnostic method.<sup>284</sup>

Spontaneously expectorated sputum is generally unsatisfactory for diagnosis of PCP, but sputum induction using 3% sodium chloride solution in an ultrasonic nebulizer usually yields a satisfactory sample. In a small study of non-AIDS patients with PCP, the diagnostic sensitivity using this method was approximately 60%.<sup>285</sup> If sputum induction is nondiagnostic, bronchoscopy should be pursued.

Trimethoprim-sulfamethoxazole (trimethoprim 15 to 20 mg/kg daily divided into three to four doses) is the treatment of choice for *P carinii*. In patients intolerant of this agent, intravenous pentamidine, dapsone-trimethoprim, and clindamycin-primaquine are acceptable alternatives. In cases of a prior non-life-threatening reaction to a sulfonamide (e.g., a nonurticarial rash), experience with AIDS patients has shown that rechallenge with trimethoprim-sulfamethoxazole is safe under close medical observation,<sup>286</sup> although some investigators would opt for desensitization.<sup>287</sup> Patients without AIDS are less likely to have adverse reactions to trimethoprim-sulfamethoxazole.<sup>282</sup> In patients with moderate or severe PCP (PaO<sub>2</sub> less than 70 mm), corticosteroids should be added based on studies of patients with AIDS-associated PCP.<sup>288</sup> In patients who are not responding to therapy, repeat bronchoscopy should be performed to exclude additional pathogens that may have been missed or may not have been present initially.

Trimethoprim-sulfamethoxazole is highly effective as prophylaxis against PCP. In children with cancer at high risk for PCP, no case of PCP occurred in patients administered daily trimethoprim-sulfamethoxazole, compared with an approximately 20% incidence in the placebo arm.<sup>289</sup> Trimethoprim-sulfamethoxazole prophylaxis was also associated with a reduction in bacterial infections. In a subsequent study of children with acute lymphoblastic leukemia, trimethoprim-sulfamethoxazole administered either daily or on 3 consecutive days weekly was fully protective against PCP.<sup>290</sup>

Defining which patients with cancer will benefit from prophylaxis against PCP is often empiric given the absence of controlled studies in several high-risk groups. Children with acute lymphoblastic leukemia and allogeneic BMT recipients are known high-risk groups that should be offered prophylaxis. In BMT recipients, the peak risk of PCP is between 1 and 4 months after transplantation, corresponding to the period of most profound T-cell immunodeficiency. Prophylaxis is generally administered shortly after engraftment until 6 to 12 months after BMT, but should be reinitiated at later periods in the setting of GVHD requiring intensification of immunosuppressive agents. Adults with acute lymphoblastic leukemia,<sup>291</sup> patients with CNS tumors receiving high-dose corticosteroid therapy,<sup>292,293</sup> and patients receiving combination corticosteroid therapy with either myelotoxic agents or fludarabine are also at high risk for PCP, and prophylaxis should be considered.

### TOXOPLASMOSIS

Reactivation of *Toxoplasma gondii* is associated with life-threatening disease primarily in patients with profound deficits in T-cell immunity. In a review of 128 reported cases of toxoplasmosis in patients with neoplastic disorders, 59 patients had Hodgkin's disease, 12 had non-Hodgkin's lymphoma, and 36 had acute or chronic leukemias.<sup>294</sup> Therapy with corticosteroids; cytotoxic agents, radiation therapy, or both; and poorly controlled malignancy are risk factors for toxoplasmas.<sup>295</sup>

Toxoplasmosis is an uncommon complication of BMT. In the largest series, toxoplasmosis was diagnosed in 12 of 3803 (0.3%) consecutive allogeneic BMT recipients and in none of 509 autologous transplant recipients at the Fred Hutchinson Cancer Center.<sup>296</sup> All 12 patients died; ten cases were diagnosed postmortem, and toxoplasmosis was believed to contribute to mortality in at least four patients. Toxoplasmosis manifested within the first 4 months of transplantation. Pretransplant seropositivity for *T gondii* and severe GVHD were the predominant risk factors.

CNS disease is most commonly observed. Altered mental status, coma, seizures, cranial nerve abnormalities, and motor weakness are the most common findings.<sup>294</sup> Cerebrospinal fluid is usually normal; however, a mononuclear pleocytosis and elevated protein level may be seen. Other organs involved may include the heart, lungs, liver, spleen, lymph nodes, bone marrow, pancreas, spleen, and skeletal muscle.

Definitive diagnosis of toxoplasmosis usually relies on demonstration of tachyzoites and cysts in histopathologic sections. Use of electron microscopy<sup>297</sup> and immunoperoxidase staining<sup>298</sup> may facilitate diagnosis. Visualization of the organism in cerebrospinal fluid using Giemsa staining is diagnostic of disease, but the sensitivity of this method is low.<sup>299</sup> Demonstration of local antibody production in cerebrospinal fluid<sup>300</sup> or aqueous humor<sup>301</sup> may facilitate the diagnosis of encephalitis and chorioretinitis, respectively. PCR is a promising diagnostic method available at specialized laboratories.

The treatment of choice for toxoplasmosis is oral sulfadiazine, 4 to 6 g/d, plus pyrimethamine (loading dose of 200 mg, followed by 50 to 75 mg daily). Folinic acid should be administered to reduce myeloid toxicity. Whether maintenance therapy is required after quiescence of disease is unknown. It is reasonable to continue a maintenance regimen (which may consist of sulfadiazine, 2 g/d, plus pyrimethamine, 50 mg/d) during periods of immunosuppressive therapy. In patients intolerant of sulfonamides, clindamycin and primaquine may be used instead.

### ACANTHAMOEBA

*Acanthamoeba* species may cause an insidious granulomatous encephalitis in immunocompromised patients, such as those receiving high-dose corticosteroid therapy, solid organ transplant recipients, and patients with AIDS. Skin manifestations include persistent ulcers, nodules, or subcutaneous abscesses. BMT recipients may have a more fulminant course characterized by obtundation, coma, and seizures, associated with a necrotizing meningoencephalitis and hydrocephalus.<sup>302</sup> A necrotizing pneumonitis and adrenalitis may also be present. A diagnosis may be established by cerebrospinal fluid analysis or biopsy showing characteristic amebic trophozoites. The treatment of choice is parenteral pentamidine.

### STRONGYLOIDES STERCORALIS

*Strongyloides stercoralis* is an intestinal nematode that can cause disseminated infection, or hyperinfection syndrome, in immunocompromised patients.<sup>303</sup> *S stercoralis* is particularly common in tropical and subtropical regions, but the parasite also is endemic in certain rural southern regions of the United States. Cross-infection between humans through contact with material soiled with feces appears to be likely in overcrowded and unsanitary conditions.<sup>304</sup> *S stercoralis* can

establish an asymptomatic chronic gastrointestinal infection through internal autoinfection, with the hyperinfection syndrome occurring several years after the initial infection, frequently in the setting of immunosuppression. This underscores the need to obtain a thorough history about prior residence in endemic areas. Corticosteroid therapy with and without other agents appears to be associated with the highest risk of disseminated disease.<sup>304</sup> Among reported cases of hyperinfection syndrome associated with cancer, approximately 90% of patients had a hematologic malignancy.<sup>304</sup>

The hyperinfection syndrome results from penetration of filariform larvae through the intestinal mucosa, followed by dissemination. Sites of dissemination include the lungs, lymph nodes, brain, and abdominal organs. Secondary bacterial infection presumably results from passage of enteric bacteria through the bowel as a consequence of gastrointestinal strongyloidiasis, and may result in peritonitis, bacteremia, and meningitis.

Diagnosis of infection relies on visualization of larvae in feces, duodenal aspirates, sputum samples, or in other body fluids or tissue. Although uncommon, patients from endemic areas should be screened for *S stercoralis* carriage, ideally before receiving immunosuppressive agents. Obtaining multiple fresh stool samples increases the diagnostic yield. Patients with *S stercoralis* infection should be treated with thiabendazole or ivermectin.

## EVALUATION AND MANAGEMENT OF FEBRILE NEUTROPENIA

Patients with cancer and neutropenic fever often have an established or an occult infection, and bacteremia is documented in approximately 20% of cases.<sup>305</sup> Because of the high likelihood of occult infection in a patient with febrile neutropenia without localizing symptoms or signs, and the potential for rapid progression to severe sepsis, prompt initiation of empiric antibiotics is essential. The likelihood of bacteremia is related to the intensity (with an ANC of less than 100/ $\mu$ L carrying the greatest risk) and the duration of neutropenia. A rapid decrease in the neutrophil count may also be a risk factor for infection, whereas evidence of marrow recovery even if the neutrophil count is still less than 500/ $\mu$ L, is a positive prognostic factor. For the purpose of this discussion, we use the following established criteria for neutropenic fever:

1. A single oral temperature of greater than 38.3°C (101°F) or greater than or equal to 38.0°C (100.4°F) over at least 1 hour.
2. ANC less than 500/ $\mu$ L or less than 1000/ $\mu$ L with predicted rapid decline to less than 500/ $\mu$ L.

Evaluation of the febrile neutropenic patient begins with a careful history and physical examination. A history of prior infectious complications associated with chemotherapy may be useful for risk stratification and selecting an empiric regimen. For example, a history of recent colitis caused by *Clostridium difficile* raises the likelihood of recurrent infection in a patient with fever and diarrhea. Prior invasive candidiasis or infection by one of the filamentous fungi may recur during subsequent neutropenic periods. The duration of neutropenia closely correlates with the risk of serious infectious complications, including the development of invasive fungal infections in patients with prolonged neutropenia (such as patients with leukemia and BMT recipients). Concomitant use of corticosteroid therapy raises the likelihood of opportunistic pathogens, such as *P carinii*, that characteristically afflict patients with defects in cell-mediated immunity. Epidemiologic exposures can provide useful clues for uncommon or rare pathogens. For example, swimming or fishing in fresh or brackish waters raises the possibility of infection by *Aeromonas hydrophila*. Exposure to salt water increases the likelihood of infection by *Vibrio vulnificus*. Fever after a dog bite raises the concern about infection by *Capnocytophaga canimorsus* (DF-2).

A meticulous physical examination is necessary, bearing in mind that typical signs of infection may be blunted or absent as a result of immunosuppression. Mucositis is commonly observed after chemotherapy and may be difficult to distinguish from gingivostomatitis caused by reactivation of HSV infection. The presence of thrush reflects compromise of cell-mediated immunity. In patients with prolonged neutropenia or who receive concomitant high-dose corticosteroid therapy, fungal infection of the palate, typically by Zygomycete or *Aspergillus* species, constitutes a surgical emergency. A black necrotic region is the most common sign of such infections. Palpation over the anterior sinuses and an ophthalmologic examination should be performed. A detailed inspection of the skin, including the nails, may disclose a lesion suggestive of systemic infection or a possible portal of entry. Examples include ecthyma gangrenosum caused by *P aeruginosa*, or erythematous papules caused by disseminated candidiasis. Catheter sites and sites of prior skin penetration (such as surgical wounds and biopsy sites) should be palpated. The perineum and perianal region are easily missed sources of infection that need careful inspection and palpation.

The initial evaluation should include the following: complete blood cell count and differential; serum chemistry, including liver associated enzymes; at least two sets of blood cultures from different sites (including from each lumen of the central venous catheter if one is present); a urine culture; and a chest radiograph. Potential sites of infection, such as skin lesions or sputum, should be obtained before instituting antibiotics. However, febrile neutropenia should be considered a medical emergency, and prompt initiation of empiric antibiotics should not be delayed if culture material is not immediately available. After the initial physical examination, it is critical to reevaluate the patient regularly to monitor the response to therapy and to identify evolving signs of infection that were not present during the initial encounter.

## ANTIBIOTIC REGIMENS

In the early 1970s, Schimpff and colleagues conducted a nonrandomized study of 75 patients with cancer and febrile neutropenia who were treated empirically with carbenicillin and gentamicin.<sup>306</sup> Treated patients with *P aeruginosa* infection had dramatically improved survival rates compared with historic controls. This study established the rationale for empiric combination antibiotic therapy, based on the wide range of resistant profiles of *P aeruginosa* and enteric gram-negative rod isolates to carbenicillin. Empiric combination therapy increases the likelihood that at least one antibiotic will have activity against the isolate before the availability of susceptibility data. In addition, the b-lactam plus gentamicin combination has synergistic bactericidal activity *in vitro*. Since this early study, typical combination regimens for neutropenic fever have included an antipseudomonal penicillin plus an aminoglycoside with or without a drug with antistaphylococcal activity, such as a first-generation cephalosporin or vancomycin.

Since the mid-1980s, the development of broad-spectrum antipseudomonal antibiotics (ceftazidime and imipenem) with a high serum bactericidal level to minimal inhibitory concentration ratio has led to a reevaluation of the need for combination antibiotic therapy. Obviating the need for an aminoglycoside would be expected to reduce nephrotoxicity in a patient population frequently treated with nephrotoxic drugs, such as CSA, cisplatin, and amphotericin B. Pizzo et al.<sup>307</sup> conducted a randomized trial comparing ceftazidime monotherapy with a combination of cephalothin, gentamicin, and carbenicillin in 550 episodes of neutropenic fever in patients with cancer at the National Institutes of Health. Approximately 45% of patients had leukemias or lymphomas, and the remainder had solid tumors. The mean duration of neutropenia was 8 to 9 days. In patients with unexplained fever, 98% of patients in both groups survived by the time neutropenia resolved. Of the patients with documented infection, the survival rate was 89% in the monotherapy arm and 91% in the combination arm. Most patients with documented infections in both treatment arms required modifications in the initial antibiotic regimen, whereas the initial regimen was usually not modified in cases of no documented infection. This study was the first to establish that initial empiric monotherapy was safe and effective in this patient population. An important caveat is that patients must be closely monitored and the antibiotic regimen modified based on subsequent clinical and microbiologic data.

In a subsequent multicenter trial, De Pauw et al.<sup>308</sup> evaluated ceftazidime versus piperacillin plus tobramycin in approximately 800 episodes of neutropenic fever. The majority of patients had leukemia or were BMT recipients. The mean duration of neutropenia was 18 days. The two regimens were similar with regard to control of infections and infection-related mortality, but less adverse reactions occurred in the ceftazidime arm. This study confirmed that ceftazidime monotherapy is a viable empiric regimen in high-risk patients with febrile neutropenia. In a metaanalysis, ceftazidime monotherapy had similar efficacy as combination regimens for empiric treatment of neutropenic fever.<sup>309</sup>

Numerous studies of monotherapy and combination therapy have been conducted that further delineate the advantages and disadvantages of various empiric regimens for neutropenic fever. The Infectious Diseases Society of America (IDSA) has published evidence-based guidelines on antibiotic therapy for neutropenic fever without a documented source.<sup>71</sup> Initial antibiotic regimens are divided into three categories: (1) monotherapy, (2) duotherapy without vancomycin, and (3) vancomycin plus one or two drugs (Table 54-6).

MONOTHERAPY
Ceftazidime
Cefepime
Imipenem
Meropenem
DUOTHERAPY
Ceftazidime plus an aminoglycoside
Cefepime plus an aminoglycoside
Antipseudomonal penicillin (e.g., piperacillin, ticarcillin, azlocillin) plus an aminoglycoside
Antipseudomonal penicillin plus ciprofloxacin
WHEN TO ADD VANCOMYCIN
Clinical instability
Isolation of a gram-positive pathogen from blood
$\beta$ -lactam allergy (see use vancomycin plus aztreonam; see text)
Severe mucositis (associated with cytosine arabinoside)*
Quinolone (ciprofloxacin, ofloxacin, moxifloxacin) prophylaxis
Intra-aortic catheter-associated cellulitis or tunnel infection
Facilities with high prevalence of methicillin-resistant <i>Staphylococcus aureus</i>
*Vancomycin need not be added if a carbapenem is used, since these agents are highly active against oral gram-positive flora.

**TABLE 54-6.** Empirical Regimens for Neutropenic Fever

## MONOTHERAPY

The IDSA considered the following four antibiotics to be appropriate as empiric monotherapy for neutropenic fever: ceftazidime, cefepime, imipenem, and meropenem.<sup>71</sup> At the National Institutes of Health, ceftazidime monotherapy has been used since the 1980s in more than 1000 patients and has an excellent record in terms of efficacy and safety. Emergence of ceftazidime-resistant isolates has been infrequent. A disadvantage of ceftazidime monotherapy is the modest or absent activity against certain gram-positive pathogens (e.g., viridans streptococci, enterococci) and gram-negative pathogens with extended spectrum  $\beta$ -lactamases (most often encountered in *E coli* and *Klebsiella* species) and Bush group 1  $\beta$ -lactamases (most commonly encountered in *Enterobacter*, *Serratia*, *Citrobacter*, and indole-positive *Proteus* species). The carbapenems (imipenem and meropenem) have a broader antibacterial spectrum that includes activity against these pathogens as well as potent activity against anaerobes.

In a randomized study of 399 episodes of neutropenic fever at the National Institutes of Health comparing ceftazidime with imipenem as initial therapy, the survival rate was approximately 98% for both regimens.<sup>310</sup> Forty-four percent of patients had leukemia or lymphoma, and the remainder had solid tumors. The mean duration of neutropenia was 9 days. Imipenem was associated with greater toxicity, including *Clostridium difficile*-associated diarrhea and nausea and vomiting.

In a study at M. D. Anderson Cancer Center, imipenem with and without amikacin was compared with ceftazidime with and without amikacin as initial therapy in 750 episodes of neutropenic fever.<sup>311</sup> The success rate (resolution of clinical and laboratory signs of infection without modification of the initial regimen) was poorest in the ceftazidime monotherapy arm (59%) but similar in the other three arms (71% to 76%). The majority of failures were due to coagulase-negative staphylococci and viridans streptococci. Nevertheless, overall mortality was less than 1%.

Cefepime is a fourth-generation cephalosporin with broad-spectrum activity appropriate for empiric therapy for neutropenic fever. In a study of activity of  $\beta$ -lactam antibiotics against gram-positive isolates from patients with cancer, cefepime had activity similar to imipenem and superior to ceftazidime.<sup>312</sup> Seventy-six percent of viridans streptococci were sensitive to cefepime versus 53% to ceftazidime. Ninety-eight percent of  $\beta$ -hemolytic streptococci were sensitive to cefepime versus 34% to ceftazidime. Cefepime has activity against greater than 95% of enteric aerobic gram-negative bacterial isolates harboring either Bush group 1  $\beta$ -lactamases or extended spectrum  $\beta$ -lactamases.<sup>313,314</sup> and <sup>315</sup> In contrast, *Pseudomonas*, *Stenotrophomonas*, and *Acinetobacter* species resistant to ceftazidime are usually cross-resistant to cefepime.<sup>315</sup> Thus, in centers where ceftazidime-resistant Enterobacteriaceae are frequent, cefepime as empiric monotherapy for febrile neutropenia may be a viable option.

In a multicenter French study of 400 patients with neutropenic fever, empiric therapy with cefepime had similar survival compared with imipenem (95% vs. 98%, respectively), but caused less gastrointestinal toxicity.<sup>316</sup> In a study of 99 patients with febrile neutropenia, empiric cefepime therapy had similar efficacy compared with piperacillin plus gentamicin, but reduced nephrotoxicity.<sup>317</sup> Cefepime at a relatively high dose (2 g every 8 hours) is approved as monotherapy for empiric treatment of neutropenic fever.

Meropenem is a new carbapenem with a spectrum similar to that of imipenem, except for enhanced activity against gram-negative and less activity against gram-positive bacteria.<sup>318</sup> In a large multicenter study of 958 patients with febrile neutropenia, meropenem monotherapy was as effective as ceftazidime plus amikacin as initial empiric therapy.<sup>319</sup> The survival rate was 98% in the meropenem arm and 97% in the combination arm, and the proportion of adverse side effects was low in both groups. The mean duration of neutropenia, defined as an ANC less than 1000/ $\mu$ l, was 16 to 17 days. Bacteremia occurred in 10% of patients in the meropenem arm and in 7% of patients in the combination arm. Meropenem monotherapy was safe and effective for neutropenic fever in two other European studies compared with ceftazidime<sup>320</sup> and ceftazidime plus amikacin.<sup>321</sup> Meropenem appears to have less gastrointestinal toxicity than imipenem and a lower frequency of seizures. Thus, meropenem appears to be an appropriate alternative to imipenem in febrile neutropenic patients.

## DUOTHERAPY WITHOUT VANCOMYCIN

The standard duotherapy regimen for empiric therapy of neutropenic fever is a broad-spectrum antipseudomonal  $\beta$ -lactam plus an aminoglycoside. The  $\beta$ -lactam/aminoglycoside synergy was thought to be important in effecting a rapid resolution of bacteremia. In addition, duotherapy increases the likelihood of the isolate being sensitive to at least one of the agents.

The hypothesis that a synergistic antibiotic regimen is superior to monotherapy as empiric treatment of neutropenic fever has not been validated in prospective clinical studies. In fact, ceftazidime singly has greater serum bactericidal activity against gram-negative bacteria compared with ticarcillin plus amikacin.<sup>322</sup>

Combination therapy using two  $\beta$ -lactam agents should generally not be used. The fact that some  $\beta$ -lactams may also be  $\beta$ -lactamase inducers raises concern about such combinations. This concern does not apply when an antistaphylococcal penicillin (e.g., oxacillin) is paired with an antipseudomonal  $\beta$ -lactam agent (e.g., ceftazidime).

Pairing an antipseudomonal  $\beta$ -lactam with a quinolone is yet another combination regimen used for neutropenic fever. The rationale of such a combination is to provide broad-spectrum activity against highly resistant gram-negative pathogens. In a small randomized study, piperacillin plus ciprofloxacin led to more rapid defervescence and reduced requirement for empiric amphotericin B compared with piperacillin plus gentamicin.<sup>323</sup> Other studies showed that azlocillin plus ciprofloxacin had similar efficacy compared with a  $\beta$ -lactam plus an aminoglycoside.<sup>324,325</sup>

An aminoglycoside as the sole agent active against gram-negative bacteria is not recommended because of the high failure rate. Ceftriaxone plus an aminoglycoside, which has the potential for single daily dosing, has been shown to be effective in some studies.<sup>326,327</sup> and <sup>328</sup> However, ceftriaxone does not have reliable activity against *P aeruginosa*. Therefore, in centers where this pathogen is encountered, the ceftriaxone plus aminoglycoside regimen may be suboptimal. In centers with a high frequency of Enterobacteriaceae resistant to third-generation cephalosporins, we advise against using empiric aztreonam as the sole agent active against gram-negative bacteria because of the likelihood of cross-resistance (see [Table 54-3](#)).

Today, with the availability of highly effective monotherapy regimens for neutropenic fever, initial empiric duotherapy regimens may be most appropriate in unstable patients and in institutions in which multidrug-resistant pathogens are frequently encountered.

## WHEN TO ADD VANCOMYCIN

The rationale to add vancomycin to an empiric regimen for neutropenic fever stems from the increased proportion of infections by gram-positive bacteria. The change in the proportion of infections in neutropenic patients from predominantly gram-negative to gram-positive bacteria is associated with the widespread use of tunneled catheters in this patient population. Catheter-associated infection by coagulase-negative staphylococci has become the most common cause of bacteremia in patients

with cancer.

Among the common gram-positive infections in neutropenic patients, the following are typically resistant to ceftazidime: MRSA, coagulase-negative *Staphylococcus* species, and *Enterococcus* species. In addition, although ceftazidime has *in vitro* activity against most viridans streptococci, serious infection by these pathogens has occurred in neutropenic patients receiving ceftazidime.<sup>70,329</sup>

Numerous studies have evaluated single and multiple drug regimens with and without vancomycin. In the largest study, ceftazidime plus amikacin with and without vancomycin were compared in 747 patients with febrile neutropenia in Europe and Canada.<sup>330</sup> The addition of vancomycin to the empiric regimen was not associated with any benefit with regard to duration of fever or morbidity or mortality related to gram-positive infections. Smaller studies of ceftazidime with or without an aminoglycoside also showed no benefit from adding vancomycin to the initial regimen.<sup>331,332</sup>

Because of the lack of efficacy of routine addition of vancomycin to empiric regimens for neutropenic fever, and because of the emergence of VRE in association with excessive vancomycin use, the IDSA guidelines have advised against the routine use of vancomycin as initial empiric therapy of neutropenic fever.<sup>71</sup> At institutions in which MRSA is common or if a patient is known to be colonized by MRSA, vancomycin should be included in the initial regimen for neutropenic fever. Erythema or tenderness at a catheter site requires the addition of vancomycin while awaiting culture results. Addition of vancomycin is reasonable in patients receiving prophylaxis with ciprofloxacin, which some studies have associated with breakthrough infections by viridans streptococci (see [Viridans Streptococci](#), earlier in this chapter). The IDSA suggests the addition of vancomycin in patients with substantial mucosal damage from chemotherapy (such as regimens containing high-dose Ara-C) because of the added risk of infection by viridans streptococci. Empiric vancomycin should be discontinued after 2 days if the initial culture results are negative or show a pathogen, such as methicillin-sensitive *S aureus*, for which other antibiotics can be used.

In neutropenic febrile patients with allergies to  $\beta$ -lactams, empiric vancomycin should be combined with antibiotics active against aerobic gram-negative pathogens. In a clinically stable neutropenic patient, vancomycin plus aztreonam is a reasonable regimen<sup>333,334</sup> (see [Table 54-6](#)). Aztreonam monotherapy is not acceptable because it has no activity against gram-positive bacteria.

## DURATION OF ANTIBACTERIAL THERAPY

### **Resolution of Fever within First 3 Days of Treatment and Persistent Neutropenia**

If the fever rapidly abates after initiation of empiric therapy in a patient with an unremarkable physical examination and negative culture results, one should assume that an occult infection exists that has responded to antibiotics. Pizzo et al.<sup>335</sup> randomized patients with prolonged neutropenia and an undifferentiated fever to either discontinuing empiric antibiotics on day 7 of therapy or continuing therapy until resolution of neutropenia. Of patients who had become afebrile, 40% had recurrent fever after antibiotics were stopped, leading to the conclusion that day 7 of therapy was too early to stop antibiotics in the setting of persistent neutropenia. Discontinuation of antibiotics on day 14 of therapy is a reasonable practice among patients who remain afebrile during therapy, but who are still neutropenic.<sup>336</sup>

Since these early studies, attempts have been made to identify low-risk patients in whom early discharge on an oral regimen could be safely done while still neutropenic. In a retrospective series of 509 pediatric patients with neutropenic fever, lack of signs of sepsis on admission (chills, hypotension, requirement for intravenous hydration), ANC greater than 100  $\mu\text{L}$ , and resolution of fever within 48 hours of therapy accurately distinguished patients who could be discharged on oral agents.<sup>337</sup> Buchanan's group reported that antibiotics could be safely discontinued and that early discharge was feasible in neutropenic pediatric patients who had become afebrile if there were no signs of infection, culture results were negative, and evidence of early marrow recovery existed.<sup>338,339</sup>

Based on these studies, the IDSA guidelines advise that low-risk patients with undifferentiated neutropenic fever who have become afebrile within 3 days of initiation of empiric parenteral antibiotics can be treated with an oral regimen (cefixime or quinolone) and discharged while still neutropenic.<sup>71</sup> In high-risk patients who become afebrile within 3 days, the IDSA recommends continuing parenteral antibiotics. If the high-risk patient remains afebrile and persistently neutropenic after 2 weeks of therapy, antibiotics can be stopped if no signs of infection exist.<sup>71</sup>

One difficulty in applying such guidelines is the lack of a uniform definition of low- and high-risk patients. The IDSA guidelines define low risk as appearing clinically well, absence of mucositis or unstable signs, and an ANC greater than 100/ $\mu\text{L}$ .<sup>71</sup> Several investigators consider whether the ANC is rising or falling and the anticipated rate of myeloid recovery to also be important predictors of risk. Talcott et al.<sup>340,341</sup> developed a risk prediction model to distinguish low- and high-risk groups with febrile neutropenia, which is further discussed in [Outpatient Antibiotic Therapy for Neutropenic Fever](#), later in this chapter.

### **Persistent Fever in the Neutropenic Patient**

After selection of an initial empiric regimen for neutropenic fever, close observation of the patient is necessary. Throughout the duration of neutropenic fever, daily physical examination should be performed. Modifications of the initial antibiotic regimen should be made on the basis of new physical examination findings pointing to a previously inapparent focus of infection, and radiographic and culture data.<sup>342</sup> If no source of infection is documented, the initial empiric antibacterial regimen need not be changed solely on the basis of persistent fever in a clinically stable patient (see [Empiric Antifungal Therapy](#), later in this chapter). Antibiotic therapy should be continued for the duration of neutropenic fever.

New symptoms and signs of infection in neutropenic patients may be subtle and should be aggressively investigated ([Table 54-7](#)). A new erythematous papular lesion may provide initial evidence for isolated cutaneous or disseminated infection by bacterial or fungal pathogens, and biopsy and culture are necessary. Catheter exit sites, surgical wounds, and biopsy sites should be meticulously inspected and palpated for signs of infection. In the neutropenic patient, fever and local tenderness may be the only signs of infection. A diffuse maculopapular rash is suggestive of a drug etiology, but a culture should be performed to rule out an infectious etiology. Blurred vision may represent keratitis or endophthalmitis caused by bacterial, viral, or candidal species, or a CNS process. Careful optical evaluation, corneal scrapings, and aspiration of the vitreous may be needed to establish the diagnosis. Sinopulmonary symptoms in a persistently neutropenic patient (longer than 10 days) or in a patient receiving high-dose corticosteroid therapy are worrisome for a fungal infection. A CT scan is more sensitive and provides superior anatomic delineation of disease than plain radiographs. Aspiration or biopsy of lesions should be performed when feasible. Abdominal pain and tenderness, typically in the right lower quadrant, raises the possibility of typhlitis. Tenesmus suggests a rectal, perineal, or prostatic infection. In cases of suspected bowel or perianal infection, the antibiotic regimen should have broad-spectrum activity against anaerobes, such as imipenem or meropenem alone, or ceftazidime plus metronidazole. Because of the large differential diagnosis of causes of persistent fever in neutropenic patients, a systematic checklist of symptoms and signs should be evaluated daily. [Table 54-6](#) summarizes the management of commonly encountered scenarios in neutropenic fever.

**TABLE 54-7.** Diagnostic Evaluation and Modifications of Therapy during Neutropenia

We suggest that two sets of blood cultures from different sites be obtained daily in patients with persistent neutropenic fever to avoid delay in making appropriate modifications to the antibiotic regimen in cases of superinfection during neutropenia. For pathogens that are not reliably isolated from the blood (such as fungal

species), frequent collection of blood cultures may increase the likelihood of making an earlier diagnosis. In addition, the common use of deep, central catheters makes line infection an ever present and easily detected cause of fever.

### **Empiric Antifungal Therapy**

The rationale for empiric antifungal therapy for persistent febrile neutropenia is that meticulous clinical examination and collection of cultures are not sufficiently sensitive for early detection of fungal infections.<sup>123</sup> Before standard implementation of empiric antifungal therapy, there was a correlation between prolonged neutropenic fever and mortality in patients with cancer, and fungal infection was frequently found at autopsy. Two randomized prospective studies showed empiric amphotericin B was associated with fewer serious fungal infections in antibiotic-treated neutropenic patients with persistent fever.<sup>343,344</sup> Because fungal infections are uncommonly encountered in the first 7 days of neutropenic fever, empiric amphotericin B (0.5 to 0.6 mg/kg daily) is typically begun between days 4 and 7 of neutropenic fever (Table 54-7). Empiric antifungal therapy should be continued for the duration of neutropenia. The potential role of lipid formulations of amphotericin B and antifungal azoles are discussed in [Antifungal Agents](#), earlier in this chapter.

### **Persistent Fever after Resolution of Neutropenia**

In most cases, an undifferentiated fever that has persisted during neutropenia will resolve around the time of myeloid recovery. In a minority of patients, a fever of unknown origin persists for several days after myeloid recovery. Similar to the neutropenic period, evaluation of fever after myeloid recovery begins with a methodic evaluation of both noninfectious causes, such as drug fever (e.g., recombinant growth factors, b-lactam antibiotics), transfusion reactions, and deep venous thrombosis, as well as infectious causes.

A careful physical examination may show a site of infection that was inapparent during neutropenia, such as a perirectal process. A chest radiograph should be obtained because pulmonary infection may not be apparent radiographically during neutropenia. Blood and urine cultures, complete blood cell count, serum chemistry, and liver enzymes should be obtained. An elevated alkaline phosphatase should prompt consideration of hepatosplenic candidiasis, even if blood culture results were negative for *Candida* species. A CT scan, magnetic resonance imaging, and ultrasound are complementary imaging modalities and may show discrete bull's-eye lesions (see [Candidiasis](#), earlier in this chapter).

In contrast to the neutropenic period, empiric antibiotics can be discontinued after resolution of neutropenia in patients who are stable with an undifferentiated fever and negative culture data. If a source of infection is known, then antibiotic therapy targeted to the specific pathogen(s), rather than broad-spectrum empiric regimens used for neutropenic fever, is advised.

## **OUTPATIENT ANTIBIOTIC THERAPY FOR NEUTROPENIC FEVER**

Because of the high morbidity and mortality in febrile neutropenic patients and the need for emergent institution of systemic antibacterial therapy, hospital admission has been regarded as necessary, and inpatient observation was typically continued until resolution of neutropenia. More recent studies have shown that patients with febrile neutropenia can be stratified according to their risk of developing major or life-threatening infectious complications. Prospective randomized studies have suggested that patients in the lowest risk group are reasonable candidates for carefully monitored empiric outpatient antibiotic therapy.

Patients with a duration of neutropenia of 7 days or less are considered to be at low risk for serious infectious complications. In a study of 590 patients with neutropenia and an undifferentiated fever who had defervesced after initiation of empiric antibiotics, the risk for recurrent fever was directly related to the duration of neutropenia. Among patients with less than 7 days of neutropenia, only 0.6% developed a recurrent fever. The frequency of recurrent fever was 4% when the duration of neutropenia was 7 to 14 days and 38% when the duration of neutropenia exceeded 14 days.<sup>345</sup> Patients with neutropenia of 7 days or less were also far less likely to require modifications in the initial antibiotic regimen compared with patients with neutropenia lasting longer than 14 days.<sup>346</sup> Therefore, patients with long-duration neutropenia are less able to contain ongoing infections or are more likely to develop new infections (or both) after initiation of appropriate empiric antibiotics.<sup>342</sup>

Talcott et al.<sup>340,341</sup> developed a risk prediction model of serious complications and mortality in patients with febrile neutropenia based on a retrospective analysis of 261 patients and validated prospectively in 444 patients with cancer and febrile neutropenia. The following features predicted a high risk of substantial morbidity (25% to 40%) and mortality (12% to 18%): (1) inpatient status at time of fever and neutropenia (mostly made up of patients with hematologic malignancy or BMT recipients); (2) outpatients with concurrent comorbidity (hypotension, organ dysfunction, altered mentation, uncontrolled bleeding, and so forth); and (3) outpatients with uncontrolled progressive malignancy. In contrast, outpatients without significant comorbidity and with controlled malignancy had a low rate of morbidity (2% to 5%) and no infection-related mortality.

Talcott's group subsequently studied 30 low-risk patients with primarily hematologic malignancies and febrile neutropenia at the Dana Farber Cancer Center.<sup>347</sup> Standard intravenous antibiotics were administered for the initial 2 days as inpatients, followed by home antibiotic therapy with gentamicin plus either mezlocillin or ceftazidime. Patients with documented infections were excluded. Only 16 (53%) patients responded to the initial antibiotic regimen; nine (30%) patients were readmitted; and four (13%) patients had serious complications, including hypotension, renal failure, disseminated fungal infection, and coagulase-negative *Staphylococcus* bacteremia. No patient died, but the incidence of serious complications and the high admission rate in this pilot study suggested that criteria for selecting patients for outpatient therapy required further refinement.

Malik et al.<sup>348</sup> conducted a prospective, randomized study comparing oral ofloxacin with combination parenteral antibiotics (amikacin plus carbenicillin, cloxacillin, or piperacillin) in 122 hospitalized febrile neutropenic patients in Pakistan. This study was not confined to low-risk patients. Approximately two-thirds of patients had a hematologic malignancy or aplastic anemia, and the mean duration of neutropenia was 9 days. The overall response to antibiotics was 77% in the oral arm and 73% in the parenteral arm. Mortality in the oral group and parenteral groups were similar (7% and 10%, respectively).

This group subsequently compared oral ofloxacin administered in the outpatient versus the inpatient setting in 169 patients with febrile neutropenia.<sup>349</sup> Only low-risk patients as generally defined by the Talcott criteria were enrolled. Two-thirds of patients had solid tumors, and the remainder had hematologic malignancies. The mean duration of neutropenia was 5 days. Approximately 80% of outpatients and inpatients responded to ofloxacin monotherapy, and 20% of patients randomized to the outpatient group were subsequently admitted for parenteral antibiotics. Successful treatment with ofloxacin was more likely in cases in which no source of fever was documented by cultures or physical examination. Mortality in the group initially treated as outpatients was 4% versus 2% in the initial inpatient group.

Hidalgo et al.<sup>350</sup> compared outpatient-administered oral ofloxacin with inpatient-administered parenteral ceftazidime and amikacin in a prospective, randomized trial in 95 low-risk febrile neutropenic patients with solid tumors. The median duration of neutropenia was 3 to 4 days. Treatment failure, defined as fever persisting for 3 days or longer, a second febrile episode, or progression of infection, occurred in 10% and 8% of patients in the oral and parenteral arms, respectively. Eight patients in the oral arm were admitted for parenteral therapy, five because of treatment failure and three because of positive blood culture results. No death or serious complication occurred in those randomized to the oral arm, and one (2%) death occurred in the parenteral arm.

Rubenstein et al.<sup>351</sup> compared outpatient oral ciprofloxacin (750 mg three times a day) plus clindamycin with parenteral clindamycin and aztreonam in 83 low-risk febrile neutropenic patients with solid tumors or leukemia at M. D. Anderson Cancer Center. Patients were observed for 2 hours, then both oral and parenteral groups were sent home to complete therapy. The response rate (defined as resolution of clinical and laboratory evidence of infection) was 88% in the oral arm and 95% in the parenteral arm. Of the 20% in both groups who had bacteremia, five of seven in the oral arm and seven of eight in the parenteral arm responded to initial antimicrobial therapy. Six patients in the oral arm and none in the intravenous arm were admitted. No mortality or severe complications occurred in either group. The oral arm had additional renal toxicity, perhaps related to dehydration, the relatively high dose of ciprofloxacin, or both. The authors considered the parenteral regimen to have greater safety than the oral one.

Subsequently, the oral regimen was changed to ciprofloxacin (500 mg) plus amoxicillin/clavulanate (500 mg) every 8 hours, and the parenteral regimen was unchanged in a study of 179 patients with mostly solid tumors. Outcomes were similar, with 90% and 87% response rates in the oral and parenteral arms, respectively. Patients with solid tumors had higher response rates than those with hematologic malignancies. All patients survived without major infectious complications or antibiotic-related toxicity.

In general, these studies are encouraging about the safety of outpatient antibiotic therapy for low-risk patients with neutropenic fever (see references [352](#), [353](#), and [354](#) for more detailed reviews). However, important limitations exist in making broad conclusions. The prospective, randomized studies described previously

individually each enrolled fewer than 200 patients, and therefore lacked sufficient power to detect small differences between treatment groups. Pooling data from different studies as a metaanalysis is made difficult by the differences in eligibility criteria, choice of antibiotics, criteria for hospital admission, and criteria for a successful outcome.

The National Cancer Institute and H. Lee Moffitt Cancer Center compared an oral regimen consisting of ciprofloxacin plus amoxicillin-clavulanate with intravenous ceftazidime alone in patients with febrile neutropenia in whom the expected duration of neutropenia was less than or equal to 10 days from the onset of fever.<sup>355</sup> All patients were hospitalized for the entire duration of neutropenic fever. A total of 116 episodes of neutropenic fever were evaluated. Approximately 75% of patients had solid tumors, and the remainder had leukemia or lymphoma. The mean duration of neutropenia in both groups was 3 to 4 days. Approximately two-thirds of febrile episodes were unexplained, and blood stream infections occurred in only 7% of episodes. Serious complications, such as hypotension or intraabdominal infection, were rarely encountered. Breakthrough infections associated with bacteremia, oral, or soft tissue infections were also rare in both groups and were controlled by modifications in the antibiotic regimen. There were no deaths.

In a European multicenter study of febrile neutropenia (defined as ANC less than 1000/ $\mu$ L), patients with an expected duration of neutropenia of less than or equal to 10 days were randomized to receive either oral ciprofloxacin plus amoxicillin-clavulanate or intravenous ceftriaxone plus amikacin.<sup>356</sup> A total of 312 patients were evaluated, approximately 70% with a solid tumor and the remainder with a hematologic malignancy. The median duration of neutropenia after antibiotics was 4 days. Two patients in the oral group and six patients in the intravenous group died of infection. At day 30 after randomization, survival was approximately 95% in both groups. Bacteremia occurred in less than 15% of patients in both groups. The duration of fever, duration of therapy, and need for modification of the initial regimen were similar in both groups.

These two well-designed studies clearly establish that for carefully selected patients with febrile neutropenia, an oral regimen consisting of ciprofloxacin plus amoxicillin-clavulanate is safe and effective. Both studies evaluated lower risk patients, but the inclusion of patients with hematologic malignancies and patients with an expected duration of neutropenia as high as 10 days after the onset of fever reflect more liberal criteria for risk stratification. Patients with comorbidities predictive of a higher risk of complications (e.g., hemodynamic instability; neurologic, hepatic, respiratory, or renal impairment; catheter infections; inability to take oral medications) were excluded. In addition, these studies were conducted in hospitalized patients and, therefore, extrapolations should not be made about the feasibility of this oral regimen in the outpatient setting.

The greatest concern about outpatient management of neutropenic fever relates to the possibility of life-threatening complications that may be reversible if detected early and appropriate interventions are made immediately (e.g., intravenous fluid, vasopressors, broadening of antibiotic coverage). Randomized clinical trials with sufficient statistical power are required to more precisely stratify patients for whom outpatient management of neutropenic fever is safe and to delineate optimal antibiotic regimens (oral versus parenteral) for different patient groups.

## ANTIBACTERIAL PROPHYLAXIS IN AFEBRILE NEUTROPENIC PATIENTS

Despite improvements in antibacterial agents used in febrile neutropenia, persistent and profound neutropenia remains the most important predictor of life-threatening infections. Prophylactic agents administered at the onset of neutropenia therefore have potential appeal as a means of reducing the incidence of infections during this high-risk period. However, the concern for emergence of antibiotic-resistant bacteria plus the lack of a survival benefit associated with antibacterial prophylaxis led to the reasonable recommendation against routine prophylaxis in neutropenic patients by the IDSA.<sup>71</sup>

Today, antibacterial prophylaxis for neutropenia is largely restricted to quinolones and trimethoprim-sulfamethoxazole. These agents have activity against Enterobacteriaceae without significant activity against commensal intestinal anaerobes, thus providing selective decontamination of the gut. The rationale for selective, as opposed to global, suppression of gut flora is based on the concept of colonization resistance. In human studies, maintenance of the normal commensal intestinal flora provides a potent barrier to acquisition of pathogenic aerobic gram-negative rods.<sup>357</sup> Thus, it has been argued that an ideal prophylactic antibiotic regimen selectively targets aerobic gram-negative bacteria without inducing alterations in the normal intestinal microflora. Quinolones and trimethoprim-sulfamethoxazole have the added advantage of achieving high serum and tissue levels after oral administration, an important consideration given that multiple portals of bacterial invasion exist in neutropenic patients.

Two meta-analyses have been conducted on trials of fluoroquinolone prophylaxis in neutropenic patients.<sup>358,359</sup> The more recent study evaluated 18 trials with 1408 patients in which quinolones were compared with either placebo or trimethoprim-sulfamethoxazole.<sup>358</sup> Patients who received quinolones had 79% fewer gram-negative infections than those without prophylaxis, leading to an overall 46% reduction in total infections. The reduction in fever was small, and in blinded trials, was not significant. Quinolones were more effective than trimethoprim-sulfamethoxazole in preventing gram-negative infections. Prophylaxis with either agent did not affect mortality.

The frequencies of quinolone-resistant gram-negative isolates, gram-positive infections, and fungal infections were not significantly affected by quinolone prophylaxis in the metaanalysis.<sup>358</sup> However, a note of caution is required. Although quinolones have remained particularly effective at preventing gram-negative bacterial infections, quinolone-resistant gram-negative infections have developed during prophylaxis at several centers.<sup>358</sup> Among gram-positive pathogens, viridans streptococcal bacteremia is of particular concern in patients receiving quinolone prophylaxis (see [Viridans Streptococci](#), earlier in this chapter).

To try to overcome the inadequate activity of quinolones against gram-positive bacteria, combination prophylactic regimens have been used. One large randomized study showed that addition of penicillin to a quinolone (pefloxacin) reduced the rate of bacteremia, especially that due to streptococcal species, compared with the quinolone alone.<sup>360</sup> Another randomized study showed that the combination of prophylactic ofloxacin and rifampin led to a reduction in gram-positive infections compared with ofloxacin alone.<sup>361</sup> However, addition of these agents to quinolone prophylaxis, of course, defeats the concept of selective decontamination. Newer generation quinolones with enhanced activity against streptococci are potential candidates for prophylaxis and warrant further study.

If prophylactic ciprofloxacin is used, vancomycin should be considered in the initial empiric regimen for neutropenic fever based on the high likelihood of breakthrough gram-positive infections. Vancomycin plus ceftazidime is a logical combination in this setting.

Trimethoprim-sulfamethoxazole as prophylaxis against *P. carinii* in children with acute lymphocytic leukemia was also highly effective as prophylaxis against bacterial infections and sepsis.<sup>289</sup> More recent studies comparing trimethoprim-sulfamethoxazole with placebo have yielded inconsistent results. This discrepancy may reflect the emergence of resistant gram-negative bacteria during trimethoprim-sulfamethoxazole prophylaxis. In comparative studies, trimethoprim-sulfamethoxazole has, in general, been shown to be less effective than quinolones with regard to protection against gram-negative infections.<sup>358</sup> Other disadvantages of trimethoprim-sulfamethoxazole prophylaxis include lack of activity against *P. aeruginosa*, potential suppression and delay of myeloid recovery, and hypersensitivity reactions. The main advantage of trimethoprim-sulfamethoxazole over quinolones relates to effective prophylaxis against *P. carinii*. Although *P. carinii* is rarely associated with isolated neutropenia, other comorbid conditions (such as AIDS) and regimens that contain intensive corticosteroid therapy predispose to infection by this organism (see [Pneumocystis carinii](#), earlier in this chapter). Trimethoprim-sulfamethoxazole may also reduce the frequency of nocardiosis, listeriosis, and toxoplasmosis in persons with compromised T-cell immunity.

## PROTECTED ENVIRONMENTS

The rationale for protective environments for neutropenic patients is derived from the same principle as selective decontamination by prophylactic antibiotics. By reducing the frequency of colonization by virulent bacteria, a germ-free environment was considered to be important in protecting neutropenic patients from infection.

However, it became clear that such stringent measures were not necessary for the majority of neutropenic patients. Nauseef and Maki<sup>362</sup> compared protective isolation (single room and use of gowns, gloves, and masks) with standard hospital care in hospitalized neutropenic patients with acute nonlymphocytic leukemia. Neither group received prophylactic antibiotics or sterilized food. The two groups were similar with respect to incidence of infection and days with fever. Paradoxically, the rate of bacteremia was higher in patients randomized to protective isolation. The availability of more effective antibacterial agents, the shift in predominance of infections from gram-negative to gram-positive pathogens in neutropenic patients, and the lack of evidence supporting the benefit of protective isolation have led to the adoption of less stringent methods of isolation at most centers. The cost and excess labor required to maintain stringent isolation and the additional emotional burden that patients and families must endure further militates against the routine use of such measures.

Isolation of aerobic gram-negative bacteria from food in hospitals is well known.<sup>363</sup> Uncooked vegetables often contain relatively large burdens of *E. coli*, *Klebsiella*

species, and *P aeruginosa*.<sup>364</sup> Thus, although not validated by controlled studies, it is reasonable to omit such foods from the diets of neutropenic patients. Similarly, tap water can harbor *P aeruginosa* and *Legionella* species. Careful hand washing before and after patient contacts remains the most effective method for preventing nosocomial infection.<sup>365</sup>

Laminar air flow units with high-efficiency particulate air filtration is the most effective means of removing aerosolized bacteria and fungal spores.<sup>366</sup> With more effective antimicrobial agents used today as empiric therapy for neutropenic fever, it is unclear that such protected environments are of benefit for most neutropenic patients. The high cost of maintaining such units makes them impractical for routine use for all neutropenic patients at most centers.<sup>367</sup> Today, the principal benefit of laminar air flow units is likely to be protection against *Aspergillus* species and other filamentous fungi. From a practical standpoint, they are usually restricted to patients at high risk for infection by molds (e.g., patients with leukemia and BMT recipients).

## MANIFESTATIONS AND THERAPY OF INFECTIONS

### BACTEREMIA

Bacteremia is a common complication of antineoplastic myeloablative chemotherapy. In a review of empiric antimicrobial regimens for neutropenic fever, the dominant risk factor for bacteremia was the duration of neutropenia.<sup>305</sup> Neutropenia lasting 1 to 5 days before trial entry was associated with a relative risk of bacteremia of 5.2 compared with no neutropenia; neutropenia of 6 to 15 days had a relative risk of 7.35. Patients with a hematologic disease and BMT recipients were also more likely to have bacteremia than patients with solid tumors. The presence of shock was highly predictive of bacteremia with a relative risk of 5.6.

In patients with suspected systemic infection, a meticulous physical examination and culture of all potential sources of infection should ideally be done before initiation of antibiotics. If it is not feasible to obtain all culture material at the time of initial evaluation, however, empiric antibiotic therapy should not be delayed. Cultures should be obtained from blood and urine, and depending on the clinical situation, from sputum, pleural fluid, and peritoneal fluid. Wounds and skin lesions should be aspirated or biopsied, and material submitted for culture. Particularly in neutropenic patients, the appearance of wounds may be deceptively benign without erythema or purulence.

Once a positive blood culture result is reported, the initial antibiotic therapy may need to be altered (see [Table 54-7](#)). Coagulase-negative *Staphylococcus* species and *Corynebacterium* (diphtheroid) species are common blood culture contaminants. However, patients with cancer often have indwelling intravenous catheters, which can be portals of entry for these bacteria, thereby increasing the risk of bacteremia. The likelihood of contamination is increased if these organisms are isolated from a single blood culture. It is therefore important to draw at least two sets of blood cultures from separate sites. *Corynebacterium jeikeium* is a virulent species associated with bacteremia and disseminated organ infection; isolation of this organism from a single blood culture requires prompt initiation of vancomycin therapy. Similarly, isolation of *S aureus* from a single blood culture (or from the urine in a febrile or septic appearing patient) should be considered to represent hematogenous infection.

If a gram-negative organism is isolated from a blood culture collected before the initiation of antibiotics, an appropriate parenteral regimen used empirically at the onset of neutropenic fever can be maintained while awaiting drug sensitivity data so long as the patient is clinically stable.<sup>368</sup> The rationale is that standard empiric antibiotic regimens for neutropenic fever and the specific regimen adopted at a given institution are selected to provide reliable coverage against all likely gram-negative pathogens. If the patient is not stable or if the gram-negative organism is isolated after initiation of antibiotics (i.e., breakthrough bacteremia), change to a new regimen is warranted (see [Table 54-7](#) for specific suggestions). Once antibiotic susceptibilities are known, therapy should be tailored appropriately.

Shock and multiple organ dysfunction are dreaded complications of sepsis. In patients with neutropenia, prompt initiation of broad-spectrum antibiotics directed against commonly encountered blood-borne pathogens is essential (e.g., *S aureus*, viridans streptococci, Enterobacteriaceae, and *P aeruginosa*). Unlike the stable patient with neutropenic fever, there is likely not to be an opportunity to modify antibiotics based on culture data if the initial regimen does not provide adequate coverage. Combination vancomycin, imipenem, and an aminoglycoside is a reasonable empiric regimen. At centers in which carbapenem-resistant *P aeruginosa* is frequent, cefepime plus metronidazole may be used instead of imipenem. Modifications should be made once culture and sensitivity data are known.

In septic shock, several interventions should be made rapidly. When possible, removal of all indwelling catheters should be performed. If a nidus of infection is identified, surgical débridement should be performed emergently, and material sent for culture and staining for bacteria and fungi. Standard supportive measures include fluid resuscitation, oxygen, and invasive hemodynamic monitoring, and vasopressor agents should be instituted. In patients with documented or suspected adrenal insufficiency, stress dose corticosteroids (e.g., hydrocortisone, 50 to 100 mg every 8 hours) should be administered. Empiric corticosteroid administration for adrenal insufficiency is appropriate in patients who have received significant corticosteroid therapy within the last year, such as for the underlying malignancy or for GVHD. However, routine use of corticosteroids for severe sepsis and shock is not warranted.<sup>369</sup>

Numerous studies have evaluated therapy directed against specific mediators of septic shock, including antibodies against endotoxin and TNF- $\alpha$  and a recombinant IL-1 receptor antagonist. Other potential strategies include endotoxin vaccine, polyclonal hyperimmune serum (to neutralize bacterial toxins), bradykinin, cyclooxygenase, leukotriene, platelet-activating factor antagonists, pentoxifylline, endogenous antibacterial peptides (such as bactericidal permeability increasing protein), and inhibition of nitric oxide.<sup>370</sup> All such therapeutic modalities directed against mediators of the sepsis cascade should be considered to be experimental.

### IMPLANTED VASCULAR CATHETERS

Tunneled, cuffed vascular catheters have been used extensively in patients with cancer, providing long-term central venous access for blood drawing and infusions. Catheter infections have been divided into several categories.<sup>371</sup> Greene<sup>371</sup> distinguished exit from tunnel infections based on whether inflammation extended greater than 2 cm from the exit site. Purulence from the exit site may be present, although in neutropenic patients, local erythema and tenderness may be the only signs of infection, making it difficult to distinguish from sterile inflammation associated with mild trauma. Tunnel infections manifest with inflammation extending along the subcutaneous tract through which the catheter was inserted. The third major category is catheter-related bacteremia or fungemia, which may occur in the presence or absence of signs of localized infection. A 5- to 10-fold greater organism recovery from blood drawn from the catheter compared with peripheral blood cultures is highly suggestive of a catheter source of septicemia. The fourth category is a septic thrombophlebitis in which a venous thrombus is documented in association with positive blood culture results.

Most exit site infections can be cured with antibiotics alone without catheter removal. At the University of Maryland Cancer Center, 160 exit site infections were identified out of 690 Hickman catheters placed, most caused by *S epidermidis* or *S aureus*.<sup>372</sup> Treatment was usually with vancomycin, and only 10 of 160 exit site infections resulted in catheter removal. In another study, 55 of 65 exit site infections were successfully treated with antibiotics and local care alone.<sup>373</sup>

In contrast to exit site infections, tunnel infections generally require catheter removal because of failure of antibiotic therapy alone. In cases of tunnel infection caused by the *Mycobacterium fortuitum* complex (*M fortuitum* and *M chelonae*), surgical excision of the tissue surrounding the tunnel may be required.<sup>374</sup>

Most cases of catheter-associated bacteremia can be cured without catheter removal, but certain situations should prompt catheter removal. Persistently positive blood culture results for longer than 3 days or recurrences of bacteremia by the same pathogen despite adequate antibiotic therapy are evidence of antibiotic failure and require catheter removal. In patients with severe sepsis (e.g., hypotension unresponsive to intravenous fluids), a new site of intravenous access should be established followed by immediate removal of all previous indwelling catheters. Certain pathogens (e.g., fungi, *M fortuitum* complex, *Bacillus* species, and antibiotic-resistant bacteria) are unlikely to clear or are prone to relapse without catheter removal.

In cases of septic thrombophlebitis, prompt catheter removal and initiation of antimicrobial therapy is essential. Anticoagulation is generally used, although its value has not been clearly established. Septic phlebitis of a central vein usually does not require surgical drainage if the catheter is removed. In cases in which a focus of infection exists in the soft tissue around the vein, surgical drainage may be necessary.<sup>375</sup>

Central catheters may be partially implanted, such as the Broviac or Hickman type in which the ports are exposed to the outside, or they may be entirely implanted. The totally implanted venous access devices have the advantage of being less likely to be traumatized or colonized by external skin flora and have fewer infections compared with catheters with external ports. In a study at Memorial Sloan-Kettering Cancer Center, 341 of 788 (43%) external tunneled catheters became infected compared with 57 of 680 (8%) completely implanted ports,<sup>376</sup> and external catheters were significantly more likely to be removed because of infection. It is possible that the more favorable infection rate associated with implanted ports is that such catheters are more likely used in patients with solid tumors who do not require

multiple ports for intravenous access; the external catheters are in turn more likely to be used in patients who require more catheter manipulations, such as those with leukemia and BMT recipients.

The use of long-term tunneled catheters with a Dacron cuff to reduce entry of skin flora is generally associated with fewer infections than nontunneled catheters. However, at the M. D. Anderson Cancer Center, nontunneled silastic catheters were associated with long durability and a low infection rate comparable with tunneled catheters.<sup>371</sup> Such an approach requires meticulous catheter care, but has the advantage of reduced expense and morbidity associated with catheter insertion and easier catheter removal.

## SKIN LESIONS AND SOFT TISSUE INFECTIONS

In the heavily immunocompromised patient with cancer, skin lesions can arise from several different etiologies (see reference [377](#) for an excellent review). Drug reactions are probably the most common noninfectious cause of cutaneous lesions. b-Lactam and sulfa antibiotics are relatively common offenders that are used extensively in this patient population. Cutaneous lesions may be manifestations of the underlying malignancy. For example, hematologic malignancies are associated with mixed cryoglobulinemia, which may produce cutaneous vasculitis. Sweet's syndrome is characterized by fever and skin lesions that may be papular, nodular, or ulcerative. These lesions may be misdiagnosed as cellulitis and be treated inappropriately with antibiotics. Histologically, a dense neutrophilic infiltrate located mostly in the mid and upper dermis is diagnostic. Sweet's syndrome is associated with hematologic malignancies and may occur during the neutropenic period. In the transplant recipient, GVHD typically presents as a diffuse maculopapular rash, and involvement of the gut and liver is common. Biopsy of skin lesions for histology and culture and staining for bacteria, fungi, mycobacteria, and viral infections is prudent to rule out infection.

Infections of the skin can either be localized or manifestations of systemic infection. Ecthyma gangrenosum is the most characteristic skin lesion associated with systemic *P aeruginosa* infection, but it is not pathognomonic (see [Fig. 54-1](#)). Ecthyma gangrenosum-like lesions can be caused by *S aureus*, enteric gram-negative rod infection, and by filamentous fungi, including *Aspergillus*, *Zygomycete*, and *Fusarium* species. Ecthyma gangrenosum begins as a raised erythematous papule or nodule that progresses to a bluish-black necrotic lesion within 12 to 24 hours. A central area of necrosis surrounded by erythema is typical. Hemorrhagic bullae may be observed. Pathologically, ecthyma gangrenosum is a necrotizing process in which masses of bacteria are often observed within the vessel wall. In neutropenic patients, infiltrating white cells may be absent.

Local soft tissue infection by *P aeruginosa* in the neutropenic patient can rapidly spread through fascial planes, causing extensive necrosis and fulminant sepsis.<sup>378</sup> The initial signs at the site of entry may be mild, pain and tenderness may be out of proportion to erythema, and purulence is likely to be absent. A needle aspiration of the lesion showing gram-negative bacilli establishes the diagnosis of invasive infection; however, a negative aspiration does not rule out the diagnosis. Prompt surgical débridement may be life saving in cases of localized disease.

*Stenotrophomonas maltophilia* can cause a variety of dermatologic infections, including mucocutaneous ulcerations, primary cellulitis, a metastatic nodular cellulitis, and ecthyma gangrenosum [see [Stenotrophomonas \(Xanthomonas\) maltophilia](#), earlier in this chapter]. *Aeromonas hydrophilia* is a gram-negative rod that grows in fresh and brackish waters and can be acquired by nosocomial transmission. Immunocompromised persons are more susceptible to extensive soft tissue infections from direct penetration through the skin, leading to sepsis. In a patient exposed to fresh or brackish water preceding an episode of cellulitis, an antibiotic regimen with activity against *A hydrophilia* should be initiated. The organism is usually susceptible to fluoroquinolones, trimethoprim-sulfamethoxazole, third-generation cephalosporins, and imipenem.

Septicemia by viridans streptococci is associated with facial flushing and a rash in 60% of cases in a series from the M. D. Anderson Center in Texas.<sup>65</sup> The rash was usually maculopapular, started on the trunk, and extended to the face and extremities. Skin exfoliation occurred on the palms and soles in 25% of patients 2 weeks after the onset of the rash. These manifestations are likely the result of acquisition of a plasmid producing a toxin associated with a toxic shock syndrome.

Bacteremia caused by *C jeikeium* is associated with skin lesions in 30% to 50% of neutropenic patients. The skin lesions often occur at catheter sites and at sites of trauma, such as bone marrow aspiration, and may only become apparent after resolution of neutropenia.<sup>72</sup> The portal of entry is usually through the skin. The lesions may be cellulitic, ulcerative, or pustular. If diphtheroids are isolated from a skin lesion, the microbiology laboratory should be asked specifically to evaluate for *C jeikeium*. *Bacillus* species are rare causes of skin infection, but can be associated with impetiginous, ulcerative, and necrotic skin lesions. *C jeikeium* and *Bacillus* species are sensitive to vancomycin.

*Clostridium* species are gram-positive anaerobes that cause deep soft tissue infection involving the fascia and muscle (see [Clostridium Species](#), earlier in this chapter). Typically, a small dusky or purplish lesion on the leg or abdominal wall rapidly expands, and as infection progresses, the lesions become necrotic, bullous, and hemorrhagic. Systemic toxicity, including fever, malaise, and mental status changes occur early. Because the infection occurs in the deep soft tissue, tenderness and evidence of vascular compromise typically precede the development of cellulitis. A rapidly progressive deep soft tissue infection with gas formation suggests clostridial myonecrosis (or polymicrobial necrotizing fasciitis). Needle aspiration characteristically shows the organism in the setting of a mild or absent inflammatory response. Extensive surgical débridement may be life saving if initiated early, although at this stage of disease, most patients die.<sup>86</sup>

The characteristic skin lesions of disseminated candidiasis are raised erythematous discrete papules, measuring approximately 0.5 to 1.0 cm in diameter. The lesions are usually not tender. Concurrent myalgias raises the possibility of *Candida* myositis.<sup>379</sup> The yeast is cultured from skin lesions in approximately one-half the cases. Therefore, a negative culture result does not rule out the diagnosis. Biopsy and fungal staining of cutaneous lesions can provide an immediate clue to the diagnosis, prompting the early addition of antifungal therapy.

*Trichosporon beigeli* is a yeast that causes sepsis and disseminated infection in neutropenic patients.<sup>144,145,380</sup> Skin lesions occur in 30% of disseminated infections and are characterized by nontender erythematous nodules that may become necrotic. Histologically, budding yeast are present in the dermis, as distinguished from *Candida* species, which produce pseudohyphae. High-dose azole therapy is considered the treatment of choice.

Cutaneous infection by filamentous fungi may be primary or may represent systemic infection. Primary cutaneous infection with molds can occur in immunocompetent patients by traumatic inoculation. However, progression to angioinvasion, infarction, extension to the deep soft tissue fascia and muscle, and dissemination denote profound immunosuppression. Walmsley et al.<sup>381</sup> described 16 cases of primary cutaneous aspergillosis in children, most of whom had leukemia or lymphoma or had undergone BMT. Eleven cases were related to intravenous arm boards, and five cases were attributed to hematogenous dissemination. Clinically, these lesions resemble ecthyma gangrenosum associated with disseminated *P aeruginosa* infection. Histologically, hyphal elements are present and may cause angioinvasion and infarction.

Infection by *Fusarium* species is being observed with increasing frequency, predominantly in leukemia patients with prolonged neutropenia. Primary cutaneous fusariosis has a varied appearance, including cellulitis, paronychia, onychomycosis resembling dermatophyte infection, as well as papular and nodular lesions, and subcutaneous nodules<sup>155</sup> (see [Fusarium Species](#), earlier in this chapter).

In the case of primary localized cutaneous infection with a mold, surgical resection is necessary and has an excellent prognosis.<sup>382</sup> In the neutropenic patient, the likelihood of subclinical systemic infection is high, and, therefore, high-dose amphotericin B (1.0 to 1.5 mg/kg daily) or a lipid formulation should be administered.

## SINUSITIS

In immunocompetent patients, sinusitis results principally from inadequate drainage of mucous secretions from the sinus cavities. Respiratory bacterial pathogens, including *S pneumoniae*, *H influenzae*, and *M catarrhalis* predominate. In patients with neutropenia or otherwise highly immunocompromised patients, infections by *P aeruginosa*, Enterobacteriaceae, and molds are more commonly observed.

Treatment of sinusitis in immunocompetent patients with cancer involves a standard antibiotic regimen, such as trimethoprim-sulfamethoxazole, amoxicillin-clavulanate, or a cephalosporin with activity against respiratory pathogens. In cases of an obstructing tumor interfering with drainage from the maxillary sinuses, surgical creation of an antral window may be required to facilitate drainage.

In neutropenic patients with symptoms or signs suggestive of sinusitis, a regimen with activity against gram-negative bacteria (such as ceftazidime) should be administered. If no improvement occurs within 3 days, a CT scan of the sinuses with diagnostic aspiration of fluid collections is recommended. A sinus endoscopy may

also be useful to visualize the upper airways and to obtain diagnostic material.

Infections by community respiratory viruses may initially manifest with sinus congestion or nonspecific upper airway symptoms. A high index of suspicion for such viruses is necessary for early therapy and prevention of nosocomial outbreaks. A nasopharyngeal or throat wash may rapidly establish the diagnosis (see [Community Respiratory Viruses](#), earlier in this chapter).

Invasive fungal sinusitis in immunocompromised patients often has devastating results. Infection by *Aspergillus* species is most common in patients with persistent neutropenia (e.g., aplastic anemia) and in BMT recipients. The agents of mucormycosis are classically associated with rhinocerebral disease, leading to necrosis of the palate, and extension to surrounding structures. Sinusitis by emerging fungal pathogens, including *Fusarium* species, *Alternaria* species, dark-walled molds, and *Pseudallescheria boydii* are being recognized with increasing frequency.<sup>154,383</sup> A cluster of fungal sinusitis in a pediatric hospital was associated with soil reservoirs disturbed by hospital construction.<sup>384</sup>

Symptoms and signs suggestive of fungal sinusitis include fever, nasal congestion, headache, maxillary tenderness, and periorbital swelling. Sinus endoscopy may show necrotic material or ulceration. Hyphal invasion into blood vessels leads to tissue infarction and hemorrhage. Mental status changes are suggestive of involvement of the brain.

Therapy for invasive mold infections involves a combined medical and surgical approach. High-dose amphotericin B (1.5 mg/kg/d) or a lipid formulation of amphotericin B should be initiated. When feasible, surgical resection of involved tissue should be performed, as medical therapy alone is unlikely to contain infection in the setting of neutropenia or severe immunosuppression. Amphotericin B should be continued even if all of the visualized necrotic tissue is fully débrided, given the likelihood of inapparent local and disseminated disease. The most important predictor of a successful outcome is resolution of neutropenia.

## PULMONARY INFILTRATES

In patients with cancer, pulmonary infiltrates pose a particularly difficult challenge. Numerous noninfectious causes of pulmonary infiltrates include congestive heart failure, pulmonary hemorrhage, infarction, drug-induced pneumonitis, radiation injury, tumor, and acute respiratory distress syndrome ( [Table 54-8](#)). In addition, common processes can have atypical radiographic appearances, and two or more pulmonary processes can exist simultaneously in this patient population. Establishing an early diagnosis is crucial so that appropriate therapy can be instituted, and the toxicity of inappropriate therapy is avoided.

**TABLE 54-8.** Differential Diagnosis of Pulmonary Infiltrates in Patients with Cancer

In heavily immunocompromised patients with cancer, such as those with leukemia and BMT recipients, pneumonia is common and is associated with a high mortality. Walsh and Pizzo<sup>385</sup> divided pulmonary infiltrates in neutropenic patients into four categories: (1) early, focal; (2) refractory, focal; (3) late, focal; and (4) interstitial or diffuse. Early infiltrates are defined as those that develop with the first onset of fever in a neutropenic patient. These infections are likely to be caused by Enterobacteriaceae, *P aeruginosa*, and *S aureus*. Because of neutropenia, physical findings of consolidation and sputum production may be absent. Two sets of blood cultures, a urine culture, a chest radiograph, and, if possible, a sputum for Gram's stain and culture should be obtained. Early in the course, the infiltrate is localized, but rapid progression to respiratory failure and sepsis is common. It is therefore essential to initiate appropriate empiric antibiotic therapy promptly and to closely monitor the response in an inpatient setting.

The optimal antibiotic regimen is controversial. The potential advantages of combination antibiotics include synergy and a reduced likelihood of the pathogen being resistant to all antibiotics in the initial regimen. An antipseudomonal penicillin (such as piperacillin or ticarcillin) or a third- (ceftazidime) or fourth- (cefepime) generation cephalosporin with activity against *P aeruginosa* may be combined with an aminoglycoside. If MRSA is common, empiric vancomycin should be added. Alternatively, standard monotherapy regimens for empiric treatment of febrile neutropenia, including ceftazidime, cefepime, imipenem, or meropenem, have sufficiently broad-spectrum activity to be used for treatment of acute bacterial pneumonia in neutropenic patients. The principle that a broad-spectrum antibiotic can be used as monotherapy for serious community-acquired and nosocomial pneumonias has gained widespread acceptance through well-designed prospective studies.<sup>386,387</sup> With regard to patients with cancer, ceftazidime monotherapy was shown to be equivalent to combination regimens as empiric therapy for neutropenic fever, including a subgroup of patients with pulmonary infiltrates. The rationale of monotherapy is to design a regimen with broad-spectrum activity against the most common pathogens and against the pathogens most likely to result in serious or life-threatening complications. Modifications of the initial regimen should be made on the basis of clinical response and microbiologic data. For this reason, use of a single antibiotic is probably not appropriate as empiric therapy for a fulminant pneumonia causing respiratory failure and sepsis, in which delay in the institution of appropriate antibiotics is likely to have disastrous consequences. The appropriateness of a particular empiric regimen for pneumonia, either monotherapy or combination therapy, depends on the frequency of isolates and their sensitivity profiles at a given institution.

If clinical improvement occurs within 48 to 72 hours, no further diagnostic measures are necessary, and antibiotic therapy should be continued until neutropenia resolves and for at least 10 to 14 days. Once neutropenia resolves, an appropriate oral antibiotic regimen could be administered for the remainder of the course.

In cases of refractory pneumonia, the possibility of a bacterial infection resistant to the empiric regimen as well as atypical causes of pneumonia become more likely. Examples of the latter group include *Legionella*,<sup>388</sup> *Chlamydia*, *Mycoplasma*, *P carinii*, *Nocardia*, and *Mycobacteria* species, as well as viral and fungal pathogens. Pneumonia and sepsis caused by enteric flora in a patient from an endemic area may result from a hyperinfection syndrome by *Strongyloides stercoralis*. A CT scan of the chest is useful in defining the location and morphology of the lesions, and an invasive diagnostic procedure (bronchoalveolar lavage, needle aspiration, open lung biopsy) may be warranted to establish the diagnosis.

Late onset of focal infiltrates applies to new pulmonary lesions developing on or after 7 days of empiric antibacterial therapy in persistently neutropenic patients. The likelihood of a fungal pneumonia in this setting is high. In contrast, development of a new pulmonary infiltrate after resolution of neutropenia is likely to represent a previous infection that was unrecognized during the neutropenic period; such infiltrates usually resolve without complications. *Aspergillus* species are the most common cause of pneumonia in persistently neutropenic patients. Less common fungal pathogens include *Trichosporon*, *Rhizopus*, *Fusarium* species, and dematiaceous molds. *Aspergillus* species and other filamentous fungi are angioinvasive and may cause pulmonary hemorrhage and infarction (see [Aspergillosis](#), earlier in this chapter). Pleuritic chest pain may result from pulmonary infarction or direct invasion of chest wall structures. As is the case for refractory pneumonia, infection with resistant bacteria, viruses, and protozoa remain in the differential diagnosis.

Diffuse pulmonary infiltrates may be due to a variety of infectious causes, including progressive bacterial infection, *Legionella*, *P carinii*, *M tuberculosis* (miliary), atypical mycobacteria, *S stercoralis*, and fungal and viral pathogens. In the BMT recipient, CMV infection is the most common cause of pulmonary infiltrates in the postengraftment period, generally between 1 to 4 months after transplant. Respiratory viruses, including RSV, parainfluenza, influenza, and adenovirus can cause severe pulmonary infection in transplant recipients. In winter months, upper respiratory symptoms and bronchospasm favor the diagnosis of RSV. Diffuse necrotizing pneumonia by varicella and HSV are also encountered in transplant recipients. Patients receiving concomitant corticosteroid therapy in addition to myeloablative therapy are at particular risk for *P carinii* infection, and, to a lesser degree, histoplasmosis, coccidioidomycosis, cryptococcosis, and reactivation of tuberculosis.

Based on careful evaluation of the patient's level of immunosuppression, time course of the illness, epidemiologic exposures, physical examination, and radiographic and laboratory data, a preliminary differential diagnosis is established. For patients who are either not responding to antibacterial therapy or whose clinical course is not suggestive of an acute bacterial process, an aggressive and expeditious approach to establishing the diagnosis is indicated. Sputum induction with hypertonic saline is diagnostic of PCP in approximately 60% of cases in patients who not infected with human immunodeficiency syndrome.<sup>285</sup> Sputum induction is also of value in diagnosing tuberculosis. If sputum induction is not diagnostic, bronchoalveolar lavage has a high diagnostic yield in alveolar infiltrates such as pneumonia caused by *P carinii*, *M tuberculosis*, and respiratory viruses. The sensitivity of bronchoalveolar lavage for focal lesions such as nodules is variable. In lesions larger than 2 cm, the sensitivity of bronchoalveolar lavage ranges from 50% to 80%, but in smaller lesions, the diagnostic yield is usually approximately 15%.<sup>385</sup> Quantitative cultures from bronchoalveolar lavage or from a protected brush catheter may increase the specificity in the diagnosis of bacterial pneumonia as distinguished from oral flora. However, the diagnostic yield of such procedures is substantially reduced by prior antibiotic therapy.

Bronchoalveolar lavage is a relatively insensitive method for diagnosing aspergillosis, detecting only approximately 50% of cases.<sup>389,390</sup> In one study of patients with leukemia, bronchoalveolar lavage failed to document all nine cases of autopsy-proven pulmonary aspergillosis.<sup>391</sup> Percutaneous biopsy may increase the diagnostic yield, but in thrombocytopenic patients, the risk of bleeding may be unacceptably high. Open lung biopsy is the definitive diagnostic method in immunocompromised patients with pulmonary lesions. This procedure also allows for easier visualization and control of bleeding. False-negative results occur in approximately 5% of open lung biopsies as a result of sampling error in the case of patchy lesions.

## CARDIAC INFECTIONS

Cardiac infections are relatively uncommon in patients with cancer. Infection can occur as a complication of thoracic surgery, such as a pneumonectomy, in which dehiscence of the bronchial stump can lead to a bronchopleural fistula and infection of the pleural space with extension to the pericardium. Meticulous and repeated débridements of infected tissue and repair of the fistula are necessary.

Endocarditis can occur as a complication of catheter-associated bacteremia<sup>392</sup> or a septic thrombophlebitis of the neck. In neutropenic patients, dental procedures should be avoided, but if they are necessary, antibiotic prophylaxis (amoxicillin) is reasonable to avoid secondary bacteremia. Evaluation by echocardiography is warranted in patients with bacteremia with signs suggestive of endocarditis, such as a new murmur or embolic phenomena.

Fungal endocarditis (principally *Candida* and *Aspergillus* species) may result from cardiac surgery and from illicit drug use.<sup>393</sup> Therapy for fungal endocarditis requires removal of the infected valve based on the poor penetration of antifungal agents into the valve, and the propensity for large vessel embolization. If valve surgery is not feasible, combination therapy generally consisting of high-dose amphotericin B (1.0 to 1.5 mg/kg/d) plus 5-flucytosine followed by prolonged fluconazole therapy has been successful in case reports of *Candida* endocarditis.<sup>394,395</sup> Rarely, filamentous fungi may also cause myocardial abscesses with direct extension to and destruction of the contiguous valve in profoundly immunosuppressed patients.<sup>396</sup>

Pericardial aspergillosis is a rare, but highly lethal complication in profoundly immunosuppressed patients with cancer.<sup>397</sup> In a review of 28 cases, pericardial involvement resulted from contiguous spread from the lungs or myocardium in all patients.<sup>398</sup> Patients with a hematologic malignancy are at highest risk for pericardial aspergillosis, reflecting the increased propensity for pulmonary *Aspergillus* infection. Clinical manifestations include chest pain, a pericardial friction rub, and pericardial constriction and tamponade.

Other pathogens associated with myopericarditis or endocarditis include *T gondii*, *C neoformans*, histoplasmosis, *Mycobacterium* species, nocardiosis, *Bartonella* species, and viral infections (e.g., HSV, CMV, influenza).

## OROPHARYNGEAL INFECTIONS

Oropharyngeal infections in patients with cancer usually result from the combination of neutropenia and the breakdown of mucosal barriers related to cytotoxic chemotherapy and radiation therapy (see [Mucosal Immunity](#), earlier in this chapter). A variety of oral manifestations may occur, including stomatitis, cheilitis, gingivitis, and periodontitis. Gingivitis is characterized by ulceration of the epithelium lining the gingival sulcus, resulting in a pocket between the gingiva and tooth. Necrotizing ulcerative gingivitis represents a severe end of the spectrum of this disease. In periodontitis, inflammation involves the supporting bone. The principal clinical sign of periodontal disease is bleeding through the ulcerated epithelium.<sup>399</sup>

Determining the incidence of oral bacterial infections in neutropenic patients is made difficult by the fact that the oral cavity is not a sterile site, making the distinction of chemotherapy-induced mucosal erosions from superimposed bacterial infection difficult. HSV is commonly shed in oral secretions and may produce mucosal ulcerations resembling chemotherapy-induced mucositis and necrotizing gingivitis. Oral mucosal candidiasis is most common in patients with profound T-cell deficiencies, such as those receiving high-dose corticosteroid therapy. Diagnosis is usually made by visual inspection alone, although in cases of uncertainty, a wet mount preparation showing pseudohyphal forms is confirmatory. A swab culture is not of diagnostic value because *Candida* species are commensals in the oral cavity. Filamentous fungi (e.g., *Aspergillus* and Zygomycete species) can cause invasive disease of the hard palate and other oral cavity structures, principally in patients with prolonged neutropenia.<sup>400</sup> The involved mucosa may initially have a dusky or violaceous appearance followed by necrosis, eschar formation, and ulceration. Surgical débridement of localized disease plus systemic antifungal therapy may be life saving.

Patients with oral mucosal disease may have difficulty eating because of pain. Malnourishment and dehydration may be severe if parenteral nutrition and fluid replacement are not initiated. Severe local infection with spread to adjacent tissue structures may occur, including paranasal sinusitis and septic thrombophlebitis. Disrupted oral mucosa may be a portal of entry for bacterial pathogens, leading to systemic infection.

If feasible, dental disease should be treated in advance of initiating chemotherapy and radiation therapy to allow for an adequate healing time. Plaque should be removed by scaling and curettage, and severely decayed or periapically infected teeth should be removed. A dentist experienced in the care of patients with malignancies should perform the initial clinical and radiographic evaluation and provide regular follow-up examinations through the course of antineoplastic therapy.

Chemical plaque control with agents such as chlorhexidine mouth rinses have been used routinely in patients with cancer, and different cancer centers use various rinsing protocols to enhance oral hygiene. Such rinses have led to a reduction in microbial counts, but their value with regard to reducing oral disease and systemic infection remains unproved. (see reference [401](#) for review).

## EPIGLOTTITIS

The diagnosis of epiglottitis should be considered in patients with fever and pain in the throat, odynophagia, difficulty handling upper airway secretions, and signs of upper airway compromise. In patients with cancer, the combination of neutropenia and mucotoxic chemotherapy and radiation therapy predisposes patients to epiglottitis.<sup>402</sup> Pathogens associated with epiglottitis in this population include common respiratory pathogens (such as *S pneumoniae* and *H influenzae*), as well as aerobic gram-negative rods and fungal pathogens. *Candida* epiglottitis is an unusual complication of neutropenia that may represent localized disease or disseminated infection.<sup>403</sup> Treatment with amphotericin B (1.0 mg/kg/d) is warranted for this potentially life-threatening infection.

If epiglottitis is considered, care should be taken to avoid unnecessary manipulations of the upper airway (e.g., probing the oral cavity with tongue depressors). Urgent consultation with an otolaryngologist should be obtained, and evaluation of the upper airway and obtaining culture material may be performed in the operating room. Tracheal intubation is required for impending upper airway obstruction.

## ESOPHAGITIS

Esophagitis is encountered commonly in patients with cancer. A gradual onset of retrosternal chest pain or burning and odynophagia are the most common symptoms. The differential diagnosis includes candidiasis, HSV, CMV (principally in BMT recipients), bacterial infections, and aspergillosis. Radiation therapy to the chest may produce an erosive esophagitis clinically indistinguishable from the infectious etiologies.

The evaluation of presumed esophagitis requires consideration of the patient's immune status. Patients with prolonged neutropenia and BMT recipients are more

likely to have an infectious etiology. In this population, *Candida* esophagitis is probably the most common etiology. More than one infectious cause may be present concomitantly. The presence of oral mucosal candidiasis increases the likelihood of *Candida* species as the etiology of esophagitis. However, the use of prophylactic topical antifungal agents (such as nystatin oral rinses) may protect against thrush while leaving the patient susceptible to esophageal candidiasis.

In highly immunocompromised patients with symptoms suggestive of esophagitis, two general strategies have been used. In the first, an endoscopy is performed initially. Whitish plaques are suggestive of candidiasis, whereas ulcerative lesions are more suggestive of viral infection. However, the gross endoscopic appearance is not specific enough to differentiate the various etiologies. Brushings and biopsy have the highest diagnostic yield. A brushing may suffice in lieu of a biopsy, which may carry the risk of bleeding, particularly in patients with thrombocytopenia.

In the second approach, empiric therapy is administered initially without an endoscopy. Fluconazole, with or without high-dose acyclovir (5 mg/kg every 8 hours), is administered as therapy for *Candida* and HSV, respectively. Alternatively, fluconazole may be administered initially, followed by acyclovir if no clinical response has occurred within 2 to 3 days. A history of oral HSV infections or presence of anti-HSV antibodies should prompt early initiation of acyclovir. In the setting of concurrent neutropenic fever, appropriate broad-spectrum antibacterial agents (e.g., vancomycin plus ceftazidime) with activity against oral flora should be added empirically. If symptoms do not rapidly abate, endoscopy should be performed.

Diagnosis of bacterial esophagitis relies on demonstration of bacterial invasion of the esophageal wall. Bacteria causing local disease include gram-positive cocci, gram-negative rods, and mixed infection.<sup>404</sup> Esophagitis may be complicated by bacteremia by predominantly gram-positive pathogens (viridans streptococci, *S aureus*, *Bacillus* species).<sup>404</sup> Erosive esophagitis may rarely lead to esophageal rupture or life-threatening bleeding.

## INTRAABDOMINAL INFECTION

Intraabdominal infections present a unique set of challenges in patients with cancer. Incorporating clinical data related to the malignancy, therapy, and the immune status of the host is critical when evaluating a potential acute abdomen. Common causes of an acute abdomen in the general population (such as cholecystitis, pancreatitis, appendicitis, and diverticulitis) also occur in patients with malignancy. Intraabdominal tumors, depending on their location, may lead to an obstructive cholangitis (e.g., pancreatic and hepatobiliary tumors) or erosion through a viscus. In some instances, tumor may replace most of the bowel wall, with perforation after initiation of cytoreductive chemotherapy. An upright abdominal film showing air under the diaphragm in a patient who has not undergone recent abdominal surgery is likely to be indicative of a bowel perforation or an intraabdominal infection caused by gas-producing organisms.

Patients with prolonged neutropenia are at risk for a necrotizing enterocolitis, referred to as *neutropenic enterocolitis* or *typhlitis*. Typhlitis likely results from a combination of neutropenia and defects in the bowel mucosa related to cytotoxic chemotherapy. This disease is most common in patients with leukemia who have undergone intensive myeloablative chemotherapy. Pediatric patients appear to be at greater risk for typhlitis than adults. Rarely, typhlitis has been reported in patients with leukemia who have not received chemotherapy.<sup>405</sup> *P aeruginosa* is the principal pathogen associated with typhlitis, though clostridial species are implicated in a minority of cases. Pathologically, typhlitis is characterized by ulceration and necrosis of the bowel wall, hemorrhage, and masses of organisms. In the setting of neutropenia, inflammation may be sparse.

Presumptive diagnostic criteria for typhlitis include fever, abdominal pain and tenderness, and radiologic evidence of right-sided colonic inflammation in patients with neutropenia.<sup>406</sup> Nausea, vomiting, and diarrhea (often bloody) are the most common associated symptoms. Abdominal distension, tenderness, and a right lower quadrant fullness or mass reflecting thickened bowel or a pericecal collection may occur. Tenderness is usually localized to the right lower quadrant, but may become diffuse. Septicemia by aerobic gram-negative bacteria (*P aeruginosa* and Enterobacteriaceae) is common; prostration and hypotension may be presenting signs.<sup>406</sup> Septicemia may be due to polymicrobial pathogens, including anaerobes. Clostridial species are the most common anaerobic pathogens, and bacteremia may result in a devastating myonecrosis (see [Clostridium Species](#), earlier in this chapter).

Diagnostic imaging by CT scans or ultrasonography should be performed in neutropenic patients with abdominal complaints. Positive findings are present in approximately 80% of cases<sup>406</sup> and include a right lower quadrant inflammatory mass, pericecal fluid, soft tissue inflammatory changes, localized bowel wall thickening and mucosal edema, and a paralytic ileus. Usually, disease is limited to the cecum, but more extensive involvement of the large bowel and disease of the terminal ileum may occur. Barium studies may show mucosal edema and effacement of the haustral markings, but are associated with a potential risk of bowel perforation.

Treatment of typhlitis involves administration of broad-spectrum antibiotics with activity against aerobic gram-negative rods and anaerobes. Imipenem or ceftazidime plus metronidazole are appropriate regimens. Supportive care, including intravenous fluids, bowel rest, and nasogastric decompression, should be instituted. Granulocyte transfusions and myeloid growth factors should be considered, as resolution of neutropenia is critical to a successful outcome.

The indications for surgery are derived from clinical experience rather than trials. Some older series suggest early surgical intervention<sup>407</sup> and others argue for a conservative approach except in situations of widespread necrosis of the colon.<sup>408</sup> Shamberger et al.<sup>409</sup> proposed the following criteria for surgical intervention: (1) persistent gastrointestinal bleeding after resolution of neutropenia, thrombocytopenia, and clotting abnormalities; (2) free intraperitoneal perforation; (3) uncontrolled sepsis despite fluid and vasopressor support; and (4) an intraabdominal process (such as an appendicitis) that would require surgery in the absence of neutropenia. Using these criteria, 20 of 25 pediatric patients with typhlitis were managed without surgery, and only one patient died of typhlitis. In cases of a localized peritonitis, a pericecal collection, or a suspected sealed off cecal perforation in a clinically stable neutropenic patient, surgical intervention may be delayed until resolution of neutropenia, given the increased surgical mortality during neutropenia. Surgical intervention involves resection of necrotic bowel, usually entailing a right hemicolectomy, ileostomy, and mucous fistula.<sup>410</sup>

Patients with cancer are at high risk for *C difficile*-associated colitis, probably in large measure due to prolonged hospitalization where environmental transmission is likely to occur, and to patients' receiving broad-spectrum antibiotics that alter the normal colonic flora and facilitate *C difficile* colonization. Hospitalized patients commonly become colonized with *C difficile*.<sup>411</sup> Clinical manifestations include asymptomatic carriage, colitis without pseudomembrane formation, pseudomembranous colitis, and fulminant colitis.<sup>412</sup> *C difficile* colitis may also increase the risk of bacteremia by enteric pathogens, including VRE.<sup>413</sup> In severe *C difficile* disease, patients may be septic. Paralytic ileus, toxic dilation of the colon, and bowel perforation may occur. An abdominal film typically shows a dilated colon with mucosal edema (*thumbprinting*).

Oral metronidazole is the standard therapy for *C difficile* colitis. Because of the risk of selection for VRE, oral vancomycin should be reserved for refractory cases and for patients intolerant to metronidazole. Patients in whom oral agents cannot be administered should receive parenteral metronidazole, because biliary excretion of the drug and exudation from inflamed colon generally result in adequate luminal concentrations of the drug.<sup>414</sup> Intravenous vancomycin is of no value in this setting because of inadequate lumen levels. In cases involving toxic dilation of the colon or perforation, surgical management typically involving a subtotal colectomy and diverting ileostomy may be life saving.

Endoscopic diagnosis of pseudomembranous colitis relies on visualization of characteristic raised, adherent, yellow plaques on the colonic mucosa. A tissue culture cytotoxicity assay that detects *C difficile* toxin B in stool is the gold standard laboratory diagnostic method. Direct culture of *C difficile* does not distinguish toxin-producing from non-toxin-producing strains, and thus, by itself, is not a useful diagnostic method. Several commercial enzyme immunoassays are available that detect *C difficile* toxins A or B, with sensitivities of approximately 80% and specificities close to 100%.<sup>415</sup>

## ANORECTAL INFECTIONS

Anorectal infections in patients with malignancy may be life-threatening. In some cases, infection may follow the development of an anal fissure. In other instances, tiny abrasions may be a portal of entry. Alternatively, infection may originate in the anal crypts. Once anorectal infection is established, fascial extension to the external genitalia, pelvic floor, retroperitoneum, and peritoneal cavity may occur. Anorectal infections, with or without extensive regional spread, may lead to septicemia and metastatic infections.

Patients with leukemia receiving intensive myeloablative chemotherapy are at greatest risk for anorectal infections. Recovery from neutropenia is the most important prognostic indicator for a positive outcome.<sup>416</sup> The most common pathogens isolated at surgery or from wound aspiration are the Enterobacteriaceae, anaerobes, group D streptococci, and *P aeruginosa*.<sup>416,417</sup> In most cases, the infection is polymicrobial.

The incidence of anorectal infections in patients receiving intensive myeloablative chemotherapy is approximately 5%.<sup>416,418</sup> Fever often precedes symptoms and

signs suggestive of anorectal infection, and perirectal pain, often exacerbated by defecation, may initially occur in the absence of physical examination findings.<sup>417</sup> Therefore, serial examinations of the perianal region are necessary.

In one series, point tenderness and poorly demarcated induration were the most consistent signs of perianal infection.<sup>417</sup> Localized erythema and warmth were also observed. Advanced disease was heralded by soft tissue breakdown and necrosis and progressive extension to the adjacent perineal and pelvic structures.

Mild perianal infection characterized by slight tenderness or small fissures may respond to initial therapy for fever and neutropenia. The presence of significant local tenderness, swelling, or skin maceration should prompt early administration of antibiotics appropriate for neutropenic fever and with activity against anaerobes (such as ceftazidime plus metronidazole or imipenem monotherapy). Digital rectal examination should not be performed due to the risk of infection and bleeding. A pelvic CT scan may aid in assessing for perirectal infection. Stool softeners, sitz baths, warm compresses, and analgesics should be provided.

Most cases of anorectal infections can be managed with appropriate broad-spectrum antibiotics and supportive measures.<sup>416,419</sup> Indications for surgery include progression of disease locally or continued sepsis despite adequate antibiotics, obvious tissue necrosis, or fluctuance. With adequate surgical drainage, pain typically resolves within 2 days.<sup>417</sup> At surgery, perirectal lesions usually consist of necrotic cavities filled with tissue debris.<sup>417</sup>

## CENTRAL NERVOUS SYSTEM INFECTIONS

CNS infections in patients with cancer can be divided into surgical and nonsurgical complications. Common surgical procedures include resection of tumor, insertion of a shunt for hydrocephalus, and insertion of a reservoir to facilitate delivery of chemotherapeutic agents and easy sampling of cerebrospinal fluid. Patients with cancer involving the brain typically receive high-dose corticosteroid and local radiation therapy, which may further increase the risk of neurosurgical infections.

Infections related to implanted hardware may manifest in a variety of ways. Infection of a shunt or an Ommaya reservoir may manifest with malfunction of the device. Overt signs of meningitis, such as meningismus and photophobia do not usually occur, but most patients have fever.<sup>420</sup> Change in mental status may be the only sign of infection. A CT scan may suggest meningitis, ventriculitis, or a brain abscess if the device is infected at the proximal end. Evaluation of the cerebrospinal fluid is required for a diagnosis. Infection may occur in the more distal region of the device manifesting as a soft tissue infection. In cases of ventriculoatrial shunts, a distal site of infection may cause persistently positive blood culture results, thrombophlebitis, right-sided endocarditis, or septic pulmonary emboli. Distal ventriculoperitoneal shunt infections are associated with peritonitis and intraabdominal collections.

Coagulase-negative staphylococci, *S aureus*, and *Propionibacterium acnes* are the most common organisms infecting intraventricular devices. Enterobacteriaceae and *P aeruginosa* account for approximately 10% of infections. Coagulase-negative staphylococci and *P acnes* usually cause indolent late postoperative infections.

When feasible, removal of the entire device should be performed and appropriate antibiotics administered.<sup>420</sup> Antibiotic therapy should be tailored to the specific pathogen isolated. In an acutely ill patient with suspected meningitis related to prior neurosurgery, empiric therapy with parenteral vancomycin should be administered to cover *Staphylococcus*, *Streptococcus*, and *Propionibacterium* species in combination with an agent with activity against Enterobacteriaceae and *P aeruginosa* (such as ceftazidime).

CNS infections unrelated to neurosurgery are relatively uncommon in patients with cancer. In two series, the incidence of CNS infections in BMT recipients was approximately 2%.<sup>421,422</sup> In a review of 58 cases of brain abscesses after BMT at the Fred Hutchinson Cancer Center, 92% were caused by fungi.<sup>423</sup> *Aspergillus* species accounted for approximately 60% of isolates and one-third were caused by *Candida* species. The remainder of fungal infections included agents of mucormycosis and *Scopulariopsis* and *Pseudallescheria* species. Approximately 90% of cases of CNS aspergillosis were associated with a pulmonary focus, whereas most cases of *Candida* brain abscess were associated with candidemia or neutropenia. Only 4 of 58 patients had a bacterial brain abscess, and one patient had cerebral toxoplasmosis. The mortality in this series was 97%.

The CNS is the most common target organ of hematogenous disseminated aspergillosis. Manifestations of CNS aspergillosis include focal seizures, hemiparesis, cranial nerve palsies, and hemorrhagic infarcts due to vascular invasion.<sup>424</sup> The presence of pulmonary infiltrates and focal neurologic deficits in an immunocompromised patient were significantly more predictive of CNS aspergillosis than for CNS candidiasis or cryptococcosis in a multivariate discriminant analysis of autopsy-proven fungal CNS infections.<sup>425</sup> *Aspergillus* brain abscesses are typically multiple, hypodense, and nonenhancing, with little mass effect. CT scans with contrast enhancement initially may reveal no focal lesions, but in a later stage may demonstrate focal ring-enhancing or hemorrhagic lesions. Magnetic resonance imaging may further facilitate early detection. Intermediate T2 signal surrounded by a rim of higher signal may be observed.<sup>421</sup> Biopsy of these lesions reveals the same pattern of vascular invasion and infarction similar to that seen in lung biopsy specimens. We suggest that CNS infections by *Candida* and *Aspergillus* species be treated with amphotericin B plus 5-flucytosine, which readily penetrates the blood-brain barrier.

Other less common causes of CNS infections in patients with cancer include members of the herpes virus family (HSV, VZV, CMV, EBV, and HHV-6), adenovirus, *L monocytogenes*, *Acanthamoeba*, *Nocardia* species, *Mycobacterium* species, and *T gondii*, which have been discussed earlier (see [Bacterial Pathogens in Cancer Patients](#), [Viral Infections](#), and [Parasitic Infections](#), earlier in this chapter).

## DEMENTIAS

Patients with cancer may develop a chronic dementia related to leukoencephalopathy, a debilitating complication of therapy for their malignancy. The combination of cranial radiation therapy and intrathecal or systemic methotrexate has been most closely linked with leukoencephalopathy, although other intrathecal regimens may produce similar findings.<sup>426,427</sup>

Progressive multifocal encephalopathy (PML) is a demyelinating disease associated with lytic infection of oligodendrocytes by the human polyomavirus JC virus. Patients may develop rapidly progressive dementia as well as focal motor or cerebellar findings. Today, this disease is most commonly seen in patients with advanced AIDS, reflecting the critical role of cell-mediated immunity in controlling this infection. Occasionally, PML is seen in heavily immunocompromised persons with hematologic malignancies and in BMT recipients.<sup>428</sup> Magnetic resonance imaging typically shows unilateral or bilateral white matter disease without mass effect or enhancement. Diagnosis is established by either brain biopsy or by detection of the JC virus in spinal fluid by PCR. There is no established therapy for PML. In patients with AIDS, highly active antiretroviral therapy has produced mixed results in patients with PML.<sup>429,430 and 431</sup> By extrapolation, it is logical to try to reduce immunosuppressive therapy in persons with cancer and PML as a means of augmenting cell-mediated immunity.

## GENITOURINARY INFECTIONS

Patients with cancer may be at an increased risk of serious urinary tract infections as a result of breaches of the normal anatomy of the genitourinary system, colonization by pathogenic organisms, and defects in host defense. The most common mechanism of seeding the bladder is via the ascending route. Barriers to entry and proliferation of pathogens include the presence of normal perineal flora, urination, mucosal epithelial lining, phagocytes, and, possibly, immunoglobulin secretion (IgA and IgG).<sup>432</sup>

A bladder catheter greatly facilitates colonization of the normally sterile bladder. A strong correlation exists between precatheterization rectal and periurethral isolates and organisms subsequently isolated from the urinary tract after bladder catheterization.<sup>432</sup> Obstruction to urinary flow permits colonization and multiplication of bacteria. In patients with cancer, obstruction of urine flow may result from tumors originating within and outside of the genitourinary tract. Tumors associated with hypercalcemia or hyperuricemia predispose to urinary stones. Impaired bladder emptying resulting in urine stasis may result from tumors involving the spinal cord. Urinary intestinal diversions are associated with a high incidence of bacteriuria and may predispose to clinically significant infections after myeloablative chemotherapy.

The epithelial lining of the bladder and a layer of mucopolysaccharide form a protective barrier against bacterial colonization and invasion. Injury to the bladder mucosa by cytotoxic agents likely increases the risk of infection. In dogs, stripping of the bladder mucinous layer led to increased colonization of the bladder mucosa by bacteria.<sup>433</sup> During neutropenia, the genitourinary tract may be an important portal of entry for systemic infections. Alternatively, the kidney may be secondarily seeded as a consequence of hematogenous infection. Neutropenic patients with a urinary tract infection are less likely to have dysuria and pyuria and are far more

likely to become bacteremic compared with nonneutropenic patients.<sup>20</sup>

Infection of the prostate, seminal vesicles, epididymis, and testes may represent localized disease or hematogenous seeding. Common bacterial infections include Enterobacteriaceae, *P aeruginosa*, *S aureus*, and enterococci. Less common pathogens include *Salmonella* species, tuberculosis (more likely to involve the kidneys and ureters), *Nocardia* species, *Candida* species, *Blastomyces dermatitidis*, and *C neoformans*.

Asymptomatic candiduria is common in patients with bladder catheters. Management of candiduria is limited by lack of knowledge about the natural history of this infection, specifically with regard to predicting in which patients systemic infection will occur. Fluconazole is effective in eradicating candiduria in the short term, but recurrent infection is likely.<sup>434</sup> Removal of indwelling bladder catheters and antibacterial agents frequently lead to clearing of candiduria. Therefore, routine treatment of candiduria in afebrile nonneutropenic patients with local or systemic antifungal agents does not appear to be warranted. Because of the risk of candidemia after genitourinary tract manipulations, candiduria should be treated before such procedures are performed.<sup>435</sup> Because of the increased risk of candidemia, neutropenic patients with candiduria should receive systemic antifungal therapy.

Hemorrhagic cystitis is a common consequence of cytotoxic regimens that cause direct bladder mucosal injury and thrombocytopenia. In BMT recipients with unexplained hematuria occurring beyond the early period (when it is an expected toxicity of the preparative regimen), a viral etiology should be considered. Adenovirus, the polyomavirus BK, and, rarely, CMV<sup>436</sup> have been associated with hemorrhagic cystitis. Childs et al.<sup>437</sup> reported adenovirus (four cases) or polyomavirus (four cases) in nine cases of hemorrhagic cystitis in patients receiving T-cell–depleted BMT.

Adenovirus can cause fatal disseminated infections in BMT recipients (see [Viral Infections](#), earlier in this chapter). Detection of urinary shedding of this virus by PCR appears to be more sensitive than cell culture methods, and may, in some cases, be a harbinger of disseminated disease.<sup>438</sup>

BK virus is ubiquitous. Approximately one-half of BMT recipients shed BK virus in the urine.<sup>439</sup> Hemorrhagic cystitis occurred four times more frequently in patients with BK viruria, and BK shedding often preceded or occurred simultaneously with cystitis. In some patients, prolonged urinary BK shedding did not result in disease. Documentation of BK viruria can be made by electron microscopy of urinary sediments, PCR, and DNA hybridization. Treatment of BK virus–associated hemorrhagic cystitis is supportive and may include prolonged bladder irrigation to prevent clot retention as well as blood transfusions.<sup>440</sup>

## IMMUNE AUGMENTATION STRATEGIES

### GRANULOCYTE TRANSFUSIONS

The rationale for granulocyte transfusions is to buy time for the neutropenic patient with a life-threatening infection by augmenting the number of circulating neutrophils until native myeloid regeneration occurs.

In the 1970s, the technology for harvesting and infusing granulocytes became available. Controlled trials of granulocyte transfusions as adjuvant therapy in neutropenic patients produced mixed results.<sup>441</sup> In the 1980s, the enthusiasm for granulocyte transfusions waned as more effective antibiotics became available, survival from serious bacterial infections was improved, and recombinant growth factors reduced the duration of neutropenia. In addition, there were concerns about the toxicity of granulocyte transfusions, including pulmonary leukostasis, risk of HLA alloimmunization (complicating platelet transfusions and conceivably myeloid engraftment after BMT), and risk of transfusion-associated infections, which appeared to outweigh their perceived benefit.

Today, the impetus to take a second look at granulocyte transfusions in large part stems from improvements made in the mobilization methods.<sup>442</sup> Recombinant G-CSF with or without corticosteroids is now routinely administered to donors approximately 12 hours before apheresis. G-CSF is a potent stimulus for neutrophil production by mobilizing myeloid precursors from marrow reserves. Using a standard continuous flow centrifugation apparatus, the mean absolute neutrophil yield per collection typically exceeds  $3 \times 10^{10}$  cells.<sup>443,444</sup> The higher number of harvested neutrophils in turn correlates with a higher neutrophil count in the recipient after transfusion.<sup>445</sup> The increased neutropenia-free period may also be related to a prolonged circulating half-life of G-CSF–mobilized granulocytes.<sup>444</sup> The qualitative functions of G-CSF–mobilized and corticosteroid-mobilized neutrophils appear to be intact, as measured by *in vitro* bactericidal activity, respiratory burst, and *in vivo* migration to experimental skin chambers.<sup>444</sup> G-CSF–mobilized granulocytes have been shown to localize to sites of inflammation after transfusion in allogeneic BMT recipients.<sup>446</sup>

Successful outcomes using granulocyte transfusions have been described in patients with life-threatening fungal infections in small series and case reports. In one nonrandomized retrospective study, no benefit of granulocyte transfusions was documented in treating fungal infections in BMT recipients.<sup>447</sup> Obviously, such reports must be interpreted with caution and do not permit general recommendations. A more recent phase I/II clinical trial using G-CSF–mobilized transfusions for treatment of refractory fungal infections in neutropenic patients with hematologic malignancies reported favorable responses in 11 of 15 patients.<sup>448</sup> Adverse transfusion-related reactions were infrequent.

In the absence of modern, prospective, randomized studies, when might granulocyte transfusions be considered? Currently, there is no justification (outside of a clinical trial) to use granulocyte transfusions either as prophylaxis or in cases of documented infections that are likely to respond to conventional therapy. We reserve granulocyte transfusions for patients with prolonged neutropenia and life-threatening infections refractory to conventional therapy. Filamentous fungi are likely to constitute the majority of such refractory infections.

If granulocyte transfusions are used, several considerations are important. In neutropenic patients, it is likely that daily or every other day transfusions will be administered, depending on the length of the neutropenia-free period after transfusions. Granulocytes should be infused quickly after harvesting, given the short storage half-life. With modern apheresis methods, the number of harvested neutrophils should exceed  $2 \times 10^9$  cells. Infusions of amphotericin B should be separated by several hours from granulocyte transfusions to avoid pulmonary toxicity.<sup>449</sup> Leukocyte compatibility should be established by HLA matching and, if available, by leukocyte cross-matching to avoid alloimmunization. In some highly alloimmunized patients, transfused granulocytes are rapidly consumed and are likely to have more toxicity than benefit. In CMV-seronegative BMT recipients, only seronegative donors should be used.

### GROWTH FACTORS

Normal myelopoiesis requires the establishment of myeloid stem cells, which, under the influence of stem cell factor, IL-3, and GM-CSF, gives rise to a the colony-forming unit granulocyte-macrophage. G-CSF acts at a later stage in concert with other growth factors to specifically drive granulopoiesis.

Many potential applications exist for recombinant colony-stimulating factors in patients with cancer, the most obvious being a reduction in chemotherapy-induced neutropenia. We discuss the use of colony-stimulating factors in two specific settings: (1) prophylaxis (growth factor is administered around the time of initiation of the myeloablative regimen), and (2) adjunctive therapy for established infection.

#### Prophylaxis

Prophylactic G-CSF has been evaluated in several prospective, randomized studies. The most consistent benefit has been a reduction in the neutropenic period. In some studies of patients with acute myelogenous leukemia receiving potent myeloablative chemotherapy, the acceleration of myeloid recovery was associated with a reduction in the duration of fever, use of antibiotics, and hospitalization.<sup>450,451</sup> The frequency of infections and the number of fatal infections were unaffected by G-CSF.<sup>450</sup> In patients with small cell lung cancer, G-CSF led to a reduction of the neutropenic period, duration of hospitalization, and rate of confirmed infections.<sup>452</sup>

Use of G-CSF in patients with a short duration of neutropenia is associated with a reduction in the neutropenic period, but no effect on the rate and days of hospitalization, duration of parenteral antibiotics, and number of documented infections.<sup>453</sup> Prophylactic G-CSF had no benefit except for a modest reduction in the neutropenic period after preparative regimens for autologous stem cell transplantation.<sup>454,455</sup>

Prophylactic GM-CSF has been evaluated in two prospective, randomized studies of elderly patients with acute myelogenous leukemia.<sup>456</sup> In one study, GM-CSF was only administered to patients who had a hypocellular or remission marrow on day 10 of induction chemotherapy.<sup>457</sup> Patients who achieved complete remission received the same study drug (GM-CSF or placebo) for consolidation chemotherapy. The median time to neutrophil recovery was significantly reduced in the GM-CSF

group as was the frequency of fatal fungal infections and early infection-related mortality. There was a trend toward increased complete remission in the GM-CSF group. Most important, the 6-month mortality was significantly reduced in the GM-CSF arm. To our knowledge, this is the only study that has shown a survival advantage attributed to a colony-stimulating factor. This study formed the basis for approval by the Food and Drug Administration of GM-CSF for patients with acute myelogenous leukemia. A larger study conducted by the International Oncology Study Group using a similar design is underway to evaluate prophylactic GM-CSF in older and younger patients with acute myelogenous leukemia.<sup>456</sup>

In another study of 388 elderly patients with acute myelogenous leukemia, prophylactic GM-CSF led to a modest reduction in the neutropenic period.<sup>458</sup> The incidence of serious infections, regrowth of leukemic cells, and treatment-related mortality was similar between the two groups. The authors concluded that GM-CSF should not be recommended for elderly patients with acute myelogenous leukemia.

The inconsistent results of studies of prophylactic colony-stimulating factors for chemotherapy-induced neutropenia are almost certainly due to important differences in the study population and in the study design. The populations differ with respect to the underlying malignancy and the chemotherapy regimen. Some studies are insufficiently powered to detect differences in morbidity between treatment arms. In addition, the timing and dosing of colony-stimulating factors vary among studies. In the case of GM-CSF, different formulations consisting of glycosylated and nonglycosylated products have been used in different trials.<sup>459</sup>

The American Society of Clinical Oncology has recommended that prophylactic colony-stimulating factors (G-CSF and GM-CSF) be used only in populations in which the frequency of febrile neutropenia is likely to exceed 40%.<sup>460</sup> The American Society of Clinical Oncology considered that certain patients receiving a relatively nonmyelosuppressive regimen may benefit from CSFs if they are at an unusually high risk for infectious complications. Such risk factors may include preexisting neutropenia, extensive prior chemotherapy or pelvic irradiation leading to a reduction in myeloid reserves, a history of recurrent febrile neutropenia associated with relatively nonmyelotoxic complications, or the presence of an open wound or an active infection. Patients with a history of a serious or life-threatening infection, such as typhlitis, or an invasive fungal infection should also be considered for CSF prophylaxis during subsequent chemotherapy cycles.

### **Colony Growth Factors in Established Infection**

The rationale for colony-stimulating factors for established infections stems from both the quantitative and qualitative effects of these agents on phagocytic cells. In neutropenic patients with life-threatening infections, survival is strongly influenced by the rapidity of neutrophil recovery. Thus, colony-stimulating factors and granulocyte transfusions are used in these settings to augment the number of circulating neutrophils.

In addition to accelerating myelopoiesis, colony-stimulating factors augment phagocyte function. G-CSF, GM-CSF, and macrophage colony-stimulating factor (M-CSF) increase the fungicidal activity of phagocytes *in vitro* against *Candida* and *Aspergillus* species.<sup>461,462,463 and 464</sup> The action of G-CSF is specific to neutrophils. M-CSF increases phagocytosis, chemotaxis, and secondary cytokine production in monocytes and macrophages.<sup>465</sup> GM-CSF stimulates various neutrophil effector functions and prolongs neutrophil survival *in vitro*, increases antibody-dependent cytotoxicity of eosinophils, accelerates the proliferation of the monocyte-macrophage system, and is a potent activator of monocytes and macrophages (reviewed in reference 465). Thus, GM-CSF may have a theoretical advantage against pathogens such as *Candida* and *Aspergillus* species, in which host defense is dependent on both neutrophil and macrophage function.

At present, published data related to colony-stimulating factors as adjunctive therapy for established infection are limited to animal studies, case reports, and open-label pilot studies in humans. Nemunaitis et al.<sup>465,466</sup> suggested that among patients with candidiasis or aspergillosis, treatment with antifungal agents plus M-CSF was associated with enhanced survival compared with historical controls. In another pilot study of eight patients with established fungal infection, adjuvant GM-CSF appeared to be promising.<sup>467</sup> These initial studies are insufficient to permit conclusions about the efficacy of these agents.

### **INTERFERON-g**

IFN-g is a macrophage-activating factor that is critical in host defense against intracellular infections such as *Leishmania* and *Mycobacteria* species. IFN-g augments generation of microbicidal reactive oxidants in phagocytes and is also a potent activator of oxidant-independent mechanisms, including augmentation of TNF- $\alpha$  production, tryptophan metabolism, granule protein synthesis, and MHC II expression.<sup>468</sup> IFN-g administered to normal volunteers was shown to increase expression of Fc $\gamma$ R1 receptors on phagocytes, leading to enhanced phagocytosis, and to increased b $_2$ -integrin expression on monocytes, which may improve phagocyte trafficking *in vivo*.<sup>469</sup> The combination of G-CSF and IFN-g overcame the suppressive effects of corticosteroids on the *in vitro* fungicidal activity of neutrophils against *Aspergillus* hyphae.<sup>25</sup> These data suggest that IFN-g may have a role in augmenting phagocyte function in immunosuppressed patients with cancer.

Currently, IFN-g is licensed as a prophylactic agent in patients with chronic granulomatous disease, an inherited disorder of the phagocyte nicotinamide-adenine dinucleotide phosphate (reduced form) oxidase that renders phagocytes defective in generating superoxide anion and its downstream reactive oxidant metabolites.<sup>470</sup> Patients with chronic granulomatous disease experience recurrent life-threatening bacterial and fungal infections. The major cause of mortality in chronic granulomatous disease is from invasive aspergillosis.<sup>471,472</sup> Prophylactic IFN-g reduced the number of serious infections by more than 70% in patients with chronic granulomatous disease.<sup>470</sup> In addition, IFN-g in combination with antimycobacterial agents had a positive effect on patients with refractory atypical mycobacterial infection resulting from defective IFN-g production.<sup>473</sup> It remains to be seen whether IFN-g may have similar positive effects on patients with cancer with iatrogenic phagocytic disorders.

In certain experimental fungal infections, host defense was enhanced by augmentation of T cells committed to Th1 phenotype, reflecting cell-mediated immunity. IL-12 is generated by activated macrophages and drives uncommitted T-helper cells to the Th1 pole to produce IL-2 and IFN-g.<sup>474</sup> This pathway appears to be critical in controlling various fungal infections. IL-12 reduced organism load in a murine cryptococcal model and acted synergistically when combined with fluconazole.<sup>475</sup> Improvement or worsening of experimental candidiasis correlated with administration of cytokines that stimulated a Th1 or Th2 T-cell response, respectively.<sup>476</sup> In a mouse model of invasive aspergillosis, administration of IFN-g and TNF- $\alpha$  were protective.<sup>477</sup> These studies provide a scientific basis for evaluating combination immunotherapy and antimicrobial therapy in fungal infections in immunocompromised patients.

### **ADOPTIVE IMMUNOTHERAPY IN BONE MARROW TRANSPLANT RECIPIENTS**

As discussed previously, the intensive preparative regimens used in allogeneic BMT result in a profound disruption of T-cell immunity. Reconstitution of T-cell immunity occurs over several months in uncomplicated cases and is further delayed in cases of GVHD requiring high-dose corticosteroid therapy and potentially antilymphocyte globulins. CMV and EBV are members of the herpes virus family that establish latent infection in normal hosts, and control of reactivation is largely mediated by CD8+ cytotoxic T lymphocytes. Cytotoxic T lymphocytes recognize intracellular proteins that are presented by surface MHC class I molecules on antigen-presenting cells.

Studies on immune reconstitution after allogeneic BMT have shown that recovery of CMV-specific cytotoxic T-lymphocyte responses confers protection from subsequent CMV disease,<sup>204,478,479 and 480</sup> and these protective responses are specific for the structural virion proteins.<sup>204</sup> Thus, one potential strategy for preventing CMV disease (aside from prophylaxis with antiviral agents) is by adoptive transfer of CMV-specific cytotoxic T-lymphocyte clones obtained from CMV-seropositive bone marrow donors and selectively expanded by *in vitro* culture. Such an approach has led to early reconstitution of CMV-specific immunity in allogeneic BMT recipients, which persisted for at least 12 weeks after infusion corresponding to the period of maximal risk for CMV disease.<sup>481</sup>

In allogeneic BMT recipients, the major risk of uncontrolled EBV infection is development of an aggressive EBV lymphoproliferative disease or lymphoma, which can be rapidly fatal. Infusions of unfractionated peripheral blood mononuclear cells from EBV-seropositive donors have been used to treat EBV lymphoproliferative disease in allogeneic BMT recipients.<sup>482</sup> However, alloreactive T cells in such unfractionated preparations may induce GVHD. A safer approach involves transfer of EBV-specific donor cytotoxic T-lymphocyte clones that have been selectively enriched *in vitro*.<sup>483,484</sup> This method has led to persistent cellular immune responses to EBV for as long as 18 months.<sup>484</sup>

#### NATURE OF THE PROBLEM

Chemotherapy-induced nausea and vomiting remain two of patients' most feared effects of cancer treatment. The incidence and severity of nausea or vomiting in patients receiving chemotherapy varies, depending on the type of chemotherapy given, dose, schedule, combinations of medications, and individual characteristics. Approximately 70% to 80% of all patients who receive chemotherapy experience nausea and vomiting.<sup>1,2</sup> Anticipatory nausea and vomiting are experienced by approximately 10% to 44% of patients who receive chemotherapy.<sup>3,4,5 and 6</sup>

The phenothiazines were the mainstay of antiemetic agents before the mid-1970s.<sup>7,8</sup> Currently, there are many efficacious antiemetic regimens for the nausea and vomiting produced by chemotherapeutic agents.<sup>9</sup> In a study conducted in 1983, cancer patients ranked nausea and vomiting as the first and second most severe side effects of chemotherapy, respectively.<sup>10</sup> After the emergence of new antiemetic agents and alterations in chemotherapeutic regimens, patients' perceptions of the most severe side effects were modified. In a 1993 study, 155 cancer patients receiving chemotherapy reported that they experienced an average of 20 physical and psychosocial symptoms: Nausea was ranked as the most severe symptom and vomiting as the fifth.<sup>11</sup> Therefore, nausea is also an important efficacy parameter when evaluating an antiemetic.

Use of these new antiemetic agents has decreased the incidence and severity of nausea and vomiting induced by chemotherapy; however, these agents have not totally prevented the problems. The consequences of not controlling the nausea and vomiting induced by cancer treatment may lead to medical complications, a failure of the patient to comply with the cancer therapy and follow-up, and a diminished quality of life.

#### PATHOPHYSIOLOGY OF NAUSEA AND VOMITING

The precise mechanisms by which chemotherapy induces nausea and vomiting are unknown; however, it appears probable that different chemotherapeutic agents act at different sites and that some chemotherapeutic agents act at multiple sites.<sup>12</sup> The fact that different chemotherapeutic agents cause nausea and vomiting by different mechanisms and that one chemotherapeutic agent may induce nausea and vomiting by more than one mechanism helps us to understand why there is no one antiemetic regimen that is effective all of the time.

Mechanisms by which chemotherapeutic agents cause nausea and vomiting are activation of the chemoreceptor trigger zone (CTZ) either directly or indirectly; peripheral stimulation of the gastrointestinal (GI) tract; vestibular mechanisms; cortical mechanisms; or alterations of taste and smell ( [Table 55.1-1](#)). For the majority of the chemotherapeutic agents, the most common mechanism is thought to be activation of the CTZ.

Simulation of chemoreceptor trigger zone  
Peripheral mechanisms  
  Damage of gastrointestinal mucosa  
  Stimulation of gastrointestinal neurotransmitter receptors  
Cortical mechanisms  
  Direct cerebral activation  
  Indirect (psychogenic) mechanisms  
Vestibular mechanisms  
Alterations of taste and smell

---

**TABLE 55.1-1.** Mechanisms of Nausea and Vomiting after Chemotherapy

The CTZ is located in the area postrema of the brain and can be reached by emetogenic chemicals via the cerebrospinal fluid or the blood. The thought is that the mechanisms of interaction between the CTZ and chemotherapy involve the release of various neurotransmitters that activate the vomiting center. Either one or a combination of these transmitters may induce vomiting. Some of the neurotransmitters located in the area postrema of the brain that may be excited and lead to emesis include dopamine, serotonin, histamine, norepinephrine, apomorphine, neurotensin, angiotensin II, vasoactive intestinal polypeptide, gastrin, vasopressin, thyrotropin-releasing hormone, leucine-enkephalin, and substance P.<sup>13</sup> Other enzymes surround the CTZ, such as adenosine triphosphatase, monoamine oxidase, cholinesterase, and catecholamines; however, their role in chemotherapy-induced emesis is unknown.

Until recently, the neurotransmitter that appeared to be the most responsible for chemotherapy-induced nausea and vomiting was dopamine. Many effective antiemetics are dopamine antagonists that may bind specifically to the D<sub>2</sub> receptor. However, there is a high degree of variation in dopamine receptor binding affinity by these drugs.<sup>14</sup> The action of some drugs that cause nausea and vomiting is affected very little or not at all by dopamine antagonists. It is known that not all the important receptors in the CTZ are dopaminergic, as the effect of dopamine antagonists is not equal to surgical ablation of the CTZ.<sup>15</sup> It has also been noted that the degree of antiemetic activity of high-dose metoclopramide cannot be explained on the basis of dopamine blockade alone.<sup>16</sup>

Histamine receptors are found in abundance in the CTZ; however, H<sub>2</sub> antagonists do not work at all as antiemetics. H<sub>1</sub> antagonists alleviate nausea and vomiting induced by vestibular disorder and motion sickness but not nausea and vomiting induced by chemotherapy.<sup>17,18</sup>

Knowledge that opiate receptors are found in abundance in the CTZ, as well as the facts that narcotics have mixed emetic and antiemetic effects that are blocked by naloxone and that naloxone has emetic properties, have led to the proposal of opiates or enkephalins as an antiemetic. High doses of naloxone augments emesis induced by chemotherapy, and low doses of narcotic may reduce emesis.<sup>19</sup> Studies to date have shown that opiates can prevent chemotherapy-induced emesis in laboratory animals; however, both butorphanol and buprenorphine have not proven to be effective antiemetics in patients who received previous chemotherapy.<sup>20,21</sup> One study by Lissoni et al.<sup>22</sup> did demonstrate that Fk-33-824 was more effective as an antiemetic in patients who received cisplatin; however, it was ineffective for

patients receiving cyclophosphamide or epirubicin.

Edwards et al.<sup>23</sup> found that arginine vasopressin levels rise to a greater extent in patients who vomit when they receive chemotherapy as compared to those who do not vomit.<sup>23</sup> It has been suggested that perhaps arginine vasopressin plays a role in nausea more than in the vomiting induced by chemotherapy. Dexamethasone, which is a known effective antiemetic, may work by reducing arginine vasopressin levels.<sup>24</sup> Another mechanism of action of corticosteroids as antiemetics may be related to modulation of prostaglandin release.<sup>25</sup>

Some evidence suggests that although no one neurotransmitter is responsible for all chemotherapy-induced nausea and vomiting, it appears that serotonin and 5-hydroxytryptamine (5-HT) receptors are particularly important in the pathophysiology of acute vomiting, whereas others may be more important in the pathophysiology of nausea and delayed emesis. The role of the 5-HT type 3 (5-HT<sup>3</sup>) receptor in chemotherapy-induced emesis was recognized by examining the mechanism of action of high-dose metoclopramide in decreasing cisplatin-induced emesis. High-dose metoclopramide, unlike other D<sub>2</sub>-receptor antagonists, has an exceptionally good capacity to decrease the emesis induced by cisplatin administration.<sup>26</sup> It has been recognized that metoclopramide has pharmacologic effects other than dopamine antagonism. Metoclopramide is a weak antagonist of peripheral 5-HT<sup>3</sup> receptors<sup>27</sup> and can stimulate GI motility by increasing acetylcholine release from the cholinergic nerves of the GI tract.<sup>28</sup> To test whether 5-HT<sup>3</sup>-receptor blockade would decrease cisplatin-induced emesis, Miner and Sanger<sup>29</sup> took a substituted benzamide, BRL 24924, which has stimulatory effects on the GI tract and is a 5-HT<sup>3</sup>-receptor blocker, and demonstrated decreased emesis in ferrets that received cisplatin. This study was repeated with a nonbenzamide, selective 5-HT<sup>3</sup>-receptor blocker MDL 72222, which has no GI-stimulating activity. The study revealed that cisplatin-induced emesis was totally blocked by this compound.<sup>30</sup> The same conclusion was reached in another study using a different nonbenzamide, the selective 5-HT<sup>3</sup> antagonist ICS 205-930.<sup>31</sup> These studies demonstrated the role of 5-HT<sup>3</sup>-receptor blockade in chemotherapy-induced emesis.

The precise mechanism of action of the 5-HT-receptor antagonists is unknown; however, they may have both a central and a peripheral effect. The GI tract contains 80% of the body's supply of serotonin, and it has been suggested that perhaps chemotherapy administration causes release of serotonin from the enterochromaffin cells of the GI tract, which then stimulates emesis via both the vagus and greater splanchnic nerve as well as stimulating the area postrema of the brain. After cisplatin administration, there is an increase in urinary excretion of 5-hydroxyindoleacetic acid, the main metabolite of serotonin, and this increase parallels the number of episodes of emesis.<sup>32</sup> Studies have shown that the 5-HT<sup>3</sup>-receptor antagonists decrease emesis from several chemotherapeutic agents, including cisplatin, cyclophosphamide, and doxorubicin.<sup>33,34,35 and 36</sup>

There has been new evidence regarding the potential role of substance P in emesis and new data about the use of neurokinin (NK1) antagonists in the management of emesis. Substance P, a neuropeptide found in the GI tract and the CTZ of the area postrema, exerts its emetic effects by binding to a specific neuroreceptor, NK1. A number of compounds that selectively block NK1 have been identified. These NK1 antagonists demonstrate a wide spectrum of antiemetic activity against numerous emetic stimuli in animal models, including several emetic stimuli that are not affected by serotonin and dopamine receptor antagonists. Studies in preclinical models have demonstrated that several NK1 antagonists have activity in the prevention of both acute and delayed cisplatin-induced nausea and vomiting. Two randomized double-blind studies have demonstrated that NK1 antagonists are beneficial in the prevention of delayed emesis.<sup>37,38</sup> These agents may also provide additional benefit in the prevention of acute nausea and vomiting when combined with a 5-HT<sup>3</sup> antagonist and dexamethasone.

The second most important mechanism whereby chemotherapy may induce emesis is peripheral effects that are thought to arise from the pharynx and the upper GI tract. Most likely, the chemotherapy does not directly stimulate the peripheral receptors. Rather, neurotransmitters probably are released as a result of local GI irritation or damage. GI tract serotonin, dopamine, opiate, histamine, and cholinergic receptors are most likely involved in the emesis induced by chemotherapy. The peripheral effects may be abolished by vagotomy, indicating that impulses from the GI tract may reach the vomiting center via the vagus and sympathetic nerves.<sup>39</sup>

Another mechanism that may be involved in chemotherapy-induced emesis could be the therapy's effect on the vestibular system. It is known that patients who have a history of motion sickness experience a greater severity, frequency, and duration of nausea and vomiting from chemotherapy than patients who do not experience motion sickness. The mechanism by which the vestibular system may lead to chemotherapy-induced emesis is unknown; however, it is postulated that sensory information that is received by the vestibular system is different from information that was expected.<sup>40</sup>

Some investigators believe that taste changes induced by chemotherapy may lead to nausea and vomiting. Some chemotherapeutic agents, such as cisplatin or gallium nitrate, can lead to loss of taste sensation or to a metallic taste in the mouth. A study conducted with patients receiving chemotherapy for malignant melanoma revealed that patients developed a more intense sense of taste for sweet, bitter, sour, and salt. After chemotherapy, the patients rated the highest concentration of sweet as lower, and the patients' discrimination between highest and lowest concentrations of sour, bitter, and sweet was decreased.<sup>41</sup> In another study of patients with breast carcinoma who received cyclophosphamide, methotrexate, and 5-fluorouracil, 36% reported a bitter taste in their mouth. One-third of the patients thought that the bitter taste caused vomiting.<sup>42</sup> The exact mechanism by which taste is changed by chemotherapy is unknown; however, it is thought that while the drugs are in the plasma or saliva, they have a direct effect on the oral mucosa or taste buds. Changes in taste may contribute both to nausea and vomiting as well as to anorexia.

Finally, chemotherapy-induced emesis may be induced by direct or indirect effects on the cerebral cortex. Animal studies have shown that nitrogen mustard partially causes emesis via direct stimulation of the cerebral cortex.<sup>43</sup> Studies demonstrate that the risk of nausea and vomiting is increased when a patient's roommate is experiencing nausea and vomiting. It is also known that the amount of sleep before receiving chemotherapy may influence whether a patient develops chemotherapy-induced emesis. In addition, large differences exist in the severity and incidence of nausea and vomiting from the same chemotherapeutic agents in different countries.<sup>44</sup> These studies indicate that indirect psychological effects can mediate chemotherapy-induced nausea and vomiting.

Aside from there being more than one mechanism by which each chemotherapeutic agent may induce emesis, chemotherapy induces emesis in a manner different from that of other classic emetic agents. Drugs such as apomorphine, levodopa, digitalis, pilocarpine, nicotine, and morphine cause vomiting almost immediately. Nitrogen mustard also may lead to emesis immediately; however, most chemotherapeutic agents and radiotherapy require a latency period before emesis begins. Also, most chemotherapeutic agents do not induce emesis in a monophasic way, as do the classic emetic agents. Chemotherapeutic agents induce emesis with a delayed onset, and the emesis has multiphasic time courses.<sup>45</sup> When managing chemotherapy-induced emesis, one should realize that there is most likely more than one mechanism involved, suggesting that there will not be one antiemetic regimen that will work for all patients all of the time.

## EMETIC SYNDROMES

Patients undergoing therapy for the treatment and possible cure of cancer with chemotherapy often are faced with the distressing side effects of nausea and vomiting. Although advances in the 1990s have provided the clinician with an array of antiemetics and varied regimens, therapy-induced nausea and vomiting have yet to be totally eliminated. The goals of antiemetic therapy are as follows: (1) to achieve complete control in all settings, (2) to provide maximum convenience for patients and staff, (3) to eliminate potential side effects of the agents, and (4) to minimize the cost of treatment with antiemetic agents and drug administration.

As a result of antiemetic investigations, five distinct but related emetic syndromes have been identified: acute chemotherapy-induced emesis, delayed emesis, breakthrough nausea and vomiting, refractory emesis, and anticipatory emesis. Traditionally, acute nausea and vomiting are defined as occurring within the first 24 hours after administration of chemotherapy. Delayed nausea and vomiting have been arbitrarily defined as occurring 24 hours after chemotherapy administration. More recent observations of the pattern of emesis indicate that delayed emesis may begin as early as 16 hours after chemotherapy administration and that serotonin may not be the primary mediator of symptoms for delayed emesis. Breakthrough nausea and vomiting are nausea and vomiting that occur despite preventive therapy. Rescue therapy is the treatment administered to patients who have not responded to the prophylactic regimens prescribed for acute or delayed nausea and vomiting. Refractory emesis occurs during subsequent cycles when antiemetic prophylaxis or rescues (or both) have failed in earlier cycles.

Anticipatory vomiting is a learned or conditioned response that typically occurs before, during, or after the administration of chemotherapy. Patients receiving one or a combination of several of the agents must receive an antiemetic regimen that is tailored to the individual pattern and emetic potential of each agent. For example, patients receiving a combination of high doses of intravenous cyclophosphamide and doxorubicin (Adriamycin) would require antiemetic coverage for the early onset of emesis usually seen with Adriamycin, as well as continued protection from cyclophosphamide-induced emesis that does not begin until 9 to 18 hours after the drug's administration.<sup>46</sup> If patients are given the opportunity to receive the optimal antiemetic regimen during their initial course of chemotherapy, the likelihood of developing anticipatory emesis with subsequent cycles is greatly reduced. Other advantages for patients include increased tolerance of dose-intensified chemotherapeutic regimens. In addition, through the prevention of emesis, patients are able to achieve an enhanced quality of life at a particularly difficult time.

Two reports, one by Hesketh et al.<sup>47</sup> and an expert consensus by the American Society of Health-System Pharmacists,<sup>48</sup> contain new guidelines for the classification

of the acute emetogenicity of chemotherapy into five levels ( [Table 55.1-2](#)). When the agents are combined, ratings are based on the combined emetogenicity of the individual agents. An algorithm for defining the emetogenicity of combination chemotherapy has been developed ( [Table 55.1-3](#)).

**TABLE 55.1-2.** Emetic Potential of Chemotherapeutic Agents

---

The most highly emetogenic agent in the chemotherapeutic combination must first be identified.

Level 1 chemotherapeutic agents do not contribute to the emetogenicity of the regimen.

Adding one or more level 2 chemotherapeutic agents increases the emetogenicity of the combination by one level greater than the most emetogenic agent in the combination.

Adding level 3 and 4 agents increases the emetogenicity of the combination by one level per agent.

## CONTROL OF EMESIS AND PATIENT CHARACTERISTICS

The methodology used in antiemetic studies has identified several useful patient characteristics and prognostic factors that may affect antiemetic control. These indicators become important for tailoring antiemetic regimens as well as designing antiemetic trials. Careful studies have defined previous experience with chemotherapy, alcohol intake history, age, and gender as influencing patient outcomes. These references are listed below.

A patient's prior exposure to chemotherapy very often determines success or failure in controlling emesis with future treatment courses. Administration of the appropriate antiemetic during an initial course of chemotherapy can very often eliminate or significantly reduce the development of anticipatory emesis, in addition to decreasing the severity of delayed emesis.

Chronic and heavy alcohol usage—defined as more than 100 g of alcohol or five mixed drinks per day, whether in the past or currently—has been shown positively to affect the control of emesis. Ninety-three percent of patients in a prospective study who had a history of high alcohol intake were able to achieve a complete response, or no emesis, after receiving high doses of cisplatin with a combination antiemetic regimen.<sup>49</sup> The hypothesis is that chemotherapy-induced emesis may be decreased in patients with a high alcohol intake because of “burnout” of the CTZ. Although emesis may be easier to control in this setting, patients nonetheless must receive an appropriate and effective antiemetic regimen. As a result, this prognostic factor has been incorporated in many prospective trials for stratification purposes.

Age as a prognostic factor cannot predict patient response to antiemetic therapy. Some studies have indicated better control in older patients, while others have reported little difference among various age groups. Age is, however, an important factor in determining the potential for the occurrence of acute dystonic reactions. Patients aged 30 years and younger are more prone to experience the acute dystonic reactions associated with the dopamine-receptor blocking agents, such as the phenothiazines, butyrophenones, and substituted benzamides. These side effects are usually characterized by trismus or torticollis. It is also important to remember that within this population of patients, chemotherapeutic agents that might necessitate antiemetics often are given over several consecutive days, increasing the possibility of the occurrence of acute dystonic reactions.<sup>50</sup> A distinct advantage for the use of the serotonin or 5-HT<sup>3</sup>-blocking antiemetic agents is that they do not cause acute dystonic reactions, making them an especially beneficial treatment option for children and younger adults.

It has been difficult to explain the rationale for poorer control of emesis in some women receiving treatment for various malignancies. A possible explanation may be that women characteristically receive chemotherapeutic regimens that contain highly emetogenic agents, such as cisplatin and cyclophosphamide, usually given in combination, and are less likely than men to have a history of a high alcohol intake. Although these may be contributing factors, multivariate analyses in some larger studies have indicated that gender is an independent consideration that must be recognized in planning and analyzing clinical studies.

Other factors also have been reported possibly to affect the incidence of nausea and vomiting after chemotherapy. A patient may develop nausea and vomiting if he or she is anxious during the chemotherapy infusion, there is an expectation of severe side effects, or the patient's roommate is experiencing nausea and vomiting. Patients who are well motivated and have a good performance status may experience a decreased incidence of nausea and vomiting.<sup>51,52</sup> Food intake before chemotherapy and the amount of sleep a patient has had may influence the degree of nausea and vomiting.<sup>53</sup> Patients who are more likely to develop nausea and vomiting are those who have had severe emesis during pregnancy<sup>54</sup> and those who are prone to motion sickness ( [Table 55.1-4](#)).<sup>55,56</sup>

## ANTIEMETIC AGENTS

## MOST ACTIVE AGENTS

As outlined in the [Pathophysiology of Nausea/Vomiting](#) section, antagonism of the type 3 serotonin receptor (5-HT<sup>3</sup>) is an important approach to controlling chemotherapy-induced emesis. Several agents are available that exert their efficacy in this manner. Metoclopramide, which was previously thought to block emesis by antagonism of a dopamine receptor (D<sub>2</sub>), probably works primarily via the 5-HT<sup>3</sup> pathway at higher doses. This explains why higher doses of metoclopramide are more effective.<sup>57</sup> However, metoclopramide is not selective for the 5-HT<sup>3</sup> pathway, and development of highly selective antagonists of the 5-HT<sup>3</sup> receptor allowed for good antiemetic effect with a lower side effect profile.

Several selective 5-HT<sup>3</sup> antagonists are commercially available in many countries: dolasetron, granisetron, ondansetron, and tropisetron. Other similar agents are available in individual countries or under investigation. Many multiple, randomized, well-controlled studies have demonstrated that these agents have equivalent antiemetic activity and safety.<sup>58,59,60,61 and 62</sup>

Nonetheless, some differences do exist among these agents. The differences are primarily in their structure and pharmacokinetic profile; however, to date none of these differences has been shown to be of clinical importance. All agents work by the identical mechanism: antagonism of the 5-HT<sup>3</sup> receptor. All appear to accomplish this maximally, and differences among the relative potencies are unimportant at the recommended doses. There is no clear evidence that one of these agents will be effective when another is not. Half-lives in the serum vary from approximately 3 to 11 hours, but activity at the receptor appears to be similar in that single doses of all agents are equally effective. All agents have good bioavailability for oral administration. When tested, oral administration is as effective as is the intravenous route.<sup>63,64,65,66,67,68 and 69</sup>

Controversy remains concerning the optimal dose of the serotonin antagonists. From current trials, it appears that maximal benefit occurs once all relevant receptors are saturated. No matter what the emetic source, if the best results are to be achieved, an adequate dose should be given. Higher doses are not advantageous once all receptors have been saturated.<sup>70,71</sup> In that these are very safe and well-tolerated agents, it has been difficult to define the best dose regimens, and different doses have been mandated in different countries. Several international consensus guidelines have been published, including those from the subcommittee for antiemetics of the Multinational Association of Supportive Care in Cancer, those from the American Association of Clinical Oncology, and those from the American Society of Health-Systems Pharmacists. As a general rule, the lowest adequately tested dose should be assumed to be the best dose in all settings ([Table 55.1-5](#)).

Antiemetic	Dosage
<b>Serotonin receptor antagonists</b>	
Ondansetron	8 mg IV × 1 24 mg PO × 1
Granisetron	10 mg/kg IV × 1 2 mg PO × 1
Dolasetron	1.0 mg/kg IV × 1 300 mg PO × 1
Tropisetron	5 mg IV × 1
<b>Substituted benzamide</b>	
Metoclopramide	1 to 3 mg/kg IV × every 3 hr
<b>Phenothiazine</b>	
Prochlorperazine	10 to 30 mg IV × 1 over 3 min 25 mg suppository PR q4h or 10 mg PO q4-6h or 10 mg suppository PR q4-6h
<b>Butyrophenone</b>	
Halooperidol	1 to 3 mg IV q4-6h 1 to 2 mg PO q4-6h
<b>Corticosteroid</b>	
Dexamethasone	10 to 20 mg IV × 1 over 3 min
<b>Glucocorticoid</b>	
Dexamethasone	2.5 to 5.0 mg PO q4-6h
<b>Anticholinergic</b>	
Lorazepam	0.5 to 2.0 mg IV q4-6h 0.5 to 1.0 mg PO q4-6h

**TABLE 55.1-5.** Doses, Schedules, and Classes of Commonly Administered Antiemetics

Although some debate persists concerning the best dose of ondansetron, the majority of trials have indicated that the lower dose (8 mg) is as effective as the higher and far more expensive dose of 32 mg.<sup>72,73</sup> The latter dose was superior in only one trial and was troubled by a high inadequate treatment rate, indicating a poorly conducted trial.<sup>74</sup> The lower granisetron dose of 10 mg/kg is as effective in all circumstances as four times the dosage.<sup>75,76</sup> The same dose recommendations continue for single-agent or combination use.

The side effect profile of the 5-HT<sup>3</sup> antagonists provides an advantage over such effective antiemetics as metoclopramide. Central nervous system effects, extrapyramidal reactions, and sedation are not observed with serotonin antagonists; this is particularly beneficial in younger patients. Common side effects include mild headaches usually not requiring treatment, transient transaminase elevations, and mild constipation with some agents.<sup>77,78,79 and 80</sup>

As indicated, the antiemetic activity of metoclopramide is likely as a serotonin antagonist, although it has substantial dopamine antagonist action as well. This latter mechanism explains the potential for extrapyramidal reactions. Studies have shown that higher doses are more effective.<sup>81,82</sup> A dose of 3 mg/kg given every 2 hours for two doses in a combination regimen has been found to be effective.<sup>83,84</sup> To date, metoclopramide appears to be at least as effective as serotonin antagonists in preventing delayed emesis and is far less expensive.<sup>85,86 and 87</sup>

Corticosteroids are valuable antiemetics. Dexamethasone is the best studied of all these agents, is available in oral and parenteral preparations and, in most countries, is very inexpensive. Although the best dose has not been established, it appears that a single 20-mg dose is adequate, with no clear indication that either higher or lower doses is preferred.<sup>88</sup> The other steroid that has been studied and that can be used is methylprednisolone. Caution must be used when treating diabetic patients or others with poor tolerance for corticosteroids. However, the short recommended course makes these agents very safe and easy to use. In preventing delayed emesis, adequate doses of corticosteroids currently are viewed as the starting point of treatment, with some studies showing advantage for metoclopramide combined with steroids.<sup>89,90 and 91</sup>

Efficacy for corticosteroids has been clearly outlined for cisplatin-containing regimens as well as other types of chemotherapy with lesser emetic potential.<sup>92,93,94,95,96,97 and 98</sup> The addition of a corticosteroid to 5-HT<sup>3</sup> antagonists significantly improves antiemetic efficacy with each of the agents. This is seen with cisplatin chemotherapy<sup>99,100</sup> as well as with such drugs as anthracyclines, cyclophosphamide, and carboplatin.<sup>101</sup> Double-blind studies have shown that efficacy is raised in from 40% or 50% of patients having complete control with single agents to 75% or 85% of patients with a combination of 5-HT<sup>3</sup> antagonist plus a corticosteroid.<sup>102,103 and 104</sup> This has led most investigators to advise that a corticosteroid should be added whenever the emetic source is thought to warrant a serotonin antagonist, unless a clearly documented reason for not using a corticosteroid in that patient has been demonstrated.

## ANTIEMETICS OF LOWER ACTIVITY

Older agents, such as phenothiazines, butyrophenones, and cannabinoids, all have some degree of antiemetic efficacy. In general, this efficacy is substantially lower than that seen with the serotonin antagonists (including high-dose metoclopramide), and the side effects are greater.<sup>105</sup> When given intravenously, phenothiazines appear to be more active than when given by other routes but are associated with hypotension (especially orthostatic), which can be severe. Thus, these agents are not highly recommended. Oral forms of all three of these agents exhibit only modest activity and are of similarly low efficacy.

Several cannabinoids have been tested in chemotherapy-induced emesis and are of both historic and lay press interest. Semisynthetic agents, such as nabilone and levonantradol; tetrahydrocannabinol (or delta 9-THC), the active agent in marijuana; and inhaled marijuana, all appear to be of low and equal efficacy, with frequent autonomic side effects. These toxicities include dry mouth, hypotension, and dizziness.<sup>106,107</sup> Dronabinol may be useful as an adjuvant to other antiemetics.

Antianxiety agents, such as the benzodiazepine lorazepam, have little efficacy as single agents in carefully conducted trials.<sup>108</sup> However, they function well against anxiety in the emotionally charged atmosphere of receiving chemotherapy, although they add only a minor antiemetic effect to more active agents.<sup>109</sup> They should be regarded as adjuncts to antiemetics and, in that role, can be useful for many patients. Recommended doses range from 0.5 to 1.5 mg. It is not clear that there is any advantage in giving these agents parenterally rather than orally when given with the most effective antiemetics. Additionally, these drugs may be useful when given to patients with anticipatory emesis, starting one or more days before the next chemotherapy dosing. Side effects mainly concern sedation, which can be marked in

some patients, especially if the drug is given intravenously (see [Table 55.1-5](#)).

## DELAYED EMESIS

With the identification of useful antiemetics for the treatment of the acute emetic syndrome, it became apparent in patients receiving high total doses of cisplatin that, despite good control of emesis during the initial 24 hours after therapy, delayed emesis became an issue. To date, the pathophysiology of this especially difficult problem remains unclear. What is known, however, is that delayed emesis is a phenomenon observed in as many as 80% of patients, typically occurring 24 to 72 hours after high total doses of cisplatin (>100 mg/m<sup>2</sup>) have been administered.<sup>110</sup> Delayed emesis may also be seen in a substantial number of patients who receive as little as 50 mg/m<sup>2</sup> cisplatin or a chemotherapy combination, including cyclophosphamide and an anthracycline. A study that outlined the natural history of delayed emesis concluded that although the emesis associated with this dilemma is less severe than that which is seen in the acute phase, it still poses significant problems with nutrition, hydration, and, possibly, a prolonged hospital course.

Initial studies revealed that delayed emesis could be controlled with a regimen of metoclopramide and dexamethasone ( [Table 55.1-6](#)). Because of the possibility of extrapyramidal side effects, such as anxiety, akathisia, restlessness, torticollis, or oculogyric crisis, with metoclopramide, the patient should routinely be given a supply of diphenhydramine that should be taken at the first sign of an extrapyramidal symptom. In the younger patient, diphenhydramine should be given prophylactically.

---

Begin 16 to 24 hours after cisplatin:  
Days 1, 2 Metoclopramide 0.5 mg/kg PO q.i.d.  
    plus  
    Dexamethasone 8 mg PO b.i.d.  
Days 3, 4 Dexamethasone 4 mg PO b.i.d.

1. Diphenhydramine should be given at the first sign of extrapyramidal symptoms and prophylactically to the young patient.
2. Regimen to be given for cisplatin >50 mg/m<sup>2</sup> or combination chemotherapy with an anthracycline and cyclophosphamide.
3. Oral 5-HT<sup>3</sup> antagonists can be substituted for metoclopramide.

---

5-HT<sup>3</sup>, 5-hydroxytryptamine type 3.

---

**TABLE 55.1-6.** Recommended Regimen for Delayed Emesis

Initial trials addressing the treatment of delayed emesis with the single-agent serotonin antagonist ondansetron were discouraging and labeled the serotonin antagonists as having low activity.<sup>111,112</sup> Two randomized studies, one with ondansetron and one with granisetron, indicated efficacy of the serotonin antagonists for delayed emesis in patients receiving chemotherapy of intermediate emetogenicity.<sup>113,114</sup>

As it is known from previous studies that a delayed antiemetic regimen with a substituted benzamide and dexamethasone controls the emesis, further research is needed to compare this standard regimen with a regimen of a serotonin antagonist and dexamethasone. One may need to differentiate between late-onset acute emesis (i.e., 18 to 48 hours after cyclophosphamide administration, for which oral granisetron and ondansetron have demonstrated benefit) versus true delayed emesis that is evident 2 to 7 days after cisplatin administration, for which the 5-HT<sup>3</sup> antagonists may not have a large advantage over standard metoclopramide-based regimens. It is likely that the mechanism of action for delayed emesis is very different from that for acute chemotherapy-induced emesis, and perhaps serotonin is not involved at all. This should be addressed further in carefully controlled clinical trials, as the cost of the serotonin antagonists is far more than the cost of a substituted benzamide.

Another group of agents that have a potential role in the prevention of delayed nausea and vomiting are the NK1 antagonists. Substance P, which is found in the GI tract and the central nervous system and can produce vomiting when injected into ferrets, exerts its effects by binding to the neuroreceptor NK1. Hesketh et al.<sup>115</sup> reported on a randomized phase II study of the NK1-receptor antagonist CJ-11,974 in the control of cisplatin-induced emesis in 61 patients. This exploratory trial revealed that CJ-11,974 was superior to placebo in controlling delayed emesis and may provide additive benefit in acute emesis and nausea control when combined with a 5-HT<sup>3</sup> antagonist and dexamethasone. In a multicenter, double-blind, placebo-controlled trial involving 159 patients who received a single dose of cisplatin, the NK1-receptor antagonist L-754,030 prevented delayed emesis and, in combination with granisetron plus dexamethasone, improved the prevention of acute emesis.<sup>116</sup>

Other agents that may be of benefit in the treatment of delayed emesis include benzodiazepines, especially lorazepam and alprazolam; the H<sub>2</sub> blockers cimetidine and ranitidine; and omeprazole. Studies are currently under way on the use of cisapride, a potent gastric prokinetic agent that does not affect the D<sub>2</sub> receptors and, therefore, does not lead to adverse extrapyramidal effects.

## ANTICIPATORY NAUSEA AND VOMITING

Anticipatory nausea and vomiting usually occur approximately 24 hours before the patient begins chemotherapy. The symptoms may occur outside the hospital, in the clinic, when talking about chemotherapy, or when the patient perceives special tastes or odors.

Acute nausea and vomiting that occur with chemotherapy are thought to be secondary to the medication. The exact mechanism of posttreatment nausea and vomiting is unknown, though is most likely secondary to the chemotherapeutic agent itself; at times, it may also involve a psychological mechanism. Anticipatory nausea and vomiting always involve a psychological mechanism in that they are triggered by events that are not secondary to the direct administration of the chemotherapeutic agent itself.

The prevalence of anticipatory nausea and vomiting varies, depending on the study cited and whether nausea and vomiting are analyzed separately. A review by Morrow and Dobkin<sup>117</sup> summarized 28 surveys that were carried out in North America since 1979. The prevalence of anticipatory nausea ranged anywhere from 14% to 63%, with a median of 33%. Many factors that appear to be associated with anticipatory nausea and vomiting have been studied ( [Table 55.1-7](#)).

---

Severe postchemotherapy side effects  
Schedule of chemotherapy  
Numerous chemotherapy cycles  
Chemotherapeutic agents with high emetogenic potential  
Age  
History of motion sickness  
Anxiety  
Depression  
Taste and odors

---

**TABLE 55.1-7.** Factors Associated with an Increased Incidence of Anticipatory Nausea and Vomiting

Numerous studies have revealed a relationship between severe postchemotherapy side effects and the development of anticipatory nausea and vomiting.<sup>118,119,120</sup> and

<sup>121</sup> The schedule of chemotherapy also appears to be related to anticipatory symptoms. Anticipatory symptoms are related to the emetogenicity of the chemotherapeutic agents in most studies.<sup>122,123</sup> and <sup>124</sup> They also are related to the length of chemotherapy, in that patients who receive chemotherapy for longer periods have a higher incidence of anticipatory symptoms.<sup>125,126</sup> and <sup>127</sup>

Motion sickness is a risk factor for the development of postchemotherapy nausea and vomiting.<sup>128</sup> One study by Morrow<sup>129</sup> of 608 patients and another study by Morrow et al.<sup>130</sup> of 355 patients found a significant relationship between motion sickness and anticipatory nausea and vomiting. In some studies, age appears to be related to anticipatory symptoms. Anticipatory nausea and vomiting occur more often in patients younger than 45 to 50 years old.<sup>131,132,133</sup> and <sup>134</sup> Possibly, age is related to anticipatory symptoms in part because younger patients receive stronger emetogenic chemotherapeutic agents, which leads to increased postchemotherapy nausea and vomiting and, therefore, increased anticipatory nausea and vomiting. Another proposed explanation is that younger patients have a higher level of anxiety while receiving chemotherapy, which may lead to increases in anticipatory symptoms. Both of these explanations are plausible, though current data do not support either.<sup>135</sup>

Other factors that have been reported to be related to anticipatory nausea and vomiting include expectations. Those patients with anticipatory symptoms report the expectation of developing nausea and vomiting after chemotherapy.<sup>136,137</sup> Type and stage of cancer also are related.<sup>138,139</sup> Anticipatory symptoms have been found to be correlated with a patient's previous response of nausea and vomiting to different situations.<sup>140</sup> It has been noted that patients with anticipatory nausea and vomiting have higher levels of depression.<sup>141</sup> A relationship between anxiety and anticipatory nausea and vomiting has also been noted,<sup>142,143</sup> though, at this time, insufficient evidence is available to indicate the way that anxiety is related to anticipatory symptoms.<sup>144</sup>

Several retrospective reviews have indicated that taste and odors are related to anticipatory nausea and vomiting.<sup>145,146,147,148</sup> and <sup>149</sup> Though a prospective study did not reveal any relationship among taste, odors, and anticipatory nausea and vomiting, Bovbjerg et al.<sup>150</sup> reported a study in which they administered a beverage to patients before their receipt of chemotherapy. The investigators found a clear relationship between anticipatory nausea and a special taste. Blasco<sup>151</sup> suggested that taste and odors may be involved not only in anticipatory nausea and vomiting but perhaps with postchemotherapy nausea and vomiting. Indeed, the role of taste and smell is largely unknown; however, it may be involved in a spectrum of GI complaints experienced by the patient with cancer. Studies by Bernstein<sup>152</sup> suggest that a learned food aversion develops to specific tastes or food and occurs because of an association of the food with unpleasant symptoms, such as nausea and vomiting. This food aversion could partially explain the anorexia associated with cancer.

Antiemetics used in the treatment of acute nausea and vomiting induced by chemotherapy are ineffective in treating anticipatory nausea and vomiting. Many studies have indicated that behavioral techniques are effective in reducing anxiety as well as reducing or eliminating anticipatory nausea and vomiting. Behavioral techniques that have been studied and found to be effective include progressive relaxation with guided imagery, systematic desensitization, hypnosis, and cognitive and intentional distraction.<sup>153,154,155</sup> and <sup>156</sup>

In one report in the literature, a lemon solution given to a patient before the receipt of chemotherapy masked taste sensations so that the patient experienced decreased anticipatory nausea and vomiting.<sup>157</sup> It has also been suggested that the use of benzodiazepines, especially lorazepam, may be helpful in treating anticipatory nausea and vomiting. However, no formal studies have established lorazepam's effectiveness in this situation.

## RADIATION-INDUCED NAUSEA AND VOMITING

The etiology of radiation-induced emesis, like chemotherapy-induced emesis, is not completely understood. However, it is clear that it is a complex, multifactorial event. The incidence, severity, and onset of radiation-induced emesis appear to be related to the size of the radiation field, the dose per fraction, and the site of irradiation. Radiation-induced emesis occurs acutely in more than 90% of patients who receive total body irradiation for bone marrow transplantation, within 30 to 60 minutes in more than 80% of patients who receive single high-dose or large-field hemibody irradiation (>500 cGy), and within 2 to 3 weeks in approximately 50% of patients who receive conventional fractionated radiotherapy (200 cGy per fraction) to the upper abdomen.<sup>158</sup> Radiation-induced emesis also occurs in those patients who receive radiosurgery to the area postrema in excess of 350 to 400 cGy in a single dose. The emesis usually occurs between 1 and 12 hours after the radiosurgery.

The exact mechanism of radiation-induced emesis remains unclear. However, as with chemotherapy-induced emesis, it is thought that it most likely is due to a peripheral mechanism in the GI tract or a central mechanism involving the CTZ. It has been proposed that several substances, including dopamine, catecholamines, and prostaglandins, are released and stimulate afferent visceral fibers, an action that then initiates sensory signals to the CTZ. As a result of both preclinical and clinical studies with serotonin antagonists, it has been suggested that serotonin may be released from enterochromaffin cells of the GI tract and may mediate emesis via mechanisms involving the 5-HT<sup>3</sup> receptors, visceral afferent fibers, and the CTZ. This mechanism is most likely involved when radiation is applied to the upper abdomen, hemibody, or total body. Radiosurgery to the area postrema most likely induces emesis from the release of serotonin in the CTZ.<sup>159</sup>

Clinical studies in the past using metoclopramide, nabilone (cannabinoid derivative), and chlorpromazine in the treatment of radiation-induced emesis revealed a response of 50% to 58%.<sup>160,161</sup> In a nonplacebo trial with domperidone, a dopamine antagonist, a response of 82% was reported.<sup>162</sup> A nonrandomized trial comparing ondansetron with other antiemetics reported response rates of 100% for ondansetron versus 43% for other antiemetics and 19% for no antiemetic treatment for patients who received middle to upper hemibody irradiation.<sup>163</sup> A randomized study by Priestman et al.<sup>164</sup> of patients who received radiotherapy to the abdomen, pelvis, and thoracolumbar spine reported response rates of 45% for metoclopramide versus 97% for ondansetron. A randomized, double-blind, placebo-controlled evaluation revealed oral ondansetron to be an effective therapy for the prevention of emesis induced by total body irradiation.<sup>165</sup> Ondansetron has been reported to be effective in radiotherapy-induced emesis in children<sup>166</sup> as well as for patients who receive radiosurgery to the area postrema.<sup>167</sup>

Data are available from two double-blind, randomized studies in the use of oral granisetron, 2 mg once daily, in radiation-induced nausea and vomiting. In a study involving patients undergoing fractionated upper abdominal radiation, patients who received oral granisetron had a significantly longer median time to first emesis than did those who received placebo (35 days vs. 9 days, respectively) and a longer median time to first nausea (11 days vs. 1 day, respectively).<sup>168</sup> In another study of patients undergoing total body irradiation, patients treated with oral granisetron had significantly greater complete control as compared to the historical control group over the entire 4-day treatment period (22% vs. 0%, respectively).<sup>169</sup>

Fauser et al.<sup>170</sup> reported on the use of oral dolasetron for the control of emesis during total body irradiation and high-dose cyclophosphamide in patients undergoing allogeneic bone marrow transplantation.

## NAUSEA AND VOMITING SECONDARY TO COMORBID CONDITIONS

A number of comorbid conditions also may lead to nausea and vomiting, even though the majority of patients with cancer develop nausea and vomiting as a result of chemotherapy or radiotherapy (Table 55.1-8). Because the mechanism of the nausea and vomiting secondary to comorbid conditions is not usually well understood, it is difficult to know which antiemetics may be helpful. A study by Bruera et al.<sup>171</sup> revealed that controlled-release metoclopramide is safe and effective in managing chronic nausea in patients with advanced cancer. Future studies must be conducted to determine the optimal doses of metoclopramide as well as other antiemetics that may be used in drug combinations (e.g., metoclopramide plus corticosteroids) for the nausea and vomiting secondary to the malignancy itself.

## COST AND BENEFIT OF ANTIEMETIC THERAPY

The important results of research that provide the medical community with additional chemotherapeutic choices and supportive care measures often translate into added health care costs for patients and families. With the increased use of expensive antiemetics and with managed care dictating the length of hospital stays, the emphasis is shifting to primary outpatient management of patient treatment courses. The challenge for physicians becomes one of providing a treatment plan in which patients are offered state-of-the-art and cost-effective therapy. This can be accomplished by applying certain guidelines.

Specifically addressing 5-HT<sup>3</sup> antagonist antiemetics and their associated cost, the choice among these agents should be made on the basis of acquisition costs and reimbursement differences. The 5-HT<sup>3</sup> antagonists all have demonstrated equivalent efficacy and side effects; therefore, once an effective dose has been established, there would be no advantage in exceeding this threshold dose. Ultimately, the 5-HT<sup>3</sup> antagonist of lowest cost should be selected for administration. Single-dose regimens given in combination with a corticosteroid provide an effective and convenient alternative in antiemetic therapy. Regimens that take advantage of a completely oral route of administration are easy and convenient for patients and are likely to reduce nursing and pharmacy costs; however, prolonged use of oral serotonin antagonists should be avoided, as there appears to be little or no value in this setting. In addition to these recommendations, adherence by physicians and nurses to established doses and schedules of antiemetics and their appropriate use can be cost-effective measures for patients and institutions.

Nolte et al.<sup>172</sup> discussed guidelines developed by the Memorial Sloan-Kettering Cancer Center for the cost-effective use of 5-HT<sup>3</sup> antagonists that resulted in substantial savings while treating more patients. The initial guidelines in 1993 were developed based on the premise that the dose of the intravenous 5-HT<sup>3</sup> antagonist ondansetron, 8 to 32 mg, could be adjusted on the basis of emetogenic potential of the chemotherapeutic regimen schema proposed by Hesketh et al.<sup>95</sup> Cost savings were documented without affecting the quality of life, as reported by the patients. The guidelines were modified in 1994 to include granisetron, 10 mg/kg, for moderately or highly emetogenic chemotherapy. When oral granisetron tablets were approved in 1995 for the prevention of highly emetogenic chemotherapeutic regimens, the guidelines were further modified to incorporate the use of oral granisetron instead of intravenous 5-HT<sup>3</sup> antagonists for moderately to highly emetogenic chemotherapy. Additional cost savings were realized while the quality of life of the patients was unaffected.

The use of an oral form of a 5-HT<sup>3</sup> antagonist for highly emetogenic chemotherapy, when data from well-controlled trials demonstrate comparable efficacy to the intravenous formulation, appears to be cost-effective.<sup>173,174</sup> One should take into consideration, when evaluating the results of these studies, whether a stringent efficacy end point was used. Some studies did not use "no nausea" as one of the criteria for a complete response. Because nausea was ranked as the most severe chemotherapy-related symptom according to a relatively recent survey, the effect of the agents on nausea should also be evaluated.

Economic considerations for the selection of antiemetic regimens should answer the following questions:

- Will the use of the regimens likely result in a reduced hospitalization?
- While receiving therapy, will patients be able to maintain their usual level of activity?
- Will nursing and pharmacy costs be reduced?
- Are there mandated restrictions on the use of an agent in hospital formularies and in clinical settings?
- Will the antiemetic regimen affect the patient's out-of-pocket expenses?

Extensive basic and clinical research has made it possible to control treatment-induced nausea and vomiting. With recognition and anticipation of nausea and vomiting, counseling of the patient and family, prophylactic intervention, flexibility in the therapeutic approach, and constant reassessment of the treatment plan, chemotherapy- and radiotherapy-induced nausea and vomiting can be managed effectively in 80% to 90% of patients. The progress made in the field of treatment-induced nausea and vomiting must be a paradigm for other symptoms faced by the cancer patient that lead to suffering and that affect the patient's quality of life.

## INTRODUCTION

In the discussion of orofacial complications and pain and its management for patients receiving chemotherapy or radiotherapy, we must consider and discuss many factors. In the brief space allocated to oral complications, we shall evaluate dentition, mucosa, and bone to understand the interrelationship of these organ systems and how they interface with orofacial pain.

Orofacial pain that develops during the course of oncologic therapy cannot simply be labeled *mucositis*. Although this is the term commonly applied to the presentation of oral symptoms that develop in an oncology patient during the course of therapy, mucositis is not simply the result of mucosal ulceration from chemotherapy or radiotherapy. We must examine the various etiologies of orofacial pain, as such pain arises from multiple origins ( [Table 55.2-1](#)). The oral environment, when in a state of imbalance, poses a serious threat to the success of both chemotherapy and radiotherapy. A complex interrelationship exists among the oral microflora, occlusal pathology, dental restorations, and mucositis. In chemotherapy, bacteria play a major role in the morbidity associated with mucositis. For patients receiving radiotherapy, oral microorganisms and restorative dental procedures have a significant impact on both transient mucositis and long-term dental management.

Dental
Root exposure secondary to periodontal (gum) attachment loss
Dental caries
Dentures
Denture sores
Occlusion
Overextension of borders
Fractured dentures or denture teeth
Denture hygiene
Orthodontic appliances
Soft tissue (mucosa)
Mucositis
Pericoronitis
Gingivitis
Periodontitis
Angular cheilitis
Epulis fissuratum
Bone
Osteomyelitis
Osteoradionecrosis
Denture-related alveolar bone resorption

**TABLE 55.2-1.** Etiologic Factors Contributing to Pain in the Oncology Patient

Oral mucositis is a significant problem in patients receiving chemotherapy or radiotherapy. Estimates of oral mucositis incidence among cancer therapy patients range from 40% of those receiving standard chemotherapy to 76% of bone marrow transplant patients.<sup>1</sup> Virtually all patients who receive radiotherapy to the head and neck area develop oral complications. Mucositis not only is painful but also can limit adequate nutritional intake and decrease patients' willingness to continue treatment. Severe mucositis with extensive ulceration may necessitate costly hospitalizations, parenteral nutrition, and use of narcotics. Mucositis diminishes the quality of life and may result in serious clinical complications. A healthy oral mucosa serves to clear microorganisms and provides a chemical barrier that limits penetration of many compounds into the epithelium. A mucosal surface that is damaged increases the risk of a secondary infection and may even prove to be a nidus for systemic infection. Mucositis may result in the need to reduce the dosage of subsequent chemotherapy cycles or to delay radiotherapy, which ultimately may affect a patient's response to therapy.

Dentition, supporting tissue (both hard and soft), and fixed and removable prostheses must be thoroughly examined before commencement of therapy. Dental caries involving previous restorations or unrestored teeth will be a source of bacteria that can be implicated in the etiology of mucositis. The xerostomia associated with radiotherapy significantly increases plaque colonization on the surfaces of teeth and prostheses. Increases in bacterial volume are directly related to mucositis symptoms and elevated caries activity on the eroded and worn surfaces of the dentition.

## DIRECT STOMATOTOXICITY

Normally, cells of the mouth undergo rapid renewal over a 7- to 14-day cycle. Both chemotherapy and radiotherapy interfere with cellular mitosis and reduce the regenerative ability of the oral mucosa. Cancer chemotherapeutic drugs that produce direct stomatotoxicity include the alkylating agents, antimetabolites, natural products, and other synthetic agents such as hydroxyurea and procarbazine hydrochloride.<sup>2</sup> Typical sequelae of these cytotoxic agents include epithelial hyperplasia, collagen and glandular degeneration, and epithelial dysplasia.<sup>3</sup> Mucositis is an inevitable side effect of irradiation. The severity of the mucositis depends on the type of ionizing radiation, the volume of irradiated tissue, the dose per day, and the cumulative dose. As the mucositis becomes more severe, pseudomembranes and ulcerations develop. Poor nutritional status further interferes with mucosal regeneration by decreasing cellular migration and renewal.<sup>4</sup>

Direct stomatotoxicity usually is seen 5 to 7 days after the administration of chemotherapy or radiotherapy. In the nonmyelosuppressed patient, oral lesions heal within 2 to 3 weeks.<sup>5</sup> The nonkeratinized mucosa is most affected. The most common sites include the labial, buccal, and soft palate mucosa, as well as the floor of the mouth and the ventral surface of the tongue. Clinically, mucositis presents with multiple complex symptoms: The condition begins with asymptomatic redness and erythema and progresses through solitary, white, elevated desquamative patches that are slightly painful to contact pressure, to large, contiguous, pseudomembranous, acutely painful lesions with associated dysphagia and decreased oral intake. Histopathologically, edema of the rete pegs will be noted, along with vascular changes that demonstrate a thickening of the tunica intima and concomitant reduction in the size of the lumen and destruction of the elastic and muscle

fibers of the vessel walls. The loss of basement membrane epithelial cells exposes the underlying connective tissue stroma with its associated innervation, which, as the mucosal lesions enlarge, contributes to increasing pain levels. Oral infections, which may be due to bacteria, viruses, or fungal organisms, can further exacerbate the mucositis and may lead to systemic infections. If the patient develops both severe mucositis and thrombocytopenia, oral bleeding may occur and may be very difficult to treat.

## **PATHOPHYSIOLOGY OF MUCOSITIS**

Sonis et al.<sup>6</sup> proposed a hypothesis as to the mechanisms of the development and healing of mucositis. The hypothesis is based on both animal and clinical data, though it remains speculative to some degree. It describes mucositis as a complex biologic process that occurs in four phases: (1) the inflammatory or vascular phase, (2) the epithelial phase, (3) the ulcerative or bacteriologic phase, and (4) the healing phase (Table 55.2-2). Each phase is interdependent and is a consequence of the effect of the chemotherapy or radiotherapy on the epithelium, as well as actions mediated by cytokines, the status of the patient's bone marrow, and the oral bacterial flora.<sup>6</sup>

---

Phase 1. Inflammatory or vascular phase; day 0
Phase 2. Epithelial phase; days 4-5
Phase 3. Ulcerative or bacteriologic phase; days 6-12
Phase 4. Healing phase; days 12-16

---

(Adapted from ref. 6.)

---

**TABLE 55.2-2.** Four Phases in the Development of Mucositis

### **PHASE I: INFLAMMATORY OR VASCULAR PHASE**

Cytokines such as tumor necrosis factor- $\alpha$ , interleukin-1 (IL-1), and perhaps interleukin-6, are released from the epithelial tissue and adjacent connective tissue shortly after the administration of chemotherapy or radiotherapy. Most likely, the initiating event in the development of mucositis is local tissue damage caused by the cytokines. Additional concentrations of cytotoxic drugs in the mucosa may result from the increased vascularity caused by IL-1. Also during this phase, increased submucosal vascularity occurs.

### **PHASE 2: EPITHELIAL PHASE**

Reduced epithelial renewal, with atrophy and ulceration, occurs as a result of both radiotherapy and chemotherapy, particularly with drugs affecting the S phase of the cell cycle, whereby the impact is on dividing cells of the oral basal epithelium. The atrophy and ulceration that occurs is most likely exacerbated by locally produced cytokines as well as functional trauma. The first two phases usually occur from days 0 to 5 of therapy.

### **PHASE 3: ULCERATIVE OR BACTERIOLOGIC PHASE**

The most complex and symptomatic phase is phase 3, during which localized areas of erosion often become covered with a fibrinous pseudomembrane. This phase usually coincides with the patient's period of maximum neutropenia. Secondary bacterial colonization, involving some gram-negative organisms, occurs, and the gram-negative organisms provide a source of endotoxin, which stimulates further cytokine release from the connective tissue around the cells. The patient's condition is exacerbated by the cytokines as well as the nitric oxide that is released. This phase usually occurs from days 6 to 12 of therapy.

### **PHASE 4: HEALING PHASE**

The final phase usually consists of renewal in epithelial proliferation and differentiation, with normalization of the patient's peripheral white blood cell count and reestablishment of the local microbial flora. The healing phase usually takes place from days 12 to 16.

## **RISK FACTORS**

Both direct and indirect factors appear to contribute to oropharyngeal mucositis. The direct factors include the chemotherapeutic agent, dosage, and schedule (Table 55.2-3), the total dose and days of radiotherapy, mucosal damage from such problems as ill-fitting dental prostheses, periodontal disease, microbial flora, salivary gland dysfunction, and patient susceptibility. Indirect factors include myelosuppression, immunosuppression, reduced secretory IgA, and bacterial, viral, or fungal infections.

**TABLE 55.2-3.** Chemotherapeutic Agents Commonly Producing Mucositis

A variety of patient-related factors have potential for affecting the development of mucositis after chemotherapy. It has been suggested that the repair of ill-fitting prostheses, extraction of offending teeth, elimination of periodontal disease, and effective oral hygiene reduce the incidence and severity of mucositis. A patient might develop more severe mucositis if his or her nutrition is poor, through impairment of mucosal regeneration. Xerostomia that develops as a result of irradiation or drug use contributes significantly to the development of oral mucositis. Drugs that can result in xerostomia include antidepressants, opiates, antihypertensives, antihistamines, diuretics, and sedatives. Although both alcohol and tobacco can impair salivary function, it has been suggested that tobacco has been associated with a decreased incidence of chemotherapy-induced stomatitis.<sup>7</sup> One recent study involving 332 outpatients receiving chemotherapy revealed no significant differences in the incidence of mucositis between patients who wore dental appliances, had a history of oral lesions and a history of smoking, and practiced different oral hygiene regimens, and those patients who did not.<sup>8</sup> These findings suggest that the risk factors for the development of chemotherapy-induced mucositis are many and complicated and that further research is needed.

Reports on the effects of age on chemotherapy-induced mucositis development are conflicting. In general, younger patients are at increased risk for developing

mucositis.<sup>7</sup> Recent reports look at gender differences and the risk of mucositis. A metaanalysis of six North Central Cancer Treatment Group (NCCTG) trials involving 731 patients (402 men and 329 women) revealed that women reported stomatitis both more often and of greater severity as compared with men.<sup>9</sup> In a pilot project using capsaicin for treating mucositis, data analysis revealed that women had a higher level of pain secondary to oral mucositis. It is also known that women are "supertasters" when tested with chemical relative phenylthiocarbamide/6-n-propylthiouracil (PROP); possibly, individuals who are supertasters and who therefore have more taste buds experience increased stomatitis ([Table 55.2-4](#)).<sup>10,11</sup>

**TABLE 55.2-4.** Risk Factors Contributing to Mucositis

## ASSESSMENT OF THE ORAL MUCOSA

A mucositis grading system allows the physician to assess mucositis severity in terms of both pain and the patient's ability to maintain adequate nutrition, so that a treatment plan can be appropriately constructed. Many different grading systems exist, most of which are based on two or more clinical parameters, including erythema, pain, and problems with eating ([Table 55.2-5](#)). An example of a common grading system is that proposed by the National Cancer Institute, which uses a numbering scale from 0 to 4. Grade 0 indicates no mucositis; grade 1, the presence of painless ulcers, erythema, or mild soreness; grade 2, the presence of painful erythema, edema, or ulcers, but not interfering with the patient's ability to eat; and grade 4, symptoms so severe that the patient requires parenteral or enteral support.<sup>12</sup>

Grade	Description
0	No mucositis
1	Painless erythema or ulcers
2	Painful erythema, edema, or ulcers, but not interfering with the patient's ability to eat
3	Severe erythema, edema, or ulcers, interfering with the patient's ability to eat
4	Severe erythema, edema, or ulcers, requiring parenteral or enteral support

**TABLE 55.2-5.** Mucositis Grading

Recently, new scoring systems have been developed for the assessment of oral mucositis. Sonis et al.<sup>13</sup> reported on a scale that uses an objective measure of mucositis, evaluating ulceration and pseudomembrane formation and erythema. Subjective outcomes of mouth pain, ability to swallow, and function were measured. Analgesia use for mouth sensitivity was also recorded. In the study that was conducted in nine centers, there was high interobserver correlation, with objective mucositis scores demonstrating strong correlation with symptoms.

At the 1989 National Institutes of Health consensus conference on oral complications of cancer therapy, clinicians and researchers agreed that effective prevention of mucositis requires a comprehensive patient examination to identify potentially complicating oral disease before the cancer therapy begins.<sup>14</sup> Significant problems that must be corrected include poor oral hygiene, periapical pathology, third molar pathology, periodontal disease, dental caries, defective restorations, orthodontic appliances, ill-fitting prostheses, and other potential sources of infection. Bacterial and fungal surveillance cultures are not necessary, but prophylactic use of acyclovir should be considered in patients who are seropositive and at high risk for reactivating herpes simplex viral infection, such as those who undergo bone marrow transplant or who have prolonged and pronounced myelosuppression. If a diagnosis is made of a fungal, viral, or bacterial infection along with the mucosal lesions, prompt treatment is necessary to avoid the risk of systemic infection.

## REMEDIES FOR THE PREVENTION AND TREATMENT OF MUCOSITIS

A standardized approach for the prevention and treatment of chemotherapy- and radiotherapy-induced mucositis is essential, although the efficacy and safety of most of the regimens have not been established. The prophylactic measures usually used for the prevention of mucositis include chlorhexidine gluconate (Peridex), saline rinses, sodium bicarbonate rinses, acyclovir, amphotericin, and ice. Regimens commonly used for the treatment of mucositis and the associated pain include a local anesthetic such as lidocaine or dyclonine, magnesium-based antacids (Maalox, Mylanta), diphenhydramine (Benadryl), nystatin, or sucralfate. These agents are used either alone or in different combinations that compose a mouthwash. Other agents used less commonly include kaolin-pectin (Kaopectate), allopurinol, vitamin E, b-carotene, chamomile (Kamillisan) liquid, aspirin, antiprostaglandins, prostaglandins, MGI 209 (marketed as Oratect Gel), silver nitrate, and antibiotics. Oral and sometimes parenteral narcotics are used to relieve the pain caused by mucositis. A new method that uses capsaicin for such pain relief is currently being studied.

### DIRECT CYTOPROTECTANTS

#### Sucralfate

Sucralfate, an aluminum salt of sucrose orasulfate, which has been used successfully to treat gastrointestinal ulceration, has been tested as a rinse for the prevention and treatment of mucositis. Sucralfate's mechanism of action appears to be by forming an ionic bond to proteins in an ulcer site, thereby creating a protective barrier.<sup>15</sup> Additionally, evidence points to an increase in the local production of prostaglandin E<sub>2</sub> (PGE<sub>2</sub>), which results in an increase in mucosal blood flow, mucus production, mitotic activity, and surface migration of cells.<sup>16,17</sup>

Anecdotal experience suggests that sucralfate might be useful in the prevention and treatment of chemotherapy-induced mucositis; however, data from the studies are conflicting. Solomon<sup>18</sup> reported a 55% objective response rate in patients receiving chemotherapy (19 patients), which was defined as a decrease in one grade on the cancer and leukemia group B (CALGB) scale of oral toxicity. In 1984 and 1985, Ferraro and Mattern<sup>19,20</sup> reported encouraging results in the use of sucralfate for chemotherapy-induced mucositis. Two randomized, double-blind clinical trials also have evaluated sucralfate for the prevention of chemotherapy-induced mucositis. Pfeiffer et al.<sup>21</sup> found a significant reduction in edema, erythema, erosion, and ulceration in 23 of 40 evaluable patients receiving cisplatin and continuous infusion with 5-fluorouracil (5-FU) with or without bleomycin. Patient preference favored sucralfate, although this preference failed to reach statistical significance. Ten of the patients did not complete the study as the swishing of the sucralfate and the placebo aggravated chemotherapy-induced nausea. The authors suggested that, to help overcome this problem, the solution should have a neutral taste and should not be swallowed after swishing. In contrast, results from a similarly designed study, in which patients receiving remission-induction chemotherapy for acute nonlymphocytic leukemia were treated with sucralfate for mucositis, did not support the

amelioration of mucositis.<sup>22</sup> The latter study also concluded that chronic administration of the sucralfate suspension had no effect on the incidence of gastrointestinal bleeding and ulceration. The authors did note that some patients reported pain relief from sucralfate.<sup>22</sup> A phase III study of sucralfate suspension versus placebo, recently completed by the NCCTG, revealed that of the 50 patients who developed stomatitis, the sucralfate suspensions provided no beneficial reduction in the duration or severity of 5-FU-induced mucositis.<sup>23</sup> In addition, the sucralfate induced considerable additional gastrointestinal toxicity.

Sucralfate has also been tested in patients receiving radiotherapy. One study compared 21 patients who received standard oral care to the head and neck with 24 patients who received sucralfate suspension four times daily.<sup>24</sup> Results revealed a significant difference in mucosal edema, pain, dysphagia, and weight loss in those patients receiving sucralfate. In a pilot study done by Pfeiffer et al.,<sup>25</sup> sequential patients who received radiotherapy to the head and neck received sucralfate at the onset of mucositis. The majority of patients had a decrease in pain after sucralfate use. A double-blind placebo-controlled study with sucralfate in 33 patients who received irradiation to the head and neck reported no statistically significant differences in mucositis; however, the sucralfate group reported less oral pain and, in these patients, other topical and systemic analgesics were started later in the course of radiation.<sup>26</sup>

A prospective double-blind study compared the effectiveness of sucralfate suspension to that of diphenhydramine syrup plus kaolin-pectin on radiotherapy-induced mucositis. Data on perceived pain, helpfulness of mouth rinses, weekly mucositis grade, weight change, and interruption of therapy were collected daily. Analysis of the two groups revealed no statistically significant differences between them. A retrospective comparison of a group of 15 patients who had not used daily oral rinses and the preceding two groups suggested that the use of a daily oral rinse with a mouth-coating agent may result in less pain, may reduce weight loss, and may help to prevent interruption of radiotherapy because of severe mucositis.<sup>27</sup>

### **Prostaglandins, Antiprostaglandins, and Nonsteroidal Agents**

Prostaglandins are a family of naturally occurring eicosanoids, some of which have known cytoprotective activity. Dinoprostone, or PGE<sub>2</sub>, has been reported to be beneficial in healing both gastric ulcers and chronic leg ulcers.<sup>28,29</sup> Pilot studies revealed the need for controlled clinical trials. In a pilot study undertaken by Kuhrer et al.,<sup>30</sup> five patients received topical dinoprostone for chemotherapy-induced mucositis. Four of the five patients reported pain relief, with healing of the ulcers within 3 to 7 days. Kuhrer's group then tested the prophylactic efficacy of dinoprostone by applying it topically to one patient who was receiving chemotherapy and who had developed previous episodes of mucositis, as well as to two patients receiving total body irradiation.<sup>30</sup> Only one of the patients who had received the dinoprostone and total body irradiation developed mucositis.

In a nonblinded study, ten patients who were receiving 5-FU and mitomycin with concomitant radiation for oral carcinomas were treated by Porteder et al.,<sup>31</sup> with dinoprostone four times daily during treatment. The control group consisted of 14 patients who were receiving identical treatment. Eight of the ten patients who received dinoprostone were evaluable, and none developed severe mucositis, as compared with six episodes in the control arm.

A third pilot study conducted with 15 patients who received radiotherapy of the head and neck found that an inflammatory reaction in the vicinity of the tumor could be detected in only 5 patients treated with topically applied PGE<sub>2</sub>, and none of the patients developed any bullous or desquamating inflammatory lesions.<sup>32</sup> A double-blind, placebo-controlled study of PGE<sub>2</sub> in 60 patients undergoing bone marrow transplant revealed no significant differences in the incidence, severity, or duration of mucositis. It was noted that the incidence of herpes simplex virus was higher in those on the PGE<sub>2</sub> arm, and, in those patients who developed herpes simplex virus, there was an increase in the severity of the mucositis.<sup>33</sup>

Benzylamine is a nonsteroidal with analgesic, anesthetic, antiinflammatory, and antimicrobial properties. Epstein and Stevenson-Moore<sup>34</sup> found, in a double-blind, placebo-controlled trial, that benzylamine produced statistically significant relief of pain from radiation-induced mucositis. Positive responses to benzylamine were reported in at least two other studies.<sup>35,36</sup> The study conducted by Epstein and Stevenson-Moore<sup>34</sup> revealed not only a trend toward reduction in pain but also a statistically significant reduction in the total area of ulceration as well as the size of the ulcer. Another study demonstrated that when indomethacin, an antiprostaglandin, was given orally, it reduced the severity and delayed the onset of mucositis induced by radiotherapy.<sup>37</sup>

### **Corticosteroids**

No placebo-controlled studies of the use of corticosteroids for chemotherapy-induced mucositis have been reported, though two reports have focused on pilot work conducted with patients who received radiotherapy. Abdelaal et al.<sup>38</sup> reported the use of a betamethasone and water mouthwash in five patients receiving radiotherapy whose mucosa remained virtually ulcer-free and who did not report any pain. The proposed mechanism of action of the steroid mouthwash was inhibition of leukotriene and prostaglandin production. Another pilot study compared 21 patients receiving radiotherapy who used an oral rinse consisting of hydrocortisone in combination with nystatin, tetracycline, and diphenhydramine with patients using a placebo rinse. Though only 12 of the 21 patients were evaluable, by the end of the radiotherapy cycles, there was a statistically significant difference in mucositis and a trend toward a reduction in pain. No patients in the treatment group needed to interrupt the radiotherapeutic regimen, whereas three patients in the control group did need to interrupt their radiotherapeutic care.<sup>39</sup>

### **Vitamins and Other Antioxidants**

Vitamins in pharmacologic doses have been used to treat mucositis. Vitamin E has been tested in chemotherapy-induced mucositis because it can stabilize cellular membranes and may improve herpetic gingivitis, possibly through antioxidant activity.<sup>40,41 and 42</sup> The efficacy of vitamin E was demonstrated by Wadleigh et al.<sup>43</sup> in a randomized, double-blind, placebo-controlled study. Eighteen patients receiving chemotherapy were randomized to receive a topical application of vitamin E or a placebo. In the vitamin E-treated group, six of nine patients had complete resolution of their mucositis within 4 days of initiating therapy, whereas in the placebo group only one of nine had resolution of the lesions during the 5-day study period. This difference was statistically significant.<sup>43</sup> Because both sucralfate and vitamin E provide some effectiveness in mucositis, a phase III study of sucralfate versus vitamin E for treatment-induced mucositis is currently under way.

Other antioxidants that have been used clinically include vitamin C and glutathione. Another antioxidant tested in a pilot study, azelastine hydrochloride has been used in many allergic diseases and has been shown to be effective in the treatment of aphthous ulcers in Behçet's disease. Osaki et al.<sup>44</sup> reported on a study involving 63 patients who had head and neck tumors and received a combination of radiotherapy and concomitant chemotherapy. Twenty-six patients received regimen 1, which consisted of vitamins C and E and glutathione, whereas 37 patients received regimen 2, which consisted of everything in regimen 1 plus azelastine. At the completion of treatment, 21 of the patients in the azelastine arm remained at grade 1 or 2 mucositis, with 6 patients having grade 3 mucositis and 10 having grade 4 mucositis. In the control group, grade 3 or 4 mucositis was induced in 6 and 15 patients, respectively, with only 2 patients having grade 1 mucositis and 2 having grade 2 mucositis. The azelastine was shown to suppress neutrophil respiratory burst both *in vivo* and *in vitro*, as well as to suppress cytokine release from lymphocytes. The authors concluded that a regimen including azelastine, which suppresses reactive oxygen production and stabilizes cell membranes, may be useful for the prophylaxis of mucositis due to chemoradiotherapy.<sup>44</sup>

b-Carotene, a vitamin A precursor with known effects on cellular differentiation, has been used for mucositis induced by radiation. b-Carotene has been shown to produce regression of oral leukoplakia lesions.<sup>45</sup> Mills<sup>46</sup> reported on the use of b-carotene in treatment-induced mucositis. Ten patients receiving radiation interspersed with two cycles of chemotherapy were given b-carotene, 250 mg/d for the first 3 weeks of therapy and then 75 mg/d for the last 5 weeks of therapy. The control group consisted of ten patients with oral cancer who were receiving the identical treatment. At the end of treatment, there was a statistically significant difference in grade 3 to 4 mucositis in the b-carotene group; there was no difference in grades 1 and 2 mucositis.<sup>46</sup>

### **Silver Nitrate**

Silver nitrate, a caustic agent, has been tested in radiation-induced mucositis. Because silver nitrate is known to stimulate cell division when it is applied to normal mucosa, it was thought that, if it were applied before cytotoxic therapy, it might enhance repair and replacement of mucosa that was damaged by cytotoxic therapy. Maciejewski et al.<sup>47</sup> reported on 16 patients who received radiotherapy to bilateral opposing fields. Silver nitrate 2% was applied to the left side of the oral mucosa three times daily for 5 days before radiotherapy and during the first 2 days of radiotherapy. The right side of the oral mucosa was unpainted and served as the control. The study revealed significantly less severe mucositis and a decrease in duration of mucositis on the mucosa that was treated with silver nitrate.<sup>47</sup> A second trial failed to confirm these results.<sup>48</sup> Silver nitrate has not been formally evaluated in the treatment of chemotherapy-induced mucositis.

## Miscellaneous Cytoprotectants

An uncontrolled study involving 98 patients with different malignancies who were receiving different medical regimens with either chemotherapy or radiotherapy reported that Kamillosan liquid taken before and after the development of mucositis helped to prevent and decrease the duration of mucositis.<sup>49</sup> In a placebo-controlled trial conducted by NCCTG, patients were randomized to receive chamomile or placebo, along with an established oral cryotherapy regimen. This study revealed that chamomile mouthwash did not reduce stomatitis associated with 5-FU chemotherapy.<sup>50</sup>

Oshitani et al.<sup>51</sup> reported on the use of topical sodium alginate, an agent that has been shown to promote healing of esophageal and gastric mucosa, in radiation-induced mucositis. Thirty-nine patients with mucositis were randomized to receive either sodium alginate or placebo. Those who received sodium alginate had a reduction in both mucosal erosions and pain.<sup>51</sup> Other topical agents used clinically for treatment-induced mucositis include Kaopectate, Benadryl, saline, sodium bicarbonate, and gentian violet. Even though the previously mentioned agents are used clinically for treatment-induced mucositis, no controlled clinical trials have yet established their efficacy.

## INDIRECT CYTOPROTECTANTS

### Hematologic Growth Factors

Hematologic growth factors currently are standard in the treatment of patients receiving high-dose chemotherapy. The effect of the hematologic growth factors on decreasing the depth and duration of chemotherapy-induced neutropenia is well established. Lieschke et al.<sup>52</sup> examined the levels of neutrophil count and assessed whether oral neutrophil count correlated with oral mucositis. In the study, the researchers found that the oral neutrophil count, similar to circulating systemic neutrophils, diminished to undetectable levels but recovered earlier than did the systemic circulating neutrophils. In those patients receiving granulocyte colony-stimulating factor (G-CSF), the mean cumulative mucositis score was less than that in patients who did not receive G-CSF.<sup>52</sup>

Gabrilove et al.<sup>53</sup> reported on 27 patients receiving methotrexate, vinblastine, doxorubicin, and cisplatin for bladder carcinoma and escalating doses of G-CSF. The patients received the G-CSF on their first cycle of chemotherapy and did not receive it on their second chemotherapeutic cycle. Significantly less mucositis was seen during the cycle in which the patients received the G-CSF. In this study, a bias may have been inherent as there is perhaps cumulative chemotherapeutic toxicity such that with each cycle of chemotherapy, the severity of mucositis increases.

Bronchud et al.<sup>54</sup> treated 17 patients with breast or ovarian carcinoma who were receiving escalating doses of doxorubicin with G-CSF support. In this study, the G-CSF did not prevent severe mucositis. In a fourth study using G-CSF, 41 patients receiving chemotherapy for non-Hodgkin's lymphoma received G-CSF, whereas 39 received chemotherapy without G-CSF. In those patients who did not receive G-CSF, the main cause of treatment delay was neutropenia, whereas in those patients who did receive G-CSF, the main cause of treatment delay was mucositis.<sup>55</sup>

In a small prospective study, patients who received platinum, infused 5-FU, and leucovorin plus granulocyte-macrophage colony-stimulating factor (GM-CSF) had a decreased incidence of grade 3 mucositis.<sup>56</sup> In a study comparing patients undergoing bone marrow transplantation in whom GM-CSF was used to historical controls, recovery of neutrophils was more rapid in the GM-CSF group; however, there was no difference in the severity of mucositis nor in duration of hospitalization.<sup>57</sup> At this time, the use of colony-stimulating factors in the prevention or treatment of mucositis is investigational.

The effect of other biologically active factors on mucositis development is currently being studied. *In vitro* studies have shown that epidermal growth factor (EGF) not only is present in saliva but has the ability to affect growth, cell differentiation, and cell migration.<sup>58,59</sup> It is known that EGF induces chemotaxis of oral epithelial cells, indicating that it may be important in maintaining the integrity of the oral epithelium, especially in wound healing. Patients with peptic ulcers have been shown to have significantly lower levels of EGF in their saliva, suggesting that EGF may be involved in either protection or repair.<sup>60</sup> In an animal study in which the animals received either 5-FU with an infusion of EGF for 7 and 15 days or a placebo, the animals that received the EGF experienced increased mucosal breakdown. The results of the study indicate that chemotherapy-induced mucositis depends on the rate of epithelial cell growth. The timing of administration of the EGF in relation to the chemotherapy may determine whether the patient develops increased oral toxicity or repair of the mucosa.<sup>61</sup> In a study conducted by Sonis et al.,<sup>62</sup> hamsters received EGF versus placebo using four different treatment schedules. In this study, delayed exposure to EGF delayed the onset of mucositis, but it had no beneficial effects on the duration or severity of mucositis.

Tumor growth factor- $\beta$ 3 (TGF- $\beta$ 3) is an inhibitor of epithelial cell growth. In a study using Syrian hamsters done by Sonis et al.,<sup>63</sup> the topical application of TGF- $\beta$ 3 resulted in a decrease in the severity and duration of chemotherapy-induced mucositis. In another study performed by Spijkervet and Sonis<sup>64</sup> with Syrian hamsters, the topical application of TGF- $\beta$ 3 significantly reduced the severity and duration of ulcerative mucositis induced by 5-FU. In animal experiments, IL-1 and IL-11 demonstrated a cytoprotective effect.<sup>65,66 and 67</sup>

### Antimicrobials

Many conflicting studies have been published on the use of chlorhexidine mouthwash for both alleviating mucositis and reducing oral colonization by gram-positive, gram-negative, and *Candida* species in patients receiving radiotherapy, chemotherapy, or bone marrow transplantation. In 1990, Ferretti et al.,<sup>68</sup> in a randomized, controlled trial, demonstrated that prophylactic chlorhexidine mouthwash reduces oral mucositis and microbial burden in cancer patients receiving chemotherapy. The majority of studies since that time have not demonstrated a reduction in mucositis in patients receiving intensive chemotherapy and using chlorhexidine mouthwash.<sup>69,70 and 71</sup> However, Weisdorf et al.<sup>70</sup> and Epstein et al.<sup>71</sup> did demonstrate a reduction in oral colonization by *Candida* species and oral candidiasis. Ferretti et al.<sup>72</sup> found that the use of chlorhexidine rinse for the prevention of mucositis was not effective, though there was a reduction in streptococcal counts. Spijkervet et al.<sup>73</sup> in a placebo-controlled, double-blind study, revealed that the colonization index of viridans streptococci was reduced after 5 weeks of chlorhexidine treatment, though such therapy did not decrease the colonization of *Candida* species, *Streptococcus faecalis*, staphylococci, Enterobacteriaceae, Pseudomonadaceae, and Acinetobacter species, and there was no difference in the development and severity of mucositis. A recent randomized, double-blind study comparing chlorhexidine mouthwash to placebo in 25 patients receiving radiotherapy revealed that there was a trend toward more mucositis as well as mouthwash-induced discomfort, taste alteration, and teeth staining in the chlorhexidine arm.<sup>74</sup> The overall statistical data lead to the conclusion that chlorhexidine may result in improved oral hygiene, but the discomfort of using the rinse negates its minimal benefits.

The endotoxins of aerobic gram-negative bacilli are implicated in the etiology of mucositis. A study by Spijkervet et al.<sup>75</sup> postulated that lozenges containing 2 mg polymyxin E, 1.8 mg tobramycin, and 10 mg amphotericin (PTA) four times daily on the oropharyngeal flora would mediate and control mucositis. These researchers compared 15 irradiated patients using PTA and two other groups of 15 patients each, one of which was using 0.1% chlorhexidine and the other of which was using placebo. In the selectively decontaminated group, the severity and extent of mucositis was significantly reduced as compared with that in the chlorhexidine and placebo groups ( $P < .05$ ). Clinically, all patients in the lozenge group showed erythema only, whereas 80% of both the placebo and chlorhexidine rinse patients experienced severe mucositis with extended pseudomembranes from the third week of irradiation. No nasogastric tube feedings were needed in the PTA group, as compared to 30% of patients in the other groups.<sup>75</sup> The potential role of PTA lozenges remains to be clarified.

IB-367, a broad-spectrum antimicrobial peptide found in porcine leukocytes, was tested in a hamster model.<sup>76</sup> The results indicated that mucositis scores were significantly lower in hamsters given topical IB-367 as compared to those receiving placebo. Though further study is needed, IB-367 might improve clinical outcomes in patients at risk for the development of mucositis.<sup>76</sup> Another antimicrobial, nystatin suspension, has been studied in the prophylaxis of candidiasis in leukemia and bone marrow transplantation patients. The majority of publications do not support the use of nystatin.<sup>77,78,79,80,81,82,83 and 84</sup>

### Pharmacologic Modulation

Another agent that has been evaluated for the prevention and treatment of oral mucositis induced by 5-FU chemotherapy is allopurinol. The rationale for allopurinol mouthwash was based on data that systemic allopurinol was able to decrease 5-FU-induced toxicity by inhibiting the enzyme orotidylate decarboxylase and formation of the metabolites of fluorodeoxyuridine monophosphate (FdUMP) and fluorouridine (FUrd).<sup>85</sup> Two pilot studies support the use of allopurinol for oral mucositis. The study by Clark and Selvin<sup>86</sup> revealed that allopurinol mouthwash substantially decreased the incidence and severity of mucositis in six patients who received bolus 5-FU chemotherapy. Another pilot study, involving 16 patients receiving 5-day intravenous 5-FU infusions and using allopurinol mouthwashes four to six times daily,

also found that the allopurinol alleviated the mucositis in all patients.<sup>87</sup> After the success of these pilot studies, the use of allopurinol became routine medical practice in many institutions. The efficacy of allopurinol was tested by the NCCTG and the Mayo Clinic in a randomized, double-blind clinical trial. Seventy-five patients were assigned to receive allopurinol mouthwash or placebo while they received their first 5-day course of 5-FU with or without leucovorin. This study demonstrated no protective effect against 5-FU-induced mucositis by the allopurinol regimen.<sup>88</sup>

Leucovorin has been used in combination with methotrexate to help decrease the oral mucositis that occurs with methotrexate. In a pilot study involving 19 patients who received edatrexate for non-small cell lung carcinoma, less mucositis was seen than was anticipated.<sup>89</sup> There is decreased mucositis when reduced folates are given systemically following methotrexate administration.<sup>90</sup> In a small crossover study, administration of leucovorin-hyaluronidase mouthwashes did not reduce the severity of mucositis induced by high-dose methotrexate.<sup>91</sup>

Glutamine administration in animal studies has been shown to lead to a reduction in both morbidity and mortality of animals who have received a variety of chemotherapeutic agents, including methotrexate. The glutamine both preserved the morphologic structure of the gastrointestinal tract and reduced the incidence of bacteremia.<sup>92,93</sup> In a randomized trial of 28 patients with gastrointestinal cancers who received 5-FU and folinic acid, no effect on oral mucositis was seen in the group who also received 16 g glutamine daily for 8 days as compared to the group who received a placebo. The authors concluded that perhaps both the dose and duration of exposure to the glutamine were not sufficient to show a decrease in mucositis.<sup>94</sup>

According to laboratory data, another agent that protects host tissues selectively from 5-FU's toxic effects without loss of antitumor effect is uridine.<sup>95</sup> A study was conducted involving 29 patients with advanced malignancies who received N-phosphoracetyl-disodium L-aspartic acid (PALA) and methotrexate, each at 250 mg/m<sup>2</sup>, followed 24 hours later by increasing doses of 5-FU (600 to 750 mg/m<sup>2</sup>), with a leucovorin rescue and uridine rescue for a 72-hour infusion. The uridine allowed dose escalation of 5-FU to 750 mg/m<sup>2</sup>, with a decrease in all toxicities of the 5-FU except mucositis, which remained as the only significant chemotherapy-induced toxic effect.<sup>96</sup> Perhaps additional studies with oral uridine will reveal a reduction of the toxicity from mucositis.

A pilot study using propantheline, an anticholinergic agent that causes xerostomia, was performed to test whether the incidence of mucositis could be reduced when patients received etoposide.<sup>97</sup> It was hypothesized that the mucosal toxicity might be related to salivary excretion of etoposide after its systemic administration. Propantheline or placebo was given to 12 patients. The results revealed a decrease in the incidence and severity of mucositis in the patients who received the propantheline.<sup>97</sup>

## CRYOTHERAPY

Cryotherapy, in the form of ice chips and flavored ice pops, has been used to prevent mucositis. The NCCTG and the Mayo Clinic undertook a controlled, randomized trial of oral cryotherapy for preventing 5-FU-induced mucositis and found that cryotherapy is helpful in reducing the severity of 5-FU-induced mucositis.<sup>98,99</sup> After this study had been completed, another was undertaken in which patients were randomized to receive 30 minutes versus 60 minutes of cryotherapy.<sup>100</sup> A total of 178 evaluable patients were studied. Both cryotherapy groups had similar degrees of mucositis. The conclusion was to continue to recommend the use of 30 minutes of oral cryotherapy for patients receiving bolus intensive courses of 5-FU-based chemotherapy.<sup>100</sup> An additional study, conducted after the original study reported by the NCCTG and the Mayo Clinic, once again confirmed that oral cryotherapy can reduce 5-FU-induced mucositis.<sup>101</sup>

## LASER

Laser as a palliative methodology for mucositis has only recently begun to be investigated. The potential for lesion and pain control using laser was initially studied in an animal model. In a study of four groups of animals having a mucosal lesion, three groups received impulse laser exposure from 60 to 600 pulses, and one group remained untreated.<sup>102</sup> The only group that demonstrated more rapid resolution of the mucosal lesion (14 vs. 21 to 25 days) was the group that received the 600 pulsed exposures.

A preliminary report revealed that laser may be beneficial in reducing the severity and duration of mucositis. A study involving 20 patients, all having different cancers and chemotherapeutic protocols, who served as the controls and 16 patients who composed the treatment group and received laser revealed reduced duration of the mucosal lesions, from a mean of 19.3 days in the control arm to 8.1 days in the treatment arm.<sup>103</sup> At this time, double-blind, randomized trials are needed to verify these earlier reports.

## ANESTHETIC COCKTAILS

Several anesthetic cocktails, made up of agents such as viscous lidocaine (Xylocaine) or dyclonine hydrochloride, have been used with some success.<sup>104</sup> The anesthetic agents relieve the patient's pain, but this relief is temporary and also prevents taste perception, which can further interfere with food intake. Other analgesics and mucosal coating agents that can control pain include kaolin-pectin, diphenhydramine, Orabase, and Oratect Gel. In a prospective, double-blinded study involving 18 patients, viscous lidocaine with cocaine 1%, dyclonine hydrochloride 1%, kaolin-pectin solution, diphenhydramine, and saline solution were compared with a placebo. The dyclonine hydrochloride 1% provided the most pain relief, whereas dyclonine hydrochloride with viscous lidocaine and cocaine 1% provided the longest pain relief.<sup>105</sup> Even though clinicians use many of the topical agents, little experimental evidence exists to establish the efficacy of many of them.<sup>106</sup>

## CAPSAICIN

Capsaicin, the active ingredient in chili peppers, is a remedy that has been used for many different pain syndromes through the years and that may prove beneficial for mucositis pain induced by chemotherapy and radiotherapy. Several studies support the medical efficacy of locally applied capsaicin in a cream vehicle in neuropathic pain syndromes. A large, multicenter trial involving 277 patients demonstrated that topically applied capsaicin used for up to 8 weeks significantly reduced pain and improved quality of life in both postherpetic neuralgia and diabetic neuropathy.<sup>107,108 and 109</sup> Other neuropathic pain syndromes for which capsaicin has been shown to be effective include postmastectomy pain,<sup>110</sup> stump pain,<sup>111</sup> trigeminal neuralgia,<sup>112</sup> reflex sympathetic dystrophy,<sup>113</sup> and Guillain-Barré syndrome.<sup>114</sup> Topical capsaicin has also been shown to decrease the pain associated with rheumatoid and osteoarthritis,<sup>115</sup> and intranasal capsaicin spray has been shown to reduce the pain associated with cluster headaches.<sup>116</sup> Topical capsaicin has been shown to improve the rate of reepithelialization of wound healing in minipigs; thus, it may prove to be efficacious in wound healing in humans.<sup>117</sup>

In a pilot project, capsaicin in a candy vehicle (cayenne pepper candy) was given to patients with therapy-induced mucositis. Patients were instructed to allow the candy to dissolve in the mouth without chewing it. After the candy had dissolved, the burn produced by the candy was allowed to fade. The patients rated their pain before and after eating the candy. The reduction in pain was highly statistically significant.<sup>10,11</sup> A double-blinded, placebo-controlled study is under way to test the efficacy of oral capsaicin for pain control.

## NARCOTICS

Many of the agents previously mentioned may have some value in preventing mucositis or palliating the pain; however, very few controlled clinical trials have established their efficacy. At present, no standard treatment has been defined for the prevention or treatment of mucositis. When mucositis is severe and interferes with nutritional intake and quality of life, it is appropriate to use any of the treatments that have already been cited, as well as oral, transmucosal or, if necessary, parenteral narcotics. Currently, a study is under way to investigate the usefulness of transmucosal fentanyl (Actiq) in the treatment of mucositis ( [Table 55.2-6](#)). A recent article also reported on the successful use of topical opioids (morphine 0.08% gel, prepared with taste supplements) in treating oral mucositis in a patient who was terminally ill.<sup>118</sup> To discover an efficacious treatment, it is essential to continue studies of the treatments already available and to develop any promising new approaches.

Medication	Indication
Amoxicillin	Oral infection
Clindamycin	Oral infection
Fluoride	Oral hygiene
Hydrocortisone	Oral inflammation
Levamisole	Oral infection
Metronidazole	Oral infection
Penicillin	Oral infection
Vancomycin	Oral infection
Zinc	Oral hygiene

**TABLE 55.2-6.** Formulary of Common Remedies for Oral Complications

## ORAL COMPLICATIONS IN RADIOTHERAPY

Before one can discuss orofacial pain, one must understand the nature and necessity of a comprehensive dental examination and how its data interfaces with the treatment regimen. In accordance with the guidelines developed by the National Institutes of Health,<sup>119</sup> it is supremely important that the oncology patient be managed by a team. We recommend that a Preventive Dental Oncology Service be established for identification and management of patients receiving head and neck oncologic surgery, irradiation, and or chemotherapy. The objective of the Preventive Dental Oncology Service program is to evaluate the oncology patient for intraoral problems as related to the specific surgery, radiotherapy, or chemotherapy and to formulate a treatment plan for resolution of the intraoral symptoms associated with therapy.

Radiotherapy for the oncology patient carries a significant risk of mucositis. However, the long-term effects of the radiation are of greater concern to the clinical team than is the transient mucositis. The decrease in the numbers of osteocytes and the concomitant loss of vascularity in the maxillary or mandibular treatment fields precludes bone healing in the event of osseous surgery after therapy. The impaired, retarded, or nonhealing wound presents as an osteoradionecrosis (ORN), which requires specific management protocols (i.e., hyperbaric oxygen and intravenous antibiotics followed by osseous resection and additional hyperbaric oxygen and intravenous antibiotics). Second to the treatment of mucositis is xerostomia.

### XEROSTOMIA

Xerostomia is a complex phenomenon that cannot be attributed to radiation damage to the salivary glands alone. To understand xerostomia and the radiotherapy patient more fully, one must review the mechanisms behind saliva production. Secretion of saliva is subject to reflex stimulation of not only a physical but of a psychic nature.<sup>120</sup> Physical stimulation of the salivary gland originates in the taste buds. The psychic stimulation of the salivary glands is via the sensory nerve receptors. Xerostomia presents with a twofold pathogenesis. First, the lack of a wetting medium reduces the ability of the chemoreceptors on the dorsum of the tongue and the palate to accept the stimuli presented with foods or liquids. This loss of physical stimulation (chemical) fails to trigger the neurogenic response to the salivary gland and the anticipated salivary response never occurs. The minimal, thickened, mucinous saliva produced by the affected glands coats the mucosa of the cheeks, tongue, and palate, forming an effective barrier that prevents physical contact of the taste buds by the dietary substances (chemophores) and diminishes the physical response to thermal and mechanical stimulation. The cumulative result of being unable to stimulate the taste buds physically has a direct corresponding effect on the psychic component of salivary gland secretions. Histopathologically, the mucosa on the dorsum of the tongue appears atrophied, the end result of which is decreased surface area on the taste buds.

In the xerostomic patient, the clinician notices a significant loss of appetite that occurs concomitantly with mucositis. The role of xerostomia, and not merely stomatitis, in weight loss must not be discounted. When the physical component of salivary stimulation is denigrated by mechanical (mucous) barriers, the anticipated taste sensation associated with specific food groups is altered. If the patient no longer can perceive what should be sour or sweet, he or she will be unable to elicit the correct sensory response through the neurogenic paths; consequently, the second component of salivary stimulation, the visual component, becomes ineffective and the xerostomia is exacerbated further. When patients no longer can achieve the sensory gratification normally associated with specific food groups, dietary intake decreases and weight loss becomes a significant factor in continuation of therapy. With the decrease of salivary enzymes necessary for the initial stages of digestion, a third factor presents itself in the weight loss arena—namely, inability to assimilate dietary nutrients efficiently. Xerostomia is compounded by other factors such as antidepressant therapy, diabetes, interstitial nephritis, aging, postmenopausal syndromes, antihypertensives, and diuretics. Vitamin A and nicotinic acid deficiencies also can affect salivary secretions.

The management of xerostomia is complex, requiring attention to the patient's medical history for drug interaction, provision of a diet that both physically and psychologically is able to stimulate the salivary responses, maintenance of excellent oral hygiene to provide physical access to the taste receptors, and monitoring of the vitamin A and nicotinic acid levels for deficiencies. Increased intake of nicotinic acid and vitamin A on a specific, monitored response-to-dose program can be effective in increasing saliva flow. Mechanical débridement of the dorsum of the tongue with a soft toothbrush and the use of a spray mister before and during meals assists in maintaining access to taste buds.

Early clinical pilot studies by Fox et al.<sup>121</sup> and Greenspan and Daniels<sup>122</sup> indicated that low doses of oral pilocarpine reduced radiation-induced xerostomia. Recently, a randomized, double-blind, placebo-controlled trial by Johnson et al.<sup>123</sup> found that pilocarpine improved saliva production and relieved symptoms of xerostomia after irradiation for cancer of the head and neck, with minor side effects that were predominantly limited to sweating.

A randomized, controlled trial of standard fractionated radiation with or without amifostine (Ethyol), administered at 200 mg/m<sup>2</sup> as a 3-minute IV infusion 15 to 30 minutes before each fraction of radiation, was conducted in 315 patients with head and neck cancer. Patients were required to have at least 75% of both parotid glands in the radiation field. The incidence of grade 2 or higher acute xerostomia (90 days from the start of radiotherapy) and late xerostomia (9 to 12 months after radiotherapy), as assessed by the Radiation Therapy Oncology Group Acute and Late Morbidity Scoring Criteria, was significantly reduced in patients receiving Ethyol. At 1 year after radiotherapy, whole saliva collection after irradiation showed that more patients given Ethyol produced 0.1 g of saliva (72% vs. 49%). In addition, the median saliva production at 1 year was higher in those patients who received Ethyol (0.26 g vs. 0.1 g). Stimulated saliva collections did not show a difference between treatment arms. These improvements in saliva production were supported by the patients' subjective responses to a questionnaire regarding oral dryness.<sup>124</sup>

With effective management of xerostomia, the thickened mucinous film that accumulates on the mucosa of the tongue, floor of mouth, palate, and buccal folds is eliminated. With this simple maintenance step that can be managed by the patient or support staff, a significant reduction in bacterial volume is achieved, which, in turn, will reduce the incidence of mucositis significantly. When xerostomia is not controlled, significant plaque and material will accumulate on the surfaces of prosthetic appliances. This bacterial film can contribute to denture irritation that will compound therapy-related mucositis and can lead to fenestration of the supporting mucosa and development of an osteonecrosis in the posttreatment patient. When xerostomia is not monitored or controlled, the clinical team can anticipate heavy plaque accumulation on the surfaces of the teeth. This plaque film is highly cariogenic and ultimately will cause dental complications involving the teeth (decay) and the supporting tissue (gingivitis and periodontitis). Patients with high plaque indices will not benefit from anticariogenic treatment using fluoride applicators, because the plaque is an effective barrier against fluoride absorption. It must be assumed that the elevated plaque matrix resulting from xerostomia poses the greatest risk in the postradiotherapy morbidity of ORN.

Because of this risk of ORN, it will be necessary for the clinical team not only to assess a patient's pretreatment periodontal health but also to query the patient regarding his or her intent to maintain adequate oral hygiene. If a patient is not psychologically prepared to play a role in his or her oral hygiene or if a patient is physically or mentally impaired and unable to manage an appropriate personal oral hygiene program, it will be prudent to consider oral surgery to remove all high-risk teeth, as a preventive measure. Amputation of a patient's dentition is a serious irreversible step and must be thoroughly planned by all members of the clinical team before proceeding.

From the dental examination, diagnostic models, and radiographs obtained before radiotherapy or chemotherapy, high-risk teeth can be identified and treated restoratively or surgically. The therapy team must recognize and identify teeth and other bone anatomy aberrations that would require posttreatment surgery. Because

of the reduction in the vascular network and the permanent alteration of osteocytes in the bone in the treatment ports, it will be necessary to perform all prospective surgeries before the initiation of radiotherapy. This will minimize the potential for ORN in cases in which an operation must be performed after radiotherapy has been completed.

High-risk teeth and bone can be summarized as impacted third molars (both bony and soft tissue); teeth in which periodontal disease has been diagnosed and that will require mucosal flap surgery for treatment; unrestored endodontically treated teeth that are at high risk for traumatic fracture; teeth that have been surgically removed, endodontically treated, and reimplanted; teeth restored with dental implants; and teeth with root resorption secondary to orthodontic therapy. Supernumerary teeth and ossifications must also be evaluated.

After the dentition has been restored and appropriate surgeries have been completed, vacuum-formed vinyl fluoride applicators are made for home-care fluoride application. These applicators provide two functions: First, they help to prevent xerostomia-induced dental caries through fluoride induction into the tooth enamel and dentin. Second, the increased ambient fluoride levels on the tooth surface and the residual fluoride that remains in the oral cavity after each fluoride application reduces the level of oral bacteria and assists in microbial prophylaxis, which aids in the reduction of mucositis. In general, 0.04% stannous fluoride gel appears to be more effective than sodium fluoride 1.1%, as it reduces the levels of *Streptococcus mutans*, which causes caries.<sup>125</sup> In the use of fluoride applicators, Shenep et al.<sup>125</sup> recommend that a 0.04% stannous fluoride gel be placed into the applicators and that these be placed on the teeth and allowed to remain there for 3 minutes. After 3 minutes, the applicators should be removed and the excess fluoride expectorated, and the patient should not be allowed to rinse, eat, or drink for 30 minutes. For the week before initiation and for weeks 1 and 2 of radiotherapy, we recommend using the fluoride three times daily. This is in anticipation that we may discontinue fluoride therapy during the third, fourth, and fifth weeks of radiotherapy. For the first 3 months after radiotherapy, we recommend twice-daily fluoride. After 3 months and a thorough dental assessment, if the plaque indices are below 5%, we will maintain the patient on once-daily fluoride maintenance for life.

Before beginning radiotherapy, a protective radiation stent is fabricated. These stents are used during the radiotherapeutic sessions for all patients who have natural dentition. The purpose of the stents is to eliminate soft tissue contact with the surfaces of large dental restorations, thereby eliminating the secondary electron scatter from radiotherapy that will cause significant localized mucositis.

From the diagnostic examination and radiographs, the practitioner must ascertain whether the patient undergoing radiotherapy has had dental implants placed for prosthetic rehabilitation. Oral implantology is rapidly becoming commonplace in the prosthetic rehabilitation of missing teeth, support for cleft palate obturators, and support for facial muloges and prostheses. If it has been determined that implants are present, the dental oncologist must be prepared to fabricate the appropriate radiation shields and blocks to protect the areas of the bone supporting the implants, to minimize increased radiation dosimetry in those portions of the mandible or maxilla.

Keus et al.<sup>126</sup> reported on the effect of customized beam shaping on normal tissue complications in radiotherapy for parotid gland tumors. They evaluated a customized beam's-eye view as opposed to unblocked portals with field sizes defined by the largest target contour found in any computed tomographic slice and found that the volume of unnecessary exposed normal tissue that received more than 90% of the prescribed dose was reduced by a factor of 4% to 44%, on average, when the volume is expressed as a percentage of the target volume in each patient. For a tumor dose of 70 Gy, the average bone necrosis probability was reduced from 8.4% to 4.1%.

As regards patients with extensive implanted, supported, fixed or fixed removable prostheses, a very large volume of gold alloy is used in the fixed prostheses and in the framework of the fixed removable prostheses. For patients with dental implants, removal of the detachable portions of the prosthesis should be completed before radiotherapy, and beam-shaping blocks should be fabricated by the prosthodontist for protection of the mandible containing the titanium implant fixture. These precautions are necessary to reduce the risk of radiation-induced ORN.

## OSTEORADIONECROSIS

ORN carries the greatest morbidity in any radiotherapy program involving osseous tissue. ORN is not an infection but nonhealing, acellular, avascular bone that may have been present for months or years before becoming clinically evident. Continuous monitoring of the radiotherapy patient by the dental oncologist on a 3-month recall basis is appropriate. This recall schedule will allow for evaluation of the plaque indices, monitoring of fluoride compliance, and maintenance of developing dental disease. Even with the best of diagnosis, planning, and staging, an osteonecrosis can develop spontaneously. Early osteonecrotic changes are subtle and difficult to detect. In many instances, ORN presents as asymptomatic dehiscence in the mucosa. As the necrosis progresses, the site can become more erythematous and painful. At this stage, it is not uncommon for the clinician to misdiagnose the signs as a minor infection and to place the patient on a regimen of antibiotics, which will minimize the symptoms but allow the necrosis to continue to progress. If teeth are present, the clinical symptoms are mobility, minimal to moderate pain, and ectopic eruption. In the early stages, routine dental radiographs are insufficient to provide an accurate diagnosis. As the necrosis advances, extraoral fistulas and intraoral antral fistulas will develop. Eventually, occlusion pathology becomes evident and, in many cases, pathologic fractures will occur.

Early definitive diagnosis using computed tomographic scans, dentiscans, bone density studies, and magnetic resonance imaging will aid in determining the extent of the necrosis so that a surgical template can be made. In very small, isolated, solitary lesions of less than 0.5 cm, surgical exposure and cautious débridement along with appropriate prophylactic antibiotics may suffice. This seldom is the case with ORN and, if remission and healing are not evident within the first 8 weeks, presurgical and postsurgical hyperbaric oxygen, intravenous antibiotics, and radical excision of the necrotic avascular bone will be necessary.

Myers and Marx<sup>127</sup> reported on the use of hyperbaric oxygen, which stimulates angiogenesis, leading to increased neovascularization and optimization of cellular levels of oxygen for osteoblast and fibroblast proliferation, collagen formation, and support of ingrowing blood vessels. The hypoxic, acellular matrix in the postirradiated field is changed to a hypercellular, hyperoxic or normally oxygenated situation. Oxygen is used as an adjunct to appropriate surgical intervention; by use of these two modalities in combination, the salvage rate for ORN and its complications of orocutaneous fistula, pathologic fractures, and severe bone loss can be increased dramatically.<sup>127</sup>

## CONCLUSION

With accurate pretherapeutic diagnosis, appropriate treatment planning, and therapeutic staging by all members of the clinical team, the incidence of ORN and other oral complications can be minimized or eliminated. The medicolegal accountability, if such pretreatment protocols are not in place, is significant and economically devastating. For no reason should a patient be denied a thorough, comprehensive examination followed by a well-formulated and well-staged treatment plan. In summary, a total team effort is mandatory for the standard of care necessary to provide the oncology patient with a comprehensive treatment plan that encompasses all medical and dental health and rehabilitation issues.

## INTRODUCTION

Pulmonary disease can be caused by a wide spectrum of pathogenetic mechanisms in patients with cancer. These include a variety of infectious agents and neoplastic disorders as well as pulmonary thromboembolic disease, pulmonary hemorrhage, pulmonary edema (cardiogenic and noncardiogenic), and leukocyte agglutinin reactions. Pulmonary toxicity caused by antineoplastic agents is being recognized more frequently, and the number of drugs known or suspected to cause lung disease is steadily increasing. Because continued use of the offending agent may cause death and because withholding the agent may result in resolution of the pulmonary toxicity, it is important to recognize radiation- and drug-induced pulmonary disease. In this section, parenchymal lung disease caused by irradiation and chemotherapy is discussed. Mechanisms of lung injury, histopathologic findings, clinical and laboratory features, and diagnosis and treatment of the abnormalities produced by radiation therapeutic and chemotherapeutic agents are reviewed.

## RADIATION-INDUCED PULMONARY TOXICITY

### MECHANISM OF LUNG INJURY

Radiation can affect dividing and nondividing cells and can cause genetic and nongenetic damage.<sup>1,2</sup> In the lung, a hypothetical reconstruction of radiation injury might be as follows: Therapeutic radiation may result in nongenetic damage that is apparent in all cells, but capillary endothelial and type I cells (epithelial lining cells) appear to be most susceptible.<sup>3</sup> Many of these cells, whether dividing or not, undergo early necrobiosis and slough. The apoptotic pathway appears to be an important mechanism of cellular destruction after radiation. Specific signal transduction pathways are activated by radiation, including sphingomyelin hydrolysis, which generates ceramide as a second messenger and leads to apoptotic DNA degradation.<sup>4</sup> Nonlethal ionizing radiation also activates a stress response in cells, which leads to up-regulation of specific nuclear transcription factors such as NF- $\kappa$ B and transcription of such specific early-response genes as c-abl, c-jun, Egr-1, and c-fos.<sup>5,6</sup> This cellular activation initiates a repair process that involves cytokines and growth factors such as basic fibroblast growth factor,<sup>7</sup> as well as interleukin-1 and transforming growth factor- $\beta$  (TGF- $\beta$ ).<sup>8</sup> Prostaglandin synthesis is also up-regulated.<sup>9</sup> Over time, capillaries regenerate, and the alveolar epithelium is repopulated by type II cells (surfactant-producing cells), because type I pneumocytes do not regenerate. Some of these type II cells redifferentiate into type I cells. If the initial injury is severe, extracellular matrix components of the lung, such as basement membrane glycoproteins and proteoglycans, are damaged. This can impede reconstruction of the delicate three-dimensional structure of the alveolar-capillary unit and result in functional derangement and scar formation, even if the cellular components are able to regenerate. Genetic damage to dividing cells, such as endothelial cells or type II pneumocytes, can also occur. Depletion of these cells may result during successive mitoses, causing a loss of integrity of pulmonary capillaries and exudation of fluid into the alveoli. At the physiologic level, loss of compliance, abnormal gas exchange, and respiratory failure can occur owing to leakage of plasma proteins into the alveolar space. This type of genetic damage may also explain why pneumonitis may be seen so late after radiation. One might speculate that some endothelial cells initially remain normal but that, in the course of the next four cell divisions, chromosomal aberrations prevent further reduplication, which leads to loss of integrity of the capillary.<sup>1</sup>

Certain factors are critical to the development of classic radiation pneumonitis. In general, damage to the lung increases as the volume of lung tissue irradiated increases. There also appears to be a threshold effect, such that irradiation of at least 10% of the lung is required to produce significant pulmonary toxicity.<sup>10</sup> This threshold may be reached in the treatment of some patients with breast cancer, depending on the specifics of their individualized treatment program.<sup>10</sup> Also, the toxic effects of radiation, as measured by symptoms and signs, radiographic changes, and physiologic tests, are proportionate to the total amount delivered to the lung. Radiation pneumonitis after a single-dose whole lung irradiation shows a threshold level and a steep sigmoid dose-response curve.<sup>11</sup> Radiation pneumonitis seldom occurs with fractionated total doses of less than 20 Gy but is highly likely when doses exceed 60 Gy.<sup>12</sup> An unusual and dramatic demonstration of this principle is the use of therapeutic pneumothorax to protect the lung when high-dose external-beam radiation therapy is given for the treatment of chest wall tumors.<sup>13</sup>

Because local control of lung cancer is greater when higher doses are delivered to the tumor,<sup>14</sup> methods are being devised to give high doses to the target tissue while sparing normal surrounding lung. One such technique is called *three-dimensional treatment planning*.<sup>15,16,17</sup> and <sup>18</sup> To spare the lung further toxicity, *in situ* isolated lung perfusion for the treatment of unresectable pulmonary tumors, preceded or followed by high-dose irradiation, soon may be available.<sup>19</sup> Studies to evaluate the therapeutic activity of inhaled chemotherapeutic agents, such as doxorubicin, on metastasis to the lung are under way also.<sup>20</sup> Whether these treatment modalities will have a sparing effect on the lung or whether they will be associated with an increase in pulmonary toxicity is unknown.

Besides the total radiation dose, the number of fractions into which it is divided and, to a lesser extent, the time span over which it is delivered are important factors.<sup>21</sup> The greater the number of fractions in which the radiation is given, the lower is the damaging effect. However, the incidence of radiation pneumonitis still exhibits a threshold effect and a steep sigmoidal dose-response curve.<sup>22</sup> *Fractionation* is different from *dose rate*, which refers to output of the machine during radiation therapy. Dose rate certainly has an effect on lung tolerance: Radiation delivered as 5 cGy/minute is less damaging than radiation delivered at 30 cGy/minute, which in turn is less damaging than radiation delivered at 2 to 3 Gy/minute. The incidence and severity of radiation damage to the lungs thus are related principally to the volume of lung tissue irradiated, the total dose, the fractions into which the total dose is divided, and the quality of the radiation.

Genetic factors also influence the severity of response to lung irradiation in animals<sup>23</sup> and presumably may do so in humans as well, although there is no current method to evaluate this clinically.

## HISTOPATHOLOGY

The histopathologic changes of radiation-induced pulmonary toxicity can be divided into early, intermediate, and late stages based on the time course and intensity of the radiation injury.<sup>24</sup> Early radiation damage (0 to 2 months after irradiation) is characterized by injury to small vessels and capillaries and subsequent development of vascular congestion and increased capillary permeability.<sup>25</sup> At this stage, a fibrin-rich exudate is present in the alveolar spaces. Hyaline membranes form on the alveoli, probably from condensation of the intraalveolar fibrin. After 1 month, an inflammatory infiltrate also is present, which may lead to a second course of increased permeability.<sup>26</sup> Abnormalities in the intermediate stage (2 to 9 months after irradiation) are characterized by obstruction of pulmonary capillaries by platelets, fibrin, and collagen. Alveolar-lining cells (primarily type II pneumocytes) become hyperplastic, and the alveolar walls become infiltrated with fibroblasts and mast cells.<sup>27</sup> If the radiation injury is mild, these changes may subside entirely; however, when the injury is severe, a chronic phase (9 months or longer after irradiation) ensues that

may persist or progress for months or years. In animal models, there is marked activation of genes that encode fibrillar collagens.<sup>8</sup> The histopathologic appearance then is dominated by dense fibrosis, thickening of the alveolar walls, vascular subintimal fibrosis, and luminal narrowing. In some instances, the lung may shrink to less than half its original size, with a thickened adherent pleura and scarred hilar structures.

In addition to this classic pattern of radiation pneumonitis, another syndrome of out-of-field pneumonitis, characterized by a hypersensitivity pneumonitis in areas of lung not directly irradiated, has been described. This syndrome, which occurs in a minority of patients, is characterized by a bilateral lymphocytic alveolitis of activated CD4+ T lymphocytes 4 to 6 weeks after strictly unilateral lung irradiation.<sup>28</sup>

## CLINICAL FEATURES

### *Signs and Symptoms*

The clinical syndrome of radiation pneumonitis develops in 5% to 15% of patients receiving high-dose external-beam radiation for treatment of lung cancer. Factors that can add to the development of radiation pneumonitis include concomitant chemotherapy, previous irradiation, and withdrawal of steroids. The incidence of radiation pneumonitis does not differ significantly between the young and the elderly, but the pneumonitis is inclined to be more severe in the latter group.<sup>29</sup> Underlying chronic obstructive pulmonary disease does not appear to potentiate radiation damage.

Symptoms of acute radiation pneumonitis usually become evident 2 to 3 months after the completion of therapy; rarely, they occur within the first month and, occasionally, as late as 6 months after irradiation. In general, the early onset of symptoms implies a more serious and more protracted clinical course. The cardinal symptom of radiation pneumonitis is dyspnea.<sup>24</sup> It may be self-limited or may progress to severe respiratory distress, depending on the extent and intensity of the injury. Patients may also have a nonproductive cough or a cough productive of small amounts of pinkish sputum. Frank hemoptysis early in the clinical course is distinctly uncommon; however, massive hemoptysis has been reported as a late complication of therapeutic pulmonary irradiation.<sup>30</sup> Fever is unusual but can be high and spiking; in severe cases, other constitutional symptoms may occur. Chest pain, which is rarely a prominent feature, may be due to fractured ribs, pleural changes, or coughing. Symptoms of airway obstruction can occur in the first few days of radiation therapy and usually are associated with swelling of a central bronchogenic carcinoma. Severe respiratory distress can result and may be prevented by the administration of steroids the day before and several days after the initiation of radiation therapy. Hemoptysis and other manifestations of radiation pneumonitis may also occur in patients given palliative endobronchial brachytherapy<sup>31</sup> or after surgical implantation of radioactive seeds.

On physical examination, signs of pulmonary involvement are minimal. Occasionally, moist rales, a pleural friction rub, or evidence of pleural fluid may be heard over the area of irradiation. In severe cases, tachypnea and cyanosis may be present and, occasionally, evidence of acute cor pulmonale appears, usually predicting a fatal outcome. Finger clubbing due to radiation is distinctly unusual and, if present, is most likely caused by the underlying malignancy. Skin changes corresponding to the ports of irradiation often are present but provide no clue as to the presence or severity of the pulmonary reaction beneath.

Although patients with acute pneumonitis may show complete resolution of signs and symptoms, most develop gradual, progressive fibrosis. In some cases, patients present with radiation fibrosis without a previous history of acute pneumonitis. The permanent changes of fibrosis evolve over 6 to 24 months but usually remain stable after 2 years. Patients with fibrosis may be asymptomatic or may have varying degrees of dyspnea. The major complications of radiation pneumonitis occur late in the disease and are secondary to persistent fibrosis of a large volume of lung. These include cor pulmonale and respiratory failure.

### *Diagnostic Imaging*

Although radiographic abnormalities invariably are found concurrently with clinical radiation pneumonitis, these changes may be seen in asymptomatic patients as well. Early radiographic changes include a ground-glass opacification, diffuse haziness, or indistinct normal pulmonary markings over the irradiated area.<sup>32</sup> Later, the chest radiograph may show alveolar infiltrates or dense consolidation with or without air bronchograms. As the pneumonitis progresses to fibrosis, the radiographic appearance changes to that of linear streaks radiating from the area of pneumonitis and of contraction toward the hilar, the perimediastinal, or the apical areas. Pleural effusions, if present, are usually small and always coincident with the pneumonitis.<sup>33</sup> They can persist for long periods but often disappear spontaneously and never increase over a period of stability unless secondary complications occur, such as radiation-induced pericarditis. Mediastinal or hilar adenopathy and cavitation are almost always attributable to causes other than radiation pneumonitis.<sup>2</sup> Pneumothorax occasionally is associated with radiation fibrosis but not with acute pneumonitis.

One of the most characteristic features of radiation pneumonitis and fibrosis is that the radiologic changes are confined to the outlines of the field of radiation. In a few cases, extensive changes outside the field, even in the contralateral lung, have been observed. This syndrome of out-of-field pneumonitis is thought to represent a hypersensitivity response to the radiation.<sup>34</sup> Other possible explanations for this phenomenon include obstruction of lymphatic flow from radiation-induced mediastinal fibrosis<sup>35</sup> and absorption of x-rays by regions outside the irradiated ports.<sup>36</sup>

Some data suggest that computed tomographic scans of the chest and gallium 67 citrate imaging are more sensitive than chest radiography in the detection of radiation changes.<sup>37,38</sup> Correlation of abnormalities seen in these tests with the development of physiologic dysfunction and clinical toxicity requires clarification.

### *Pulmonary Function Tests*

No gross physiologic changes occur in the lung until 4 to 8 weeks after completion of irradiation, usually coincident with the period of clinical pneumonitis. Then, one sees a decrease in lung volumes, which can progress.<sup>39,40,41 and 42</sup> These changes persist indefinitely, with little evidence of recovery.<sup>41</sup> Gas exchange abnormalities, which include a decrease in diffusing capacity and arterial hypoxemia, especially with exercise, occur about the same time but show some tendency toward recovery after 6 to 12 months.<sup>40,41 and 42</sup> A fall in compliance coincident with the clinical pneumonitis is seen in most subjects.<sup>40</sup> Accordingly, the elastic work of breathing is increased, and dyspnea, a result of the increased workload, ensues.<sup>40</sup> Air flow parameters remain nearly normal in most studies.<sup>39,40,41 and 42</sup>

## DIAGNOSIS

The diagnosis of radiation pneumonitis can sometimes be made clinically on the basis of the timing of irradiation in relation to symptoms and the typical chest radiographic appearance (i.e., infiltrates corresponding to the margins of the irradiated portal). Differentiation from recurrent malignancy or infection often poses a problem, and then lung biopsy is necessary. Although histopathologic changes are nonspecific for radiation pneumonitis, when elements of the acute stages (fibrin exudate in the alveoli) are seen adjacent to the more chronic stages (alveolar fibrosis and subintimal sclerosis),<sup>43</sup> this entity can be diagnosed with reasonable certainty.

Biochemical markers that indicate radiation lung injury before the onset of clinical pathologic events would be valuable in the early diagnosis and management of patients with radiation toxicity. In irradiated animals, studies demonstrate that surfactant found in the serum may be a marker and predictor for later radiation pneumonitis.<sup>44</sup> Prospective studies are needed in humans to identify the sensitivity and specificity of monitoring serum surfactant levels as an early means of diagnosing clinical radiation toxicity. Though no standard tests currently are used to monitor patients for radiation pneumonitis (because most methods have little predictive value), some reports suggest that soluble intercellular adhesion molecule-1<sup>45</sup> or transforming growth factor- $\beta$ <sup>46</sup> may be good candidates.

## TREATMENT

Three treatment modalities have been used, prophylactically and therapeutically, for radiation-induced pneumonitis: corticosteroids, antibiotics, and anticoagulants. Of these, corticosteroid therapy is the most important.

Corticosteroid administration during irradiation in mice markedly improves the physiologic abnormalities and decreases mortality,<sup>47,48</sup> without exerting an effect on late pulmonary fibrosis.<sup>49</sup> No controlled clinical trials are available of the efficacy of steroid therapy in radiation pneumonitis in humans. Rubin and Casarett<sup>2</sup> collected data from eight studies on humans and categorized them according to whether corticosteroids were used prophylactically or therapeutically. Corticosteroids given prophylactically failed to prevent radiation pneumonitis but, when administered as clinical pneumonitis occurred, these agents prompted an objective response. In other reports, steroid therapy failed to ameliorate severe pneumonitis. Nonetheless, our practice is to begin prednisone, 1 mg/kg, as soon as the diagnosis is

reasonably certain. The initial dose is maintained for several weeks and then reduced cautiously and slowly. It has been our experience that if steroids are tapered too rapidly, symptoms can be exacerbated, necessitating higher doses for longer periods. Similarly, if corticosteroids are part of a recent chemotherapeutic regimen, stopping them abruptly can precipitate clinically evident radiation pneumonitis. Which parameters, if any, to follow during the tapering schedule are not known, and no studies are available. Generally, decisions are based on the symptoms. Most authors agree that corticosteroids have no place in the treatment of radiation fibrosis.

In experimental and clinical reports, antibiotic administration has no effect on the course or outcome of radiation pneumonitis.<sup>2,50</sup> Although there is some rationale for the use of anticoagulants in view of the effects of irradiation on the vascular system, neither heparin injections nor oral anticoagulants have been found to be beneficial.<sup>50</sup> Captopril has been shown to be effective in animal studies,<sup>51</sup> but no human trials have been reported. The mechanism of action of captopril in this setting probably is not its inhibition of angiotensin-converting enzyme.<sup>52</sup> Pentoxifylline also has some effects on the late phase of pneumonitis in animal models.<sup>53</sup>

## RADIATION-RELATED BRONCHIOLITIS OBLITERANS WITH ORGANIZING PNEUMONIA

Although bronchiolitis obliterans with organizing pneumonia (BOOP) is an unusual histopathologic pattern for drug-induced lung injury, radiation damage resulting in BOOP has been reported.<sup>54</sup> Patients with lung cancer usually receive the highest doses of radiation to the largest volume of lung tissue, which makes them more susceptible to radiation injury as compared with other patients receiving irradiation. Most of the cases of radiation-related BOOP, however, have occurred in patients receiving radiation to the breast. Whether the low dose or indirect radiation that these patients receive makes them more susceptible to this type of lung injury is not known. Besides the unusual pathologic pattern in these irradiated patients, clinical and radiologic differences are evident, as compared to conventional radiation pneumonitis. Whereas dyspnea is the hallmark of radiation-induced lung injury, fever and cough are the predominant features of radiation-related BOOP. Radiographically, the infiltrates can begin in the radiated areas but always progress outside the portal and, in approximately 40% of the cases, the radiographic abnormalities were observed on the side contralateral to the irradiated breast. Although patients respond dramatically to corticosteroid therapy with no obvious evidence of residual damage, there is a 67% relapse rate when the drug is tapered or discontinued. As with conventional radiation-induced pneumonitis, no studies are available on the minimal effective dose or duration of therapy but, in view of the high relapse rate, it seems prudent to taper corticosteroid therapy very slowly, with meticulous vigilance for clinical signs of relapse.

To spare the lung the toxic effects of chemotherapy, several unique treatment modalities are now being investigated. These include isolated lung perfusion (one or both lungs) with doxorubicin for either metastatic disease or bronchoalveolar carcinoma. In one study, six patients received the perfusate and, although no major responses were observed, the patients tolerated the procedure well and five of the six did not have any serious complications.<sup>19</sup> Antitumor efficacy in mice and dogs has been observed with inhaled chemotherapeutic agents<sup>20</sup>; clinical human testing now is under way in patients with metastatic lung disease using doxorubicin via nebulization.

## CHEMOTHERAPY-INDUCED PULMONARY TOXICITY

The list of chemotherapeutic agents reported to cause cytotoxic drug-induced lung disease continues to grow ( [Table 55.3-1](#)). Recently added agents are docetaxel and gemcitabine. An overview of the potential mechanisms of lung damage, a summary of the pathologic findings, and common clinical features of pulmonary toxicity are discussed in this section. Characteristics of pulmonary disease caused by some of these drugs are presented.

AGENT	ASSOCIATED AGENTS
ANALGESICS	Codeine Morphine
ANTIBIOTICS	Chloramphenicol Doxorubicin Erythromycin Gentamicin Isoniazid Nitrofurantoin Spectinomycin Streptomycin Tetracycline Vancomycin
CHEMOTHERAPEUTICS	Bleomycin Cisplatin Doxorubicin Etoposide Fluorouracil Gemcitabine Ifosfamide Irinotecan Mitomycin Methotrexate Naveloxin Paclitaxel Vinorelbine
DIETARY SUPPLEMENTS	Aspirin Ginseng Licorice Soybean Vitamin E Vitamin K
HERBALS	Aspirin Ginseng Licorice Soybean Vitamin E Vitamin K
IMMUNOSUPPRESSANTS	Cyclosporin Methotrexate Prednisone Tacrolimus Vincristine
OTHER	Amiodarone Cisplatin Doxorubicin Etoposide Fluorouracil Gemcitabine Ifosfamide Irinotecan Mitomycin Methotrexate Naveloxin Paclitaxel Vinorelbine

**TABLE 55.3-1.** Chemotherapeutic Agents Associated with Pulmonary Parenchymal Disease

## MECHANISMS OF PULMONARY INJURY

The details of the pathophysiology of specific chemotherapeutic agents, except for bleomycin, generally are not known; however, several mechanisms of pulmonary toxicity mediated by these agents have been proposed. Certain cytotoxic drugs may induce pulmonary injury by triggering the formation of reactive oxygen metabolites, including the superoxide anion,<sup>55</sup> hydrogen peroxide, and hydroxyl radicals, primarily from activated neutrophils. Bleomycin induces reactive oxygen radicals by forming a complex with Fe<sup>3+</sup>. Consistent with a direct pathologic role for this mechanism, iron chelators ameliorate the pulmonary toxicity of bleomycin in animal models.<sup>56</sup> Reactive oxygen species can produce direct toxicity through participation in redox reactions and subsequent fatty acid oxidation, which leads to membrane instability.<sup>57</sup> Oxidants can cause other inflammatory reactions within the lung. For example, the oxidation of arachidonic acid is an initial step in the metabolic cascade that produces immunologically active mediators, including prostaglandins and leukotrienes.<sup>58</sup> Cytokines such as interleukin-1, macrophage inflammatory protein-1 (MIP-1), monocyte chemoattractant protein-1 (MCP-1), and TGF- $\beta$  are released from alveolar macrophages in animal models of bleomycin toxicity.<sup>55,59,60</sup> and <sup>61</sup> Cytotoxic drugs may also affect the local immune system. Because the lung is exposed to so many substances that can activate its immune system, there appears to be a pulmonary immune tolerance state to avoid unnecessary overreactions.<sup>62</sup> This tolerance state may, in part, be a result of effector and suppressor cell balance.

Cytotoxic drugs can alter the normal effector and suppressor balance, which may cause tissue damage.<sup>63,64</sup> and <sup>65</sup> Other homeostatic systems within the lung can be affected as well, such as the balance between collagen formation and collagenolysis.<sup>62</sup> Through modulation of fibroblast proliferation and phenotype,<sup>66</sup> excessive collagen deposition may result in severe, irreversible pulmonary fibrosis. Bleomycin is one cytotoxic agent that has this potential.<sup>67,68</sup> and <sup>69</sup> In addition, bleomycin may up-regulate collagen synthesis in fibroblasts by stimulating transcription directly through a TGF- $\beta$  response element in the procollagen (I) $\alpha$  promoter as well as by an autocrine loop involving extracellular release of TGF- $\beta$ .<sup>69</sup> Mast cells may also be involved in the inflammatory and fibrotic process.<sup>70</sup> Imbalance between the protease and antiprotease system has been implicated as well in a number of pulmonary disorders, including drug toxicities.<sup>62</sup> Bleomycin and cyclophosphamide produce substances that can inactivate the antiprotease system, enhancing the effects of proteolytic enzymes on the lung. Bleomycin also causes profound effects on the fibrinolytic system, altering the balance between fibrin deposition and fibrinolysis on the alveolar surface, leading to fibrin deposition.<sup>71</sup> Drugs may damage the lung through a variety of other mechanisms, and considerable investigation should be done to define and clarify the exact mechanism of lung injury for each chemotherapeutic drug.

One of the potential determinants of bleomycin toxicity is the cytoplasmic cysteine proteinase bleomycin hydrolase, which is the major enzyme responsible for metabolizing bleomycin to a nontoxic molecule.<sup>72</sup> In animal models, bleomycin hydrolase knockout mice are highly susceptible to bleomycin toxicity.<sup>73</sup> The two organs that are the most common targets for bleomycin toxicity—lung and skin—harbor the lowest levels of the enzyme.<sup>74</sup> With the cloning of the human gene encoding bleomycin hydrolase,<sup>75</sup> studies are needed to determine whether genetic variability of this enzyme can account for increased individual susceptibility to bleomycin pulmonary toxicity.

## HISTOPATHOLOGY

The histopathologic changes of drug-induced pulmonary toxicity demonstrate common features. Similar to radiation-induced damage, abnormalities are seen in endothelial and epithelial cells. The vascular damage is characterized by endothelial swelling with exudation of fluid into the interstitium and the intraalveolar spaces. There is destruction and desquamation of type I pneumocytes, with proliferation of type II pneumocytes. Mononuclear cell infiltration and fibroblast proliferation with

fibrosis are common findings; the character of the inflammatory cellular infiltrate may be a feature that distinguishes the toxicity of one drug from another. Bronchoalveolar lavage studies in patients with methotrexate pulmonary toxicity have shown the presence of a T-lymphocytic alveolitis, whereas studies on some patients with bleomycin toxicity have revealed a polymorphonuclear alveolitis.<sup>63,76</sup> Eosinophil infiltration has been associated with drugs that cause apparent hypersensitivity reactions, such as methotrexate, procarbazine, and bleomycin.<sup>62,63,77,78</sup>

## CLINICAL FEATURES

Table 55.3-2 lists predisposing factors associated with enhancement of drug-induced pneumonitis.<sup>79,80,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96,97,98</sup> and <sup>99</sup> Because bleomycin toxicity is relatively common, it warrants special mention. Although it drastically increases with doses in excess of 450 to 500 mg, toxicity can occur with much lower doses, especially when other risk factors are present. One study described 9 of 45 patients (20%) who developed lung toxicity when they received bleomycin after cisplatin infusion.<sup>95</sup> Renal damage after cisplatin administration, with subsequent accumulation of bleomycin, was a likely cause of the high pulmonary toxicity and mortality rate of 67%. Extreme caution is recommended in the administration of combined bleomycin and cisplatin chemotherapy; if possible, bleomycin should precede cisplatin infusion to minimize the risk of lung toxicity. Some data suggest that continuous infusion of bleomycin may be associated with less pulmonary toxicity than bolus therapy<sup>96</sup>; however, these data are inconclusive, and further studies are warranted. Supplemental oxygen is a classic cofactor in bleomycin pulmonary toxicity.<sup>97</sup> An increased risk of pulmonary toxicity (4 of 12 patients, fatal in 75%) was described in a small, uncontrolled study of patients receiving granulocyte colony-stimulating factor in combination with bleomycin-containing combination chemotherapy [BACOP (bleomycin, Adriamycin, cyclophosphamide, Oncovin, prednisone)] for non-Hodgkin's lymphoma.<sup>98</sup> However, larger studies have not confirmed any increased risk of bleomycin toxicity with the use of granulocyte colony-stimulating factor.<sup>99</sup>

Risk Factor	Drug
Total dose	Bleomycin, <sup>79</sup> carmustine <sup>80</sup>
Age	Bleomycin, <sup>81</sup> carmustine <sup>82</sup>
Oxygen therapy	Bleomycin, <sup>83,84,85</sup> cyclophosphamide, <sup>86</sup> mitomycin <sup>87</sup>
Simultaneous or prior radiation therapy to lungs	Bleomycin, <sup>88</sup> busulfan, <sup>89</sup> mitomycin <sup>90</sup>
Increased toxicity when given with other drugs	Carmustine, <sup>91</sup> mitomycin, <sup>92</sup> cyclophosphamide, <sup>93</sup> bleomycin, <sup>94</sup> methotrexate, <sup>95</sup> etoposide <sup>96</sup>
Preexisting pulmonary disease	Carmustine <sup>97</sup>

**TABLE 55.3-2.** Factors Associated with Increased Risk of Drug-Induced Pneumonitis

The interest in administration of several cycles of high-dose chemotherapy followed by peripheral stem cell rescue for treatment of breast cancer and lymphoma has led to reports of pulmonary toxicity of agents not previously thought to be highly toxic to the lung, such as etoposide.<sup>100</sup> Importantly, careful studies of pulmonary function after high-dose chemotherapy containing cyclophosphamide, cisplatin, and carmustine [1,3-Bis(2 chloroethyl)-1-nitrosourea (BCNU)], followed by autologous bone marrow transplant, for treatment of breast cancer show a delayed drop in diffusing capacity averaging 30% by week 18.<sup>101</sup> The majority of patients were symptomatic with dyspnea and responded well to systemic corticosteroids.<sup>101</sup> More of this type of toxicity can be anticipated in the future as this treatment modality becomes more common and new regimens for high-dose chemotherapy are studied.

Long intervals between drug administration and onset of clinical toxicity have been described. Late-onset pulmonary fibrosis has been reported many years after discontinuing cyclophosphamide<sup>102</sup> and carmustine.<sup>103</sup>

## Signs and Symptoms

The cardinal symptom of drug-induced pulmonary toxicity is dyspnea. Nonproductive cough, fatigue, and malaise are other commonly associated complaints. Other characteristics of chemotherapy-induced pulmonary disease are outlined in Table 55.3-3. Although symptoms usually develop over a period of several weeks to months, hypersensitivity drug-induced lung disease can develop over hours. Fever may be a common finding with this type of toxicity. Chest pain has been reported during infusion of bleomycin<sup>104</sup> or immediately after therapy with methotrexate<sup>105</sup>; however, it is an unusual manifestation of toxicity. A syndrome of acute dyspnea, probably due to acute direct toxicity to the pulmonary vasculature, can occur during or shortly after vinca alkaloid infusion when given in combination with mitomycin for treatment of non-small cell lung cancer.<sup>106</sup> Because hemoptysis is an uncommon feature of drug-induced pulmonary toxicity, when it is present, other diagnoses should be considered. Physical examination of the lungs may be normal or may reveal end-inspiratory "Velcro" rales. Finger clubbing is distinctly unusual, but it may be related to the underlying malignancy.

**TABLE 55.3-3.** Characteristics of Pulmonary Disease Caused by Commonly Used Chemotherapeutic Agents

All-*trans*-retinoic acid treatment of acute promyelocytic leukemia induces a distinct syndrome of respiratory distress, which are thought to be mediated by newly differentiated leukemia cells that are marginating into the pulmonary circulation, thereby increasing capillary permeability and releasing cytokines that induce neutrophil migration into the interstitium. High doses of corticosteroids are the most effective treatment.<sup>107</sup> Steroid prophylaxis of this syndrome has been reported to be useful.<sup>108</sup>

Paclitaxel (Taxol) and Docetaxel (Taxotere) cause bronchospasm and, in some cases, frank anaphylaxis or pulmonary edema, probably on the basis of a hypersensitivity reaction to the solvent needed to dissolve these agents. Prophylaxis with corticosteroids, administration of H<sub>1</sub> and H<sub>2</sub> histamine blockers, and slowing of the infusion rate are effective in reducing the incidence and severity of these reactions.

## Diagnostic Imaging

The most common radiographic abnormality associated with drug-induced pulmonary toxicity is a reticulonodular pattern, which may be basilar or diffuse. Pleural effusions are uncommon but have occasionally been reported in association with mitomycin, busulfan, methotrexate, and procarbazine toxicity.<sup>109,110,111</sup> and <sup>112</sup> Hypersensitivity lung disease associated with methotrexate and procarbazine may present with bilateral acinar infiltrates that clear rapidly.<sup>112</sup> In some instances, the chest radiograph is normal, even in the presence of histologically proved pulmonary infiltration and fibrosis.<sup>111,113</sup> Most commonly, methotrexate and carmustine

toxicity have been reported with normal chest radiographic findings. Hilar adenopathy is distinctly unusual and has been reported only with methotrexate toxicity. <sup>111</sup> Nodules with or without cavitation, simulating metastatic disease, have been seen with bleomycin toxicity. <sup>114,115</sup>

Both high-resolution, thin-section computed tomographic chest scans and gallium scintigraphy have been shown to be more sensitive techniques than chest radiography for detecting pulmonary parenchymal changes in association with drug toxicity. <sup>116,117</sup> Scintigraphy with technetium 99 aerosols appears to be highly sensitive for subtle capillary permeability defects in bleomycin toxicity. <sup>118</sup> The full relation of these changes to the development of functional or physiologic impairment is unclear, and further studies are needed. Magnetic resonance spectrometry may eventually be useful to differentiate among fibrosis, edema, and hemorrhage in the lung but, at present, it is not helpful in diagnosing interstitial lung disorders such as drug toxicity. <sup>119</sup>

### Pulmonary Function Tests

The most common abnormalities associated with chemotherapy-induced pulmonary toxicity are a reduced diffusing capacity for carbon monoxide and a restrictive ventilatory defect. <sup>62</sup> Isolated gas transport abnormalities, manifested by a decrease in the diffusing capacity or arterial hypoxemia, especially with exercise, have been seen. Screening pulmonary function tests to predict which patients receiving chemotherapy are likely to develop toxicity would be helpful but have not been established for most pulmonary toxic agents. In bleomycin toxicity, changes in the diffusing capacity may be transient, whereas decreases in total lung capacity seem to correlate better with radiographic abnormalities. <sup>120</sup>

### DIAGNOSIS

Although one might have a high clinical suspicion of drug-induced pulmonary toxicity, lung biopsy is usually necessary for a definitive diagnosis. Because pathognomonic pathologic changes associated with drug-induced pneumonitis often are not present, a biopsy is necessary to eliminate other specific diagnoses, such as opportunistic infection and malignancy. Through the use of bronchoalveolar lavage, several studies reported the presence of a characteristic or predominant cell associated with particular drugs. <sup>63,76</sup> Although these data might be of value in understanding the pathogenesis of drug-induced lung disorders, their usefulness in diagnosing drug toxicity is limited.

A serum marker for drug-induced pulmonary toxicity would be very useful. Though such a serum marker does not currently exist, initial studies of serum collagen type III N-propeptide in patients receiving neoadjuvant preoperative mitomycin, vinblastine, and cisplatin for stage III non-small cell lung cancer appear promising. <sup>121</sup> This peptide is elevated in serum after bleomycin treatment, but it does not correlate with toxicity. <sup>122</sup> Elevated levels of TGF- $\beta$  in plasma after high-dose chemotherapy for breast cancer predicted an increased risk of pulmonary toxicity after autologous bone marrow transplantation. <sup>123</sup>

### TREATMENT

The most effective way to manage pulmonary toxicity associated with chemotherapeutic agents is to prevent it. Animal studies of bleomycin toxicity showed a beneficial preventive effect of dietary supplementation with taurine and niacin; no comparable human studies have been reported. If toxicity occurs, withdrawal of the offending agent is the cornerstone of therapy. Although no controlled studies in humans have systematically examined the efficacy of corticosteroids, a trial of these agents probably is warranted in most cases. <sup>124,125</sup> The optimal dose and duration of therapy are not known; however, 1 mg/kg/d usually is initiated, with a slow and careful tapering schedule, because clinical deterioration after tapering has been reported. <sup>126,127</sup> One report described the case of a 23-year-old male patient who underwent a single lung transplantation because of presumed drug-induced pulmonary fibrosis 12 years after undergoing chemotherapy for acute lymphocytic leukemia. <sup>128</sup> The use of lung transplantation in the treatment of advanced drug-induced pulmonary fibrosis should be considered in appropriate patients, as more experience with successful lung transplantation in this setting is accumulating. <sup>129</sup>

## INTRODUCTION

The treatment of cancer has been vastly improved by the expansion of chemotherapeutic agents and refinement of radiotherapy over the past three decades. However, many of the most effective antineoplastic agents and mediastinal irradiation produce toxic effects on the heart. This chapter describes some of these problems and discusses attempts at prevention and management.

## CHEMOTHERAPY

### ANTHRACYCLINES

The anthracyclines have been associated with cardiomyopathy since their introduction in the late 1960s. Early reports included isolated cases of unexplained cardiac failure in patients undergoing treatment with daunorubicin <sup>1,2</sup> and <sup>3</sup> and later, in the early 1970s with doxorubicin. <sup>4,5,6,7</sup> and <sup>8</sup> Lefrak et al. <sup>9</sup> reported a series in 1973 of 399 patients treated with doxorubicin. He found a 30% incidence of cardiac failure in the patients who received more than 550 mg/m<sup>2</sup> of doxorubicin, and a lower incidence in those who received less. This introduced the concept of increasing cardiotoxicity with cumulative doses above a *safe threshold* cumulative dose. In 1974, Halazun et al. <sup>10</sup> reported a series of children with acute lymphoblastic leukemia, in remission, treated with two different maintenance protocols, one including and one excluding daunorubicin. There was a 10% incidence of cardiac failure in the arm with daunorubicin and none in the arm without. This report clearly demonstrated the relationship of anthracycline treatment to the incidence of cardiac failure, while it excluded the influence of active malignancy or the stress of induction therapy as contributory factors. Von Hoff et al. demonstrated, in 5613 patients treated with daunorubicin <sup>11</sup> and in 4018 patients treated with doxorubicin, <sup>12</sup> a continuous, almost exponential increase of incidence of cardiac failure with increasing cumulative dose. Subsequently, Bristow et al. <sup>13,14</sup> used endomyocardial biopsy to show that pathologic lesions progressively worsened in a linear relationship to the increase in total cumulative dose, in contrast to the nonlinear increase in myocardial dysfunction. This contrast suggested a threshold of *tolerable myocardial damage* beyond which the administration of additional drug would result in clinical symptomatology. Both clinical and pathologic abnormalities increased at any dose level in patients who received mediastinal radiotherapy. <sup>15</sup>

#### Clinical Presentation

Anthracycline cardiomyopathy has been described as having three clinical presentations: acute, subacute, and late. The acute toxicity <sup>16</sup> presents as a myopericarditis and probably results from the combination of acute myocyte damage from drug exposure and the effects of the catecholamine and histamine <sup>17</sup> surge provoked by the administration of anthracyclines. This occurs within days of a dose and includes transient arrhythmias, <sup>18,19</sup> pericardial effusion, and myocardial dysfunction, sometimes leading to transient cardiac failure and occasionally death. <sup>13,16</sup> Histologically, acute myocyte disruption and sometimes infiltration of the myocardium by granulocytes, lymphocytes, and histiocytes <sup>20</sup> are seen.

The classic subacute presentation has a more insidious onset and appears from 0 to 231 days after the last dose (up to 30 months later), <sup>21</sup> with a peak onset of symptoms at 3 months from the last dose. <sup>11</sup> The clinical picture presents with increasing tachycardia and fatigue, progressing in some patients to tachypnea, dyspnea, and finally pulmonary edema, right-sided congestive signs, and low cardiac output. The mortality of patients actually manifesting congestive heart failure in these early series ranged up to 60%, although some patients could be stabilized with intensive cardiac treatment, <sup>22,23</sup> and many showed remarkable improvement of cardiac function over the first few years after chemotherapy. <sup>23,24,25</sup> and <sup>26</sup> However, evaluation of hemodynamics with exercise has revealed significant underlying abnormalities even in asymptomatic patients with normal resting parameters. <sup>27</sup> The pathology noted on endomyocardial biopsy and autopsy within the first 2 years after completion of anthracyclines includes disruption and loss of myofibrils, mitochondrial swelling, and disruption of the sarcoplasmic reticulum producing intramyocyte vacuolization. <sup>15,28,29</sup> With mild toxicity such damage is patchy, whereas with higher doses and toxicity it is found more extensively throughout the heart, with progression to myocyte necrosis and loss. Changes in children and adults are similar except for the more frequent appearance of lipid droplets within the myocytes of children younger than age 10. <sup>30</sup> While some authors have reported the finding of infiltrates of T lymphocytes in biopsy specimens otherwise indicative of subacute anthracycline cardiomyopathy, <sup>31</sup> classically a lymphocytic infiltrate is absent. <sup>30</sup> The biopsy findings after treatment with anthracycline analogues have been similar. <sup>30</sup> Later pathologic examination, 41 to 47 months from chemotherapy, reveals hypertrophy of the remaining myocytes without fibrosis, and diminution of vacuolization, suggesting healing and compensation. <sup>32</sup>

The late presentation of anthracycline cardiomyopathy has been described to occur 5 or more years after completion of anthracycline therapy. <sup>33,34,35,36,37,38,39,40,41,42,43,44,45,46,47,48,49,50</sup> and <sup>51</sup> It involves late clinical decompensation of patients who had recovered from subacute cardiac symptoms <sup>33,34</sup> and <sup>35</sup> (Fig. 55.4-1), or the occurrence of cardiac failure *de novo* in patients with no previous symptoms, 6 to 25 years after anthracycline therapy. <sup>33,34,35,36,37</sup> and <sup>38,42</sup> It has also been demonstrated subclinically, as abnormal systolic cardiac function in 23%, <sup>33,34</sup> and <sup>35,42</sup> abnormal myocardial mass in 52%, <sup>38,39,40</sup> and <sup>41</sup> and abnormal exercise response in up to 80% of patients. <sup>43,44</sup> and <sup>45</sup> While some authors have reported abnormalities of diastolic function <sup>40,46</sup> others have found no significant diastolic changes. <sup>47,48</sup> The conflicting results may reflect different sensitivity of different diastolic measurements used. <sup>49</sup> As with subacute toxicity, an increased incidence of late abnormalities correlates with increasing cumulative dose of anthracycline received, and mediastinal irradiation is an additive risk factor. <sup>34,41,42,50</sup> However, late

abnormalities of resting echocardiography were found in patients treated with as little as 75 mg/m<sup>2</sup> of doxorubicin,<sup>39</sup> and late abnormalities of exercise response were seen in 55% of patients treated with low cumulative doses (median, 263 mg/m<sup>2</sup>).<sup>45</sup> A correlation of late cardiotoxicity with individual dose intensity has been reported.<sup>41</sup> Abnormalities of myocardial mass are said, by some authors, to be more pronounced in patients treated in early childhood, implying a negative effect on myocardial growth.<sup>38</sup> Abnormalities of systolic function did not correlate with age during chemotherapy.<sup>34</sup> Measurements of systolic function<sup>34,35</sup> and myocardial wall thickness<sup>39</sup> deteriorate progressively with increasing time after anthracyclines as emphasized in reports including patients followed for more than 15 years after completion of anthracycline therapy<sup>42</sup> (Fig. 55.4-2). Serious arrhythmias have been identified in symptomatic and asymptomatic patients at late cardiac follow-up, including ventricular tachycardia and fibrillation and second-degree heart block.<sup>34,35,37,45,51</sup> Several young patients with late cardiomyopathy have experienced sudden death up to 15 years after chemotherapy.<sup>34,35,36</sup> and<sup>37</sup> The pathology found on biopsy and autopsy of patients with late cardiotoxicity is predominantly fibrosis and hypertrophy of remaining myocytes, with little remaining vacuolization.<sup>34,35,36</sup> and<sup>37</sup> Thus, even asymptomatic patients who have been treated with anthracyclines need long-term cardiac follow-up, and new symptoms suggestive of arrhythmia and especially syncope need vigorous investigation. Cardiac status on noninvasive testing during the year after completion of therapy is predictive for the likelihood of late abnormality ( Fig. 55.4-3) and indicates the advisable frequency of follow-up.<sup>34,35</sup>

**FIGURE 55.4-1.** The clinical course of a patient after subclinical anthracycline cardiotoxicity. The initial increase and then progressive decrease of her fractional shortening on echocardiography and increasing requirements for therapeutic support of cardiac function can be seen. Despite an early fractional shortening of 11%, she gradually improved over the first 6 years. She discontinued diuretics, achieved modest exercise tolerance, and completed high school. Her fractional shortening on echocardiography reached 30% 6 years posttherapy. However, 8 years postdoxorubicin she required increasing amounts of diuretics for recurrent edema. Ten years postchemotherapy she had progressive deterioration of exercise tolerance and fractional shortening despite increasingly intensive medical management. During the last 2 years she was found to have moderately frequent premature ventricular contractions but no syncope or runs of ectopic ventricular beats. She was deemed unsuitable for cardiac transplant. Finally at 20 years post initial diagnosis and 17 years after her last anthracycline dose, she developed a tachy-bradyarrhythmia leading to sudden syncope and cardiac arrest. CHF, congestive failure; RT, radiotherapy; VPCS, ventricular premature contractions.

**FIGURE 55.4-2.** The percent of patients found to have abnormal echocardiogram results at the time of long-term follow-up is illustrated. Despite a similar cumulative anthracycline dose (495 vs. 420 mg/m<sup>2</sup>), 38% of those followed 10 years or longer had decreased fractional shortening (FS) as compared with 18% of those followed less than 10 years ( $P < .004$ ). More than 50% of the abnormalities (11 of 21) seen in the 10 year or longer group were moderate (FS = 21% to 24%) or severe (FS  $\geq 20\%$ ), while the degree of abnormality was mild (FS = 25% to 28%) in 77% (20 of 26) of the abnormal patients with shorter follow-up.

**FIGURE 55.4-3.** An echocardiogram (ECHO) taken after completion of anthracycline therapy has prognostic implications for cardiac function on late follow-up (LTFU). Eighty-seven percent of patients who had normal fractional shortening on echocardiography taken during the year posttherapy remained normal at LTFU, whereas only 29% of patients who were even mildly abnormal on end therapy echocardiography were normal at LTFU ( $P < .0001$ ). FU, follow-up; TD, total dose.

### Mechanisms of Pathogenesis

An understanding of the mechanism of cardiotoxicity provides the basis for attempts at prevention. There are many mechanisms proposed and several may interact to cause the multiple sites of intracellular injury seen histologically. In the mitochondria, there is a deletion mutation of mitochondrial DNA that increases proportionate to dosage and duration of anthracycline exposure.<sup>52</sup> In addition, doxorubicin is found to bind to cardiolipin in the inner mitochondrial membrane<sup>53,54</sup> with two deleterious results. The electron transfer in the respiratory chain, which is dependent on the binding of cardiolipin to cytochrome c for its interaction with cytochrome oxidase, and the activation by cardiolipin of the nicotinamide-adenine dinucleotide phosphate to cytochrome c oxidoreductase complex (complex I to III), for the synthesis of adenosine triphosphate (ATP), is disrupted. This leads to depletion of ATP and phosphocreatine concentrations and depression of contractility.<sup>55</sup> In addition, the doxorubicin-cardiolipin complex promotes transfer of electrons through doxorubicin, forming a doxorubicin free radical that can reduce molecular oxygen, producing O<sub>2</sub><sup>-</sup>. This induces the generation of free hydroxyl radicals and hydrogen peroxide, leading to mitochondrial membrane damage, further disruption of enzymatic respiration, and more extensive lipid peroxidation.<sup>53,54</sup> Oxidative damage is worsened by the concomitant decrease, during chemotherapy, in glutathione peroxidase, which normally serves as a free radical scavenger. Glutathione is especially important in myocytes, which lack catalase, which serves as a scavenger in other tissues. Free radical lipid peroxidation was identified<sup>56,57</sup> as an important mechanism of myocyte damage and has been found to depend, in the heart, on an iron-doxorubicin complex.<sup>54,58,59</sup> The resultant disruption of the sarcoplasmic reticulum and direct effects of the metabolite doxorubicinol<sup>60,61</sup> have been shown to cause disturbances of Ca<sup>2+</sup> transport,<sup>54,62</sup> such as decrease in calcium release channels,<sup>63</sup> which is critical to regulation of cardiac action potentials, contraction, and relaxation.<sup>64</sup> Chronically, there is alteration of contractile proteins and their enzymes with a shift in the ratio of prevalent isomyosin types and decreased production of a myosin

heavy chains, perhaps as an adaptation to chronic low-energy states. <sup>65</sup>

## Prevention

**MONITORING.** Attempts at prevention of cardiomyopathy initially involved limitation of total cumulative dose below 450 to 550 mg/m<sup>2</sup>. This limit was chosen to avoid the rapid increase in prevalence of clinical cardiac dysfunction, in excess of 30%, which occurs above that dose range. However, arbitrary dose limitation was inadequate because of variability of individual tolerance. Therefore, therapy has been modified according to serial monitoring of cardiac status, by various means, to identify increasing risk of unacceptable toxicity. Monitoring of systolic time intervals and of electrocardiography (ECG) for QRS voltage loss <sup>66</sup> or ST-T changes was too nonspecific or showed changes too late to direct prevention. Serial echocardiography has been helpful to identify changes in systolic and diastolic function, especially in children, in whom echo images are clear and more easily measurable. <sup>67,68,69,70,71,72</sup> and <sup>73</sup> The fractional shortening is the most frequent parameter followed, although some groups follow end-systolic wall stress and the relationship between wall stress and velocity of circumferential fiber shortening. <sup>71</sup> Early trends of rate of decrease in fractional shortening, at lower cumulative doses, have been reported to be predictive of eventual cardiac findings at end therapy, after higher cumulative doses. <sup>73</sup> Changes in posterior wall thickness appear to be more useful in late follow-up than for monitoring during chemotherapy. <sup>73</sup> Digitized echocardiography, with calculation of velocity of wall motion, thickening, and velocity of change of left ventricular chamber size in systole and diastole have been employed to enhance sensitivity. Radionuclide cardiac angiography has been used by many authors to follow systolic <sup>74,75,76</sup> and <sup>77</sup> and diastolic function, <sup>78,79</sup> and specific guidelines for modification of chemotherapy on the basis of radionuclide ejection fraction in adults, proposed by Schwartz et al., have gained wide acceptance. <sup>74</sup> Adherence to these guidelines reduced the incidence of cardiac failure from 21% to 3% in their study. The addition of measurements of contractility during exercise for comparison with those at rest has added sensitivity according to some authors, <sup>75,76</sup> and <sup>77</sup> but has been less helpful according to others. <sup>80</sup> Recommendations for monitoring, including radionuclide studies and quantitation of pathologic damage by endomyocardial biopsy, have been offered by investigators from Stanford University Medical Center. <sup>77</sup> However, these recommendations do not suggest monitoring until a cumulative dose of 450 mg/m<sup>2</sup> unless the baseline study is abnormal, the patient is older than 70 years of age, or has hypertension, other cardiac disease, or was receiving mediastinal irradiation. This will not identify early sensitivity in patients without those particular risk factors. Another format for monitoring, using a combination of echocardiography and radionuclide studies, was formulated by the multiinstitutional Cardiology Discipline Committee of the Children's Cancer Study Group. <sup>67,68</sup> These recommendations include cardiac evaluation before anthracyclines and further monitoring before every other course until a cumulative dose of 300 mg/m<sup>2</sup> and every course beyond this. Endomyocardial biopsy, which has proven to be safe and effective in experienced hands, with a complication rate of 1.5%, <sup>81,82</sup> is suggested to clarify abnormal or equivocal results. <sup>67</sup>

Although, not yet included in current routine monitoring, several newer modalities have been used for detection of toxicity. Tantalum 178 first-pass radionuclide imaging has allowed calculation of both right and left ventricular systolic function. <sup>83</sup> Indium-111-antimyosin scintigraphy <sup>84,85</sup> uses a monoclonal antibody labeled with <sup>111</sup>In that binds with cardiac myosin, which becomes exposed when cardiac myocytes are injured. Increasing uptake of <sup>111</sup>In during anthracycline therapy would imply increasing cardiac damage. Abnormalities of uptake of <sup>111</sup>In have been seen before a decrease in radionuclide ejection fraction <sup>86</sup> and could be used to compare damage from different methods of administration of conventional anthracyclines <sup>86</sup> or from different cardiotoxic agents. <sup>87</sup> This method was also reported to discriminate patients with sustained cardiotoxicity from those with transient decreases in ejection fraction or myocardial metastasis. <sup>88</sup> In studies in rats, the amount of cardiac <sup>111</sup>In uptake correlated with both histologic changes and end-diastolic pressure, and there was specific immunolocalization of the radiotracer in injured myocytes as opposed to normal neighboring ones microscopically. <sup>89</sup>

Another radionuclide, radioiodinated metaiodobenzylguanidine (<sup>123</sup>I-MIBG), has been used to indicate early anthracycline cardiotoxicity. MIBG is an analogue of norepinephrine and reflects cardiac adrenergic neuron integrity that is disrupted with anthracycline damage. Animal studies <sup>90</sup> and clinic trials <sup>91,92</sup> demonstrated abnormalities of uptake and clearance of MIBG even before abnormalities of systolic and diastolic function are seen by echocardiography. These MIBG abnormalities were proportionate to severity of systolic dysfunction in patients with toxicity.

Positron emission tomography has been used to identify metabolic changes suggesting cardiac damage in patients receiving chemotherapy. <sup>93</sup><sup>31</sup>P nuclear magnetic resonance spectroscopy has also demonstrated metabolic changes that correlate with the amount of doxorubicin-induced degeneration of myofibrils microscopically. <sup>94</sup>

Reports on the usefulness of monitoring serum levels of troponin T postmyocardial infarction, to detect limited myocardial necrosis, prompted investigation of this method's usefulness to detect early anthracycline damage. Although animal study results seem promising, <sup>95</sup> clinical trials are still in progress. Therefore, this method remains investigational and is not yet recommended for routine monitoring. Some investigators have reported that elevated serum natriuretic peptide, which is released in response to chronic or acute increase in atrial transmural pressure and stretch, may be a marker for anthracycline damage. <sup>96</sup>

Schwartz et al. correlated prolongation of the corrected QT interval (QTc) on 12-lead ECG with increasing anthracycline dose in both acute and chronic anthracycline cardiomyopathy. <sup>97</sup> Careful attention to concomitant electrolyte and calcium imbalance is clearly mandatory to avoid false results. Jakacki et al. suggested an algorithm combining measurement of QTc with fractional shortening on echocardiography and a history of exercise intolerance for screening. <sup>98</sup> Another new measurement from signal-averaged ECG, that of ventricular late potentials, may also have predictive value. <sup>99</sup>

**SCHEDULE MODIFICATION.** Other attempts to prevent cardiomyopathy involve decreasing the peak dose of anthracycline delivered to the heart by modification of schedules of delivery. <sup>100,101,102,103,104,105</sup> and <sup>106</sup> Legha et al. demonstrated that patients receiving continuous infusions of doxorubicin developed lower peak plasma levels the longer the time of the infusion. <sup>100</sup> Thus, levels with a 48-hour infusion were lower than with a 24-hour infusion and a 96-hour infusion of the same dose per course produced still lower levels. They proved by comparing endomyocardial biopsy scores in patients receiving doxorubicin that patients receiving their dose by 48- or 96-hour infusion had significantly lower biopsy scores, indicating less cardiomyopathy than patients receiving the dose by 20-minute bolus. In addition, the patients receiving 96-hour infusions had lower biopsy scores than those receiving 24-hour infusions. Infusions were administered through an indwelling intravenous line using a battery-powered portable pump. Currently, continuous infusion chemotherapy is usually given through a surgically implanted central venous access catheter. A study by Shapira et al., using radionuclide cardiac angiography to evaluate cardiotoxicity, demonstrated a decline in left ventricular ejection fraction (LVEF) of only 6% after a total cumulative dose of 400 mg/m<sup>2</sup> administered by only 6-hour continuous infusion, compared with a decrease of 21% in patients who received the same range of total doxorubicin dose by 20-minute bolus. <sup>102</sup> Casper et al. confirmed the cardioprotective effects of 72-hour infusion in a prospective randomized trial of 82 patients with soft tissue sarcoma. <sup>101</sup> The article suggested, however, that continuous infusion might have a negative effect on antitumor efficacy, although this was not conclusive since their infusion patients had tumors with worse prognostic features than their bolus patients. Other uncontrolled trials using continuous infusion for various solid tumors have shown no decrease in efficacy. <sup>105</sup> Reports of prospective randomized trials comparing infusion with bolus for treatment of leukemia, in which efficacy can be measured by percent cell kill on bone marrow sampling, <sup>103</sup> and in osteogenic sarcoma in which it is measured as histologic response of the surgically removed tumor after preoperative chemotherapy, <sup>106</sup> have shown no significant decrease in antitumor efficacy with continuous infusion. In fact, in the leukemia study, efficacy was better with infusion. <sup>103</sup> Schedules dividing the planned monthly doxorubicin dose into smaller weekly dosages have also decreased pathologic and physiologic abnormalities, allowing higher cumulative doses to be given. <sup>107,108</sup>

## Cardioprotective Agents

Free radical scavengers vitamin E, <sup>109</sup> ascorbic acid, <sup>110</sup> N-acetyl-cysteine, <sup>111</sup> and others <sup>112,113</sup> have shown promise in animals but no clear benefit in patients, although results of one study in rats using the lipid-lowering antioxidant agent probucol seem encouraging. <sup>114</sup> Similarly, trials of concomitant administration of verapamil, <sup>115,116</sup> prenylamine, <sup>117</sup> other calcium channel blockers, and b-adrenergic and histamine blockers <sup>118,119</sup> to prevent the effects of excessive vasoactive agents, antiinflammatory agents, carnitine, digoxin, <sup>120</sup> and amrinone <sup>121</sup> have not yet proven definitively useful in patients. Studies are ongoing examining the usefulness of coenzyme Q10 <sup>122</sup> and amifostine. <sup>123</sup> Encapsulation of the anthracycline in liposomes and binding to agarose <sup>124</sup> were initially disappointing. However, the use of more stable liposomal complexes has provided some protection. <sup>125,126</sup>

Attempts to exploit the importance of the iron-doxorubicin complex appear to be more successful. The classic chelator deferoxamine did not prevent anthracycline cardiomyopathy in normal as opposed to iron overloaded cardiac cells. <sup>127</sup> However, 1-2-bis(3,5-dioxopiperaziny-1-yl) propane, known as ICRF-187, ADR-529, or dexrazoxane and commercially as Zinecard or Cardioxane, an iron chelator that achieves better intracellular concentration, has been shown in various animals, <sup>128,129</sup> and <sup>130</sup> and several human studies to exhibit significant protection against anthracycline cardiomyopathy. Animal studies have demonstrated healing of lesions within 3 months after discontinuation of therapy in rabbits treated with ICRF. <sup>131</sup> Initial clinical trials included a pilot study of 12 patients with various solid tumors <sup>132</sup> and a randomized therapeutic trial in women with breast cancer. <sup>133,134</sup> and <sup>135</sup> Patients were evaluated both by radionuclide ejection fraction and myocardial biopsy. Incidence of clinical toxicity, degree of decrease of ejection fraction, and biopsy score were significantly less in the ICRF arm. These results have been confirmed in a large

multicenter trial, in adults with breast cancer using fluorouracil, doxorubicin, and cyclophosphamide (FAC), and small cell lung cancer, using similar cardiac monitoring.<sup>136,137,138 and 139</sup> Smaller trials have been equally promising in pediatric patients.<sup>140,141,142 and 143</sup> The multicenter adult trial<sup>136,137,138 and 139</sup> and larger pediatric trials<sup>143</sup> have also attempted to examine the effect of ICRF on antimalignant efficacy, which seems, in most cases, to be preserved.<sup>143</sup> Investigators had hoped to combine the protective effects of infusion scheduling of doxorubicin and concomitant ICRF. To that end, studies of infusional ICRF are in progress.<sup>144</sup>

This agent appears to also provide cardiac protection for anthracycline analogues such as epirubicin<sup>85,145,146</sup> and mitoxantrone.<sup>146,147 and 148</sup>

**NEW ANALOGUES.** Analogues of daunorubicin and doxorubicin have been studied in clinical trials. Many agents that appear to have decreased cardiotoxicity in animal studies and even in early clinical trials eventually have been found to have similar toxicity to the parent compound. Patients treated with zorubicin experienced cardiotoxicity that was additive to prior anthracycline toxicity and some developed cardiac failure.<sup>149,150</sup> 4'Epi-doxorubicin is another analogue with cardiotoxicity similar to or possibly less<sup>151,152 and 153</sup> than doxorubicin. Incidences of atrioventricular block, ventricular fibrillation, decreased ejection fraction, and decreased velocity of circumferential fiber shortening<sup>154,155</sup> have been reported in phase I and II trials with another analogue, aclarubicin. Demethoxy daunorubicin (Idarubicin) has shown activity in patients whose malignancy has become resistant to daunorubicin. However, it is also cardiotoxic.<sup>156,157</sup> Its myelotoxicity is approximately four times that of daunorubicin milligram for milligram. When given in amounts of equivalent myelotoxicity, the cardiotoxicity is also similar.<sup>157,158</sup> Thus, careful monitoring of this agent would be warranted above a cumulative dose of 75 mg/m<sup>2</sup>. Cardiac failure and subclinical decrease in ejection fraction occurred in patients treated with the analogue esorubicin. A 5% drop in mean LVEF was noted at 240 mg/m<sup>2</sup> and a 10% drop at 480 mg/m<sup>2</sup> of this agent.<sup>159</sup> Animal studies of 4'-deoxy-4'-iodo-doxorubicinol indicate acute and chronic cardiotoxicity but possibly less than daunorubicin.<sup>160</sup> The ideal anthracycline has not yet been found.

### Management

Clinical anthracycline cardiomyopathy needs to be managed with inotropic support and afterload reduction,<sup>20</sup> often initially by the intravenous route. Angiotensin-converting enzyme inhibitors have played an important role in stabilizing cardiac failure and delaying further myocardial deterioration.<sup>37,51</sup> Current reports suggest that selective  $\beta$ -receptor blockers, such as metoprolol<sup>161</sup> and more recently carvedilol,<sup>162</sup> may be useful in patients who do not improve with these modalities. Control of malignant arrhythmias may require intensive medical management with drugs such as amiodarone and mexiletine or placement of indwelling automatic cardioverters and pacemakers.<sup>37,42,51</sup> Most patients can be stabilized and show clinical improvement. Patients who have been refractory to treatment or have repeat bouts of pulmonary edema and are free of malignancy have benefited from cardiac transplantation.<sup>163,164,165,166 and 167</sup>

### MITOXANTRONE

Mitoxantrone hydrochloride is an anthracenedione that is similar in structure to doxorubicin. It was found to be toxic to cardiac cells in culture despite a lack of production of free radical peroxidation.<sup>147</sup> The toxicity appeared to involve an interaction with iron similar to that of doxorubicin.<sup>147</sup> Animal studies revealed conflicting findings in different species. There were ECG abnormalities in treated monkeys and dose-related impairment of contractility in the rabbit heart,<sup>168</sup> but no ECG changes or progressive anthracycline-like lesions on endomyocardial biopsy specimens of Beagle hearts.<sup>169</sup> There were cases of cardiac failure and arrhythmia (mainly supraventricular) reported from the early phase I and II trials under the auspices of the National Cancer Institute.<sup>170,171</sup> The incidence of myocardial dysfunction and cardiac failure increased with increasing cumulative dose as with doxorubicin.<sup>170,172</sup> Significant decreases in ejection fraction occurred in these trials around 110 mg/m<sup>2</sup><sup>170</sup> and a rapid increase in incidence of cardiac failure was noted at 160 mg/m<sup>2</sup>.<sup>172</sup> Later studies have continued to detect cardiomyopathy and cardiac failure in patients with<sup>173</sup> and without<sup>174</sup> prior anthracycline therapy, and conduction delay, with prolongation of PR, QRS, and QT interval on ECG, was also reported.<sup>175</sup> A British patient trial reported a 46% incidence of abnormal LVEF, using radionuclide angiography during rest and cold pressor stress, in patients who received a wide range of doses.<sup>176</sup> A Greek cooperative study found decreases in ejection fraction of greater than or equal to 10% within normal range, in 10% of patients tested, and they reported minimal changes in echo systolic function and significant changes in systolic time intervals in the patient cohort as a whole, after receiving 60 mg/m<sup>2</sup> combined with cyclophosphamide and fluorouracil.<sup>177</sup> An Italian trial reported ECG abnormalities in 41%, echocardiographic abnormalities in 66%, and a greater than or equal to 15% decrease in radionuclide LVEF in almost 25% of patients receiving a cumulative dose of 28 to 84 mg/m<sup>2</sup>.<sup>178</sup> The overall incidence, reported by Immunex Laboratories, of subclinical moderate to serious decrement in LVEF was 13%, and the incidence of cardiac failure, up to a cumulative dose of 140 mg/m<sup>2</sup>, was 2.6%.<sup>179</sup>

### AMSACRINE

Amsacrine (AMSA) is an acridine derivative used mainly in nonlymphoblastic leukemia. It has been associated with myocardial infarction<sup>180</sup> and ventricular and supraventricular arrhythmias including fatal ventricular fibrillation.<sup>181,182,183 and 184</sup> Many of these arrhythmias have been attributed to coexisting electrolyte abnormalities, particularly hypokalemia, and more recently AMSA has been safely administered even to patients with preexisting atrial<sup>189</sup> and ventricular<sup>185</sup> arrhythmias. Noninvasive monitoring of cardiac function during a prospective study of AMSA revealed reversible abnormalities on serial echocardiography in 18 of 27 patients and cardiac failure in 7 of 27 patients.<sup>186,187</sup> Echocardiographic abnormalities generally appeared within a week of AMSA therapy and resolved in most, once therapy was discontinued. Four patients died with persistent cardiac failure. The incidence of echocardiographic abnormalities was related to total dose of AMSA, rate of AMSA administration, and the total dose of anthracyclines previously received. No patient who received less than 200 mg/m<sup>2</sup> AMSA in 48 hours, after having received less than 400 mg/m<sup>2</sup> of anthracyclines, had echocardiographic abnormalities. In contrast, all patients who received greater than or equal to 200 mg/m<sup>2</sup> of AMSA within 48 hours after having received greater than 400 mg/m<sup>2</sup> of anthracyclines exhibited echocardiographic abnormalities.<sup>186</sup> More recently, Arlin et al. treated 24 patients with preexisting myocardial dysfunction with AMSA greater than 200 mg/m<sup>2</sup>/48 hours and reported no occurrences of cardiac failure in this group.<sup>188</sup> Nine of the patients had radionuclide ejection fractions determined after AMSA treatment and two of nine showed a further decrease of ejection fraction by more than 10%. It is not stated how soon after treatment the radionuclide angiograms were obtained. Therefore, it is possible that there were additional transient deficits that were not detected in this study. However, the absence of any clinical cardiac failure in these heavily treated patients is significant.

### CYCLOPHOSPHAMIDE

There is still disagreement if doses of cyclophosphamide under 100 mg/kg/week contribute to cardiomyopathy,<sup>13,24,107,189</sup> and in our experience such doses do not. However, higher doses used for cytoreduction and immunosuppression before bone marrow transplantation can cause an acute hemorrhagic pancarditis. It was initially described in case reports,<sup>190,191 and 192</sup> animal studies,<sup>193</sup> and autopsy series<sup>194,195</sup> as involving a serosanguinous pericardial effusion, mural thickening with edema, and endocardial, myocardial, and epicardial hemorrhage. This results from endothelial capillary damage that allows extravasation of fluid and red cells into cardiac and pulmonary tissues. Reports of patient series<sup>196,197,198 and 199</sup> described the acute course, with an onset during the first week posttreatment, peak toxicity at 7 to 9 days, and improvement over the next 3 weeks. Abnormal findings of diastolic dysfunction, small to moderate pericardial effusion, restrictive cardiomyopathy, sometimes mimicking pericardial tamponade, and later systolic dysfunction, were found in more than one-half the patients.<sup>197,198 and 199</sup> The most frequent ECG change seen was decreased voltage, which did not necessarily correlate with impairment of function.<sup>197,198 and 199</sup> Abnormalities of T waves and ST segment and arrhythmias are seen,<sup>200</sup> including complete heart block<sup>201</sup> and ventricular tachyarrhythmias.<sup>200</sup> Some arrhythmias may be due to the infusion of the cryopreserved marrow graft.<sup>202</sup> The majority of patients remained asymptomatic.<sup>197,199,203</sup> Some had mild symptoms of fluid retention, edema, and tachypnea, and a few had an extremely fulminant course of cardiac failure shock and death that was resistant to even intensive treatment. Risk factors of previous anthracycline therapy and previous abnormal cardiac function were identified and the importance of dose and rate of delivery was stressed.<sup>197,204</sup> A weekly dose of 170 mg/kg over 4 days without anthracyclines and 120 mg/kg over 2 days after anthracyclines predicted risk for at least subclinical changes. More rapid delivery of 120 mg/kg over 24 hours produced fulminant cardiomyopathy in one patient.<sup>192,194</sup> Mildly symptomatic patients responded to diuretics and, if necessary, transient digitalization or intravenous inotropic agents. Those with the more fulminant course required prolonged intravenous inotropic support, respiratory assistance, and hemofiltration.<sup>199</sup> Pericardial drainage has not been helpful usually, although rare cases of true cardiac tamponade responding to pericardiocentesis have been reported.<sup>205</sup> In most cases the effusion can be managed with analgesics and corticosteroids.<sup>206</sup> To avoid this clinical cardiotoxicity, patients have been screened during the past decade with echocardiography or radionuclide studies to identify abnormal cardiac function and the pretransplant regimen adjusted for higher risk patients by administering the cyclophosphamide over additional days or using a preparative regimen without cyclophosphamide. A pretreatment radionuclide LVEF of less than 50%,<sup>207,208</sup> or even less than 55%,<sup>209</sup> has been correlated with increased risk of cardiotoxicity.<sup>207,208 and 209</sup> Studies have suggested that giving the cyclophosphamide by infusion or in smaller twice-a-day doses decreased the incidence of systolic dysfunction, although changes of myocardial mass were still seen.<sup>208</sup> Evaluation of patients' hemodynamics during exercise at least a year after transplant has shown significant abnormalities in children treated for malignancy before transplant with anthracyclines. However, the few children

with aplastic anemia, who had not received anthracyclines, were normal.<sup>210</sup>

## IFOSFAMIDE

Ifosfamide, an alkylating oxazaphosphorine related to cyclophosphamide, has been associated with atrial ectopy (including atrial fibrillation) and, less commonly, ST-T wave changes and bradycardia. These abnormalities were noted in patients who had received doses as high as 6.25 to 10.0 g/m<sup>2</sup> over 3 to 5 days.<sup>211</sup> One series reported an incidence of congestive heart failure in 9 of 52 patients enrolled in a phase I trial of high-dose ifosfamide with other agents with autologous marrow transplantation.<sup>212</sup> ECG abnormalities, negative inotropic effects, and pathologic myocardial damage were also found in animals who received high doses of ifosfamide.<sup>213,214</sup>

## RETINOIC ACID

*Trans*-retinoic acid is an active agent for the treatment of acute promyelocytic leukemia. However, in more than 10% of patients, a syndrome is produced, known as *RA syndrome*, involving fever, dyspnea, pleural and pericardial effusion, pulmonary infiltrates, peripheral edema, and transient myocardial dysfunction and heart failure.<sup>215</sup> This is especially prevalent during the first 2 weeks of therapy and has responded to dexamethasone.

## TAXANES

Paclitaxel (Taxol) has been described as causing abnormalities of cardiac rhythm, conduction, and function. In preclinical studies, paclitaxel produced arrhythmias and slowing of beat frequencies of rat cardiac cells growing *in vitro*.<sup>216</sup> Cases of clinically significant disturbances of cardiac rhythm and conduction were reported during phase I and II trials of this agent.<sup>217</sup> Significant sinus bradycardia (heart rate, 30 to 50 bpm) was common, occurring in up to 29% of patients in a phase II trial for ovarian cancer.<sup>218</sup> Several patients exhibited progressive although transient atrioventricular conduction delay from first-degree heart block, to complete heart block, to asystole<sup>218</sup> on continuous ECG monitoring during paclitaxel infusion as a single agent. Associated presyncope and syncope have been reported,<sup>217</sup> requiring temporary pacing. Episodes of sustained and nonsustained ventricular tachycardia have been reported with the combination of paclitaxel and cisplatin.<sup>219</sup> However, Markman et al. used this combination successfully in patients with significant preexisting cardiac risk factors.<sup>220</sup> Since few of their patients had significant preexisting conduction disorders, it is still recommended that patients with arrhythmia or abnormal conduction be monitored with continuous ECG during paclitaxel administration. The combination of paclitaxel with doxorubicin for the treatment of breast cancer has resulted in an increased incidence of clinically significant deterioration of left ventricular function at a lower cumulative dose of doxorubicin. It has been suggested that this is due to interaction between the two agents resulting in decreased elimination of the doxorubicin and that the cumulative doxorubicin dose should be limited to 340 to 380 mg/m<sup>2</sup> in this combination.<sup>221</sup> Preliminary experience with the synthetic analogue docetaxel (Taxatere) suggested similar potential for dysrhythmia; however, clinical trials have not shown cardiotoxicity of this agent or significant increase in doxorubicin toxicity when docetaxel and doxorubicin are combined.<sup>222</sup>

## HOMOHARRINGTONINE

Homoharringtonine is an alkaloid from the Chinese *Cephalotaxus*. It is another drug that causes reversible atrioventricular block,<sup>223</sup> ventricular ectopy,<sup>224</sup> supraventricular tachycardia, and ST-T wave changes in animals<sup>225</sup> and patients.<sup>223</sup> It has also produced cardiac failure and hypotension, with vacuolar degeneration of the myocardium on pathologic examination.<sup>223,225</sup>

## VINCRIStINE AND VINBLASTINE

Vincristine has been associated with cardiac autonomic dysfunction. One study demonstrated a loss of cyclic respiratory phase-related heart rate variation in nine children during vincristine treatment.<sup>226</sup>

Vincristine<sup>227,228</sup> and vinblastine<sup>230</sup> have also been associated with myocardial infarction. Angina pectoris was reported in up to 38% of patients during treatment with vinblastine combined with cisplatin and bleomycin.<sup>231</sup> Another study of the same combination, reported angina with infarct-like ECG changes and apical akinesia occurring repeatedly, during multiple courses, in a 47-year-old patient with normal coronary angiography.<sup>232</sup> This seemed to clearly implicate the chemotherapy as the cause.

## MITOMYCIN C

Mitomycin C has been reported to increase the incidence of anthracycline cardiotoxicity when these agents are combined<sup>233</sup> due to enhancement of formation of superoxide and hydrogen peroxide.<sup>234</sup> It has more recently been described as a cause of acute congestive heart failure in a woman who received a cumulative dose of 225 mg/m<sup>2</sup> of mitomycin as a single agent<sup>235</sup> and in another patient when 30 mg/m<sup>2</sup> of mitomycin was added to treatment with 150 mg/m<sup>2</sup> of doxorubicin.<sup>236</sup> The overall incidence of cardiotoxicity is said to be under 10% and limited to patients receiving a cumulative dose of at least 30 mg/m<sup>2</sup>.<sup>236,237</sup>

## 5-FLUOROURACIL

The cardiotoxicity of 5-fluorouracil was first identified by Dent and McColl in 1975.<sup>238</sup> A survey of 1083 patients in 1982 reported cardiotoxicity in 1.1% of all patients, and 4.6% of patients with prior evidence of heart disease.<sup>239</sup> By 1990 there were more than 67 clinical cases described.<sup>240</sup> Since then, more frequent use of continuous infusion 5-fluorouracil increased awareness of the problem, and more sophisticated monitoring has increased the reported incidence. Thus, by 1991 another large cooperative series of 1145 patients included 31 patients with cardiac symptoms including four cardiotoxic deaths, an incidence of almost 3% of all patients.<sup>241</sup> An even higher incidence of cardiotoxicity of 7.6% was reported from a prospective study of high-dose continuous infusion in 1992.<sup>242</sup> An incidence of silent ischemic ECG changes, as high as 68%, was identified in patients monitored by continuous 24-hour ambulatory ECG during fluorouracil infusion.<sup>243</sup> The cardiotoxicity described has involved (1) precordial pain (both nonspecific and anginal)<sup>240</sup>; (2) ECG ST-T wave changes (nonspecific and ischemic)<sup>240,243,244</sup>; (3) acute myocardial infarction (rare)<sup>244,245</sup> and <sup>246</sup>; (4) atrial arrhythmias (including atrial fibrillation) and, less frequently, ventricular ectopy (including refractory ventricular tachycardia and fibrillation)<sup>243,244,245,246,247</sup> and <sup>248</sup>; (5) ventricular dysfunction (usually global, less frequently segmental); (6) cardiac failure, pulmonary edema, and cardiogenic shock (with and without ischemic symptoms)<sup>246,248,249,250,251</sup> and <sup>252</sup>; and (7) sudden death.<sup>246,247</sup> In most cases the arrhythmias were treatable and the *ischemia-like* symptoms and ECG changes disappeared if the infusion was discontinued, or responded to nitrates, allowing the infusion to continue. The abnormalities of segmental and global ventricular function reverted to normal within days to weeks of cessation of infusion. However, some patients needed intravenous inotropic and vasodilator support during the initial period.<sup>248,249</sup> and <sup>250,252,253</sup> In most cases with chest pain with or without ECG changes, the creatine phosphokinase (CPK) MB fraction remained normal.<sup>240,246,249,251</sup> Most frequently, patients developed cardiac toxicity during the second or later course of treatment, but some experienced problems during the first course.<sup>240</sup> Those who developed cardiac toxicity and recovered, usually had symptoms again when rechallenged with another infusion.<sup>240,246,248</sup> Some investigators reported success in preventing cardiotoxicity with calcium blockers such as nifedipine and diltiazem,<sup>254</sup> whereas others had less success.<sup>251,255</sup> There was no influence of age or sex on incidence.<sup>240</sup> Symptoms were reported in a 38-year-old man<sup>252</sup> and several women in their 40s<sup>240,249,250</sup> with no prior cardiac history. Cardiac findings have occurred when 5-fluorouracil was given by infusion or bolus, as a single agent, or with cisplatin and other drugs.<sup>240,244</sup> While some believed that cardiac irradiation<sup>256</sup> and preexisting heart disease<sup>239,243</sup> were risk factors, others did not.<sup>240,257</sup> Several investigators have documented normal coronary arteries in patients with severe symptoms.<sup>246,250</sup> One investigator excluded increased proclivity for coronary vasospasm by challenging a patient, who had previous angina during fluorouracil infusion, with ergonovine during a posttreatment coronary study.<sup>246</sup> Findings on autopsy and endomyocardial biopsy have shown diffuse, interstitial edema, intracytoplasmic vacuolization of myocytes, and no inflammatory infiltrate.<sup>258</sup> Acute infarcts have been demonstrated pathologically in some, but not all, patients with clinical infarction.<sup>240</sup>

The ischemic-like pain and ECG findings, with lack of CPK MB changes, with frequent response to nitrates and at times to calcium channel blockers, in the setting of anatomically normal coronary angiograms plus reversible contractility deficits, would suggest coronary vasospasm as a mechanism for fluorouracil cardiotoxicity. However, the global dysfunction, possibly due to *stunned myocardium*, and lack of universal response to coronary vasodilators leaves some questions about this hypothesis and some postulate a myocarditis or myocardiopathy etiology.<sup>259,260</sup> and <sup>261</sup>

Although the mechanism is still uncertain, it seems clear that careful observation for cardiac symptoms and arrhythmias is warranted during drug infusion, especially

in patients who have been symptomatic in prior courses.

## CISPLATIN

Cisplatin has been associated with arrhythmias such as atrial fibrillation<sup>262</sup> and with angina and ST-T wave changes on ECG.<sup>263,264,265 and 266</sup> These may be caused or exacerbated by electrolyte imbalances from the excessive hydration and forced diuresis required for the drug's administration.

## INTERFERON

Cardiotoxicity has been identified in 44 of 432 patients from 15 phase I clinical trials of interferon-a, a<sub>2</sub>, b, and g.<sup>267</sup> Significant abnormalities of cardiac rhythm and conduction,<sup>267,268,269 and 270</sup> ischemia and infarction,<sup>267,271,272,273 and 274</sup> and cardiomyopathy<sup>267,274,275 and 276</sup> were observed. These problems were identified with all types of interferon used except interferon-b, which was used in only a small subset of the patients.<sup>267</sup> No correlation with patient age, individual dose, or cumulative dose was identified although some patients had less toxicity when retreated at doses lower than the dose producing toxicity.<sup>267,275</sup> Cardiomyopathy was seen in patients after more prolonged treatment,<sup>275</sup> but the other forms of toxicity were seen frequently during the first 5 weeks of treatment, even within 1 to 7 days of initiation of therapy.<sup>267</sup> The occurrence of ischemia and infarction was definitely related to a prior history of ischemic heart disease and may have related to increased myocardial oxygen demand from the fever and stress of the flu-like syndrome accompanying treatment or to peripheral and coronary arterial constriction.<sup>267</sup> The arrhythmias were less clearly related to prior heart disease but may have been exacerbated by the features of this flu-like syndrome as well. Arrhythmias and ischemic ECG changes were identified in mice treated with interferon-a with no myocardial lesions on necropsy, suggesting mediation by peripheral effects.<sup>270</sup> Arrhythmias have been seen in up to 20% of patients in clinical trials.<sup>269</sup> The arrhythmias observed include fatal<sup>277</sup> and reversible<sup>278</sup> ventricular fibrillation, ventricular tachycardia,<sup>268,269</sup> atrial flutter and fibrillation, atrioventricular block, and less severe atrial and ventricular ectopy.<sup>267</sup> Sudden death was seen in two patients.<sup>267</sup> Cardiomyopathy, presenting as cardiac failure, with severe decrease in radionuclide ejection fraction to 10% to 33%, was seen in seven patients during prolonged administration of interferon-a or interferon-a<sub>2</sub>.<sup>275,276,279,280</sup> The cardiomyopathy was reversible in four of the patients after cessation of interferon, with and without inotropic, diuretic, and afterload reduction therapy. Congestive symptoms disappeared and ejection fractions improved to 29% to 46%. Two patients were able to be retreated with lower doses of interferon without return of failure. Three of the patients with reversible cardiomyopathy had acquired immunodeficiency syndrome (AIDS) with Kaposi's sarcoma.<sup>275</sup> However, AIDS-associated cardiomyopathy is not reversible. Two others had chronic myelogenous leukemia<sup>279</sup> and hairy cell leukemia,<sup>276</sup> and two more patients had other cancer.<sup>280</sup> Myocardial biopsy in one patient revealed only mild focal intramyocyte vacuolization.<sup>275</sup> The etiologic mechanism is unknown. *In vitro* studies have been conflicting. One study in isolated rat cardiac myocytes, incubated with interferon, showed inhibition of contractility and depletion of ATP,<sup>281</sup> while another similar study did not.<sup>282</sup> Some postulate an interaction between interferon and noradrenaline.<sup>267,283</sup> Cautious observation for cardiac symptoms and monitoring of rhythm appear to be warranted for these agents with reduction in dose for significant abnormalities.

## OTHER BIOLOGIC AGENTS

Interleukin-2 and tumor necrosis factor produced no reduction of ATP or decrease in contractility when incubated with isolated rat cardiac myocytes for 24 to 48 hours.<sup>282</sup> However, a major reduction of ventricular stroke work index was found in patients with a variety of solid tumors monitored with indwelling arterial and pulmonary catheters during interleukin-2 treatment.<sup>284</sup> This resulted from a poor increase in cardiac index in comparison with the decrease in peripheral resistance. All patients developed a capillary leak syndrome<sup>285</sup> requiring dopamine and crystalloid support. Deleterious effects on blood pressure, systemic resistance, and stroke work appeared to peak at approximately 4 hours after individual doses and to worsen with subsequent doses.<sup>284</sup> In addition, there has been a significant (4% to 30% in various trials) incidence of apparent myocardial infarction with this agent.<sup>274,284,285,286,287,288,289 and 290</sup> One patient with elevated CPK MB fraction, focal injury pattern on ECG, and segmental wall motion abnormality on radionuclide angiography underwent coronary angiography, revealing normal coronary arteries.<sup>291</sup> This suggested a pathogenesis involving coronary vasospasm or focal myocarditis. A series of 199 patients had an incidence of 6% arrhythmias including ventricular tachycardia, 53% hypotension, and 25% elevated CPK MB.<sup>292</sup> Another biologic agent, interleukin-4, has been associated with myocarditis.<sup>293</sup>

A new biologic agent OK432 derived from *Streptococcus* was suspected of inducing an autoimmune cardiomyopathy. However, it was shown not to provoke the formation of antiheart antibody or ECG changes in rabbits or human patients.<sup>294</sup> Continued evidence of lack of cardiotoxicity should remove an obstacle toward its development as an active anticancer agent.

Trastuzumab (Herceptin), a humanized monoclonal antibody developed to target the HER2 receptor (an epidermal growth factor receptor that is overexpressed in many types of tumor cells), has been associated with cardiotoxicity in several clinical trials.<sup>295,296 and 297</sup> The toxicity was manifested as deteriorating systolic function with either asymptomatic decrease in ejection fraction or congestive heart failure similar to anthracycline toxicity. This was observed, however, mainly in patients who had previously received anthracyclines or were concomitantly receiving anthracyclines.<sup>296</sup> Therefore, it is not clear that trastuzumab is itself cardiotoxic or rather potentiates the cardiotoxicity from the previous or ongoing anthracycline therapy. The mechanism of the cardiotoxicity is unknown and histologic information from endomyocardial biopsy is not available. However, clinical and noninvasive evidence of abnormal systolic function was seen more than four times as frequently in patients treated with doxorubicin plus trastuzumab (27%) as in patients treated with doxorubicin alone (6%) in a phase III clinical trial.<sup>295,296</sup> In another randomized clinical trial there was more congestive heart failure in patients treated with paclitaxel and trastuzumab (11%) than in patients treated with paclitaxel alone (1%).<sup>297</sup> In a third trial, a single-arm study, there was a 7% incidence of congestive failure in 213 patients receiving trastuzumab alone.<sup>297</sup> Clearly the cardiotoxic potential of this promising agent will require further investigation, and patients treated with both trastuzumab and an anthracycline need careful monitoring.

## OTHER AGENTS

Case reports have attributed cardiotoxicity to several other agents. Melphalan,<sup>298</sup> Bis(helenal)malonate,<sup>299</sup> mithramycin,<sup>300</sup> and bis[1,2-bis(diphenylphosphino)ethane] gold (I) chloride (a cytotoxic antineoplastic drug containing gold),<sup>301</sup> teniposide,<sup>302</sup> etoposide,<sup>303</sup> busulfan,<sup>304</sup> and deoxycofomycin<sup>305</sup> have been implicated in this respect.

## AGENTS USED FOR SUPPORTIVE CARE

Patients undergoing therapy for cancer usually receive various medications, in addition to their chemotherapeutic agents, especially for supportive care and treatment of toxicity. Some of these may also have cardiotoxic effects. For example, granisetron, an antiemetic, has been associated with sinus bradycardia, atrioventricular block varying from increased PR interval to Wenckebach's and junctional rhythm.<sup>306</sup> The cytokines, granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor, have been associated with pericardial effusion.

## RADIATION-INDUCED HEART DISEASE

Cardiac complications resulting from mediastinal irradiation were considered rare and insignificant for a long period in the history of radiotherapy.<sup>307,308</sup> Since the mid-1960s, when follow-up information on a large number of patients who had been cured of Hodgkin's disease (HD) with higher doses of radiation became available, the heart has no longer been considered radioresistant.<sup>309</sup> Radiation-induced heart disease has now been characterized<sup>310,311 and 312</sup> and investigated in experimental animals,<sup>313,314,315,316 and 317</sup> and the pathologic features of the damage have been described with regard to the coronary arteries and all three layers of the heart.<sup>318,319,320,321,322 and 323</sup>

Pericarditis and pericardial effusion have been regarded as the most common side effects of cardiac irradiation.<sup>310</sup> However, modern techniques of irradiation, dose fractionation, and reduction of the heart volume irradiated in most malignancies have substantially reduced the frequency of this complication during the last decade.<sup>324</sup> At the same time, evidence has accumulated to suggest that ischemic heart disease resulting from radiation-induced CAD is the most concerning long-term risk of cardiac irradiation, particularly in high-risk patients.<sup>325,326,327,328 and 329</sup>

The clinical spectrum of radiation-induced heart disease involves most structures of the heart and is summarized as follows:

- Pericardial disease
- Acute pericarditis during irradiation

- Delayed acute pericarditis
- Pericardial effusion
- Constrictive pericarditis
- Myocardial dysfunction
- Valvular heart disease
- Electrical conduction abnormalities
- Coronary artery disease

Although the pathologic and clinical manifestations of radiation-induced heart disease may overlap in many patients, they are discussed separately in the following paragraphs.

## PERICARDIAL DISEASE

### *Incidence*

The risk of radiation-induced pericardial disease depends on both the dose given and on the volume of the heart irradiated. <sup>310,312,322,330,331</sup> Even when a large volume of the heart (60% or more) is irradiated at or below 40 Gy, the risk for mild pericarditis is below 5%, and severe pericarditis is rare. <sup>324</sup> Smaller heart volumes (20% to 30%) may tolerate up to 60 Gy, with an expected 2% risk of mild pericarditis. The importance of both volume and dose in the production of radiation pericarditis in HD was demonstrated in an analysis of mantle field radiotherapy practices at Stanford. <sup>332</sup> In instances in which the whole pericardium was irradiated, the pericarditis incidence was 20%, but when most of the left ventricle was excluded, it was reduced to 7%. When an additional block was implemented to shield most of the heart after 30 Gy, the incidence was reduced to only 2.5%. An update of the Stanford data corroborated this finding, demonstrating a sharp decrease in the risk of death from cardiac complications other than acute myocardial infarction for patients who received mediastinal irradiation after 1972. <sup>326</sup> Indeed, all series that showed a high risk of pericarditis <sup>333,334</sup> and <sup>335</sup> are of patients treated with a radiation technique, energy, and fractionation schedules that are no longer considered to be an acceptable standard of care in most centers. <sup>329</sup> With current radiotherapy techniques for HD and breast cancer, pericarditis is an infrequent event. <sup>329,331,336,337</sup>

### *Pathology*

Clinical and pathologic changes involving the pericardium are the most common abnormalities described after cardiac irradiation. <sup>317,323</sup> The macroscopic abnormalities consist of pericardial thickening and effusion. <sup>310</sup> Collagen replaces the normal adipose tissue, fibrinous exudate is present on the surface and interstitially, and proliferation of small blood vessels can be observed microscopically. <sup>310</sup> The pericardial fluid is protein rich and may contain strands of fibrin. The fluid ranges in appearance from serous to grossly sanguineous. <sup>311</sup> Over time, the fibrinous exudate may organize with the fibrotic pericardium and epicardium to develop into constrictive pericarditis. The mechanism for pericardial fibrosis and effusion is not clear. It may result from increased capillary permeability and inhibition of the local fibrinolytic mechanism. <sup>310,338</sup> Radiation-induced hypothyroidism should also be considered in the etiology of pericardial effusion after mediastinal irradiation. <sup>339</sup>

### *Acute Pericarditis during Radiation*

Acute pericarditis during the course of radiotherapy is rare. It is almost always associated with massive mediastinal tumors adjacent to the heart. The signs and symptoms are of acute nonspecific pericarditis with chest pain, fever, and often ECG abnormalities. It does not lead to a significant risk of late pericardial damage and is not an indication for interrupting the radiation course. <sup>310,312,327</sup>

### *Delayed Pericarditis*

Radiation-induced pericarditis typically occurs within the first year after mediastinal irradiation. The common range is between 4 months to several years after treatment. <sup>310,312,335,340,341</sup> and <sup>342</sup> Pericardial disease presents either as an acute pericarditis, as a pericardial effusion that may be asymptomatic, or as a combination of both. The symptoms of delayed acute pericarditis are indistinguishable from those of other types of pericarditis and usually consist of fever, pleuritic chest pain, pericardial friction rub, ST-T segment changes, and a decrease of the QRS voltage in the ECG. <sup>310,311,335</sup>

Pericardial effusion may be large and manifest as an enlarged cardiac silhouette. <sup>343</sup> The differential diagnosis of pericardial effusion after radiation includes recurrent malignancy, idiopathic pericarditis, myxedema, and pericardial abscess. <sup>311,344,345</sup> It is estimated that 10% to 30% of patients with radiation-related pericardial effusion develop tamponade and require pericardiocentesis. <sup>334,346,347</sup> Most cases of radiation-induced pericarditis and pericardial effusion resolve spontaneously, usually within 16 months. <sup>347</sup> Approximately 20% of patients with delayed pericarditis progress within 5 to 10 years to develop symptomatic constriction requiring pericardiectomy. <sup>348</sup>

### *Treatment*

Careful cardiac evaluation and monitoring with echocardiography and radionuclide ventriculography should be performed whenever radiation-induced heart disease is suspected. <sup>340,343</sup> Patients with mild symptoms and no hemodynamic compromise may be followed without treatment or may receive symptomatic therapy with salicylates or other nonsteroidal antiinflammatory agents. <sup>310,311</sup> There are reports of a few patients who have received corticosteroids with apparent improvement. <sup>349</sup> However, relapse of symptoms or unmasking of latent radiation injury following rapid withdrawal of corticosteroid therapy has been reported. <sup>350,351</sup> Symptomatic pericardial effusion or clinical evidence for hemodynamic compromise warrants a drainage procedure. Pericardiocentesis with or without percutaneous placement of an indwelling catheter is successful in the majority of patients. <sup>337,352</sup> Failure to relieve tamponade with pericardiocentesis, recurrence of effusion, or the presence of symptomatic constrictive pericarditis requires pericardiectomy. <sup>314,335,353</sup> The mortality of this procedure in patients with postradiation pericarditis is high. Cameron and colleagues <sup>354</sup> reported a postoperative mortality of 21%, and a review by Ni and associates <sup>355</sup> showed an early mortality of 22% in patients operated on for radiation-induced pericarditis and a late mortality (after 30 days or more) of 35%. The high rate of complication in previously irradiated patients is attributed to the existence of additional radiation injury to other cardiac and thoracic structures. Occult constrictive pericarditis requires no surgical intervention and usually has a good prognosis. <sup>311</sup>

## MYOCARDIAL DYSFUNCTION

When myocardial dysfunction is detected after standard-dose mediastinal irradiation, it is typically mild or subclinical. <sup>311,329,356,357</sup> Impaired exercise capacity in asymptomatic postradiation patients has been reported. <sup>358,359</sup> In patients who were studied 15 days after mediastinal irradiation, a transient decrease in LVEF was observed. Complete recovery of ejection fraction 2 months after irradiation and no additional change in patients who were also receiving doxorubicin was documented in this study. <sup>360</sup> Noninvasive studies using echocardiography and radionuclide angiogram detected subtle left ventricular dysfunction in HD patients evaluated a few years after mediastinal irradiation. <sup>334,353,355</sup> The majority of patients with abnormal ventricular function findings, however, do not have clinical heart failure. <sup>351</sup>

The magnitude of the potential contribution of cardiac irradiation to the risk of doxorubicin-induced cardiomyopathy is not well established. But some data suggest potentiation of anthracycline-induced cardiotoxicity when combined with radiotherapy. <sup>11,15,22,356,357</sup> and <sup>358</sup> The histopathologies of radiation heart disease and anthracycline heart disease are different, <sup>359</sup> and the combined effects are probably additive rather than synergistic. <sup>307,359,360</sup> Reducing the doxorubicin dose to 300 to 350 mg/m<sup>2</sup> in the setting of cardiac irradiation has been recommended. <sup>11</sup> In programs of combined modality therapy for HD that included relatively low doses of doxorubicin (up to 250 mg/m<sup>2</sup>) and mediastinal irradiation of 20 to 40 Gy, no significant clinical myocardial dysfunction was detected. <sup>361,362,363,364,365,366,367,368</sup> and <sup>369</sup> However, longer follow-up is required to fully appreciate the potential risk of combined modality cardiac toxicity. <sup>34</sup>

Symptomatic myocardial dysfunction after a radiation dose that does not exceed 60 Gy is rare. <sup>310</sup> The few cases described with intractable heart failure had myocardial fibrosis as part of pancarditis, a generalized process with damage to all three layers of the heart. The hemodynamic pattern is usually of restrictive cardiomyopathy and is difficult to distinguish from constrictive pericarditis. <sup>310,311,338</sup> Its coexistence with pericarditis explains the poor outcome of pericardiectomy when attempted under these circumstances. <sup>310,355</sup> In a pathologic analysis of cardiac tissue from patients with radiation-induced heart disease, interstitial fibrosis (of various degrees) of the myocardium was mostly pericellular and perivascular. The degree of fibrosis was proportional to the radiation dose and was not enhanced in cases in

which doxorubicin therapy was also administered.<sup>323</sup>

## VALVULAR DISEASE

Clinically significant valvular heart disease resulting from mediastinal irradiation is rare.<sup>310,311,370,371</sup> In a review of radiation-associated valvular disease, only ten patients with symptomatic postradiation valvular disease could be found.<sup>370</sup> Analysis of 635 patients treated for HD before the age of 21 years revealed 29 patients who developed new murmurs of indeterminate significance. Of those, 14 received mediastinal doses of 44 Gy or more, and two patients who received high-dose irradiation died of valvular heart disease.<sup>326,327</sup> When echocardiographic studies were performed in asymptomatic HD patients more than 7 years after mediastinal irradiation, valvular abnormalities were detected in 25% to 33% of the patients, although there was rarely any clinical significance. Of interest is a report from Norway that showed a significantly higher risk of cardiopulmonary complications for female subjects after radiation for HD.<sup>357,372,373</sup> and<sup>374</sup> Most of the changes were found in the mitral or aortic valve and consisted of thickening or regurgitation.<sup>323,357,370,372,375</sup> In one series,<sup>358</sup> mild pulmonary stenosis was detected in three patients 6 to 12 years after radiotherapy. Fibrous thickening of the valvular endocardium was found at autopsy in 13 of 16 young patients who received over 35 Gy to the heart, but none of them had apparent valvular dysfunction.<sup>318</sup> The mean interval from irradiation to detection of valvular disease in asymptomatic and symptomatic patients was 11.5 and 16.5 years, respectively.<sup>370</sup> The contribution of irradiation to clinically significant valvular disease appears to be small.<sup>323,329</sup>

## ELECTRICAL ABNORMALITIES

Many ECG abnormalities were recorded years after mediastinal irradiation, the most common clinically significant abnormality being complete atrioventricular block.<sup>340,358,376,377,378,379,380,381,382</sup> and<sup>383</sup> Slama and colleagues<sup>380</sup> reported that radiation-related atrioventricular block was typically infranodal and occurred at long intervals (mean of 12 years), after radiation doses above 40 Gy, most frequently in patients with abnormal conduction on ECG before the advent of complete block, and who had other radiation-related cardiac abnormalities. At postmortem examination, fibrosis of the conduction system has been reported.<sup>377,380</sup>

Another aspect of radiation therapy and heart disease relates to the management of patients with implanted cardiac pacemakers.<sup>386</sup> Although transient interference from electromagnetic noise (with the exception of betatrons) is not a problem in properly functioning radiotherapy equipment, pacemaker-dependent patients should be closely observed during the first treatment with a linear accelerator.<sup>385</sup> Placing the pacemaker in an unshielded radiotherapy field may cause cumulative damage to the pacemaker components.<sup>384</sup> The absorbed dose to the pacemaker should be estimated before treatment. If the total dose to the pacemaker might exceed 2 Gy, the pacemaker function should be checked weekly to detect any indicator of damage that may require replacement of the device.<sup>384</sup>

## CORONARY ARTERY DISEASE

Experiments in laboratory animals,<sup>313,314,315</sup> and<sup>316,386,387</sup> and<sup>388</sup> analysis of pathologic specimens,<sup>318</sup> clinical observations,<sup>333,389,390</sup> and<sup>391</sup> and, in the 1990s, long-term risk analysis in large series of patients treated for HD<sup>325,326</sup> and<sup>327,392,393</sup> and<sup>394</sup> all indicate that mediastinal irradiation may facilitate the development of CAD.

Studies in rabbits on an atherogenic diet and exposed to radiation showed extensive atherosclerotic coronary damage to a degree disproportionately higher than what might have been expected from the summation of the changes induced by radiation alone and by high-cholesterol diet alone.<sup>387</sup> Similar observations have been made in other experimental animals.<sup>388,389</sup>

An autopsy study in 16 young patients (aged 15 to 33 years) who received over 35 Gy to the heart showed that 16 of 64 (25%) major coronary arteries had significant stenosis (greater than 76% obstruction) compared with only 1 of 40 (2.5%) obstructed coronary arteries in a group of age- and sex-matched controls.<sup>318</sup> In this study, the proximal portion of the arteries had significantly more narrowing than the distal parts. McEnery and coworkers<sup>391</sup> described coronary angiograms of 15 patients with CAD after chest irradiation. Eight of these 15 had significant narrowing (more than 50% diameter) of the left main coronary artery, and four had severe ostial stenosis of the right coronary artery. Stenosis at the origin of the coronary arteries appears to be a common finding for radiation-associated CAD.<sup>328,395,396,397</sup> and<sup>398</sup> After mediastinal irradiation, there is a greater likelihood for right coronary or left main or left anterior descending coronary artery lesions as opposed to circumflex lesions, which might be due to the fact that the former vessels, particularly at their origin, receive more radiation.<sup>399</sup> Coronary spasm following radiotherapy has also been documented in patients who developed acute myocardial infarction with patent coronary arteries.<sup>391,400</sup>

Reports of CAD in young patients who had received mediastinal irradiation for HD have long indicated that radiation is a facilitating factor in this multifactorial disease process.<sup>311,318,389,390</sup> and<sup>391,399</sup> However, only more recently could analyses of large databases of patients with HD demonstrate a significantly increased risk of mortality from myocardial infarction after mediastinal irradiation. These studies are summarized in [Table 55.4-1](#). Although only approximately 1% to 2% of HD patients in these series died of myocardial infarction, the observed risk in all six series was still higher than expected.<sup>325,326,327,328</sup> and<sup>329,336,392,393</sup> Boivin and associates<sup>392</sup> analyzed the risk of mortality from CAD in 4665 patients treated for HD and followed for an average of 7 years. The age-adjusted relative risk of death with myocardial infarction after mediastinal irradiation was 2.6 and was even higher (relative risk, 4.0) when myocardial infarction was considered as a direct cause of death. In this study, the onset of increased risk was rapid, within the first 5 years of observation. None of the risk factors for CAD significantly altered the relative risk estimates.

Source	Center	Patients	Letal Myocardial Infarction	Relative Risk	95% Confidence Interval

\*Includes one patient who died of cardiomyopathy.  
\*Myocardial infarction or sudden death.

**TABLE 55.4-1.** Relative Risk of Mortality from Myocardial Infarction after Mediastinal Irradiation for Hodgkin's Disease

Current mantle radiotherapy techniques, better fractionation schemes, and modern equipment deliver smaller doses of radiation to the coronary arteries and may have a lower risk of promoting CAD.<sup>331</sup> In the study by Boivin and colleagues,<sup>392</sup> the relative risk of acute myocardial infarction was reduced from 6.33 for patients treated during the years 1940 to 1966 to 1.97 (with no significant difference from unity) for patients irradiated from 1967 to 1985.

Hancock and coworkers<sup>326,327</sup> analyzed the risk of cardiac disease in patients with HD who were treated at Stanford from 1961 to 1991. The analysis that was limited to children and adolescents younger than age 21 years at the time of treatment showed that the relative risk for death from acute myocardial infarction in this age group was 41.5 (95% CI, 18.1 to 82.1) and that the actuarial risk of fatal or nonfatal myocardial infarction at 22 years was 8.1%.<sup>327</sup> Of note, all deaths in this study occurred in patients who received relatively high doses of radiation (42 to 45 Gy) to the mediastinum. When the Stanford analysis was extended to include 2232 HD patients of all age groups, the relative risk for death from acute myocardial infarction was 3.2 (95% CI, 1.5 to 5.8).<sup>326</sup> This study showed that patients younger than 20 years who received high-dose irradiation had the highest relative risk, the risk decreases with increasing age, and patients older than 50 years of age had no increased risk. However, these results contrast with data published by other investigators,<sup>325,328,392</sup> suggesting an increased risk of acute myocardial infarction for the older age groups. The small number of patients in the Stanford study who received radiation doses of less than 30 Gy did not allow an adequate analysis of the dose effect. The average interval between HD treatment and death from acute myocardial infarction was 10.3 years, but risk was already significant during the first 5 years following treatment and remained elevated throughout the follow-up period (more than 20 years).<sup>326</sup>

Two European studies analyzed the ischemic heart disease in HD patients who received standard fractions and dose (30 to 42 Gy) of mediastinal irradiation.<sup>328,329</sup>

Both studies demonstrated an increase of ischemic heart disease after mediastinal irradiation. The study from Rotterdam, with a median follow-up of 14 years, reported that 12% of the patients experienced ischemic heart disease, with death rate of 4.7% (from myocardial infarction or sudden death).<sup>328</sup> When compared with expected incidence, the standardized mortality ratio was 5.3 (CI 2.7 to 9.3). Of importance, a multivariate analysis of risk factors in the Rotterdam study showed that increasing age, gender (male), and a pretreatment cardiac medical history were significant for developing ischemic heart disease. Treatment-related parameters did not affect the risk.<sup>328</sup> In a study from Zurich, a detailed analysis of the effect of other CAD risk factors on the radiation-induced risk was performed. The study showed that while the risk of CAD after irradiation increased by 4.2 for all patients, in irradiated female patients and in all irradiated patients without other cardiovascular risk factors (smoking, hypertension, obesity, hypercholesterolemia, diabetes), the risk remained as expected in the normal population.<sup>329</sup>

Long-term mortality data from three trials, which randomized breast cancer patients to receive postmastectomy radiotherapy as opposed to no additional treatment, demonstrated a higher incidence of cardiac death in the irradiated group.<sup>401,402 and 403</sup> The excess in mortality did not appear until after 10 years posttreatment.<sup>402,403</sup> In one study, the increase in mortality risk was significant only in women who were irradiated for tumors in the left breast.<sup>403</sup> It was also increased in patients treated with orthovoltage irradiation as opposed to those treated with more modern supervoltage equipment.<sup>403</sup>

These data demonstrate the risk associated with coronary artery irradiation. It should be emphasized that the old breast irradiation techniques used in these particular studies delivered high doses of radiation to the heart.<sup>331,404</sup> These techniques are no longer in use in most centers. Long-term follow-up of patients in similar randomized trials who were treated with heart-sparing techniques did not show increased cardiovascular morbidity.<sup>405,406 and 407</sup> Prophylactic irradiation of the internal mammary nodes using a single anterior photon beam (*hockey stick technique*), which may deliver a high dosage to the heart, is not indicated in most patients irradiated for breast conservation or postmastectomy.<sup>408,409</sup> Breast cancer patients irradiated with modern techniques, energies, and fractionation schedules are unlikely to receive a significant dose of radiation to the coronary arteries.<sup>404,410,411 and 412</sup>

Conventional-dose doxorubicin-containing chemotherapy used as adjuvant in combination with locoregional irradiation was not associated with a significant increase in the risk of cardiac events. However, higher doses of adjuvant doxorubicin were associated with a threefold to fourfold increased risk of cardiac events. This appears to be especially true in patients treated with higher dose volumes of cardiac irradiation.<sup>413</sup>

The radiation threshold for an increased risk of CAD has not been determined. Lederman and associates<sup>414</sup> reported that patients with seminoma who received a relatively low dose of mediastinal irradiation (median, 24 Gy) had more ischemic heart disease compared with a similar group of patients whose mediastinums were not irradiated. It should be noted, however, that the observed cardiac risk in the irradiated group did not differ significantly from the expected risk of a comparable normal population.

Monitoring and reduction of other contributing CAD factors in patients who received mediastinal irradiation should be part of the follow-up of patients who underwent mediastinal irradiation. However, the value of routine noninvasive or invasive cardiac studies in asymptomatic patients has not been determined.<sup>329,373,415,416,417 and 418</sup> Still, early detection of CAD should be encouraged, particularly in irradiated patients with other CAD risk factors,<sup>329</sup> because angioplastic or surgical intervention may be indicated in special anatomic or clinical situations. Successful treatment of radiation-induced coronary disease with bypass surgery and with angioplasty has been reported.<sup>391,419,420</sup> In some cases, surgery may be technically difficult because of mediastinal and pericardial fibrosis.<sup>391</sup>

Although the mechanism of radiation-induced coronary heart disease remains unclear, insult to the endothelial cell is considered to be a central event in the pathogenesis of damage to the coronary arteries.<sup>397</sup> Research indicates that programmed cell death (apoptosis) is the underlying mechanism for postradiation endothelial cell death.<sup>421</sup> Growth factors that interfere with the apoptotic pathway, such as bFGF, may prevent radiation-induced death of endothelial cells, as in the study by Fuks and colleagues,<sup>421</sup> who demonstrated that treatment with bFGF during chest irradiation of experimental animals decreased postradiation blood vessel stenosis and significantly increased the survival of the bFGF-treated animals following radiation. These findings provide a basis for future interventions that may decrease the risk of radiation-induced heart disease.

## CONCLUSION

It is hoped that increased awareness and knowledge about potential cardiotoxicity from chemotherapy and radiotherapy will enable physicians to adequately monitor patients and modify therapy so as to minimize serious acute and chronic cardiac sequelae. The growing information about late cardiac effects should facilitate early diagnosis and therapeutic intervention for the benefit of previously treated patients.

[Chapter References](#)

#### INTRODUCTION

Alopecia is a psychologically distressing but common side effect of many chemotherapeutic agents and radiation therapy. As patients embark on new therapies, hair loss can induce a negative body image, cause depression and alter interpersonal relationships, and arouse enough anxiety to cause some patients to reject potentially curative treatment. In one study, 88% of women who received perioperative chemotherapy for early breast cancer considered alopecia to be the most traumatic aspect of therapy.<sup>1</sup> Adolescents have particular difficulty in coping with hair loss during a time of adjustment to the diagnosis of cancer.<sup>2</sup>

Frank discussion of the problem by clinicians and oncology nurses, with recognition of patients' stress and personal loss of self-esteem, is helpful in preparing affected patients to confront this event.<sup>3</sup> Although not all patients are entirely satisfied by current methods for the prevention of total scalp hair loss or the use of wigs after hair loss, care-givers can offer supportive listening, some practical suggestions, and identification of resources. Often, the presence of a spouse, family member, or friend during such a discussion with patients is helpful to place the problem in perspective and to aid affected families and patients in adapting.<sup>4</sup>

The hair loss caused by scalp irradiation is unpredictable. Epilation can begin at doses of 500 cGy and generally progresses, causing spotty areas of baldness as the course of treatment continues. The prospects for hair regrowth diminish with increasing doses.<sup>5</sup> Irradiation ports on extremities have been noted to be hair-free 10 years after radiation therapy and may never have hair regrowth. In lower-dose ranges, regrowth begins 8 to 9 weeks after cessation of therapy. Patients should be cautioned that new hair may be different in character from pretreatment hair.<sup>6</sup>

The extent of body hair loss by patients in any chemotherapeutic program is both drug- and dose-dependent and is related to the frequency of cycle repetition. Often, it is caused by more than one drug used concurrently ([Table 55.5-1](#)). Long-term therapy may result in loss of pubic, axillary, and facial hair in addition to scalp hair. Often, the loss of scalp hair occurs in an acute episode while washing. It should be emphasized to patients that alopecia from chemotherapy is reversible, with hair regeneration beginning 1 to 2 months after therapy is discontinued. Alterations in color and texture of hair may occur: Shade of hair may be lighter or darker and often is curlier as it regrows.<sup>7</sup> Hair loss may begin 1 to 2 weeks after a single chemotherapeutic dose and reaches maximum loss within 2 months in most drug sequences. Doxorubicin and cyclophosphamide are common cytologic agents known to cause epilation after two cycles at doses of doxorubicin greater than 50 mg/m<sup>2</sup> and cyclophosphamide greater than 500 mg/m<sup>2</sup>. Although agents differ in degree to which they cause hair loss, alopecia may be expected with other single-agent antibiotics, alkylators, nitrosoureas, and especially their combinations.<sup>8</sup>

Actinomycin
Amesotrine
Bleomycin
Cyclophosphamide
Epirubicin
Etoposide
Fluorouracil
Idarubicin
Interferon
Irinotecan
Leucovorin
Methotrexate
Mitomycin
Mitomycin
Mitoxantrone
Nitrosourea
Paclitaxel
Taxol
Vincristine
Vincore

Note: The degree or extent of alopecia is inversely proportional to dose, schedule of sequences, rate and route of delivery, and various combinations of agents used concurrently.

TABLE 55.5-1. Single Agents with Potential to Induce Reversible Alopecia

#### HEAD COVERING

Most patients will choose to cover their heads during periods of hair loss. Nurses and clinicians can suggest wigs or head covering with stylish scarves, turbans, or hats. Wigs should be selected before hair loss begins so that the patient is prepared when alopecia occurs and so that hair color and style can be matched. Hairpieces are tax-deductible medical expenses and are covered by some medical insurance policies. The American Cancer Society (ACS) can provide wigs free of charge through their "wig bank" program. Several small private businesses have been developed by former patients who distribute or sell head coverings of various designs. An ACS patient service called *Look Good, Feel Better* has been developed in partnership with the National Cosmetology Association and the Cosmetic, Toiletry, and Fragrance Association Foundation. This service specifically assists women in compensating for hair loss and skin changes to enhance self-image during cancer treatment.<sup>9</sup> Volunteer beauticians and cosmetologists help women to improve their appearance and to feel more comfortable with changes in appearance, such as dry, discolored, or blotching skin; loss of eyebrows and eyelashes; discolored nails; and alopecia. Such volunteers provide instruction with makeup and give advice about wigs and other types of head coverings. Information about group programs and their location is available through an ACS toll-free telephone number, 1-800-395-LOOK, 24 hours daily, 7 days per week. The support program is active in all 50 states and Puerto Rico, with groups designed especially for teenagers in limited areas around the country. The program celebrated its tenth anniversary in 1999, having provided this service to more than 250,000 women.

#### PREVENTION OF ALOPECIA

Since 1966, interventions have been proposed to prevent scalp hair loss from chemotherapy.<sup>9</sup> The rationale for these procedures is to prevent drug circulation to the hair follicles by causing temporary vasoconstriction and decreasing tissue metabolism at the time of peak plasma drug level, with either an occlusive scalp tourniquet or localized hypothermia. The pharmacokinetic profiles of the drugs to be used should be understood before either of these methods is considered. Scalp-cooling systems must maintain temperatures below 22°C to have any effect. Occlusion of the superficial scalp veins must begin before the drugs are given and, to be effective, must be extended beyond the time of the peak plasma drug levels.<sup>9,10 and 11</sup>

Various types of scalp-icing devices have been manufactured by several different American companies. Although the U.S. Food and Drug Administration (FDA) initially had approved the marketing of cooling caps intended to cause localized scalp hypothermia, early in 1990 the FDA reviewed these applications and became concerned that the safety and efficacy of these devices had not been substantiated by adequate clinical data.<sup>12,13,14,15 and 16</sup> Regulatory action was initiated to address the following concerns:

- The potential for scalp metastasis posed by the use of these devices.
- The potential for reducing drug circulation to other anatomic sites beyond the scalp, such as the skull and possibly the brain.
- The effectiveness of preventing hair loss and effects of specific cytologic doses and other variables on the results achieved.

On the basis of these factors, the FDA halted the commercial distribution of these devices. Five years after their withdrawal, no company has come forward with supporting clinical evidence of reasonable safety and effectiveness, according to Frances Moreland Curtis of the FDA's Division of General and Restorative Devices

(written communication, August 1995).

Though indications demonstrate that continuous-flow systems with thermostatically controlled cooling caps still are used in Europe, they seem to be limited to regimens containing a single anthracycline alopecia-inducing agent.<sup>16</sup> Limitations of safety and inconclusive and conflicting reports of the usefulness of scalp hypothermia should be factors discussed with patients seeking information about these devices and hair preservation techniques.

## INTRODUCTION

For young adults who have cancer, the success of treatment with regimens that are toxic to gonadal function has made infertility an important problem. When the cancer is controlled, quality of life then becomes a major issue. To many of these young men and women, a major quality-of-life issue is the ability to have a normal child.

Both neoplastic disease and its treatment can interfere with normal sexual and reproductive function ( [Table 55.6-1](#)). Testicular and ovarian cancer directly involves the gonad, and prostate, endometrial, and cervical cancer directly involves the reproductive tract. Surgical treatment for any of these diseases results by necessity in the loss of these important reproductive organs. Retroperitoneal lymph node dissection (RPLND) for testicular and colon cancer, as well as prostatectomy and surgery involving the bladder neck, may result in loss of the ability to ejaculate. Primary and metastatic tumors in the hypothalamus and pituitary can directly affect gonadotropin secretion, resulting in secondary hypogonadism. Both chemotherapy and radiation can cause a variety of toxic effects on the male and female gonads. Cytotoxic therapies delivered to women during pregnancy might have teratogenic effects on the fetus.<sup>1,2</sup> If fertility is maintained or returns, there remains the concern about the heritability of cancer and at least a theoretical risk of mutagenic alterations to germ cells caused by cytotoxic therapies.

Tumor	Direct gonadal involvement Reproductive tract involvement Hypothalamic and pituitary involvement
Surgery	Concern about heritability of cancer susceptibility Removal of gonad Genital mutilation Failure of emission and retrograde ejaculation Impotence and loss of orgasm
Radiotherapy or chemotherapy	Germ cell depletion Loss of gonadal hormones Mutagenic changes in germ cells Teratogenic effects on fetus
Chemotherapy	Seminal transmission of drug
Radiotherapy (cranial)	Loss of gonadotropic hormones

**TABLE 55.6-1.** Impact of Cancer and Cancer Therapy on the Reproductive System

The reproductive consequences of cancer therapy affect many people. In the United States, 17,000 men 15 to 45 years old are diagnosed each year with Hodgkin's disease, lymphoma, bone and soft tissue sarcomas, testicular cancer, or leukemia.<sup>3,4</sup> Of these, more than 3000 are treated with doses of alkylating agents, platinum drugs, or radiation sufficient to induce prolonged azoospermia. Similarly, 35,000 women aged 15 to 45 years old are treated for breast cancer (mostly), Hodgkin's disease, lymphoma, and leukemia; at least 80% of these patients receive radiation or alkylating agent-based cytotoxic therapies. These treatments cause not only sterility but also premature menopause and the associated estrogen deficiency in nearly 20,000 women. In addition, 12,000 children younger than 15 years are diagnosed each year with cancer, including leukemia, nervous system tumors, lymphomas, and other solid tumors.<sup>5</sup> Survival is approaching 80%, and because 85% of patients receive chemotherapy or gonadal or pituitary irradiation, reproductive dysfunction is a significant concern.

## EFFECTS OF CYTOTOXIC AGENTS ON ADULT MEN

### BIOLOGIC CONSIDERATIONS

The sensitivities of the seminiferous (or germinal) epithelium and the endocrine components of the testis to killing by cytotoxic therapies are related to the relative proliferation rates of the different cells.<sup>6</sup> The germ cells consist of stem spermatogonia, differentiating spermatogonia, spermatocytes, spermatids, and sperm. Among

the germ cells, which are within the seminiferous epithelium, the differentiating spermatogonia proliferate most actively and are extremely susceptible to cytotoxic agents. In contrast, the Leydig cells, which are in the interstitium and produce the androgens, and the Sertoli cells, which provide support and regulatory factors to the germ cells, do not proliferate in adults and so survive most cytotoxic therapies. These cells may, however, suffer functional damage. Frequently after cytotoxic therapies, germinal tissue appears completely absent, a state described as *germinal aplasia*, and only the Sertoli cells remain lining the tubules. This could be a result of killing of the spermatogenic stem cells, the loss of the ability of the somatic cells to support the differentiation of a few surviving stem cells, or a combination of both.

After cytotoxic treatment, sperm count diminishes with a time course that depends on the sensitivities of the different spermatogenic cells and their kinetics of maturation to sperm. Because the later-stage germ cells (spermatocytes onward) are relatively insensitive to killing and progress with invariant kinetics, sperm count is not immediately affected. However, these cells are susceptible to the induction of mutagenic damage, and studies in rodents have shown they can become spermatozoa and transmit mutations induced in their DNA to the next generation.<sup>7</sup> The eventual recovery of sperm production depends on the survival of the spermatogonial stem cells and their ability to differentiate. In both rats and humans, surviving stem cells may fail to produce differentiating germ cells for a year or more after cytotoxic insult.<sup>8,9</sup>

The loss of germinal cells has secondary effects on the endocrine function of the testis and the hypothalamic-pituitary-gonadal axis. Inhibin secretion by the Sertoli cells declines and, as inhibin limits follicle-stimulating hormone (FSH) secretion by the pituitary, serum FSH rises. Because germinal aplasia reduces testis size and there is a concomitant reduction in testicular blood flow,<sup>10</sup> less testosterone is distributed into the circulation, and as testosterone inhibits pituitary luteinizing hormone (LH) secretion, serum LH increases. Conversely, LH is the primary stimulator of Leydig cell testosterone synthesis, and the reduced blood flow also lessens Leydig cell exposure to circulating LH. These alterations of pituitary-gonadal feedback could elevate serum LH and reduce serum testosterone levels even in the absence of any Leydig cell injury.

### CHARACTERISTICS OF GONADAL TOXICITY

Although subnormal semen profiles, ejaculatory dysfunction, and low libido in treated patients are most likely a result of treatment, other causes must be considered, too. A sexual and reproductive history should include developmental factors such as age of testicular descent and puberty; surgery or injury to the genitals; diseases that might affect reproduction; drug, chemical, or heat exposure; and pretreatment fertility and libido status. A physical examination should consist of examination of the testicles and secondary sexual characteristics such as beard and hair distribution pattern. Laboratory tests entail semen analysis and a hormone profile. Normal values and those associated with germinal aplasia are outlined in [Table 55.6-2](#).

	Testis		Sperm Count (million/mL)	Semen Analysis		Testosterone (ng/dL)
	Length (cm)	Volume (mL)		Follicle-Stimulating Hormone (mIU/mL)	Luteinizing Hormone (mIU/mL)	
Normal	5.0-10	1.5-5	15-200	<12	>2	300-1000
Germinal aplasia	<5	<1	0	>12	<2	<300

**TABLE 55.6-2.** Typical Clinical and Laboratory Features for Diagnosis of Male Reproductive Dysfunction

During the first 2 months of cytotoxic therapy, sperm counts may remain normal or be only moderately reduced. Some regimens cause azoospermia 2 to 3 months after the initiation of therapy,<sup>11,12</sup> corresponding to the interval during which the sensitive differentiating spermatogonia become sperm. With other regimens, oligospermia or even normospermia may be maintained.<sup>13</sup>

Increases in FSH are associated with germinal aplasia. Although FSH measurements have sometimes been used as a surrogate for sperm count, they only show an imperfect correlation,<sup>14</sup> in part because of interpatient variability in baseline FSH levels.<sup>15</sup> After cytotoxic therapy, LH tends to be elevated and serum testosterone levels in the low normal range.<sup>16</sup> This has been interpreted as indicating subclinical, compensated Leydig cell failure; however, changes in testicular blood flow can also explain these observations.<sup>10</sup> The only treatment that produces testosterone insufficiency in a high proportion of adult patients is high-dose (30 Gy) radiation direct to the testes, which directly damages Leydig cell function.<sup>17</sup>

The induced azoospermia can be either temporary or prolonged, depending on the ability of surviving stem spermatogonia to proliferate, differentiate, and produce spermatozoa, which in turn depends on the nature of the cytotoxic agent and dose ([Table 55.6-3](#)). If treatment is limited to the cytotoxic agents that do not kill stem spermatogonia or block their differentiation into spermatozoa, normospermic levels are usually restored within 3 months after the cytotoxic therapy. However, if agents that inactivate stem spermatogonia or affect differentiation are used, longer periods of azoospermia ensue. At lower doses of these agents, recovery to normospermic levels can occur within 1 to 3 years, but at higher doses, azoospermia can be more prolonged or even permanent. The probability that spermatogenesis will recover decreases with the duration of azoospermia.<sup>12,18</sup> However, in a few men spermatogenesis recovered after as long as 20 years of azoospermia.<sup>19</sup> FSH levels drop to normal when sperm production recovers. When sperm count recovers after cytotoxic therapy, sperm motility appears to be normal,<sup>12,18,20</sup> and fertility is generally restored. However, when the duration of azoospermia is long, recovery may sometimes plateau at less than 1 million/mL,<sup>12</sup> which may not be compatible with fertility.

Agent (Cumulative Dose for 30 Days)	Effect
Bleomycin (2.0 Gy/m <sup>2</sup> )	Prolonged azoospermia
Carboplatin (2.0 g/m <sup>2</sup> )	
Cyclophosphamide (20 g/m <sup>2</sup> )	Prolonged azoospermia (rarely, but resolution time not available)
Fluorouracil (8 g/m <sup>2</sup> )	
Docetaxel (200 mg/m <sup>2</sup> )	Unknown because always given with other highly vomiting agents
Etoposide (100 mg/m <sup>2</sup> )	
Epipodophyllin (1.2 g/m <sup>2</sup> )	Can be additive with other agents in causing prolonged azoospermia, but cause only temporary reduction in sperm count when not combined with other agents
Immunosuppressants (1.0 g/m <sup>2</sup> )	
Testosterone (200 mg/m <sup>2</sup> )	Only transient reduction in sperm count at short-term treatment periods; 100% recovery of sperm count within 3 months; no additive effects are possible
Testosterone (200 mg/m <sup>2</sup> )	
Testosterone (200 mg/m <sup>2</sup> )	Unlikely to affect sperm production
Testosterone (200 mg/m <sup>2</sup> )	
Testosterone (200 mg/m <sup>2</sup> )	No effect on sperm production
Testosterone (200 mg/m <sup>2</sup> )	

**TABLE 55.6-3.** Effects of Different Antitumor Agents on Sperm Production in Men

To evaluate the effects of cytotoxic therapy, the initial gonadal status must be considered. Men with both seminomas and nonseminomatous germ cell tumors have impaired semen quality even before cytotoxic therapy is instituted. Approximately 65% are oligospermic (counts less than 20 million/mL), 50% have less than 10 million/mL, and 13% are azoospermic,<sup>21,22</sup> compared with values of 9%, 5%, and 1%, respectively, in control populations.<sup>23</sup> In approximately 40% of the patients with reduced semen quality, this impaired testicular function is a result of irreversible abnormalities associated with the uninvolved gonad (e.g., carcinoma *in situ* or a history of cryptorchidism) that predate the onset of cancer.<sup>24</sup> In the other 60%, it may be a result of reversible factors such as elevated chorionic gonadotropin produced by the tumor with resulting increases in estradiol.<sup>25</sup> In addition, emission and ejaculation may have been compromised by earlier RPLND so that the sperm density may not accurately reflect gonadal function.<sup>26</sup> In contrast to the severe dysfunction in testicular cancer, in Hodgkin's disease only 21% of Hodgkin's disease patients are oligospermic and 2% are azoospermic, and the distribution of counts in the remainder is not significantly different from normal.<sup>27</sup> The presence of low-grade fever and B symptoms was not predictive for poor semen quality.<sup>27-28</sup> Similarly, in other lymphomas and sarcomas, pretreatment sperm counts tend to be

and the granulosa cells under LH and FSH stimulation, cause the LH surge that triggers ovulation. The day-to-day sequential variations in FSH, LH, and estradiol are essential for menstrual cyclicity and the female reproductive processes. The close interaction between granulosa cells and oocytes makes it difficult to identify which type of cell is the target of cytotoxic agents; death of either results in atrophy of the other. Because destruction of oocytes results in loss of follicles and steroidogenesis, germ cell loss leads directly to estrogen insufficiency.

The time between recruitment of follicles and their ovulation is approximately 85 days. When maturing follicles are destroyed by cytotoxic therapy, temporary amenorrhea results. If primordial follicles are reduced below the minimum number necessary for menstrual cyclicity, irreversible ovarian failure occurs and the amenorrhea is permanent. Different species of experimental animals have yielded conflicting information regarding the sensitivity of primordial follicles to radiation<sup>62</sup> and cyclophosphamide<sup>63,64</sup> and do not yet allow prediction of response in women.

### CHARACTERISTICS OF GONADAL TOXICITY

Because the size of the germ cell population in women cannot be estimated, menstrual and reproductive histories are important in assessing the effects of cytotoxic therapy on ovarian function. Information on the patient's menstrual cycle during and after therapy, as well as oral contraceptive use, should be noted. To determine if effects are related to cytotoxic therapy, pretherapy ovarian function should be evaluated from the history of menarche, menses, pregnancies, and oral contraceptive use. The occurrence of symptoms of recent primary ovarian failure, including hot flashes, night sweats, insomnia, mood swings, irritability, vaginal dryness, dyspareunia, decreased libido, and bladder infection, should be recorded. Laboratory measurements of hormone levels are most definitive in the diagnosis of primary ovarian failure; FSH is the most sensitive, but LH and estradiol levels are also useful (Table 55.6-5). The symptoms of ovarian failure may be masked and the hormone levels altered if the woman is taking oral contraceptives.

Menstrual Phase	Follicle-Stimulating Hormone (mIU/mL)	Luteinizing Hormone (mIU/mL)	Estradiol (pg/mL)
Prepubertal	0-3	0-2	0-10
Follicular	3-20	2-15	10-200
Midcycle	5-15	30-150	200-700
Luteal	1-12	0.5-20.0	15-250
Ovarian failure	10-150	10-60	<50

**TABLE 55.6-5.** Typical Laboratory Features for Diagnosis of Ovarian Failure

Some of the variability reported in the literature regarding the incidence of ovarian failure after cytotoxic therapy is a result of the lack of consistent definitions.<sup>65</sup> Menopause should be defined as more than 12 months without a menstrual period, treatment-related amenorrhea as at least 6 months without menstrual periods in a premenopausal patient, and oligomenorrhea as a reduction in the frequency of menses to between 40 days and 6 months. Because the mechanisms of temporary and irreversible treatment-related amenorrhea may be different, posttreatment follow-up time should be given, and they should be distinct outcomes.

Cytotoxic therapy often induces temporary amenorrhea, which may last a few months or up to 7 years.<sup>66</sup> Some of this temporary amenorrhea is a result of direct ovarian damage, causing failure of follicular recruitment or loss of maturing follicles. Alternatively, stress and malnutrition or weight loss can also cause temporary gonadal dysfunction by altering hypothalamic activity and estrogen metabolism.<sup>67</sup> The destruction of growing follicles and the resulting temporary amenorrhea during treatment appear to be independent of age.<sup>68</sup> Although some patients with treatment-induced temporary amenorrhea do display menopausal symptoms, these symptoms are usually indicative of permanent ovarian failure. In contrast, permanent treatment-induced amenorrhea, which is equivalent to ovarian failure, dramatically increases in an apparently continuous manner with age at treatment<sup>69,70</sup>; examples are given in Table 55.6-6 and Table 55.6-7. This trend is expected as the number of follicles decreases with increasing age. The permanent amenorrhea may begin during chemotherapy or subsequently after several years of oligomenorrhea.<sup>71,72</sup>

Agent	Prepubertal	Age 20†	Age 30†	Age 40†	Age 50†	Age 60†
<b>CUMULATIVE DOSES TO CAUSE PERMANENT OVARIAN FAILURE</b>

**TABLE 55.6-7.** Probability of Ovarian Failure in Postmenarchal Women with Combination Chemotherapy Regimens Containing Alkylating Agents

If cytotoxic therapy depletes the pool of primordial follicles, premature ovarian failure should occur even in young women who continue menstruating after cytotoxic therapy.<sup>71,73</sup> In women aged 13 to 19 years at diagnosis treated with alkylating agent chemotherapy and radiotherapy below the diaphragm, the median age at menopause is 32 years, compared with 44 years for women treated with radiotherapy or chemotherapy alone, and 49 years for controls.<sup>74</sup> The degree of acceleration of menopause in these women correlated with the probability of induction of primary ovarian failure by the different therapies.<sup>75</sup>

Cytotoxic therapy-induced ovarian failure and premature menopause can accelerate bone density loss.<sup>76</sup> However, when only chemotherapy is used, some residual

ovarian function may be present and can ameliorate the loss.<sup>77</sup>

## INDIVIDUAL DRUGS

As in men, only alkylating agents appear to produce permanent gonadal failure in women (see [Table 55.6-6](#)), and the cumulative dose appears to be more important than the dose rate. Administration of low daily doses of cyclophosphamide over several months<sup>78</sup> is only slightly less effective at inducing permanent ovarian failure than is a high dose in 4 days.<sup>73</sup> Melphalan, chlorambucil, busulfan, mitomycin C, and doses of cisplatin of 600 mg/m<sup>2</sup> or higher<sup>87</sup> also produce permanent ovarian failure. Procarbazine is likely to be highly sterilizing inasmuch as permanent ovarian failure is observed in all procarbazine-containing combinations and, in the case of cyclophosphamide, Oncovin, procarbazine, and prednisone (COPP), the dose of cyclophosphamide is insufficient to cause this effect (see [Table 55.6-7](#)).

Other agents studied do not induce permanent ovarian failure. 5-Fluorouracil up to 30 g did not induce amenorrhea in women with a median age of 35.<sup>76</sup> Methotrexate (200 g) plus vincristine (40 g),<sup>92</sup> etoposide (5 g),<sup>93</sup> and cisplatin (less than 450 mg/m<sup>2</sup>) plus doxorubicin (less than 400 mg/m<sup>2</sup>)<sup>87</sup> failed to produce permanent ovarian failure in women 15 to 30 years of age. Doxorubicin, bleomycin, vincristine, and dacarbazine (ABVD), must not induce ovarian failure because none is observed after treatment of women up to age 41.<sup>94</sup> Reproductive effects of hormonal agents, such as tamoxifen, which interferes with pregnancy in animals,<sup>95</sup> should be reversible.

## RADIATION THERAPY

Radiation is highly effective at inducing permanent ovarian failure with a marked age-dependence in sensitivity<sup>96</sup> (see [Table 55.6-6](#)). In adult women, irradiation of the ovaries occurs in the treatment of Hodgkin's disease and during total body irradiation in preparation for hematopoietic stem cell transplantation. Irradiation of the paraaortic nodes results in cumulative doses of only 1.5 Gy to the ovaries and does not appear to interfere with menstruation in most patients.<sup>88,97</sup> When total nodal irradiation for Hodgkin's disease or pelvic radiation for cervical cancer is given, and the ovarian dose can be reduced to 4 to 5 Gy by translocation (oophoropexy) and shielding of the ovaries, a partial preservation of fertility in younger women results.<sup>70,98</sup> Total body irradiation in preparation for bone marrow transplantation delivers 8 to 12 Gy to the gonads, which destroys ovarian function in all adult women, even the young ones.<sup>73,85</sup> Fractionation appeared not to spare the ovary, as 27% of women receiving 10 Gy in a single fraction recovered ovarian function as opposed to only 10% of those receiving 12 Gy in 6 days.<sup>37</sup>

## COMBINATION REGIMENS

All combinations that include procarbazine or high doses of other alkylating agents [e.g., mechlorethamine, vinblastine, procarbazine, and prednisone (MOPP); COPP; and chlorambucil, vinblastine, procarbazine, and prednisone (ChlVPP)] induce ovarian failure in almost all older women and even in some younger ones (see [Table 55.6-7](#)). Recovery is better when the dose of procarbazine is reduced by using the MOPP/ABVD regimen.<sup>90</sup> Radiation and MOPP chemotherapy clearly have an additive (but not synergistic) effect, and the combination results in a higher incidence of ovarian failure than either modality alone.<sup>70</sup>

Similarly, regimens using high doses of cyclophosphamide, as used in treatment of breast cancer, also produce ovarian failure; however, the age dependence obscures any possible dose dependence.<sup>69,79,91</sup> Lower doses of cyclophosphamide usually given along with antimetabolites and other agents for treatment of leukemia do not destroy primordial follicles nor produce permanent ovarian failure.<sup>35,68</sup> Combination chemotherapy regimens without alkylating agents tend not to produce ovarian failure.

## EFFECTS OF CYTOTOXIC AGENTS ON CHILDREN

### BIOLOGIC CONSIDERATIONS IN BOYS

In the prepubertal testis, the immature Sertoli cells are the most numerous cells in the seminiferous tubules.<sup>99</sup> They proliferate at an extremely low level in the prepubertal period, only increasing twofold in numbers, but there is a marked increase during puberty. Spermatogonia are the only germ cells present and transform from an appearance of fetal germ cells to that of adult spermatogonia. They proliferate at a low level, increasing sixfold from birth to 10 years. Leydig cells cannot be identified in the interstitial spaces from shortly after birth until puberty. At puberty, new Leydig cells are formed from mesenchymal cells already in the interstitium, involving extensive proliferation of the precursors.<sup>100</sup> The appearance of the Leydig cells elevates secretion of testosterone, which, along with enhanced FSH levels, initiates spermatogenesis at a median age of 13.

### EXTENT OF GONADAL TOXICITY IN BOYS

The germinal epithelium in the prepubertal testis does not appear to be any more resistant to cytotoxic therapy than that in the adult. The concept that prepubertal are less sensitive than adult testes<sup>101</sup> derived from comparison of cyclophosphamide doses given on a milligram per kilogram basis and the failure of prepubertal boys to show elevation of FSH after chemotherapy.<sup>102</sup> But when treated patients are followed after puberty by sperm count and hormone evaluation, the sensitivity of the prepubertal testis to a variety of cytotoxic regimens is apparent. Appropriately expressing chemotherapy doses to boys on a milligram per square meter basis and using calculated radiation doses, the sterilizing effects of a variety of chemotherapy regimens<sup>103,104,105,106</sup> and radiotherapy<sup>86,108</sup> can be predicted on the basis of the sensitivity of the adult testis (see [Table 55.6-3](#) and [Table 55.6-4](#)).

As in adults, radiation and alkylating agents, such as procarbazine, cyclophosphamide, and chlorambucil, are the most sterilizing and produce prolonged and sometimes permanent azoospermia. The nitrosoureas (carmustine, lomustine), which are also alkylating agents, and cisplatin likewise produce prolonged germinal aplasia.<sup>39,87</sup> In addition, high doses of doxorubicin and cytosine arabinoside appear to be additive with the preceding agents in producing gonadal damage.<sup>109</sup> In general, regimens lacking alkylating agents, such as some used for acute lymphocytic leukemia, allow pubertal progression of spermatogenesis even during treatment<sup>110</sup> and do not appear to affect postpubertal sperm counts<sup>111</sup> or fertility.<sup>75</sup>

Chemotherapy does not have major effects on Leydig cell function, and hence the timing of pubertal development and postpubertal testosterone levels are generally normal.<sup>112</sup> There is one report that treatment with MOPP chemotherapy during puberty results in gynecomastia<sup>102</sup>; however, other studies indicate that this incidence is not above background levels.<sup>107,113</sup> Preliminary data do indicate, however, that approximately 30% of boys treated with busulfan plus cyclophosphamide show delayed puberty.<sup>66</sup> In contrast, direct testicular irradiation, used in treatment of leukemia or sarcomas, produces dramatic Leydig cell damage. There is significant age dependence, as children are more sensitive than adults<sup>114</sup> and within the prepubertal period, the youngest are most sensitive.<sup>115</sup> The incidence of extremely low testosterone levels and failure to complete puberty rises from 0% at 7.5 Gy,<sup>116</sup> to 0% to 50% at 12 Gy,<sup>66,117</sup> 75% at 24 Gy,<sup>118,119</sup> and 100% at 27 to 30 Gy.<sup>114</sup>

### BIOLOGIC CONSIDERATIONS IN GIRLS

Despite the low levels of circulating gonadotropins, the immature ovary is far from quiescent. In addition to primordial follicles, maturing follicles up to and including the large antral stage appear within a few months after birth.<sup>120</sup> After 6 years of age, FSH levels, the numbers and diameters of large antral follicles, and estrogen levels all increase. The lack of gonadotropin support prevents full follicular development or ovulation before menarche.

### EXTENT OF GONADAL TOXICITY IN GIRLS

Prepubertal girls appear to be even less susceptible than young postpubertal women to ovarian failure induced by cytotoxic therapy (see [Table 55.6-6](#)). Furthermore, girls treated between the ages of 0 and 12 do not appear to experience premature menopause during their 20s and 30s as is the case with those treated at ages 13 to 19.<sup>74</sup> However, additional numbers and longer follow-up are needed.

Radiation is the most damaging agent to the prepubertal ovary. Doses of approximately 20 to 30 Gy induce permanent ovarian failure in nearly all girls.<sup>121,122</sup> Doses of 8 to 15 Gy, given as single doses or in a few fractions, usually with some cyclophosphamide in preparation for bone marrow transplantation, cause permanent ovarian failure and failure of pubertal development in only 50% of girls, with those at younger ages being less sensitive than older ones.<sup>66,115</sup> Fractionated doses of up to 7 Gy cause little failure of ovarian function or pubertal development,<sup>86,123</sup> although there can be additive detrimental effects of chemotherapy.

Most chemotherapy regimens, including high doses of cyclophosphamide up to 48 g, <sup>86</sup> do not cause failure of pubertal development and menarche. Although various combination chemotherapy regimens used for treatment of leukemia and Hodgkin's disease reduce the number of growing follicles, no significant change in numbers of primordial follicles could be measured, <sup>124</sup> and puberty and associated ovarian function develop normally. <sup>112,125</sup> Even with the standard MOPP chemotherapy for Hodgkin's disease, 90% of prepubertal girls develop normally. <sup>86,126</sup> However, regimens with high doses of certain alkylating agents can produce detectable ovarian damage in a significant percentage of prepubertal girls. ChIVPP (30% failure) <sup>127</sup> and carmustine or lomustine (greater than 90% failure) <sup>128</sup> produce transient biochemical evidence of ovarian failure, but there is no evidence that they interfere with pubertal development. In contrast, busulfan plus cyclophosphamide actually inhibits puberty in 50% of girls. <sup>66</sup>

## GONADAL DYSFUNCTION AFTER CRANIAL IRRADIATION

Whereas gonadal irradiation causes primary hypogonadism, cranial irradiation is associated with secondary hypogonadism due to damage to the hypothalamus, gonadotrophs in the pituitary, or both. In patients with pituitary or suprasellar lesions, gonadotropin deficiency is often present before antineoplastic therapy; however, patients with nasopharyngeal cancer or brain tumors have normal hypothalamic-pituitary-gonadal axes until they receive therapeutic irradiation with fields encompassing the hypothalamic-pituitary areas. There is no convincing evidence that any of the cytotoxic drugs directly impair hypothalamic and anterior pituitary function.

In children, prophylactic cranial irradiation with 24 Gy for leukemia does not affect LH or FSH pulsatile secretion in the first 6 years. <sup>129</sup> Irradiation of children for cranial tumors with doses of 25 to 55 Gy to the hypothalamic-pituitary region decreased LH and FSH secretion in 11% of cases within 6 years in one study. <sup>130</sup> However, in some cases radiation doses between 18 and 47 Gy, sometimes combined with chemotherapy, may not inactivate the mechanisms necessary for gonadotropin production and secretion, but indirectly stimulate this process before puberty, and hence increase LH and FSH levels and cause precocious puberty. <sup>131,132</sup> Because growth hormone deficiency is common in these patients, precocious puberty further exacerbates the risk of adult shortness.

In adults, decreased LH and FSH secretion, measured after gonadotropin-releasing hormone (GnRH) stimulation, is observed after cranial irradiation. The damage increases with treatment dose <sup>133</sup> and time interval since treatment. <sup>134</sup> LH and FSH deficiency is observed in 33% of patients 5 years after treatment with 20 Gy, but 66% are affected 5 years after 35 to 49 Gy, progressing to 100% by 10 years. <sup>135</sup> This results in oligomenorrhea in women and low testosterone in men; hyperprolactinemia might mediate the observed gonadal dysfunction in some cases. <sup>136,137</sup>

In many patients who receive multimodality treatment, complex hormonal dysregulation may develop; although cranial irradiation, for example, may affect the hypothalamus and pituitary, total body or abdominal irradiation and concomitant chemotherapy may induce primary gonadal failure.

## PRESERVATION OF FERTILITY, HORMONE LEVELS, AND SEXUAL FUNCTION

### CHOICE OF REGIMENS

It is sometimes possible to choose between nearly equally curative regimens on the basis of their sterilizing potentials. The principle is to minimize the doses of the agents in [Table 55.6-3](#) and [Table 55.6-6](#) that are most sterilizing. A classic example is to use ABVD instead of MOPP to treat Hodgkin's disease. <sup>13</sup> In the treatment of non-Hodgkin's lymphoma, regimens that minimize the dose of cyclophosphamide, such as VAPEC-B, produce less gonadal failure in men than does cyclophosphamide, hydroxydaunorubicin (Adriamycin), Oncovin, prednisone, and bleomycin (CHOP-Bleo). <sup>138</sup>

### GONADAL SHIELDING

Except when they must be irradiated because of neoplastic involvement or anatomic inclusion within the irradiated target, the gonads are outside or are shielded from the direct radiation beam. Nevertheless, an appreciable radiation dose from the accelerator head, collimator scatter, or internal lateral scatter may reach the gonads. Even at moderately low radiation doses, the possibilities of additive effects from chemotherapy and genetic damage to the sperm make it desirable to further minimize the radiation dose.

Gonadal dose depends on distance from the field edge, field size, and photon energy; it can vary from 0.1% to 10.0% of the prescribed dose within the field. <sup>139</sup> Pelvic radiation fields result in significant doses to the testis. Clamshell type shields <sup>139,140</sup> and beam blocking can reduce testicular doses approximately fivefold to approximately 2 Gy for the inverted Y field used for Hodgkin's disease and approximately 0.5 Gy for the hemipelvic field used for seminoma. When treatment of the hemiscrotum after unilateral orchiectomy for testicular cancer is indicated, a special positioning device to retract the remaining testicle out of the treatment field and provide shielding above the area <sup>141</sup> can reduce the dose to the gonad to 0.6 Gy. <sup>142</sup>

To shield the ovaries, an oophoropexy, in which the ovaries are surgically translocated, usually to the midline behind the uterus, must be performed. That region is then shielded from the direct radiation beam using lead blocks. Some investigators report reductions in cumulative ovarian doses to approximately 4 to 5 Gy during total nodal irradiation <sup>143</sup> and good preservation of fertility in younger women <sup>86</sup> (see [Table 55.6-6](#)); however, others report higher doses and poorer recoveries. <sup>97</sup>

### MALE GERM CELL CRYOPRESERVATION

Semen cryopreservation is an extremely important procedure for men who want to preserve their fertility potential after cytotoxic treatment for cancer. The significance of notifying the patient of the potential risk of iatrogenic sterility as early as possible cannot be overemphasized. Physicians often are aware early during the diagnostic process that the patient will most likely need to receive potentially sterilizing cytotoxic therapy, although the exact diagnosis, stage, and treatment regimen have not yet been decided. This time should be used to initiate and complete the cryopreservation procedure. The banking of at least three semen samples with at least a 48-hour period of abstinence between samples is recommended. This usually requires 5 to 8 days to complete. Additional samples (four) and longer abstinence periods (72 hours) to achieve higher total sperm counts may be considered. But fewer samples with shorter times are often obtained because of the need to initiate anticancer therapy quickly, and it is important to avoid possible increased genetic damage in sperm collected after the start of therapy. <sup>7</sup> It is even possible to obtain semen with normal characteristics from 14- to 17-year-old boys. <sup>144</sup> In boys unable to obtain samples by masturbation, penile vibratory stimulation or electroejaculation have been used. <sup>145</sup>

Because of the low overall success rate with artificial insemination using banked semen in the past, it had been recommended that only samples with high sperm counts and motilities be stored. Currently, the success of *in vitro* fertilization (IVF) and intracytoplasmic sperm injection (ICSI) make cryopreservation of all samples containing any live sperm appropriate. The cost of sperm banking three samples, including analysis and storage for 5 years, is approximately \$1200 at a university medical school clinic, although it may be higher at private sperm banks. The patient should be made aware that conception rates are only 30% with interuterine insemination (cost per cycle, approximately \$250). If the sperm count or motility are significantly impaired, more complicated assisted reproductive technologies may be necessary. The average cost of IVF without ICSI, including the drugs used, is \$10,000 per cycle and with ICSI it is approximately an additional \$1200 per cycle.

The transplantation of a population of testicular cells, including stem spermatogonia from a donor mouse to a recipient mouse, in which endogenous stem spermatogonia were killed with busulfan, restored spermatogenesis and fertility. <sup>146</sup> Restoration of spermatogenesis is also possible with cryopreserved cells. <sup>147</sup> This suggests the possibility that testicular tissue may be harvested from men before sterilizing cytotoxic therapy and cryopreserved as a cell suspension, for later injection back into the testis after the completion of chemotherapy. Currently, a trial is underway at the Christie Hospital, Manchester, England. <sup>148</sup> This technique would be most valuable for boys, who may be too young to produce sperm, especially because the prepubertal testis is enriched in spermatogonia. <sup>146</sup>

### FEMALE GERM CELL CRYOPRESERVATION

Freezing oocytes, unlike sperm, is currently still experimental. There have been offspring born using frozen human oocytes in IVF procedures <sup>149</sup>; however, the success rate is low. In addition, currently used procedures for freezing human and animal oocytes may increase chromosomal aberrations. <sup>150</sup> Furthermore, obtaining mature oocytes is limited to patients in whom there are no contraindications to hormone-induced superovulation. It is also possible to freeze embryos obtained by IVF or by uterine lavage after natural coitus, <sup>151</sup> but these methods are rarely practical with cancer patients, especially when cytotoxic therapy must be initiated without

much delay.

Another alternative under active investigation is the surgical removal of ovarian tissue, cryopreservation of tissue slices, and grafting back to the remaining vessels after chemotherapy. This procedure restored ovarian endocrine function and fertility in sheep.<sup>152</sup> Follicular development has been observed in human ovarian tissue implanted into immunodeficient mice.<sup>153</sup> Restoration of hormone production and follicular growth after transplantation of cryopreserved ovarian tissue has been reported,<sup>154</sup> but the true long-term success of this technique remains to be determined.<sup>148</sup> One limitation is the concern that the technique may reintroduce malignant cells to patients in remission.<sup>155</sup> Isolating a follicle from the thawed tissue and maturing an oocyte *in vitro* would be a preferable option, but at present the technique has only been developed in the mouse.

## ASSISTED REPRODUCTIVE TECHNOLOGIES

Assisted reproductive technologies have and still are undergoing rapid advances, providing new options for survivors of cancer with gonadal damage to achieve fertility.<sup>156</sup> Previously, intrauterine artificial insemination, often using controlled ovarian hyperstimulation, had been the only method available. Only approximately 30% of women whose partners were cancer patients were able to achieve pregnancy,<sup>157</sup> because of the limited number of samples, poor semen quality in some patients, and loss of motility during freezing and thawing.

Currently, IVF, and especially IVF with ICSI, either as the primary modality or after unsuccessful attempts with artificial insemination, are important in achieving pregnancies from stored semen after the completion of cytotoxic therapy. In IVF, only approximately 100,000 motile sperm are placed in a small droplet of medium with an oocyte, and fertilization is allowed to occur. In ICSI, one spermatozoon is selected with a micropipette and microinjected into the cytoplasm of an oocyte.<sup>158</sup> In both procedures, the oocytes are examined for fertilization and embryo cleavage, and multiple embryos are reimplanted into the uterine cavity. Multiple oocytes can be fertilized in a single IVF cycle, and the embryos that are not transferred can be frozen for implantation at a later time. IVF, however, requires hormonal induction of multiple ovulations, and the implantation of several embryos increases the risks of fetal loss and multiple births.

Because freezing and thawing may result in complete loss of sperm motility, IVF may not be possible in some cases, but IVF with ICSI can still be used.<sup>158</sup> ICSI can be performed with semen samples with 0% motility as long as the sperm are viable.<sup>158</sup> It is possible to select sperm for injection from individuals with exceptionally low counts (e.g., 100 per ejaculate) and even from the testis (testicular sperm extraction).<sup>159,160</sup>

If the number and quality of the sperm meet standards set by a given clinic, IVF alone is used. However if the standards are not met or if IVF has failed, IVF with ICSI is then used. With ICSI, the fertilization rate is 50% to 60%. The success rate of IVF or IVF with ICSI is 22% per initiated cycle and 26% per completed cycle.<sup>161</sup> When multiple cycles are used, these procedures offer couples a success rate of 80% to 100% for achieving a pregnancy.<sup>157,162</sup>

There appear to be no increases in congenital malformations in the offspring from IVF or ICSI; however, there is a small increase in the incidence of chromosomal abnormalities, mostly in the numbers of sex chromosomes.<sup>163</sup> Some of the chromosome abnormalities observed after the use of ICSI for primary male infertility are not caused by ICSI but are already in the spermatozoa of the infertile patient<sup>164</sup>; the latter should not be a factor in cryopreserved sperm from cancer patients.

## HORMONAL METHODS OF PRESERVING FERTILITY

Although hormone treatments have been used to enhance the survival of germ cells and their ability to recover after cytotoxic treatments, there currently are no reliable methods for hormonal protection of gonadal function in humans.

Pretreatment of male rats with gonadal steroids,<sup>165</sup> GnRH analogues,<sup>166</sup> or GnRH analogues combined with antiandrogens,<sup>167</sup> all of which suppress gonadotropin and testosterone levels and action, enhance recovery of spermatogenesis and fertility after procarbazine, irradiation, or cyclophosphamide. The original proposal that these treatments protect the spermatogonia from killing by suppressing their proliferation<sup>168</sup> is incorrect, as the protective hormone treatments neither suppress spermatogonial proliferation<sup>169</sup> nor enhance stem spermatogonial survival.<sup>170</sup> Rather, the hormones appear to act via suppression of testosterone levels to protect the subsequent ability of the somatic cells of the testis to support the recovery of spermatogenesis from surviving stem spermatogonia. In rats, stem spermatogonia survive some cytotoxic therapies but are unable to differentiate,<sup>171,172</sup> and hormone treatment, even given after the cytotoxic treatment, can stimulate recovery of spermatogenesis.<sup>171</sup> The presence of stem spermatogonia in testes of cancer patients during prolonged periods of iatrogenic azoospermia suggests that this procedure may be applicable to humans as well. Only one out of eight clinical trials has been able to demonstrate protection of spermatogenesis in humans by hormone treatment before and during cytotoxic therapy.<sup>173,174</sup> and<sup>175</sup> The failures may, in part, be attributed to the administration, along with the GnRH agonist (GnRH-Ag), of testosterone, which has been shown in the rat to reduce the recovery of spermatogenesis. The continuation of testosterone-suppressive treatment after completion of cytotoxic therapy, which was successful in the rat,<sup>176</sup> has not been tested in humans.

In the female rat, there is one convincing study showing protection of ovarian function. The number of developing follicles several months after cyclophosphamide treatment was enhanced when GnRH-Ag had been given along with cyclophosphamide.<sup>177</sup> It is not apparent how GnRH-Ag worked as recruitment of primordial follicles is gonadotropin independent. However, GnRH-Ag also inhibits the normal physiologic loss of primordial follicles by recruitment and atresia.<sup>178</sup> Thus, GnRH-Ag treatment for several months might prolong fertility in rodents because it could be given for an appreciable fraction of their reproductive lifetime, but if this were the mechanism, it would not have a significant effect in women, who have a 40-year interval from menarche to menopause. Clinical studies attempting to protect ovarian function in women with GnRH-Ag<sup>179,180</sup> or oral contraceptives<sup>181,182</sup> during treatment for Hodgkin's disease have yielded contradictory results.

Despite clinical symptoms of ovarian failure, there may be some residual ovarian function remaining after chemotherapy; the possibility is less likely after gonadal radiation.<sup>77</sup> It is possible to stimulate ovulation and fertility after apparent chemotherapy-induced ovarian failure, at least for a short time, with a brief course of gonadotropin treatment<sup>183</sup> or with steroid hormone replacement therapy.<sup>85</sup>

## OPTIMIZATION OF FERTILITY AFTER TREATMENT

Men whose sperm count recovers after cancer therapy usually achieve normospermic levels, but some remain oligospermic for extended periods. Although controlled studies have not been done, these men appear to have normal fertility based on their sperm count, and the incidence of infertility in these patients does not appear to be any higher than the 15% rate among couples in the general population. In contrast, cancer patients with recovered sperm counts ranging from below 1 to 10 million/mL, levels associated with subfertility when they occur in the general population, are able to successfully father children.<sup>14,43,51</sup> In cases of infertility with oligospermic counts, management of the patient should be the same as in those from a normal population with male factor infertility. Of the various procedures, IVF and IVF with ICSI appear to offer the most promise.<sup>184</sup>

In most women who continue to have menstrual function after cytotoxic therapy for cancer, infertility should generally be treated as in a normal population. The one major exception is those who received high doses of abdominal radiation (10 to 16 Gy for hematopoietic stem cell transplantation and more than 20 Gy for Wilms' tumor), particularly in childhood. These patients have increased rates of adverse pregnancy outcomes, including fetal or neonatal deaths, premature deliveries, low-birth-weight babies, and neonatal deaths, and hence these pregnancies must be closely monitored.<sup>37,185</sup>

## HORMONE REPLACEMENT THERAPY

It is important to test for ovarian failure and to start hormone replacement therapy rapidly because, in some cases, a 2- to 3-year delay in administering estrogen replacement therapy may result in an irreversible loss of bone mass and increased risk of osteoporosis.<sup>76</sup> In addition, estrogen deficiency places women at increased risk for morbidity and mortality from cardiovascular disease and causes sexual dysfunction.<sup>186</sup> Estrogen replacement can be provided orally, transdermally, or by injection.<sup>187</sup> If a patient has an intact uterus, estrogen should generally be combined with progesterone to prevent endometrial hyperplasia and cancer.<sup>188</sup>

In male subjects, germinal aplasia is often associated with testosterone levels in the low to normal range, and they may experience reduced bone mineral density.<sup>16</sup> Some of these men with reduced libido after chemotherapy report improvement after testosterone treatment.<sup>53</sup> Testosterone replacement is important in cases of overt Leydig cell failure in prepubertal boys to promote secondary sexual characteristics, growth, and bone density. It can be provided transdermally or by injection<sup>188</sup>; the

use of oral anabolic preparations should be discouraged.

## MODIFIED NERVE-SPARING SURGERY

Ejaculation of semen involves emission, by which semen is deposited in the posterior urethra by contractions of the vas deferens, seminal vesicles, and prostate, and antegrade ejaculation, which requires coordinated tightening of the bladder neck, relaxation of the external sphincter, and expulsion of semen. Most of these processes are controlled by nerve fibers that arise from the lumbar ganglia at L1 to L4 and then course anteriorly over the aorta and coalesce into multiple trunks, forming the hypogastric plexus overlying the aorta and sacrum below the origin of the inferior mesenteric artery. <sup>24</sup>

Surgery in the treatment of testicular, prostate, and bladder cancer can produce neurologic dysfunction resulting in failure of emission, retrograde ejaculation, impotence, and loss of orgasm. However, improvements in surgical techniques have reduced these adverse outcomes without diminishing the efficacy of treating the cancer.

RPLND has an important role in the treatment of nonseminomatous testicular germ cell tumors. Procedures for radical RPLND that were standard before 1972 almost always produced failures of emission and ejaculation. Based on the location of positive nodes, a modified template of dissection (unilateral dissection below the inferior mesenteric artery), which avoids disturbance of the lumbar sympathetic fibers, particularly at the hypogastric plexus, was developed, <sup>24</sup> preserving ejaculation of semen in 50% to 85% of men. The RPLND technique has been further refined by identifying the postganglionic fibers and retracting them from the lymph nodes over and around the aorta, which are then dissected out and removed in multiple small packages, sparing the nerve fibers, <sup>189</sup> preserving ejaculation of semen in 89% of men. <sup>190</sup>

Improved surgical techniques also preserve sexual function in many men undergoing surgery for prostate and bladder cancer. <sup>191</sup> By avoiding damage to the nerve fibers that are located in neurovascular bundles that innervate the penile corpora cavernosa, sexual function, including the ability to have an erection sufficient for vaginal penetration and orgasm, is maintained in 70% to 80% of men undergoing radical prostatectomy for localized prostate cancer or radical cystoprostatectomy for invasive bladder cancer. In addition, a promising technique for those patients who do require nerve excision with the prostate is that of bilateral sural nerve grafts. <sup>192</sup> It is too early to quantify the true effectiveness of this technique, but the results are encouraging.

## MANAGEMENT OF RETROGRADE EJACULATION

In patients with ejaculatory dysfunction after RPLND, sympathomimetic agents may enhance seminal emission and partially or completely convert the patient to antegrade ejaculation. <sup>26</sup> Drugs, such as pseudoephedrine HCl, ephedrine sulfate, phenylpropanolamine HCl, or imipramine HCl, should be given sequentially as 2-week trials until improvements in semen volume and sperm count are observed. Pregnancies have been reported but, in general, medical therapy must be combined with some additional techniques to use sperm from retrograde ejaculation.

When retrograde ejaculation is present, sperm may be recovered from the bladder by direct voiding or by catheterization with irrigation. <sup>193</sup> For greater sperm survival, it is important to ensure a dilute, slightly alkaline urine and then to dilute the voided semen-urine mixture with buffering media to reduce harmful urine components.

When medical treatment is not successful at producing emission and ejaculation, electroejaculation has been successful in more than 70% of patients. <sup>194</sup> After administration of general anesthesia, a rectal probe is used to electrically stimulate sympathetic efferent fibers and smooth muscle. Although most patients have some antegrade ejaculate, catheterization should always be done to collect the retrograde semen. Sperm motility tends to be low after electroejaculation, and the fecundity per cycle is at most 9% using artificial insemination. IVF with ICSI is now being used to enhance pregnancy rates. <sup>184</sup>

## GENETIC CONCERNS

### BIOLOGIC CONSIDERATIONS

Many anticancer agents damage DNA and interfere with DNA replication, DNA repair, and chromosome segregation in both animal and human cells. They induce mutations in germ cells of animals that cause genetic disease. <sup>195</sup> Because the studies that have been or can be done in humans are limited, risk estimates are derived from the induction of single-gene mutations and chromosomal aberrations, both of which contribute significantly to human genetic disease in the mouse. <sup>196</sup>

Radiation, procarbazine, melphalan, and mitomycin C produce single-gene mutations in murine spermatogonia, whereas seven other tested chemotherapeutic drugs do not. <sup>195,197</sup> Risk can be estimated by using the doubling dose (i.e., dose to produce twice the background rate of mutation) from the mouse and the incidence of clinically significant dominant genetic traits in human liveborn due to new mutations. <sup>196</sup> Doubling doses for single-gene mutations in mouse spermatogonial mutations are 1 Gy for subchronic radiation and 0.4 g/m<sup>2</sup> for procarbazine. <sup>198</sup> At the mouse doubling dose, the incidence of dominant mutations in humans should be increased by 0.2%; however, data from offspring of atomic bomb survivors indicate that estimates based on the mouse may overestimate the human genetic risk. <sup>199</sup>

Radiation is the only agent that effectively induces stable reciprocal chromosomal translocations in stem spermatogonia that can be visualized in spermatocytes or in offspring. <sup>196</sup> Although the mouse data indicate that a fractionated dose of 1 Gy would induce translocations in 0.06% of the offspring, the induction of translocations in human germ cells appears to be higher than in the mouse. <sup>200</sup>

In male rodents, meiotic and postmeiotic germ cells are more sensitive to induction and transmission of mutations than are stem spermatogonia. <sup>7</sup> Therefore, mutational risks are highest when a pregnancy occurs within one spermatogenic cycle (time for stem cell to become sperm) after the man is exposed to the damaging agent. In men, this higher risk period extends from the start of cytotoxic therapy until 3 months after the last course. (In practice, waiting 6 months after therapy to effect a pregnancy is recommended for safety.) After this time, the incidence of mutations is at the lower level found in sperm that were exposed to the mutagen as stem cells, which determines the genetic risk for the remainder of the reproductive lifetime.

Fewer studies of the mutagenicity of cytotoxic agents have been done in the female subject. Single-gene and chromosomal mutations are induced by radiation in the developing oocytes of female mice at a similar rate as in stem spermatogonia. <sup>196</sup> Procarbazine induces a similar level of specific-locus mutations in primordial oocytes as in stem spermatogonia. <sup>201</sup> Most alkylating agents and a variety of other drugs induce chromosome aberrations or mutations in oocytes in growing follicles, resulting in embryonic death. <sup>195,197</sup> Although there are insufficient data to determine whether growing oocytes are more sensitive to induction of mutations than primordial oocytes, it is still prudent for a woman to wait at least 3 months after cytotoxic treatment before conceiving.

These animal studies show that there are theoretical genetic risks to the offspring of treated patients of both sexes. Calculations predict that the incidence of congenital abnormalities would be increased by less than 2%, even at the highest doses of cytotoxic therapies and, hence, large-scale controlled studies will be required to measure effects in human populations.

### GAMETE GENOMIC ANALYSIS

Because epidemiologic studies of genetic damage in humans require large numbers of offspring, direct analysis of the genetic material of gametes has potential advantages for identifying mutations in human germ cells. Such analyses are practical only in the male subject because harvest of female gametes is impractical. Several assays have been developed and new methods are under investigation ( [Table 55.6-8](#) ).

Marker/Method	Description
Single locus	
Analysis of DNA sequences in offspring and parents	Southern blot analysis of polymerase chain reaction-amplified, highly variable minisatellite sequences from small pools of individual sperm <sup>207</sup>
Chromosomal abnormality	
Chromosome alterations at testis	Reproductive tract biopsies in spermatocytes obtained by testicular biopsy <sup>208</sup>
Sperm karyotype	Interphase karyotype of sperm with fluorescently labeled chromosomes and fluorescence-activated cell sorting <sup>209</sup>
Fluorescence <i>in situ</i> hybridization of sperm	Conventional probes for chromosome number and multiple probes per chromosome for structural alterations <sup>210</sup>

**TABLE 55.6-8.** Mutational End Points Used in Human Germ Cells

Sperm karyotyping has demonstrated the persistence of structural and numeric chromosomal abnormalities several years after radiation or chemotherapy.<sup>204,207</sup> Currently, the more efficient technique of fluorescence *in situ* hybridization of sperm is being used to measure the rates of aneuploidy and chromosome breakage. There was a significant sixfold increase in aneuploidy<sup>208</sup> and chromosome structural aberrations<sup>209</sup> during mitoxantrone, vincristine, vinblastine, and prednisone (NOVP) chemotherapy, demonstrating that there are genetic risks if conception or storage of sperm occurs during cytotoxic therapy. Fluorescence *in situ* hybridization failed to show any significant persistence of the increase in aneuploidy 6 months after the completion of NOVP or cisplatin, etoposide, and bleomycin (PEB) chemotherapy,<sup>205,210</sup> but increases after MOPP chemotherapy did persist.<sup>209</sup>

Minisatellite repeat number mutations in human spermatozoa<sup>202</sup> could also be a useful marker for detecting mutations. Minisatellite mutations were increased in offspring of men exposed to radioactive fallout from Chernobyl.<sup>211</sup> However, studies so far have not detected any significant induction of these mutations by radiotherapy or chemotherapy for cancer.<sup>212</sup>

## PREGNANCY OUTCOME

Nearly all of the case reports, small series, and a few large retrospective case studies of the outcomes of pregnancies in, or produced by, survivors of cancer indicated no significant increase in birth defects or genetic disease, above the background in the general population of approximately 4%, in offspring conceived after cytotoxic treatment.<sup>213</sup> The results from the atomic bomb studies in Japan also show no significant increase in genetic damage in 30,000 offspring born to radiation-exposed parents.<sup>199</sup> These observations should reassure those who wish to have children after treatment for cancer. However, they do not rule out the possibility of a small genetic risk.

The largest published studies involved patients who were children or adolescents at the time of treatment.<sup>214,215</sup> A total of 630 offspring from patients receiving potentially mutagenic therapy (radiation proximal to the gonads or alkylating agents) showed no significant increases in birth defects or other genetic diseases. A study of incidence of cancer in offspring of patients treated with potentially mutagenic therapies also found no increase above control populations in the induction of cancer (excluding highly heritable cancers).<sup>216</sup> There was, however, a fourfold increase in adverse reproductive outcomes observed in women who received more than 20 Gy abdominal radiation in childhood, primarily for Wilms' tumor.<sup>185</sup> The cause of this increase appears not to be genetic but rather irreversible radiation damage to the uterine musculature and blood flow.<sup>217</sup>

The largest study of offspring from adults treated with cytotoxic therapies involved 368 conceptions in women treated with methotrexate alone or in combination for choriocarcinoma or invasive mole; there were no significant increases in miscarriages, stillbirths, neonatal deaths, or congenital abnormalities.<sup>218</sup> In male subjects, a study of 70 offspring from testicular cancer patients treated with radiotherapy, chemotherapy, or both revealed no apparent increase in congenital malformations; the power of the study was sufficient to rule out an increase greater than threefold.<sup>219</sup> In a large case-control study (parents of children with a congenital anomaly versus parents of normal children), the relative risk that treatment with mutagenic therapy would cause congenital abnormalities was close to 1, and the upper confidence limits were approximately 2.<sup>220</sup>

The lack of observable increases in birth defects or genetic diseases in nearly all studies makes it highly probable that there is less than a twofold increase in genetic risk after radiotherapy or chemotherapy of both adults and children. However, larger studies will be required to determine whether that limit can be further reduced, and further research is needed to evaluate new chemotherapeutic agents.

There are limited reports of outcomes of pregnancies in which conception occurred while the father was undergoing cytotoxic therapy. No significant increases in untoward pregnancy outcomes or birth defects were reported in a review of nine conceptions.<sup>221</sup> However, one child with trisomy was conceived shortly after the completion of therapy,<sup>222</sup> and this aneuploidy might be attributable to mutagenesis in maturing germ cells. If conception does occur during these times, the couple should be informed of the risks, which may only be moderate, to evaluate the continuation of the pregnancy.

The teratogenic risk from cytotoxic therapy delivered to a woman during pregnancy can be much higher than mutagenic risk from prior exposure. The decisions of whether to initiate, continue, modify, or withhold therapy and whether to continue or terminate the pregnancy are extremely complex.<sup>1</sup> There are documented risks from fetal radiation doses as low as 0.2 Gy in the first trimester and from somewhat higher doses in the second trimester.<sup>223</sup> All of the cytotoxic chemotherapeutic agents are classified as teratogens<sup>224</sup>; however, some may be given in the second and third trimester of pregnancy. Treatment with fluorouracil, doxorubicin, and cyclophosphamide during this period did not result in any pregnancy complications, congenital abnormalities, or immediate postpartum deficits; methotrexate was deliberately excluded from the combination.<sup>2</sup>

## COUNSELING

Cancer patients should be informed by their physician about the possibilities of sterility and genetic risk from the disease and treatment ( [Table 55.6-9](#)). They should also be told about psychological and physical effects on sexual desire, erectile function, and the ability to achieve orgasm.

Discuss risk of infertility after cancer treatment, the option of sperm banking, and the possibility of healthy children if fertility is preserved.
Explain options for gamete or embryo cryopreservation.
Inquire about family history of cancer.
Strongly encourage birth control during cancer treatment; up to 6 months after the end of treatment, becoming pregnant or producing a pregnancy is contraindicated.
Discuss theoretical concerns about mutational damage.
Discuss the limited data for humans regarding congenital malformations and genetic disease, which indicate no measurable excess above the background level 4% risk for any pregnancy.
Recommend that any pregnancy after therapy should be monitored with ultrasound and amniocentesis offered because of the theoretically increased genetic risk.

**TABLE 55.6-9.** Guidelines for Reproductive and Genetic Counseling of Couples Seeking Pregnancy after Cancer Diagnosis and Treatment

During treatment, sexual relations between partners may continue, but reliable contraception should be used. The genetic and teratogenic risk of conception when either partner is undergoing treatment should be outlined. In addition, the seminal transmission of chemotherapeutic drugs should be mentioned, and the use of

condoms when sexual intercourse occurs within 24 hours of administration of a chemotherapeutic agent to the man should be recommended.

The probability that sterility will result from the planned cytotoxic therapy should be calculated from the cumulative doses of agents and combinations that cause prolonged azoospermia (see [Table 55.6-3](#) and [Table 55.6-4](#)) and ovarian failure (see [Table 55.6-6](#) and [Table 55.6-7](#)). This risk should be communicated to the patient.

Pretreatment sperm banking should be offered to all male patients interested in having children after the completion of cytotoxic therapy. The risks of sterility from a given treatment and the probability that more aggressive, highly sterilizing treatment may be needed before there is another opportunity for semen storage should be considered in making the decision on sperm banking. The costs of semen cryopreservation and other assisted reproductive technologies should be presented, and the patient should be reminded that these are not standard benefits in the majority of health insurance programs in the United States.

Female patients should be told that the use of cryopreserved ovarian tissue is experimental at this time. If therapy can be delayed for several months and the woman has a partner, embryo cryopreservation may be possible. Women should also be told about the risks of chemotherapy-induced premature menopause. If this does occur, it is important to present a balanced discussion of potential benefits of prompt initiation of hormone replacement therapy versus the risk (e.g., possibly endometrial and breast cancers) so that an individually appropriate decision may be reached.

#### INTRODUCTION

Modern chemotherapy and radiotherapy have increased substantially the survival of patients with cancer. In particular, cure rates have shown dramatic improvement for patients with Hodgkin's disease, testicular cancer, and pediatric malignancies. Less impressive, but nonetheless convincing, improvements in survival also have been achieved for patients with breast cancer, non-Hodgkin's lymphoma (NHL), and several other tumors. Now that substantial numbers of cancer patients experience such a favorable prognosis, it becomes increasingly important to evaluate the long-term complications of treatment. Because the survival benefits associated with modern treatments have been greatest for those cancers that occur at relatively young ages, cured patients are subject to long-term side effects, which may not emerge until several decades after treatment. Paradoxically, research conducted since the late 1970s has clearly demonstrated that some of the modalities used to treat cancer have the potential to induce new (second) primary malignancies. Of the many late complications of treatment, second cancers are generally considered to be the most serious, because they not only cause substantial morbidity but also considerable mortality. For example, among 15-year survivors of Hodgkin's disease, second cancer deaths have been reported to be the largest contributor to the substantial excess mortality that these patients experience.<sup>1</sup> Increased risks of second cancers have been observed after radiotherapy, chemotherapy, or combined modality treatment.

In any discussion of treatment-related second malignancies, it is of primary importance to remember that not all second cancers are due to therapy. The occurrence of two primary malignancies in the same individual may reflect the operation of numerous influences. Multiple primary cancers may result from host susceptibility (genetic predisposition or immunodeficiency), common carcinogenic influences, a clustering of risk factors, treatment for the first tumor, diagnostic surveillance, a chance event, or the interaction of these factors. In view of the high prevalence of cancer in the general population and the increasing incidence of most cancers with age, it is important to exclude the role of chance in the development of second cancers. To this end, comparison with cancer incidence statistics derived from the general population is crucial. If a second malignancy is demonstrated to occur in excess, the contributions of other risk factors need to be ruled out convincingly before the increased risk can be attributed to treatment. The temporal trend of excess second cancer risk may provide an important initial clue to etiology; for example, the risk of solid tumors after radiotherapy generally increases with time since exposure. The evaluation of the carcinogenic effects of therapy, however, is complicated by the fact that therapeutic agents are frequently given in combination. Appropriate epidemiologic and statistical methods are required to quantify the excess risk and to unravel the role of treatment and other factors.

Whenever interpreting results of second cancer studies, it must be kept in mind that the problem of treatment-induced malignancies has arisen by virtue of the success of cancer therapy. As more becomes known about the influence of various treatment factors on second cancer risk, therapies may be modified to decrease the risk while maintaining equal levels of therapeutic effectiveness.

The major aspects of second malignancy risk in relation to cancer treatment are addressed in this chapter. After a discussion of methods used for the assessment of second cancer risk, an overview of the carcinogenic effects of radiotherapy and chemotherapy is presented. Subsequently, the risk of second malignancies after treatment for Hodgkin's disease, NHL, testicular cancer, breast cancer, ovarian cancer, and pediatric malignancies is reviewed. Emphasis is on large studies that have been published most recently.

#### METHODS TO ASSESS SECOND CANCER RISK

Estimates of second cancer risk after treatment of various primary malignancies derive from several sources, including population-based cancer registries, hospital-based cancer registries, or clinical trial series.<sup>2</sup> The epidemiologic study designs generally used are the cohort study and the case-control study.

In a cohort study, a large group of patients with a specified first malignancy (the cohort) is followed for a number of years to determine the incidence of second cancers. To evaluate whether second cancer risk in the cohort is increased compared with cancer risk in the general population, the observed number of second cancers in the cohort is compared with the number expected on the basis of age-, gender-, and calendar year-specific cancer incidence rates in the general population. The analysis takes into account the observation period of individual patients (person-years).<sup>3</sup> The relative risk of developing a second cancer is estimated by comparing the ratio of the observed number of second cancer cases in the cohort to the number expected. When the relative risk is increased, the question arises as to whether the excesses are due to therapy. This issue can be evaluated by comparing risks between treatment groups, preferably within specified follow-up intervals and, when possible, with a reference group of patients not treated with radiotherapy and chemotherapy. Second cancer risk in the cohort (and in different treatment groups) can also be expressed by the cumulative (actuarial estimated) risk,<sup>4</sup> which yields the proportion of patients alive at time  $t$  (e.g., 5 years from diagnosis) who can be expected to develop a second malignancy. When the cohort's death rate due to causes other than second malignancy is high, the assumptions underlying the actuarial method may not be valid, and competing risk techniques should be considered to estimate cumulative risk.<sup>5,6</sup> Because many treatment-related cancers are rare in the general population (e.g., leukemia, sarcoma), a high relative risk (compared to the population) may still translate into a rather low cumulative risk. Absolute excess risk, which estimates the excess number of second malignancies per 10,000 patients per year, perhaps best reflects the second cancer burden in a cohort. This risk measure is also the most appropriate one by which to identify those second malignancies that contribute the most to elevated risks.

Each of the data sources used to construct a cohort has its own set of advantages and disadvantages. Population-based cancer registries frequently have large numbers of patients available, which allows the detection of even small increases in the site-specific risk of second cancers.<sup>7</sup> An additional advantage is that the observed and expected numbers of cancers derive from the same reference population. Disadvantages of this approach include the limited availability of treatment data, underreporting of second cancers<sup>8,9</sup> (in particular hematologic malignancies and bilateral cancers in paired organs), and different diagnostic criteria for second cancers. Population-based registries differ greatly in these aspects and, hence, in their usefulness for second cancer studies. If treatment data are not available, it is impossible to determine whether excess risk for a second malignancy is related to treatment or to shared etiology with the first cancer. Despite their disadvantages, population-based registries are especially well suited to broadly evaluate which second cancers occur in excess after a wide spectrum of different first primary malignancies. They also provide a valuable starting point for case-control studies that evaluate treatment effects in detail (see later in this section).

A major strength of clinical trial databases is that detailed treatment data on all patients are available. Comparison of second cancer risk between the treatment arms of the trial controls for any intrinsic risk for a second malignancy associated with the first cancer. Limitations of most trials include the small number of patients involved and the frequent lack of data on subsequent therapy. The dearth of large numbers becomes more serious when the second cancer of interest has a low background incidence (e.g., leukemia). Furthermore, the end points of interest in the majority of clinical trials include only treatment response and survival, not the development of second cancers. Therefore, many clinical trials do not routinely collect information on second malignancies, and some do not collect any data beyond

5 years. Routine reporting and assessment of second malignancy risk should become an integral part of clinical trial research. <sup>10</sup>

Many large cancer treatment centers maintain registries of all admitted patients. Most of these registries have been in existence for decades and collect extensive data on treatment and follow-up. As compared with trial data, hospital registries provide larger patient numbers and a wider variety of treatments and dose levels, which may yield important information on drug and radiation carcinogenesis. Most studies of second cancer risk after Hodgkin's disease have been based on data accrued from hospital registries. <sup>11,12 and 13</sup>

The cohort study is not an efficient design when examining detailed treatment factors (e.g., cumulative dose of alkylating agents) in relation to second cancer risk. Most cohorts are fairly large (to yield reliable estimates of second cancer risk), rendering the collection of detailed treatment data for all patients prohibitively expensive and time-consuming. In such instances, the so-called nested case-control study within an existing cohort is the preferred approach. The case group consists of all patients identified with the second cancer of interest, whereas the controls are a matched sample of all patients in the cohort who did not develop the cancer concerned, although they experienced the same amount of follow-up time. Matching factors typically include age, gender, and calendar year of diagnosis of the first cancer. Even when the control group is three times as large as the case group, detailed treatment data need only be collected for a small proportion of the total cohort. In each case-control investigation, it is critical to the validity of the study that the controls are truly representative of all patients who did not contract the second cancer of interest. In data analysis, treatment factors are compared between cases and controls, and the risk associated with specific therapies is estimated relative to the risk in patients who received other treatments. The cumulative risk of developing a second malignancy cannot be derived from a case-control study. Treatment-specific absolute excess risks can be estimated, however, when the case-control study follows a cohort analysis. Although case-control methodology has not been applied to the investigation of second cancer risk for a long period, <sup>14,15</sup> several landmark studies have already demonstrated its strengths. <sup>8,16,17,18,19,20,21 and 22</sup>

## CARCINOGENICITY OF INDIVIDUAL TREATMENT MODALITIES

### RADIOTHERAPY

The carcinogenic potential of ionizing radiation was first recognized in the mid-twentieth century, <sup>23,24 and 25</sup> and comprehensive reviews have now been published. <sup>26,27 and 28</sup> Much of the data with regard to radiation effects in humans has derived from epidemiologic studies of the atomic bomb survivors in Japan, <sup>29,30,31 and 32</sup> occupationally exposed workers, <sup>33,34</sup> patients given large amounts of diagnostic radiation, <sup>35,36</sup> and patients treated with radiotherapy for malignant <sup>16,19,37,38 and 39</sup> and nonmalignant diseases. <sup>40,41,42,43 and 44</sup> Most types of cancer, with the exception of chronic lymphocytic leukemia, can be caused by exposure to ionizing radiation. <sup>26,30,45</sup> Boice et al. <sup>28</sup> have ranked various body tissues with regard to cancer induction by radiation; certain sites, such as the thyroid, female breast, and bone marrow, clearly are more radiosensitive than others.

The excess risk of leukemia attributable to irradiation is observed within a few years after exposure, with a peak at 5 to 9 years, and a slow decline thereafter. <sup>16,27,30,40,41</sup> Some controversy exists as to whether, and when, leukemia risk decreases to background levels in the population. <sup>16,30,41,46,47</sup> In the atomic bomb survivors, risk declined more rapidly for those exposed earlier in life. <sup>30</sup> Increased risks of solid tumors have been shown to emerge much later. After a minimum induction period of 5 to 10 years, <sup>12,13,37,40,41,48</sup> solid tumor risk appears to follow a time-response model consistent with a multiplicative relationship with the underlying incidence in the population—that is, risk after exposure is proportional to the background incidence of cancer over time. <sup>27,41</sup> Data are inconsistent as to whether the risk remains elevated throughout life. Studies in the atomic bomb survivors <sup>31</sup> and in women treated for benign gynecologic disorders <sup>41,49</sup> have shown that the excess relative risk per Gray (Gy) tends to be fairly stable over time for at least 30 years after radiation. However, the last update of the mortality experience of ankylosing spondylitis patients showed that, 25 years after irradiation, risk had decreased for a number of malignancies. <sup>40</sup> In the few studies of second cancer risk in which the time course beyond 20 years from first treatment was evaluated, the relative risks of solid tumor development tended to decrease in very long-term survivors. <sup>50,51</sup> The most recent cancer incidence report on the Japanese atomic bomb survivors, with 42 years of follow-up, indicated that the excess relative risk decreased with time for the younger age-at-exposure groups and remained virtually constant for the older cohorts. <sup>31</sup> Cancer incidence data from the atomic bomb survivors and five other groups exposed to radiation have been analyzed to specifically address the evolution of risk with increasing time since exposure in childhood. <sup>52</sup> Ten to 15 years after radiation exposure, the relative risk of solid tumors decreased with increasing follow-up time (5.7% to 6.1% per year). The excess absolute risk, however, significantly increased with time since exposure. <sup>52</sup>

An important part of our knowledge of radiation carcinogenesis derives from populations exposed to relatively low levels of radiation, such as the atomic bomb survivors. For solid tumors, convincing evidence for a strongly linear radiation dose-response in the lower dose ranges (up to approximately 5 Gy) has emerged. <sup>31,35,40</sup> The results for leukemia are less consistent, but data from most studies are compatible with a linear trend for doses of less than 1.5 to 2.0 Gy. <sup>16,30,45</sup> Extrapolation of radiation effects from low doses to the high-dose ranges used therapeutically cannot be done with certainty, because of the possibility of cell killing at high doses. Therefore, more recent studies of second cancer risk have focused on the shape of the radiation dose-response curve in the high-dose range.

Radiation-related leukemia risk depends on a number of parameters, such as radiation dose to the active bone marrow, dose rate, and percentage of marrow exposed. Consistent evidence indicates that the excess risk of leukemia per unit radiation dose is much higher at low doses than at the high doses administered for the treatment of malignant disease. <sup>16,30,45,47</sup> This phenomenon has been attributed to cell killing or inactivation of potentially leukemic cells at the higher radiation doses. <sup>16,27</sup> Many studies in cancer patients have shown that high radiation doses to a limited field confer very little or no increased risk of leukemia. <sup>8,17,18,20</sup> Both in the atomic bomb survivors and in patients who received radiotherapy for cervical cancer, leukemia risk appeared to increase with increasing average dose to the bone marrow until approximately 4 Gy, above which leukemia risk was progressively reduced with increasing dose. <sup>16,30</sup> However, leukemia risk in survivors of uterine cancer showed little evidence for a downturn in risk at bone marrow doses as high as 6 to 14 Gy <sup>45</sup>; at more than 1.5 Gy, the dose-response pattern was more or less flat, and the risk after continuous exposures from brachytherapy at comparatively low doses was similar to that after fractionated exposures at much higher doses from external beam radiotherapy. Clearly, more research is needed into the effects of dose fractionation and portion of bone marrow irradiated. Age at exposure to irradiation does not appear to greatly influence the risk of radiation-induced leukemia, <sup>30,41,45,53</sup> although decreasing relative risk with increasing age at exposure has been reported for one radiogenic leukemia subtype [acute lymphocytic leukemia (ALL)]. <sup>47</sup>

In contrast, studies of radiogenic breast cancer have demonstrated that age at exposure is a major determinant of risk, with the greatest risk for those irradiated as children and adolescents. <sup>32,50,54</sup> Irradiation may thus affect cells of the mammary ducts before full organ development begins. Atomic bomb survivors who were younger than 10 years old at the time of the bombing had an excess relative risk per Gy five times that of women who were older than 40 years when exposed. A strong trend of increasing breast cancer risk with decreasing age at exposure was also observed in patients irradiated for Hodgkin's disease, <sup>13,39,50,55</sup> with no excess breast cancer risk apparent among women irradiated at 40 years or older. <sup>13,22,35,39,55</sup> In two studies, increased breast cancer risk after radiation exposure in childhood emerged at an early age (younger than 40), before the peak incidence in the population. <sup>50,56</sup> In the low-dose range, breast cancer risk increases linearly with radiation dose. <sup>35,36,44</sup> For a specified dose, the age-specific excess rates of breast cancer were found to be remarkably similar across studies in the Japanese atomic bomb survivors and in medically irradiated populations in the United States. <sup>32,35</sup> Very few studies have examined whether linear dose-response extends to the higher dose ranges used therapeutically. However, long-term survivors of Hodgkin's disease who were younger than 20 years when they received breast doses between 4 and 45 Gy from mantle field irradiation were reported to have a 40- to 75-fold increased risk of breast cancer. <sup>13,39,57</sup> One study found that a higher radiation dose to the mantle region (20 Gy or more vs. less than 20 Gy) was associated with a significantly greater increase of breast cancer risk. <sup>57</sup>

Risk of lung cancer also rises with increasing radiation dose in the lower dose range, <sup>31,40</sup> but studies in survivors of Hodgkin's disease <sup>38</sup> and breast cancer <sup>58</sup> suggest that the risk may level off at doses higher than 9 to 10 Gy. A similar leveling of risk at doses of 10 Gy or more has been observed for radiation-induced thyroid cancer. <sup>59,60</sup> However, even at thyroid doses up to 60 Gy, the risk of thyroid cancer did not decrease. <sup>60</sup> For bone sarcoma, two studies in survivors of childhood cancer <sup>19,61</sup> show no evidence of increased risk for doses less than 10 Gy to the site of the bone tumor. Beyond 10 Gy, risk for bone sarcoma rose sharply with increasing dose, reaching more than 90-fold at doses of 30 to 50 Gy. <sup>61</sup> Importantly, studies have shown that, also for solid tumors other than breast cancer, the excess relative risk due to radiation is much greater for children and adolescents than for adults. <sup>12,31,50,55,62,63</sup> Significantly greater relative risks with younger age at radiation exposure have been reported for lung cancer, <sup>63</sup> thyroid cancer, <sup>31</sup> bone sarcoma, <sup>12,62</sup> and gastrointestinal cancer. <sup>50,63</sup> After radiation in childhood, the excess relative risk per Gy for thyroid cancer [RR, 7.7; 95% confidence interval (CI), 2.1 to 28.7] is higher than for any other solid malignancy. <sup>31</sup>

For radiogenic lung cancer, the interaction of radiation with other risk factors, such as smoking, has been examined. Studies in uranium and tin miners exposed to radon have indicated that smoking and radiation may act multiplicatively (or at least supraadditively) in the causation of lung cancer, <sup>64,65 and 66</sup> implying that the

absolute risk of developing radon-induced cancer is much higher in smokers than in nonsmokers. In Hodgkin's disease patients, the combined effects of smoking and high-dose radiotherapy for Hodgkin's disease were significantly stronger than multiplicative.<sup>38,67</sup> In the latter study, the increase in lung cancer risk with increasing radiation dose was significantly greater among patients who continued to smoke after diagnosis of Hodgkin's disease than among those who refrained from smoking. As discussed more extensively in the previous edition of this text,<sup>68</sup> interaction models accounting for the sequencing of radiation and smoking suggest that radiation may act as a powerful promoter of cells initiated by smoking.

The carcinogenic effects of therapeutic irradiation deserve much more study. Issues to be clarified include the shape of the radiation dose-response curve in the higher dose range, the duration of radiation-induced cancer risk and, importantly, the interaction of radiotherapy with environmental carcinogens (e.g., smoking) and genetic susceptibility. Increasing evidence suggests that genetic factors contribute to the development of radiation-induced cancers. This is perhaps best demonstrated in survivors of hereditary retinoblastoma who harbor a heterozygous germline mutation in the RB1 tumor suppressor gene, and who have a much greater risk of developing osteosarcomas within the radiation field than children irradiated for nonhereditary retinoblastoma.<sup>69</sup> In addition, two studies showed that patients with a positive family history of cancer are more likely to develop radiation-associated second malignancies.<sup>70,71</sup> In view of the postulated radiation sensitivity of heterozygous carriers of the mutated ataxia-telangiectasia (ATM) gene, it has been speculated that AT heterozygotes (approximately 1.0% of the population) may have an increased risk of radiation-induced cancer, specifically breast cancer.<sup>72,73</sup> In two studies, however, no ATM mutations were found in a total of 56 women who had developed breast cancer after radiotherapy for Hodgkin's disease.<sup>71,74</sup> Further studies should focus on the identification of other genes that may influence susceptibility to the DNA damaging effects of radiation. Such research will provide more insight into the mechanisms underlying radiation carcinogenesis and will also be of clinical benefit in minimizing radiation exposure to the most susceptible subgroups of the population.

## CHEMOTHERAPY

The development of acute myeloid leukemia (AML) after chemotherapy for malignant disease was reported as early as 1970 by Kyle et al.<sup>75</sup> In the following three decades, the occurrence of this late effect has increased to the extent that, in some institutions, treatment-related AML now comprises up to 10% to 20% of all such entities.<sup>76</sup> Moreover, it is now established that the spectrum of treatment-related leukemia extends beyond AML. ALL, for example, is increasingly recognized as therapy-related<sup>77,78</sup> and may comprise 5% to 10% of all secondary acute leukemias.<sup>78</sup> Chronic granulocytic leukemia accounts for a small percentage of secondary leukemia,<sup>77,79</sup> and has been included in numerous analytic studies in which associations with prior chemotherapy have been evaluated,<sup>8,17,18,20,80,81</sup> although separate risk estimates have not been presented. To date, only chronic lymphocytic leukemia has not been convincingly associated with prior exposure to chemotherapy.

Chemotherapy is far more potent than radiotherapy in inducing leukemia. It has become evident that at least two major syndromes of treatment-related leukemia may exist<sup>82,83</sup>: "classic" alkylating agent-induced AML and acute leukemia related to the topoisomerase II inhibitors. Risk of alkylating agent-related leukemia typically begins to increase 1 to 2 years after the start of chemotherapy, peaks in the 5- to 10-year follow-up period, and decreases afterward.<sup>8,13,17,20,84</sup> Even in large patient series, the number of long-term survivors has typically been too small to determine whether 15 to 20 years after chemotherapy the risk of leukemia returns to the background level of the population.<sup>13</sup> Although one registry-based study indicates that leukemia risk might persist among 15-year survivors of testicular cancer,<sup>85</sup> it is not clear whether these late excesses might reflect the influence of salvage therapy. More than 50% of leukemias after alkylating agent therapy present initially as myelodysplastic syndromes (MDS), whereas *de novo* AML is preceded by MDS much less frequently.<sup>77</sup> Most cases of MDS progress to AML within 1 year.<sup>77</sup> Cytogenetic studies of alkylating agent-related AML/MDS have shown unbalanced chromosome aberrations, typically with loss of whole chromosomes 5 or 7 (or both), or various parts of the long arms of these chromosomes.<sup>86</sup> Morphologically, alkylating agent-related AML most commonly consists of French-American-British (FAB) subtypes M1/M2, but most subtypes,<sup>77</sup> including erythroleukemia,<sup>20</sup> have been observed. Survival after secondary AML is generally quite poor, typically only several months.<sup>87</sup>

Alkylating agents with known leukemogenic effects in humans include mechlorethamine, chlorambucil, cyclophosphamide, melphalan, semustine, lomustine, carmustine, prednimustine, busulfan, and dihydroxybusulfan.<sup>20,77,82,88,89</sup> and <sup>90</sup> Controversial findings have been reported with regard to procarbazine,<sup>88,91</sup> which demonstrates an underlying mechanism of action similar to alkylating agents. Few studies have addressed the relative leukemogenicity of the various alkylating drugs, but a strong body of evidence to date suggests that, at doses of equal therapeutic effect, cyclophosphamide is substantially less leukemogenic than melphalan, mechlorethamine, chlorambucil, lomustine, and thiotepa.<sup>8,17,20,89,90,92</sup> The risk of alkylating agent-related AML has been shown to increase with increasing cumulative dose or duration of therapy.<sup>20,89,90</sup> Few studies have attempted to separate the effects of cumulative dose, duration of treatment, and dose intensity, which tend to be highly correlated, but limited evidence to date suggests that cumulative dose may be a pivotal determinant of risk<sup>20,89</sup> (discussed later in [Hodgkin's Disease](#)).

The platinating agents cisplatin and carboplatin are among the most important cytotoxic drugs introduced since the 1960s and are widely used to treat many cancers. The platinum compounds, however, demonstrate carcinogenicity *in vitro* and in laboratory animals,<sup>10</sup> forming intrastrand and interstrand DNA cross-links similar to bifunctional alkylating agents. In a population-based study of women with ovarian cancer,<sup>81</sup> cisplatin-based combination chemotherapy was linked to significantly increased risks of leukemia (*P* trend for cumulative dose <.001) in a multivariate model adjusted for other treatment parameters (discussed later in [Ovarian Cancer](#)). Future studies should evaluate whether other drug combinations that include platinum might also be linked to elevated risks of leukemia, because it is not clear whether cisplatin acts as a human leukemogen only in combination with selected cytotoxic agents.

The topoisomerase II inhibitors, especially the epipodophyllotoxins, have been implicated in the development of a clinically and cytogenetically distinct type of AML. The International Agency for Research on Cancer (IARC) has concluded that the epipodophyllotoxins etoposide and teniposide are probably carcinogenic to humans.<sup>93</sup> Raitan and coworkers<sup>94</sup> were the first to recognize the potentially leukemogenic properties of etoposide-containing regimens in patients with non-small cell lung cancer, which also has been documented for patients with other types of malignancies.<sup>95,96</sup> and <sup>97</sup> As compared with "classic" alkylating agent-induced AML, epipodophyllotoxin-related AML has a shorter induction period (median, 2 to 3 years) and generally lacks a preceding phase of MDS. Furthermore, this type of AML appears to be characterized by balanced translocations involving chromosome bands 11q23, 21q22, and 3q23,<sup>93,98</sup> as well as morphologic features consistent with acute monoblastic or myelomonocytic leukemia (M4 or M5 according to the FAB criteria).<sup>82,99,100</sup> It is unclear whether epipodophyllotoxin-related AML has a better prognosis than "classic" alkylating agent-related AML, which is notoriously resistant to antileukemic treatment.<sup>86,97</sup>

Evidence has accumulated that the anthracyclines doxorubicin and 4-epi-doxorubicin, which are intercalating topoisomerase II inhibitors, may induce a similar type of AML as the one related to epipodophyllotoxin treatment.<sup>17,101,102</sup> In 1987, the IARC concluded that doxorubicin was probably carcinogenic to humans, based on a review of limited data.<sup>88</sup> As with many cytotoxic drugs, an evaluation of the carcinogenic potential of doxorubicin is complicated, because it is typically given in combination with other chemotherapeutic agents, including alkylators.<sup>17,101,102</sup> and <sup>103</sup> Curtis et al.<sup>20</sup> found no increase in the risk of leukemia associated with doxorubicin therapy for breast cancer, after adjusting for the effects of alkylating agents and radiotherapy. Although increasing dose of doxorubicin to treat childhood cancer seemed weakly associated with an increased risk of leukemia after adjustment for alkylating agents,<sup>18</sup> the investigators concluded that the excess risk was almost completely attributable to alkylators. In a study of children with Wilms' tumor,<sup>104</sup> the relative risk of leukemia (six cases) after doxorubicin-containing regimens was approximately 14-fold; however, because a relatively constant dose (300 mg/m<sup>2</sup>) of doxorubicin was used and data for treatment of relapse were incomplete, evaluation of a dose-response relation was not possible.

The relative leukemogenicity of the anthracyclines and different epipodophyllotoxins is not known. Furthermore, it is unclear whether the schedule of administration or the cumulative dose is the major determinant of leukemia risk (discussed in more detail later in the sections [Testicular Cancer](#) and [Pediatric Malignancies](#)).<sup>95,96</sup> and <sup>97,105,106</sup> In view of the widespread use of epipodophyllotoxins and anthracyclines in curative treatments, continued evaluation of the leukemogenic potential of these agents is urgently needed.<sup>83,106</sup> Detailed descriptions of molecular mechanisms involved in the development of AML after administration of these cytotoxic drugs have been provided elsewhere.<sup>82,83,107,108</sup> and <sup>109</sup> As postulated by Pedersen-Bjergaard and Rowley,<sup>82</sup> cytostatic drugs with different mechanisms of action [i.e., direct binding to DNA (alkylating agents) and inhibition of DNA-topoisomerase II (epipodophyllotoxins and anthracyclines)] may have a synergistic effect in leukemogenesis.

The antimetabolites have generally not been regarded as carcinogenic,<sup>88</sup> and Cheson et al.<sup>110</sup> observed that nucleoside analogue therapy for chronic lymphocytic leukemia did not appear to confer a significantly increased risk of second cancer. However, in a report<sup>111</sup> from St. Jude's Children's Research Hospital, it was shown that children with ALL who received cranial irradiation and who had wild-type thiopurine methyltransferase phenotype had an 8.3% cumulative risk of brain cancer, while children with ALL who received irradiation and had a defective phenotype had a 42% risk (*P* = .0077). Patients also had received concurrent systemic chemotherapy with high-dose (75 mg/m<sup>2</sup>) 6-mercaptopurine plus high-dose methotrexate. It was hypothesized that the defective thiopurine methyltransferase activity resulted in higher exposures to thioguanine nucleotide metabolites of 6-mercaptopurine during the period of radiation.

Just as the pharmacology of effective cancer chemotherapy is impacted by underlying principles of pharmacokinetics and pharmacodynamics (see [Chapter 19.1](#)), these influences likely contribute to the development of secondary leukemia. The possible role of polymorphisms in drug-metabolizing genes, including the cytochrome P-450 enzymes, glutathione S-transferases, and arylamine N-acetyltransferases in chemotherapy-related leukemias has been reviewed. <sup>112</sup> Felix et al. <sup>113</sup> described an association between CYP3A4 genotype and treatment-related leukemia. Other factors in the development of chemotherapy-related leukemias may include interindividual differences in repair of DNA damage, <sup>114,115</sup> germline mutations in tumor suppressor genes, <sup>76,112</sup> administration of concomitant medications, and interpatient variation in renal and hepatic function. Clarification of the important interrelationships between these factors are critical to a better understanding of individual susceptibility to secondary leukemia. Because cancer patients frequently receive large doses of cytotoxic drugs, interindividual differences in drug absorption, distribution, metabolism, and excretion are accentuated. Until these influences and their interrelationships are better understood, empiric end points, such as the development of acute hematopoietic toxicity after chemotherapy, might be explored for their value as possible surrogate markers of secondary leukemia risk. <sup>89</sup> For cytotoxic agents for which both oral and intravenous formulations are available, the route of administration in describing dose-response associations with secondary leukemia risk should also be taken into account. <sup>81</sup> Whether chemoprotectants such as amifostine (WR-2721), which ameliorates the myelosuppressive effects of alkylating agents <sup>116</sup> and platinum compounds, <sup>117</sup> might possibly contribute to decreased risks of second leukemias should be examined.

Many chemotherapeutic agents are known mutagens and animal carcinogens, <sup>88</sup> and the induction period of solid tumors may be longer than the observation period available in published research. Thus, the question of whether the increased risks of leukemia after chemotherapy might be later followed by excess solid tumors is important. To date, the causal link between cyclophosphamide and bladder cancer represents one of the few established relationships between a specific cytostatic drug and a solid tumor (reviewed later in [Non-Hodgkin's Lymphoma](#)). <sup>21,118,119</sup> Elevated risks of bone sarcomas <sup>19,61</sup> and possibly lung cancers <sup>120,121</sup> also have been observed after alkylating agent chemotherapy. The contribution of chemotherapy to radiation-induced solid tumors <sup>50,55,104,111,122</sup> should also be investigated. For example, as discussed in the section [Pediatric Malignancies](#), doxorubicin has been found to potentiate the development of second solid tumors after radiation for Wilms' tumor. <sup>104</sup> The investigators of this study <sup>104</sup> hypothesized that doxorubicin may inhibit the repair of radiation-induced damage, likely through its interaction with DNA topoisomerase II. Newton et al. <sup>123</sup> reported a significantly shorter time to bone sarcoma in children given both anthracyclines and radiation to treat cancer. The radiation enhancement properties of other cytotoxic drugs (e.g., platinum, hydroxyurea, and 5-fluorouracil) have been well described <sup>124</sup>; whether these features might be correlated with increased risk of solid tumors in cancer patients who survive long term after radiotherapy might also be explored.

## RISK OF SECOND MALIGNANCY IN PATIENTS WITH SELECTED PRIMARY CANCERS

### HODGKIN'S DISEASE

In view of the excellent cure rates that are currently achieved in the relatively young population of Hodgkin's disease patients, it has become increasingly important to evaluate how the occurrence of second cancers affects their long-term survival. Since the first reports of increased second cancer risk in Hodgkin's disease patients in the early 1970s, <sup>125,126</sup> nearly all major treatment centers have evaluated second cancer risk in their patients. An excess of AML in chemotherapy-treated patients and an increased risk of solid tumors in radiotherapy-treated patients have been reported consistently in the literature. <sup>127</sup> The overall risk of selected second malignancies compared with the general population is given in [Table 55.7-1](#), based on a combined analysis of three studies that included a total of 9618 patients. <sup>50,63,128</sup>

The largest relative risk (95-fold) is observed for AML, followed by a 19-fold increased risk for NHL, tenfold excesses for connective tissue and bone cancers, and a ninefold elevated risk for thyroid cancer. Moderately increased risks (two- to fivefold) are observed for a number of solid tumors, such as cancers of the lung, stomach, colon, breast, mouth, and pharynx, as well as melanoma. Because AML and NHL are diseases with a low incidence in the general population, even a high relative risk compared to the population may translate into a low cumulative (actuarial) risk. As shown in [Figure 55.7-1](#), for the entire follow-up period, the cumulative risk of solid tumors far exceeds that of leukemia or NHL. <sup>50</sup> Absolute excess risk is the best measure to judge which subsequent tumors contribute most to the second cancer burden. [Table 55.7-1](#) shows that, compared with the general population, Hodgkin's disease patients experience an excess of 62 malignancies per 10,000 person-years of observation. Solid tumors account for the majority of excess cancers (38 per 10,000 patients per year), with lung cancer contributing 13 excess cases per 10,000 person-years. Leukemia and NHL each account for approximately 12 cases per 10,000 person-years.

The evolution of second malignancy risk over follow-up time varies by tumor site. In the majority of studies, increased leukemia risk is observed as early as 2 to 4 years after initiation of chemotherapy, with peak occurrence between 5 and 9 years and decreasing risks thereafter. <sup>8,13,48,50,57,63</sup> In studies with large numbers of long-term survivors, significantly increased relative risks are still observed for 15 years after first treatment. <sup>13,50,63</sup> The relative risk of NHL is already greatly increased in the first 5 years after treatment. In some studies, the risk remains rather constant over time, <sup>48,55</sup> whereas others report that risk increases with time since treatment. <sup>12,13</sup> The relative risk of solid tumors is minimally elevated in the 1- to 4-year follow-up period and increases steadily with increasing follow-up time from 5 years since first treatment. <sup>12,13,48,50,55,63,84</sup> For several tumor sites (breast, thyroid), the excess risk does not become apparent until after 10 or even 15 years of observation. In the few studies that include data on 20-year survivors, the relative risk of solid tumors continued to increase through the 15- to 20-year follow-up period. <sup>13,39,50,55,57,63,84,122</sup> Almost no data are available on the time course of risk 20 or more years after treatment. In a study of patients diagnosed with Hodgkin's disease before age 40 in the Netherlands, the relative risk of solid tumor development in 25-year survivors was somewhat lower than in the 15- to 24-year follow-up period (RRs of 5.3 and 8.8, respectively;  $P = .29$ ), suggesting that relative risk may decrease in very long-term survivors. <sup>50</sup> In this study, the 25-year risk of developing any second malignancy was 27.7% (95% CI, 23.1% to 32.8%), compared with 4% in the general population (see [Fig. 55.7-1](#)). <sup>50</sup> Because the relative risks of leukemia, NHL, and solid tumors each show a distinctive pattern with time since first treatment, the absolute excess risks in 10-year survivors differ greatly from those observed in the entire patient population. Based on combined estimates from two of the studies included in [Table 55.7-1](#), <sup>50,63</sup> lung cancer contributes most to the absolute excess risk in 10-year survivors, with 22 excess cases per 10,000 patients per year, followed by NHL (16 per 10,000 per year), gastrointestinal tract tumors (15 per 10,000 per year), and leukemia (7 per 10,000 per year). In females, breast cancer accounts for most of the absolute excess risk in 10-year survivors (58 per 10,000 per year). <sup>39,50</sup>

**TABLE 55.7-1. Relative Risk of Second Cancers after Hodgkin's Disease: Combined Results from Three Large Studies in 9618 Patients**

For several second malignancies, the association with treatment factors has been investigated in detail. Leukemia after Hodgkin's disease is certainly the most studied malignancy induced by treatment, and extensive knowledge of its risk factors has emerged.<sup>127</sup> Radiotherapy alone is associated with very little or no increased risk of leukemia,<sup>12,48,63,84,89</sup> whereas alkylating agent chemotherapy is linked with greatly elevated risk. Several studies have compared the leukemogenicity of different chemotherapy regimens. Risk of AML rises sharply with an increasing number of mechlorethamine, vincristine, procarbazine, and prednisone (MOPP or MOPP-like) cycles.<sup>8,89</sup> The risk associated with 10 to 12 MOPP cycles appears to be approximately three to five times higher than the risk after six MOPP cycles.<sup>8,89</sup> Since the 1980s, MOPP-only chemotherapy has been gradually replaced by doxorubicin, bleomycin, vinblastine, and dacarbazine [ABV(D)]-containing regimens in many centers. Only a few reports have described AML occurrence after ABV(D) alone. Patients treated with ABVD in the Milan Cancer Institute, where this regimen was designed, were shown to have a significantly lower risk of AML than MOPP-treated patients (15-year cumulative risks of 0.7% and 9.5%, respectively).<sup>129</sup> Another study showed that Hodgkin's disease patients treated with MOPP/ABV(D)-containing regimens in the 1980s had a substantially lower risk of AML/MDS than patients treated in the 1970s with MOPP alone (10-year cumulative risks of 2.1% and 6.4%, respectively,  $P = .07$ ).<sup>13</sup> The German-Austrian Pediatric Hodgkin's Disease Group observed a low risk of AML (1.1% at 15 years) after regimens that contained relatively low doses of procarbazine, doxorubicin, and cyclophosphamide, without mechlorethamine.<sup>130</sup>

An important question is whether radiotherapy adds to the leukemia risk associated with chemotherapy. Evidence that combined modality treatment results in greater risk than chemotherapy alone is provided by several reports,<sup>84,129,131</sup> whereas other large series indicate that the risk of AML after combined treatment is comparable to that after chemotherapy alone.<sup>8,12,13,48,57,63,89,91</sup> These inconsistent results may be due partly to differences in treatment regimens between studies but also to lack of adjustment for type and amount of chemotherapy in some reports. The interaction between radiotherapy and chemotherapy could be evaluated most rigorously in the large case-control study by Kaldor and associates,<sup>8</sup> which included 163 cases of leukemia after Hodgkin's disease. When examining the combined effects of radiation dose to the active bone marrow and number of mechlorethamine-procarbazine containing cycles, it was found that, for each category of radiation dose (less than 10, 10 to 20, and more than 20 Gy to the marrow), leukemia risk clearly increased with the number of chemotherapy cycles. In contrast, among patients with a given number of chemotherapy cycles, risk of leukemia did not consistently increase with higher radiation dose. Taken together, the preponderance of available data does not support the hypothesis that the combination of chemotherapy and radiotherapy confers a higher risk of leukemia than chemotherapy alone.

Several studies have identified splenectomy as an independent risk factor for the development of AML,<sup>8,84,91,129,132</sup> with an approximate twofold difference in risk between patients who did and did not undergo a splenectomy. In other reports, however, splenectomy was either not linked or was only weakly related to leukemia risk.<sup>57,131</sup> The mechanism underlying the association with splenectomy remains unclear, but a relationship with immunologic function of the spleen seems likely.<sup>89</sup>

The modifying effect of host-related factors, such as age, on leukemia risk in Hodgkin's disease survivors has been examined in a number of studies and has been reviewed elsewhere.<sup>127</sup> The reported higher *cumulative* risk of AML in older Hodgkin's disease patients as compared to younger ones simply reflects the higher baseline incidence of the disease in older persons. In the few studies that have analyzed *relative* risk of leukemia by age, based on comparisons to general population expectations, no differences between age groups were observed,<sup>12,50,55</sup> or the relative risk of AML was even significantly greater at younger ages than at older ages.<sup>8,63</sup> The risk of AML in relation to treatment-associated acute and chronic bone marrow toxicity has been examined in only one study to date.<sup>89</sup> Significantly increased risks of leukemia were found among patients who developed thrombocytopenia, either in response to initial therapy or during follow-up. After adjustment for type and amount of chemotherapy, patients who showed a decrease of 70% or more in platelet counts after initial treatment had an approximately fivefold higher risk of developing leukemia than patients who showed a decrease of 50% or less. Severe acute thrombocytopenia may indicate greater bioavailability of cytotoxic drugs, which would likely contribute to the development of leukemia.

Although increased risks of NHL after Hodgkin's disease are consistently reported, the causes of the excess risk are not well understood.<sup>127</sup> Because increased risks of NHL occur in immunosuppressed patients, such as transplantation recipients,<sup>133</sup> and because Hodgkin's disease may be accompanied by immunosuppression,<sup>134</sup> several investigators have argued that the elevated risk of NHL may be attributed to Hodgkin's disease itself rather than to its treatment. This view is supported by several studies in which risk did not vary appreciably between treatments.<sup>12,48,55,63</sup> In other studies, however, the risk of NHL was found to be lowest among patients treated with radiotherapy alone and highest among patients who received intensive combined modality treatment, both initially and for relapse.<sup>13,84,135,136</sup> The inconsistent results regarding the relationship with treatment may be partly attributed to diagnostic misclassification—that is, misdiagnosis of the primary tumor as Hodgkin's disease, whereas NHL was represented according to modern lymphoma classification schemes.<sup>127</sup> In only very few studies were diagnostic pathology slides of the second NHL and original Hodgkin's disease reviewed to avoid such misclassification.<sup>13,48</sup> Although transformation to NHL may be part of the natural history of some types of Hodgkin's disease, the role of intensive combined modality treatment and its associated immunosuppression should be explored further.

Increased risks of solid cancers after Hodgkin's disease generally have been attributed to radiotherapy.<sup>12,13,39,48,50,55,57,84,122,127,137</sup> Excesses of melanoma, however, are more likely to be related to immunosuppression accompanying Hodgkin's disease or its treatment, because elevated risks appear as early as in the 1- to 4-year follow-up interval.<sup>63,138</sup> The other sites for which excess solid cancers have been reported (lung, breast, gastrointestinal tract, thyroid, bone, connective tissue) are those for which elevated risks also have been described in other radiation-exposed cohorts.<sup>26,28</sup> One case-control study examined lung cancer risk in relation to the radiation dose to the affected lung area, as well as the modifying effect of the patient's smoking habits.<sup>36</sup> Based on 30 cases of lung cancer in a cohort of 1939 patients with Hodgkin's disease, it was observed that lung cancer risk rose with increasing radiation dose ( $P$  trend = .01), with a relative risk of 9.6 (95% CI, 0.93 to 98.0) for patients who received 9 Gy or more as compared to those who received less than 1 Gy. The increase in risk of lung cancer with increasing radiation dose was significantly greater among patients who smoked after diagnosis of Hodgkin's disease than among those who refrained from smoking.

A very important question is whether chemotherapy for Hodgkin's disease can also induce solid cancers, and if so, at which sites. A few studies have raised concern about a possible long-term effect of chemotherapy on lung cancer risk.<sup>48,63,120</sup> The British National Lymphoma Investigation cohort study of 2846 patients<sup>48</sup> showed a significantly increased risk of lung cancer after chemotherapy alone, with the relative risk (4.2; 95% CI, 2.2 to 7.3) of similar magnitude as that observed in patients treated with either extensive radiotherapy or combined modality treatment. A similar excess risk of lung cancer in patients given chemotherapy, but no radiotherapy, was found in a more recent expansion and update of this study.<sup>63</sup> No increased risk of lung cancer, or solid tumors overall, followed chemotherapy alone in several other series.<sup>12,50,57,84,89</sup> However, the expected number of solid tumors 10 or more years after chemotherapy alone was less than two in nearly all negative studies, rendering it impossible to exclude a moderate increase in risk. If chemotherapy indeed affects solid tumor risk, one would expect that patients receiving combined modality treatment would have a greater relative risk than patients treated solely with radiotherapy. Only one study to date has reported a significantly greater risk for solid cancers overall after chemotherapy and radiotherapy compared with irradiation alone,<sup>55</sup> whereas no such difference has been found in the majority of investigations.<sup>12,48,57,84,89,128</sup> However, for selected solid cancer sites (e.g., gastrointestinal tract), larger risks were observed after combined modality treatment than after irradiation alone.<sup>50,63,122</sup> For lung cancer risk in irradiated patients, two case-control studies showed no association with chemotherapy overall, the number of cycles, or the cumulative doses of mechlorethamine and procarbazine,<sup>38,120</sup> which argues against an important contribution of chemotherapy to lung cancer risk.

The inconsistent results reported with regard to the influence of chemotherapy on solid tumor risk may be partly related to the fact that most studies considered all solid tumors combined, whereas chemotherapy may differentially affect the risk of tumors at disparate sites. A study from the Netherlands Cancer Institute demonstrated that the addition of salvage chemotherapy to initial radiotherapy, as compared to initial irradiation alone, did not influence the risk of solid cancers overall but significantly increased the risk of solid tumors other than breast cancer (RR, 9.4, compared to 4.7 for initial irradiation alone).<sup>50</sup> Conversely, patients who received salvage chemotherapy were found to experience significantly lower risks of breast cancer than patients treated with radiotherapy alone (RRs of 2.8 and 7.6, respectively), possibly related to premature ovarian failure due to intensive chemotherapy.<sup>50</sup> Additional studies are warranted to examine which cytotoxic drugs might be responsible for site-specific increased risks of solid tumors.

The strongly elevated risk of breast cancer after radiotherapy for Hodgkin's disease has become a major concern for female survivors.<sup>139,140</sup> and <sup>141</sup> In a Dutch study, 27 cases of breast cancer were observed in 544 female patients diagnosed with Hodgkin's disease during adolescence or young adulthood and were followed for an average of 14 years.<sup>50</sup> Women with follow-up equal to or exceeding 15 years had 9.4-fold increased risk of breast cancer as compared with the general population. The risk of developing breast cancer increased dramatically with younger age at first irradiation. Fifteen-year survivors who had radiation treatment before 20 years of age had an 18-fold increased risk of breast cancer; women irradiated at ages 20 to 29 had a sixfold increased risk; and a small, nonsignificant increase was observed

for women irradiated at age 30 or older (RR, 1.7). A similar trend, with even larger relative risks, has been reported from Stanford University.<sup>39</sup> An approximately 100-fold increase of breast cancer risk has been observed after treatment at younger than 16 years of age, with relative risks ranging from 17 to 458.<sup>39,55,57,142</sup> This huge variation in estimated risk is not surprising in view of the large differences between series in important variables such as proportion of patients irradiated, duration of follow-up, and completeness of follow-up. Generally, surveys with more complete follow-up have found lower relative risks of breast cancer<sup>50,63,142,143</sup> than those in which completeness of follow-up was less satisfactory or not addressed.<sup>55,57,144</sup> Incomplete follow-up may lead to overestimation of second malignancy risk if patients who remain well lose contact with clinical follow-up, whereas those with second cancer come to attention because of this. The very high *actuarial* risks reported in two U.S. studies (34% at 25 years after first treatment for women treated at younger than 20 years of age,<sup>144</sup> and 35% at 40 years of age for those treated when younger than 16 years<sup>57</sup>) are likely to be exaggerated estimates, not only because of losses to follow-up, but also because the actuarial method is less appropriate when including events that occur at follow-up intervals later than those at which data for most of the patients were censored.<sup>139</sup> In the more recently published Dutch study, with (nearly) complete follow-up, the 25-year actuarial risk of breast cancer amounted to 16%, both for women first treated before the age of 20 and at ages 20 to 30.<sup>50</sup> In two studies, the majority of breast cancers arose within or at the margin of the anterior radiation field, in breast tissue that had received a treatment dose of 40 to 46 Gy.<sup>35,57</sup> Because it is not known whether breast cancer risk is linearly related to radiation dose in the therapeutic dose range, it will be of interest to see whether the reduced mantle field doses in current treatment protocols will result in lower breast cancer risk.

Several studies have demonstrated that age at treatment for Hodgkin's disease is also a crucial determinant of increased relative risks for solid malignancies other than breast cancer.<sup>50,63,122</sup> Van Leeuwen and colleagues<sup>50</sup> reported that the relative risks of nonbreast solid tumors were 4.9, 6.9, and 12.7 for patients first treated at ages 31 to 39, 21 to 30, and 20 or younger, respectively (Table 55.7-2). Data from Stanford University and the United Kingdom show that the highest relative risks for gastrointestinal cancers (approximately eightfold)<sup>63,122</sup> and thyroid cancer<sup>63</sup> occur among patients treated before age 25, with no excesses observed for those treated after 45 years of age. Importantly, Table 55.7-2 demonstrates that the *absolute excess risk* of developing a solid cancer does not show much variation by age at first treatment, probably because the increasing background incidence of solid tumors with age in the population at large outweighs the stronger increase of *relative* risk at younger ages.

TABLE 55.7-2. Relative and Absolute Excess Risks of Second Cancer in 1253 Patients with Hodgkin's Disease, According to Age at Start of Treatment

The strongly increased relative risks of solid tumors in patients treated for Hodgkin's disease at a young age only become manifest after an extended follow-up period. This might point to a prolonged induction period, but it may also be due to this young patient group reaching an age at which solid tumor incidence begins to rise in the general population. Although a few studies addressed the relative risk of solid malignancies according to attained age,<sup>39,50,122</sup> only one study distinguished the separate contributions of age at first treatment and attained age.<sup>50</sup> Solid tumor risk was greatest among patients treated at a young age (20 years or younger), but the largest relative risk emerged *before* the patients attained the age range at which solid tumors normally occur. Among patients first treated at age 20 or before, the relative risk of developing a solid tumor at ages 40 to 49 was significantly lower than the relative risk of solid tumor development before age 40 (RR, 4.2 vs. 27.9;  $P = .0001$ ). It is notable that a similar finding has been reported with regard to breast cancer risk among atomic bomb survivors in Japan.<sup>145</sup>

In conclusion, the occurrence of treatment-related second cancers is a major problem in survivors of Hodgkin's disease. The substantial increase in solid tumor risk with time since Hodgkin's disease diagnosis necessitates careful, lifelong medical surveillance of all patients. The greatly increased risk of NHL throughout follow-up demonstrates the importance of performing biopsies in recurrent Hodgkin's disease. Because smokers experience a significantly greater risk of lung cancer attributable to radiotherapy than nonsmokers, physicians should make a special effort to dissuade Hodgkin's disease patients from smoking, even before treatment starts. Women treated with mantle field irradiation before age 30 are at greatly increased risk of breast cancer. The importance of regular breast examinations should be explained to them, and they should be taught to perform monthly breast self-examination. From 8 years after irradiation, the follow-up program of these women should include yearly breast palpation and mammography. Physicians should also be alert to the higher risk of gastrointestinal cancers in patients who received paraaortic and pelvic radiation fields. Thorough examination of gastrointestinal complaints is indicated. An important question to be answered in future research is whether, in long-term survivors, chemotherapy contributes to the risk of solid tumors, and if so, which cytotoxic drugs are responsible for the excess risk. The most devastating second malignancy to occur among patients cured of Hodgkin's disease remains chemotherapy-related leukemia. Because the poor prognosis of this complication cannot be changed by early diagnosis, it is promising that leukemia risk has decreased dramatically with the introduction of ABV-based regimens in the 1980s. It is hoped that current treatment protocols that limit the dose and fields of radiotherapy will similarly reduce the late risk of solid cancers.

## NON-HODGKIN'S LYMPHOMA

Although surveys in the past<sup>146,147</sup> concluded that NHL patients are not at increased risk for second solid tumors, most either predated the advent of modern therapeutic approaches or lacked sufficient statistical power to detect all but very high risks. Due largely to the introduction of effective treatment, NHL patients now demonstrate a 5-year relative survival rate of approximately 51%.<sup>148</sup> Commensurate with improvements in life expectancy, several large follow-up studies of NHL patients reported significantly increased risks of second cancers.<sup>149,150</sup> In the largest published study to date, the incidence of second malignancies was estimated in 29,153 patients diagnosed with NHL between 1973 and 1987 in one of nine population-based areas participating in the National Cancer Institute's Surveillance, Epidemiology and End Results (SEER) program.<sup>149</sup> Significantly increased risks were observed for all second cancers taken together (observed/expected [O/E] = 1.2; O = 1231), with excesses increasing with follow-up time to reach 1.8 in 10-year survivors. A subsequent international survey of 6171 2-year survivors of NHL confirmed the increased risk of second cancer and showed that significant excesses persisted for two decades.<sup>150</sup> In an update of the SEER program data, which included more than 48,000 patients diagnosed with NHL between 1973 and 1993, significantly increased site-specific risks were observed for cancers of lip (O/E = 2.0), lung (O/E = 1.4), kidney (O/E = 1.3), bladder (O/E = 1.4), thyroid (O/E = 2.0), and bone (O/E = 4.1), as well as AML (O/E = 3.6) (L. Travis, unpublished observations). Although registry-based treatment data are incomplete, it appeared that chemotherapy was related to subsequent AML and to bladder cancer and that radiotherapy was associated with AML and, possibly, cancers of lung, bladder, and bone.

The excesses of second genitourinary cancers<sup>21,118</sup> and AML<sup>14,90,151,152,153,154</sup> and <sup>155</sup> have been examined in relationship to treatment for NHL. The largest investigation<sup>21</sup> of secondary bladder tumors was set within a cohort of 6171 2-year survivors of NHL and included 31 patients with transitional cell carcinoma, along with 17 cases of kidney cancer. Detailed information on chemotherapeutic drugs and cumulative dose was collected for all subjects, and radiation dose to the target organ was estimated from individual radiotherapy records. A significant 4.5-fold risk of bladder cancer followed therapy with cyclophosphamide, with risk strongly dependent on cumulative dose (Table 55.7-3).

Cyclophosphamide	Median Dose or Duration*	Cases	Controls	Adjusted Relative Risk†	95% Confidence Interval
<b>CUMULATIVE DOSE</b>					
<20 g	10.0 g	8	30	1.4	0.5-4.4
20-50 g	34.0 g	5	6	4.3*	1.3-20.8
≥50 g	87.3 g	5	2	14.5*	2.3-94.8
<b>DURATION OF THERAPY</b>					
<1 y	6 mo	8	30	1.3	0.5-3.0
1-2 y	18 mo	5	6	3.7	0.6-22.8
≥2 y	35 mo	7	8	11.8*	2.3-61.8

\*P < .05.  
†P < .001.  
(From ref. 71, with permission.)

**TABLE 55.7-3.** Risk of Bladder Cancer According to Cumulative Dose and Duration of Cyclophosphamide Therapy

Significantly elevated sixfold and 14.5-fold risks followed cumulative doses of 20 to 50 g and 50 g or more, respectively ( *P* trend = .004). Neither radiotherapy nor cyclophosphamide was associated with excess kidney cancers. The absolute risk of bladder cancer predicted during 15 years of follow-up was on the order of three excess cancers per 100 NHL patients who had been given cumulative doses of between 20 and 50 g. At cumulative doses of 50 g or more, the excess risk increased to approximately seven bladder cancers per 100 NHL patients.

NHL treatment has been linked to excess risks of AML in several studies,<sup>14,90,151,152,153,154</sup> and <sup>155</sup> which have been reviewed.<sup>155</sup> Because leukemic progressions of NHL (lymphocytic leukemias) are relatively frequent, histopathologic confirmation of AML diagnosis has been an essential part of all series in which leukemia risk was examined. The largest investigation to date<sup>90</sup> included 11,386 2-year survivors of NHL, among whom 35 cases of AML or MDS were identified. The risk of AML was only weakly associated with the use of cyclophosphamide-containing regimens (RR, 1.8; 95% CI, 0.7 to 4.9) and did not increase with increasing cumulative dose or duration of treatment. However, the median cumulative dose of cyclophosphamide was only 12.5 g, which is considerably lower than in previous studies<sup>14,152</sup> in which nine leukemia cases each were included and substantially higher risks (RR, 105 and 76, respectively) were reported. The weak association between cyclophosphamide at lower dose levels and AML,<sup>90</sup> however, supports other evidence that the drug has a low leukemogenic potential.<sup>8,20,92</sup> Among 10,000 NHL patients treated for 6 months with chemotherapy regimens containing low cumulative doses of cyclophosphamide, an excess of four AMLs might develop in 10 years of follow-up.<sup>90</sup> This is an important conclusion in view of the frequent use of cyclophosphamide-containing regimens in current treatment regimens for NHL. Risk of AML after alkylating agent therapy did not vary significantly by age at NHL diagnosis or gender when evaluated by multivariate methods.

Low-dose total body irradiation (TBI), as used in past treatment approaches for NHL, seems linked with an unusually high occurrence of secondary leukemias.<sup>155,156</sup> This treatment modality used very low individual TBI fraction sizes (most commonly 10 to 15 cGy) given several times a week until a cumulative dose of approximately 150 cGy was administered. The risk of leukemia after low-dose TBI was quantified in a study of 61 2-year NHL survivors who received low-dose TBI as primary therapy.<sup>155</sup> Four patients developed AML (RR, 117 compared with population rates; 95% CI, 31.5 to 300.0). A fifth patient was diagnosed with MDS. All five patients with secondary hematologic malignancies had received salvage treatment with either alkylating agents alone or combined modality therapy. It is noteworthy that the excess risk of AML after low-dose TBI<sup>155</sup> was much greater than the risk observed in the larger international investigation of AML after NHL,<sup>90</sup> although similar chemotherapy regimens were used. Other types of NHL treatment that combine high-dose, large-field radiotherapy with alkylating agents also have been associated with very large risks (100- to 1000-fold) of AML.<sup>14,151</sup> It is likely that the chemotherapy contributed to the excess risk of leukemia, either directly or by enhancing the effect of low-dose TBI.<sup>155</sup> Studies of laboratory animals suggest that low-dose TBI may expand the number of bone marrow stem cells subject to potential transformation by alkylating agents.<sup>157</sup>

Estimates of the cumulative risk of secondary MDS/AML 5 to 6 years after autologous bone marrow transplantation (ABMT) for NHL range from 4% to 18%.<sup>6,158,159</sup> Based on long-term follow-up of a large cohort, Friedberg et al.<sup>160</sup> reported that the actuarial risk at 10 years was approximately 20%, with no evidence of a plateau. Because most lymphoma patients tend to be intensively treated, even before ABMT,<sup>158,159</sup> the roles of prior therapy and the preparative regimen for transplantation in the development of leukemia are difficult to distinguish.<sup>6,158,159</sup> In a review, Traweek et al.<sup>161</sup> concluded that although the available evidence suggests that prior therapy makes a pivotal contribution to risk of secondary leukemia, an ancillary role for the transplantation procedure itself can not be excluded. The investigators<sup>161</sup> suggested that the incidence of leukemia after ABMT for lymphoma might be reduced by earlier transplantation or stem cell harvest (or both) and the screening of bone marrow for karyotypic abnormalities before autologous grafting. Based on analyses of pretransplant specimens, Abruzzese and colleagues<sup>162</sup> suggested that, in many cases of MDS after ABMT, stem cell damage results from prior chemotherapy.

In conclusion, survivors of NHL are at increased risk for a number of second malignancies, albeit much less so than patients with Hodgkin's disease. To date, the excess risks of AML and bladder cancer have been demonstrated to be treatment-related. To assess risk factors for leukemia after ABMT, there is a strong need for a large study with data on prior therapy, the transplant preparative regimen, and the transplantation procedure itself.

## TESTICULAR CANCER

The introduction of cisplatin into chemotherapy protocols for testicular cancer represents one of the landmark accomplishments of modern cancer treatment.<sup>163</sup> Testicular cancer is now largely curable, with a 5-year relative survival rate of approximately 95%.<sup>148</sup> Although effective therapy for early-stage seminoma with infradiaphragmatic radiotherapy has been used for many decades, treatment with platinum-based chemotherapy for nonseminoma and advanced seminoma was not widely available until the late 1970s. In the interim period, radiotherapy fields to treat testicular cancer have decreased in size and smaller doses are used,<sup>164</sup> but patients treated with earlier, more aggressive approaches remain at risk for possible late sequelae. Few studies have addressed the long-term risks of second cancers among a sizable number of survivors<sup>85,165,166</sup> and <sup>167</sup> that also take into account the histologic type of testicular tumor.<sup>85</sup> The largest study of second malignant neoplasms after testicular cancer included 28,843 1-year survivors diagnosed with a first primary cancer of the testis between 1935 and 1993 and reported to 16 population-based cancer registries in North America and Europe.<sup>85</sup> More than 3300 testicular cancer patients survived more than 20 years after diagnosis. Second cancers, excluding contralateral testis, developed in 1406 patients (O/E = 1.43; 95% CI, 1.36 to 1.51) ( [Table 55.7-4](#)).

	Observed	Expected in 1-Year Survivors	O/E Ratio	95% Confidence Interval
All second cancers*	1406	983	1.43	1.36-1.51
All solid tumors*	1251	874	1.43	1.36-1.51
Bladder	105	12	8.8	6.2-12.4
Small intestine	11	3	4.4	1.8-10.6
Rectum	10	6	1.6	0.7-3.5
Stomach	10	6	1.6	0.7-3.5
Colon	10	6	1.6	0.7-3.5
Prostate	10	6	1.6	0.7-3.5
Kidney	10	6	1.6	0.7-3.5
Bladder	10	6	1.6	0.7-3.5
Thyroid	10	6	1.6	0.7-3.5
Connective tissue	10	6	1.6	0.7-3.5
Acute nonlymphocytic leukemia	10	6	1.6	0.7-3.5
Acute myeloid leukemia	10	6	1.6	0.7-3.5
Chronic lymphocytic leukemia	10	6	1.6	0.7-3.5
Chronic myeloid leukemia	10	6	1.6	0.7-3.5

\*Includes 10,000 patients diagnosed with a first primary cancer of the testis who survived 1 or more years.  
†Includes multiple, contralateral contralateral cancers. ‡Category of all solid tumors other than bladder, prostate, kidney, and connective tissue.  
§P < .05.  
(From ref. 85, with permission.)

**TABLE 55.7-4.** Observed and Expected Numbers of Selected Second Malignant Neoplasms among 1-Year Survivors of Testicular Cancer<sup>a</sup>

The absolute risk was 16 excess cancers per 10,000 men per year. Significantly elevated risks were observed for all second solid tumors (O/E = 1.4; O = 1251), with significant site-specific excesses for ALL, acute nonlymphocytic leukemia, melanoma, NHL, and cancers of the stomach, colon, rectum, pancreas, prostate, kidney, bladder, thyroid, and connective tissue. Second cancer risk was similar after seminomas (O/E = 1.4) and nonseminomatous tumors (O/E = 1.5), with little variation in site-specific patterns. Increased risks for cancers of small intestine (O/E = 4.4) and rectum (O/E = 1.6) were observed only for seminomas, whereas patients with

nonseminomatous germ cell tumors (GCT) showed elevated twofold risks for hepatobiliary cancer. Risk of solid tumors increased with time since diagnosis of testicular cancer to reach 1.5 after 20 years ( $F$  trend = .00002). Among 20-year survivors, 369 (O/E = 1.5) solid tumors were reported, with significant excesses for cancers of stomach (O/E = 2.3), colon (O/E = 1.7), pancreas (O/E = 3.2), prostate (O/E = 1.4), kidney (O/E = 2.3), bladder (O/E = 2.8), and connective tissue (O/E = 4.7).<sup>85</sup> The actuarial risks of developing any second cancer, excluding contralateral testicular tumors, were 15.7% and 22.6%, respectively, 25 and 30 years after testicular cancer diagnosis. The corresponding population expected risks were 9.3% and 13.1%, respectively. The somewhat higher cumulative risk of second cancer at 25 years for men with seminomas (Fig. 55.7-2) reflects the younger mean age of the patients with nonseminomatous tumors, because the excess cumulative risks were comparable.

**FIGURE 55.7-2.** Cumulative risk of second malignant neoplasms among 28,010 1-year survivors of testicular germ cell tumors (GCT). Percentages in parentheses indicate the actuarial risk at 25 years. Within the figure, 95% confidence intervals for point estimates are shown by vertical bars. (From ref. 85, with permission.)

Increased risks for cancers of the stomach, bladder and, possibly, pancreas seemed associated with antecedent radiotherapy, whereas leukemia was linked with both prior radiation and chemotherapy. In the past, large doses (mean, 13 to 26 Gy) of radiation could be delivered to the stomach during irradiation of paraaortic lymph nodes for testicular cancer.<sup>85</sup> In prior smaller surveys, a significant eightfold risk of stomach cancer ( $n = 2$ ) was associated with infra- and supradiaphragmatic irradiation for testicular tumors,<sup>165</sup> and a four- to fivefold risk with was associated with abdominal radiotherapy ( $n = 10$ ).<sup>166</sup> The study by Travis et al.<sup>85</sup> demonstrated that the increased risks for stomach cancer persisted for at least two decades after diagnosis of testicular cancer. After irradiation for peptic ulcer disease, significant excesses of stomach cancer extend beyond 30 years.<sup>168</sup> A pattern of increasing risk of pancreas cancer with time in the international study,<sup>85</sup> with excesses mainly in testicular cancer patients who received initial radiotherapy, was suggestive of a radiogenic effect, consistent with the location of the pancreas in the radiation field (mean organ dose, 17 to 34 Gy) during therapy for testicular cancer. The pancreas is not considered particularly susceptible to the carcinogenic effects of ionizing radiation,<sup>2c</sup> except when very high doses (e.g., on the order of 13 Gy) are given.<sup>168</sup>

Few large, comprehensive studies that quantify the high risk of contralateral testicular cancer (CLTC) have been published,<sup>166,169</sup> which has historically been attributed to common predisposing factors, such as cryptorchism or atrophic testis. Van Leeuwen and colleagues<sup>166</sup> assessed the risk of all second malignancies, including CLTC, in a population-based cohort of 1909 testicular cancer patients for whom complete treatment data and nearly complete follow-up information were available. With a median follow-up of 7.7 years, 20 CLTCs were observed (RR, 35.7; 95% CI, 21.8 to 55.2). Importantly, it appeared that chemotherapy may have reduced the risk of CLTC compared with patients who received radiation or surgery alone.

The increased risk of leukemia after testicular cancer is an order of magnitude lower than that observed in patients with Hodgkin's disease. Moderately elevated risks have been observed after chemotherapy,<sup>95,96</sup> but also after irradiation alone.<sup>165,166</sup> Mediastinal nonseminomatous GCTs are known to be associated with an inherent predisposition to develop secondary leukemias,<sup>170</sup> however, such a relationship has not been reported for testicular tumors. In men with mediastinal GCT and leukemia, both cancers contain the cytogenetic abnormality *i(12p)* pathognomonic of GCT,<sup>171</sup> consistent with a common derivation.<sup>170</sup> In contrast, cytogenetic studies of leukemias that follow testicular cancer have displayed alterations characteristic of treatment-related AML.<sup>172,173</sup> and <sup>174</sup> Analytic studies that have examined the risk of leukemia after testicular cancer have typically excluded mediastinal GCT.

In the early years of platinum-based chemotherapy, the majority of patients received the PVB regimen (cisplatin, vinblastine, bleomycin). The absence of excess leukemia risk after this regimen has been documented in several large studies.<sup>95,166,175,176</sup> and <sup>177</sup> In contrast, a number of studies have reported a 20- to 330-fold increased risk of AML after etoposide-containing regimens, which were introduced for the treatment of testicular cancer in the early 1980s.<sup>95,96,172,174</sup> In most of these schedules, etoposide is combined with a platinum compound and other active drugs (bleomycin), but classical alkylating drugs are generally not used. More recently, the IARC concluded that sufficient evidence indicates that etoposide in combination with cisplatin and bleomycin is carcinogenic to humans.<sup>93</sup>

The report by Pedersen-Bjergaard and colleagues<sup>95</sup> was one of the first to note that leukemias induced by epipodophyllotoxins were cytogenetically distinct from classical alkylating agent-related AML. All five cases of AML/MDS were observed in the subgroup of 82 patients who had received cumulative doses of more than 3000 mg/m<sup>2</sup> of etoposide (most patients had three 3-weekly cycles with etoposide, 200 mg/m<sup>2</sup> daily, for 5 days, resulting in a cumulative dose of 3000 mg/m<sup>2</sup>). Most etoposide-containing treatment regimens for testicular cancer have used lower cumulative doses of etoposide (up to 2000 mg/m<sup>2</sup>) and also a lower dose intensity (100 to 120 mg/m<sup>2</sup>). On the basis of the combined data from five studies, Bokemeyer and Schmolli<sup>167</sup> estimated that the relative risk for AML was approximately 20-fold increased in patients treated with conventional etoposide-containing regimens (cumulative dose less than 2000 mg/m<sup>2</sup>). Because of the low background incidence of AML in the population, this rather high relative risk translates to a low cumulative risk of 0.6% (95% CI, 0.3 to 0.9%) at 5 years.

In conclusion, patients treated for testicular cancer have less than one-third of the excess risk of second malignancy experienced by patients with Hodgkin's disease. The increased risk of stomach cancer should alert clinicians to the importance of thorough examination of gastrointestinal complaints in patients who received radiotherapy to the paraaortic lymph nodes. Because all reports of increased risks of gastrointestinal cancer have derived from studies in which patients were treated with high doses of radiation, it is important to determine whether smaller risks will follow the lower doses (20 to 25 Gy) that are currently used. Reassuringly, PVB chemotherapy seems to carry a negligible risk of leukemia. Although high-dose etoposide therapy (more than 2000 mg/m<sup>2</sup> in combination regimens) is associated with substantial excess leukemia, cumulative risk after conventional-dose etoposide-containing regimens is low. Radiotherapy regimens for testicular cancer have been modified with the introduction of smaller fields, lower doses, and elimination of prophylactic mediastinal radiation, but the late sequelae of therapy given decades ago continue to emerge. In the future, radiation dose to second cancer sites for which risks are elevated should be estimated in individual patients, along with specific chemotherapeutic agents to further delineate the contribution of treatment factors. Long-term follow-up studies are also needed to evaluate the risk of second solid tumors among testicular cancer patients treated with modern cisplatin-based chemotherapy.<sup>10,81</sup>

## OVARIAN CANCER

Because survival for ovarian cancer patients has improved significantly within the last two decades,<sup>148</sup> the study of second primary cancers has assumed increasing clinical importance.<sup>178</sup> The site-specific risk of solid tumors after ovarian cancer has been quantified in a large population-based study of more than 32,000 women with ovarian cancer, including 4402 10-year survivors.<sup>178</sup> Almost 1300 second cancers ( $n = 1296$ ) were reported, representing a significantly increased risk (O/E = 1.3; 95% CI, 1.2 to 1.4). Significant excesses were observed for cancers of colon (O/E = 1.3), rectum (O/E = 1.4), breast (O/E = 1.2), and bladder (O/E = 2.1), as well as leukemia (O/E = 4.2). Ocular melanoma (O/E = 4.5) was also significantly increased. Secondary leukemia appeared to be linked with antecedent chemotherapy, whereas radiotherapy was associated with cancers of connective tissue, bladder and, possibly, pancreas. The risk of solid tumors was elevated during all follow-up intervals, including 10 to 14 years (O/E = 1.3) and 15 years or more (O/E = 1.3) after ovarian cancer. Fifteen-year survivors experienced significant excesses of cancers of pancreas, bladder, and connective tissue. The cumulative risk of second cancers at 20 years was 18.2% compared with a population-expected risk of 11.5% (Fig. 55.7-3).

**FIGURE 55.7-3.** Cumulative risk of second malignant neoplasms among 32,251 2-month survivors of ovarian cancer. Percentages in parentheses are actuarial risk at 20 years. Within the figure, 95% confidence intervals for point estimates are shown by vertical bars. (From Travis LB, Curtis RE, Boice JD Jr, et al. Second malignant neoplasms among long-term survivors of ovarian cancer. *Cancer Res* 1996;56:1564, with permission.)

In an analytic study of bladder cancer after ovarian cancer, Kaldor et al.<sup>119</sup> found increased risks after radiotherapy only (RR, 1.9; 95% CI, 0.8 to 4.9) compared with patients treated with surgery alone. Cyclophosphamide-based chemotherapy, with or without radiotherapy, was associated with a fourfold risk.

Large risks of AML and preleukemia have been documented after ovarian cancer, and they have been linked to therapy with melphalan,<sup>17,92</sup> cyclophosphamide,<sup>17,80,92</sup> and chlorambucil.<sup>17,179</sup> In one large population-based study of more than 28,000 ovarian cancer patients in whom 96 leukemias were diagnosed, platinum-based combination chemotherapy was associated with a significantly increased fourfold risk compared with women who received neither alkylating drugs nor radiotherapy.<sup>81</sup> Excesses of leukemia increased with increasing cumulative platinum dose ( $P$  trend for dose  $<.001$ ) (Table 55.7-5).

Drug and Dose	Number of Patients with Leukemia	Number of Blinded Control Patients	Median Dose in Control	Relative Risk (95% Confidence Interval)
<b>Platinum-based</b>				
<i>Best</i>				
100 mg	4	30	400 mg	1.9 (0.7-5.0)
500 mg	4	30	400 mg	2.1 (0.6-8.0)
750 mg	7	30	400 mg	4.1 (1.1-14.8)
1000 mg	11	30	400 mg	7.4 (2.0-26.7)*
<i>Standard</i>				
400 mg	3	30	5.4 Gy	1.0 (0.3-3.0)
617 mg	16	30	6.0 Gy	4.1 (1.4-11.5)
1070 mg	3	30	14.2 Gy	7.9 (2.0-30.6)*
<b>Specific drug</b>				
Cisplatin	18	30	400 mg	3.1 (1.4-6.6)
Carboplatin	1	4	1000 mg	4.3 (1.2-16.0)
Best	1	4	1000 mg	10.0 (2.0-50.0)
Cyclophosphamide	1	4	1000 mg	10.0 (2.0-50.0)
Chlorambucil	1	4	1000 mg	10.0 (2.0-50.0)

**TABLE 55.7-5.** Risk of Leukemia According to the Cumulative Dose of Platinum, Duration of Therapy, and Specific Drug<sup>a</sup>

Although the platinating agents were frequently given in combination with cyclophosphamide, doxorubicin, or both, a multivariate model that took into account the cumulative amount of these drugs did not provide an improved fit to the data ( $P >.5$ ) compared with a model that took into account only dose categories of platinum. Although the risk of leukemia after platinum-based chemotherapy tended to be somewhat higher among younger patients, differences in relative risk according to age were not significant ( $P$  for heterogeneity = .48). Radiotherapy without chemotherapy (mean bone marrow dose, 13.4 Gy) did not increase the risk of leukemia,<sup>81</sup> but few women received radiation alone. Patients given radiotherapy and platinum-based chemotherapy, however, had a significantly ( $P = .006$ ) higher risk of leukemia than those who received platinum-based chemotherapy alone in a multivariate model adjusted for cumulative amount of the drug. A dose response was observed for platinum among women treated and not treated with radiotherapy, with risks higher within the radiation group; in all of the latter patients, radiotherapy had been given as part of initial treatment. It is unlikely that women newly diagnosed with ovarian cancer would receive both platinum and radiotherapy in view of modern treatment recommendations.<sup>180</sup> However, the possibility that the risk of leukemia after treatment with platinum might be increased by radiotherapy should be investigated among patients with other cancers, especially cancers of bladder and head and neck, given therapeutic strategies to increase dose intensities of both modalities in the treatment of these tumors.<sup>181</sup>

The risk of leukemia associated with the cumulative dose of melphalan<sup>17,92</sup> and, importantly, route of administration<sup>81</sup> also has been evaluated among women with ovarian cancer. In the largest study to date,<sup>81</sup> significant excesses of leukemia followed intravenous (RR, 22.9) and oral (RR, 9.0) melphalan, and risks increased with increasing cumulative dose and duration of therapy. Intravenous melphalan was six times more leukemogenic than platinum.

In conclusion, survivors of ovarian cancer experience significantly increased risks of secondary leukemias and solid tumors. Despite the elevated relative risk of leukemia after modern platinum-based chemotherapy for ovarian cancer, the absolute risk is small.<sup>81</sup> Of 10,000 ovarian cancer patients treated for 6 months with cumulative doses of cisplatin between 500 and 1000 mg or 1000 mg or more and followed for one decade, an excess of 21 and 71 leukemias, respectively, was predicted based on observed risks.<sup>81</sup> Thus, Travis and colleagues<sup>81</sup> concluded that the significant improvement in clinical response provided by platinum-based treatment for advanced ovarian cancer, with 5-year survival rates of up to 20% to 30%,<sup>180,182</sup> far exceeded the relatively small excesses of leukemia. Further interdisciplinary investigations are needed to elucidate the carcinogenic risks associated with modern therapies for ovarian cancer and with shared susceptibility mechanisms, including genetic and reproductive factors. Meanwhile, in proposing recommendations for the follow-up and management of women with ovarian cancer,<sup>180</sup> it is important to recognize their long-term predisposition to an array of second cancers.

## BREAST CANCER

Numerous studies have demonstrated that women with breast cancer are at a three- to fourfold increased risk of developing a new primary cancer in the contralateral breast.<sup>183,184</sup> Significant excesses relative to the general population also have been observed for cancers of the ovary,<sup>183,185</sup> uterus,<sup>183,186,187</sup> lung,<sup>58,183,185,188,189</sup> esophagus,<sup>190</sup> colon-rectum,<sup>183,185,187</sup> connective tissue,<sup>183,189,191,192</sup> and thyroid,<sup>183,185</sup> as well as melanoma<sup>183,189</sup> and leukemia.<sup>101,185,189,194</sup> For some of these cancers, such as those of the contralateral breast, ovary, and uterus, and possibly melanoma, the excesses may be fully or partly explained by a common etiology (e.g., genetic predisposition or hormonal risk factors). Other excess risks may be treatment-related or reflect the interaction of several factors. Adjuvant chemotherapy, hormonal treatment, and radiotherapy, and combinations of these modalities, are being administered to a growing proportion of breast cancer patients. In view of the proven therapeutic benefit of these treatments<sup>195,196</sup> and the prolonged life expectancy of those treated, it has become exceedingly important to evaluate the carcinogenic potential of adjuvant treatment.

Contralateral breast cancer accounts for 40% to 50% of all second tumors in women with breast cancer,<sup>183</sup> and the 15-year cumulative risk of developing contralateral disease amounts to 10% to 13%.<sup>197,198</sup> With this high risk, even small effects of treatment may have a large impact in terms of absolute numbers of contralateral breast cancers. The effect of radiation treatment for the initial breast cancer was evaluated in two large case-control studies in Connecticut and Denmark that involved 655 and 529 women with contralateral breast cancer, respectively. The mean radiation doses to the contralateral breast were estimated at 2.8 and 2.5 Gy, respectively.<sup>22,199</sup> Both studies found that radiotherapy did not contribute to the high risk of contralateral disease among women treated after the age of 45. In the Connecticut study, however, significantly elevated risks were observed for women who underwent irradiation before the age of 45, with a radiation-associated relative risk of 1.9 among those who survived for at least 10 years.<sup>22</sup> Significant excess risk in women irradiated at a young age was not found in the Danish study, possibly because it included fewer women younger than 45 years of age.<sup>199</sup> Based on the Connecticut study, Boice and associates<sup>22</sup> estimated that approximately 11% of all second breast cancers in women irradiated before age 45 could be attributed to radiotherapy.

Several large studies have shown that hormonal treatment with tamoxifen reduces the risk of contralateral breast cancer by approximately 40%.<sup>186,187,195,200,201</sup> Data collected by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG), based on 37,000 women from 55 trials, demonstrated that longer durations of tamoxifen use were associated with greater reductions in risk, such that 1 year, 2 years, and 5 years of treatment produced risk reductions of 13%, 26%, and 47%, respectively.<sup>195</sup> It is not yet known whether the protective effect of tamoxifen against contralateral disease persists over prolonged follow-up periods (more than 10 years). Some studies have provided evidence that adjuvant chemotherapy may also reduce the risk of contralateral breast cancer, a phenomenon that is likely to be mediated through drug-induced premature ovarian failure.<sup>153,196,202</sup>

Several studies have assessed the risk of leukemia after adjuvant chemotherapy and radiotherapy for breast cancer. The relationship between AML risk and drug dose was examined in detail in the large case-control study by Curtis and associates.<sup>20</sup> These investigators identified 90 cases of leukemia or MDS among 82,700 women diagnosed with breast cancer between 1973 and 1985 in five areas of the United States. Compared with patients treated without alkylating agents and irradiation, the risk of AML was significantly elevated after locoregional radiotherapy alone (RR, 2.4), after treatment with alkylating agents alone (RR, 10.0) and after treatment with alkylating agents in combination with radiotherapy (RR, 17.4). The risk of AML associated with combined modality treatment was significantly greater than that for alkylating agents alone ( $P = .02$ ). The study included large numbers of women who had been treated with only one alkylating agent, including cyclophosphamide. Cumulative cyclophosphamide doses of less than 20 g were associated with an approximately twofold, nonsignificant increase in risk (compared with women not exposed to alkylating agents), whereas women treated with 20 g or more had a 5.7-fold risk of AML (95% CI, 1.6 to 20.6). Women who received melphalan experienced tenfold risks of AML compared with women treated with cyclophosphamide ( $P < .001$ ). After adjustment for the effects of chemotherapy, the risk of AML increased significantly with higher doses of radiation to the active bone marrow, with a sevenfold risk increase for patients who received 9 Gy or more (compared to patients not treated with radiotherapy).

Present-day adjuvant treatment of early breast cancer is in several ways different from the treatments evaluated in this large study by Curtis et al.<sup>20</sup> In the 1980s, the cumulative doses of cyclophosphamide were reduced [approximately 12 to 15 g with six standard cycles of CMF (cyclophosphamide, methotrexate, and fluorouracil) or FAC (fluorouracil, doxorubicin, and cyclophosphamide)]. Regional radiotherapy is less frequently used. On the basis of their data, Curtis and associates<sup>20</sup> estimated that, among 10,000 patients with breast cancer treated for 6 months with a cyclophosphamide-based regimen and followed for 10 years, an excess of only five cases of treatment-related AML would be expected to develop.

The low risk of AML after CMF-based chemotherapy was confirmed by the Milan Cancer Institute<sup>203</sup> and the Eastern Cooperative Oncology Group,<sup>204</sup> with cumulative risks of AML of 0.23% at 15 years and 0.18% at 7 years, respectively. Thirty-nine percent of women treated with CMF-based chemotherapy in the Milan series<sup>203</sup> also received doxorubicin, and no clear evidence indicated a synergistic effect of cyclophosphamide and doxorubicin on leukemia risk. Radiation therapy (applied only after breast-conserving surgery) did not add to the risk of AML. The University of Texas M. D. Anderson Cancer Center has reported a higher risk of leukemia after standard dose-intensity FAC treatment. Fourteen cases of leukemia were observed among 1474 patients, for an estimated cumulative risk of 1.5% (95% CI, 0.7 to 2.9) at 10 years. The risk of AML was significantly higher when chemotherapy was given in combination with radiotherapy (2.5% vs. 0.5%).<sup>103</sup>

There has been an increasing trend toward the use of dose intensification strategies in chemotherapy protocols for breast cancer. Typically, these regimens contain high-dose cyclophosphamide in combination with one of the anthracyclines (doxorubicin or 4-epidoxorubicin) and other active drugs. The risk of AML associated with such dose-intensive chemotherapy has not yet been quantified, but evidence suggests that the combination of anthracyclines and alkylating agents (including cisplatin) may be leukemogenic.<sup>101</sup> With the increasing tendency to administer high doses of cytotoxic drugs accompanied by bone marrow support, there is certainly a strong need to closely monitor the subsequent risk of AML.

Patients treated with CMF-based chemotherapy have not been reported to be at increased risk of solid tumors.<sup>203,205</sup> More prolonged follow-up, however, is needed to evaluate possible carcinogenic effects 15 years or more after treatment.

Conclusive evidence has emerged that tamoxifen is associated with a moderately increased risk of endometrial cancer.<sup>186,187,195,200,206,207,208,209</sup> and <sup>210</sup> The consistent results across studies with different designs, the duration-response relationship observed in several investigations,<sup>206,207,209,211,212</sup> and the established estrogen-agonist effects of tamoxifen on the endometrium<sup>213,214</sup> and <sup>215</sup> strongly support a causal relationship.<sup>208</sup> The individual studies, which are summarized in [Table 55.7-6](#), show that the use of tamoxifen for 2 years is associated with an approximately twofold increased risk of endometrial cancer, whereas use for 5 or more years produces four- to eightfold excess risks. Although the risk estimates in some studies may be affected by a certain degree of detection bias as a result of gynecologic examinations in women with side effects from tamoxifen, the magnitude of the observed risk is unlikely to be explained by such bias.<sup>208</sup> Furthermore, the analysis of the EBCTCG not only shows increased incidence of endometrial cancer in women randomized to tamoxifen treatment (as compared to women not randomized to tamoxifen) but also significantly increased mortality due to endometrial cancer.<sup>195</sup> From [Table 55.7-6](#), it is clear that elevated risks of endometrial cancer have been observed after daily tamoxifen dosages of 20 mg, 30 mg, or 40 mg. In the Netherlands case-control study, which included different dose intensities, daily dosage did not affect endometrial cancer risk in a model accounting for duration of use, and the duration-response trends were similar, with daily doses of 40 mg, or 30 mg or less.<sup>211</sup> Very few studies have addressed the risk for ex-users. In three investigations,<sup>209,211,212</sup> recent and former users of tamoxifen were found to experience very similar increases in risk; however, only a few patients had discontinued tamoxifen more than 2 years before the diagnosis of endometrial cancer.

Author (Year)	Study Design	Number of Tamoxifen Users	Number of Endometrial Cancer Cases	Relative Risk (95% CI)	Notes

**TABLE 55.7-6.** Risk of Endometrial Cancer after Tamoxifen Therapy in Women with Breast Cancer

Only two studies have addressed the combined effects of tamoxifen and other risk factors for endometrial cancer.<sup>209,211</sup> In the largest study conducted to date, Bernstein and colleagues<sup>209</sup> reported that women who previously used estrogen replacement therapy experienced greater increases in endometrial cancer risk associated with tamoxifen use than women not exposed to estrogen replacement therapy. Furthermore, the effects of tamoxifen on endometrial cancer risk were stronger among heavy women than among thin women. In the Dutch study, however, body weight did not modify the increased risk associated with tamoxifen use.<sup>211</sup>

An important question is whether the clinicopathologic characteristics and ultimate prognosis of endometrial cancers after tamoxifen treatment are different from those in patients not treated with tamoxifen. In four small studies, the stage distribution and histologic features of endometrial cancers in tamoxifen-treated women were not remarkably different from those diagnosed in nontreated women.<sup>186,200,206,216</sup> Magriples and colleagues,<sup>217</sup> however, reported a higher frequency of poorly differentiated and high-grade tumors with a poor prognosis in tamoxifen-treated patients. In the Dutch study, which included 309 patients with endometrial cancer after breast cancer, endometrial tumors of FIGO stage III and IV occurred more frequently among long-term tamoxifen users (2 or more years) than in nonusers (17% vs. 5%,  $P = .006$ ). Based on a centralized review of diagnostic pathology slides, long-term tamoxifen users more often developed malignant mixed mesodermal tumors or sarcomas of the endometrium than did nonusers (15% vs. 3%,  $P = .02$ ). Furthermore, the tumors diagnosed among long-term tamoxifen users were more often p53-positive and estrogen receptor-negative. [Figure 55.7-4](#) shows that the 3-year actuarial endometrial cancer-specific survival in this study was significantly worse for long-term tamoxifen users than for nonusers, largely due to the less favorable tumor characteristics associated with tamoxifen use.<sup>211</sup> The association between tamoxifen use and specific clinicopathologic and molecular characteristics of subsequent endometrial cancer deserves further investigation in large studies.

**FIGURE 55.7-4.** Actuarial endometrial cancer-specific survival according to duration of tamoxifen use. (From ref. 211, with permission.)

Animal experiments have shown that tamoxifen can act as a hepatic carcinogen in rats.<sup>218,219</sup> However, no increased risk of hepatocellular cancer in tamoxifen-treated patients has been observed to date.<sup>186,187,195,200</sup> In the large metaanalysis of the EBCTCG, women randomized to tamoxifen had a slightly lower mortality from primary liver cancer than the control group.<sup>195</sup> The joint analysis of Scandinavian tamoxifen trials showed an elevated risk of gastrointestinal cancer after tamoxifen use (RR, 1.9; 95% CI, 1.2 to 2.9)<sup>187</sup>; however, the excess risk was due to colorectal and stomach cancer, not liver cancer. Furthermore, a study from the SEER program found that tamoxifen was associated with a 50% increased risk of colorectal cancer in the period 5 or more years after diagnosis.<sup>220</sup> No such risk increase was observed in the EBCTCG data.<sup>195</sup>

Increased risks of lung cancer after breast cancer have been largely attributed to radiotherapy.<sup>58,188,221</sup> No appreciable risk increase has been observed within 10 years of treatment, but two- to threefold elevated risks have been reported in 10-year survivors.<sup>58,188,189</sup> The association between breast radiotherapy and subsequent lung cancer risk was found to be stronger for the ipsilateral lung, which supports a radiogenic effect.<sup>188,221</sup> Using individual patient dosimetry, Inskip and associates<sup>58</sup> assessed the effect of radiation dose to the lung in a case-control study of lung cancer after breast cancer. Sixty-one lung cancers were identified among 8976 10-year survivors of breast cancer treated in Connecticut between 1935 and 1971. Mean radiation dose was 15 Gy to the ipsilateral lung and 4.6 Gy to the contralateral lung. A nonsignificant increase in lung cancer risk was noted with increasing radiation dose to the affected lung, with an approximate threefold excess risk for patients who received 5 to 10 Gy. Risk seemed to level off at doses higher than 10 Gy, as has been observed in a similar study of lung cancer after Hodgkin's disease.<sup>36</sup> The results were used to predict that, among 10,000 10-year survivors of breast cancer who received an average lung dose of 10 Gy, approximately nine radiogenic lung cancers would be expected to develop per year. Current radiotherapy practices for breast cancer involve high-energy megavoltage treatment to localized radiation fields, which results in considerably lower lung doses than the orthovoltage and cobalt-60 radiation treatments used in the studies described above. The risk of radiogenic lung cancer should be correspondingly lower (i.e., approximately one excess lung cancer per 10,000 women-years per Gy) beginning 10 years after radiotherapy.<sup>58</sup> In one study, smokers were found to be at greater risk of radiation-associated lung cancer than nonsmokers.<sup>221,222</sup>

Heightened concern with regard to the subsequently increased risk of angiosarcomas in the irradiated conserved breast has been expressed.<sup>192,193</sup> In a nationwide study, 21 Dutch patients with angiosarcoma of the breast after breast-conserving treatment and localized radiation were reported, with a median latency of 6 years.<sup>193</sup> The incidence of angiosarcoma in the breast was estimated at 1.6 per 1000 patients treated with breast conservation per year. Although the absolute excess risk is small, the relative risk is more than 1000-fold increased in comparison with the incidence of this very rare disease in the general population. In a nationwide case-control study in Sweden<sup>191</sup> of 116 women with soft tissue sarcoma after a diagnosis of breast cancer between 1958 and 1992, it was found that the risk of sarcomas other than angiosarcoma increased with the amount of radiation, but stabilized at high doses. The study included 40 angiosarcomas (located mostly in the ipsilateral arm, with only two cases in conserved breasts). The risk of angiosarcoma was 9.5-fold increased in women with lymphoedema of the arm, but radiotherapy was not a risk factor.

In conclusion, only part of the elevated risk of second malignancies after breast cancer is due to treatment. The intrinsically increased risk of developing a contralateral tumor is unlikely to be meaningfully affected by current radiotherapy for the initial breast cancer, whereas tamoxifen reduces the risk of contralateral disease. Standard dose-intensity CMF treatment is associated with a low excess risk of leukemia, whereas conventional FAC treatment may be associated with a somewhat higher risk. Whether the risk of leukemia will increase further with the introduction of dose-intensification strategies should be explored. Although tamoxifen causes a moderate increase in endometrial cancer risk, the proven clinical benefit of this drug in controlling breast cancer<sup>195</sup> far outweighs the excess morbidity and mortality due to endometrial cancer. Clinicians should be alert to signs and symptoms in women taking tamoxifen, and long-term users should be advised to seek prompt gynecologic evaluation on the development of symptoms. The effectiveness of screening for endometrial cancer has not been demonstrated. Consequently, outside of research settings, there is no basis for regular gynecologic examinations in asymptomatic patients taking tamoxifen. The absolute excess risk of lung cancer is likely to be small with current radiotherapy techniques for breast cancer. Nevertheless, there is ample reason to advise breast cancer patients to stop smoking when they receive radiation treatment.

## PEDIATRIC MALIGNANCIES

Survival rates for children with cancer have improved substantially since the late 1970s. Consequently, a rapidly growing young population is subject to the late effects of cancer treatment for life. The overall pattern of second cancer risk in the population of childhood cancer survivors has been described in several large studies.<sup>51,62,223,224</sup> and <sup>225</sup> Most recently, de Vathaire and colleagues<sup>51</sup> reported on the long-term risk of second cancer in a cohort of 4400 3-year survivors of childhood cancer (excluding patients with leukemia) treated in eight centers in France and the United Kingdom. The risk of second solid malignancies was increased 9.2-fold compared to the general population (95% CI, 7.6 to 11.0), and the absolute excess risk was 188 cases per 10,000 patients per year. The 30-year cumulative risk was 7.7% (95% CI, 5.0 to 8.2%). Olsen and collaborators<sup>223</sup> observed a 3.6-fold increased risk of second malignancy (95% CI, 3.1 to 4.1) in 30,880 children diagnosed with cancer and reported to the population-based cancer registries of five Nordic countries between 1943 and 1987. The cumulative risks of developing a second tumor within 25 years were 3.7% and 3.5%, respectively. Among 9170 2-year survivors of childhood cancer who were treated by members of the U.S. Late Effects Study Group (LESG), the risk of developing a second malignancy was increased 15-fold compared to the general population (95% CI, 13 to 17), with a cumulative incidence of 12.1% at 25 years.<sup>62</sup> The lower risks in the European studies may be related to their population-based nature (less selection),<sup>223,224</sup> to treatment differences between Europe and the United States, and to differences between the study populations with respect to calendar years of diagnosis and length of follow-up. In all studies, the largest relative risks were found for second primary bone tumors (133-fold and 43-fold increased risks in the LESG<sup>225</sup> and British cohort,<sup>224</sup> respectively) and second soft tissue sarcoma. Large risks were also observed for second thyroid cancer, gastrointestinal cancers, brain tumors, and leukemia. Retinoblastoma is the initial malignancy that has been consistently associated with the highest risk of subsequent tumors.<sup>51,62,223,224</sup>

Only a portion of the excess second cancer risk in survivors of childhood cancer is related to treatment. Retinoblastoma is the prototype of an initial malignancy in which genetic factors are responsible for a large part of subsequent cancers. Familial retinoblastoma is caused by inherited mutations of the RB1 tumor suppressor gene, which has been localized to the long arm of chromosome 13q14.<sup>226,227</sup> Approximately 80% of hereditary retinoblastoma patients have bilateral disease. In a long-term follow-up study of 1604 1-year survivors of retinoblastoma diagnosed between 1914 and 1984 (median follow-up, 20 years), the incidence of second cancers as well as risk factors for second malignancy were evaluated.<sup>65</sup> Overall, the risk of second malignancy was increased 17-fold compared to the general population expectation. The excess risk was restricted to the 961 patients with hereditary retinoblastoma (RR, 30; 95% CI, 26 to 47), with strongly increased relative risks for cancers of the bone, soft tissues, nasal cavities, and brain, and for melanoma (relative risks of 446, 103, more than 100, 14, and 51, respectively). No significantly increased risk of second malignancy was observed among 643 nonhereditary retinoblastoma patients (RR, 1.6; 95% CI, 0.7 to 3.1). Fifty years after retinoblastoma diagnosis, the cumulative risk of second primary cancer was 51.0% ( $\pm$  6.2%) in hereditary cases, and only 5.0% ( $\pm$  3.0%) in nonhereditary cases. As shown in [Figure 55.7-5](#), radiotherapy significantly increased the risk of second cancers in patients with hereditary retinoblastoma (50-year cumulative risk of 58% vs. 27% in nonirradiated hereditary patients). Radiotherapy did not significantly affect risk in nonhereditary retinoblastoma patients.<sup>65</sup> In a case-control investigation that included 52 patients with bone sarcoma, 31 with soft tissue sarcoma, and 89 controls without sarcoma, Wong and associates<sup>66</sup> also collected individual radiation dosimetry data. For all sarcomas combined, risk was significantly elevated at all dose levels, even at 5.0 to 9.9 Gy, and a significant increase in risk was observed with increasing radiation dose to the site of tumor (relative risk of 11 for doses of 60 Gy or more as compared with doses of 0 to 4.9 Gy) For the first time in humans, a radiation dose-response relationship was also demonstrated for soft tissue sarcoma, with a 12-fold risk increase at doses of 60 Gy or greater. Osteosarcomas and soft tissue sarcomas developing after hereditary retinoblastoma harbor similar RB1 mutations as those found in retinoblastoma.<sup>228,229</sup> Radiation is thus likely to cause

somatic mutations needed to produce sarcomas in carriers of germline RB1 mutations.

**FIGURE 55.7-5.** Cumulative incidence ( $\pm$  s.e.) of second cancers after diagnosis of retinoblastoma in 961 patients with hereditary disease, by radiation treatment. (From ref. 69, with permission.)

Wilms' tumor is another example of an initial malignancy in which genetic predisposition contributes to the excess risk of second cancers. <sup>225</sup> The National Wilms' Tumor Study Group reported on the second malignancy experience of 5278 patients followed for an average of 7.5 years. <sup>104</sup> Forty-three second malignancies were observed, with an overall relative risk of 8.4 (95% CI, 6.1 to 11.4). The 15- and 20-year cumulative risks of developing a second tumor were 1.6% and 3.8%, respectively. Significant excesses were seen for leukemia (RR, 7.0), lymphoma (RR, 9.0), osteosarcoma (RR, 19), soft tissue sarcoma (RR, 22), and hepatocellular carcinoma (RR, 56). <sup>104</sup> (N. E. Breslow, written communication, April 1996). Among patients not treated with radiation or doxorubicin, risk of second malignancy was increased threefold, reflecting genetic predisposition. <sup>104</sup> Each 10 Gy of abdominal irradiation was found to increase second malignancy risk by 43% in the absence of doxorubicin and by 78% in its presence. Treatment with both doxorubicin and more than 35 Gy of abdominal irradiation was associated with a relative risk of 36 (95% CI, 16 to 72). <sup>104</sup> Because the small numbers of individual second malignancies precluded an analysis by site, it is unclear whether these results apply equally for leukemia, sarcoma, and other tumors.

ALL, the most common malignancy in childhood, is also associated with an increased risk of subsequent cancer. In a series of 9720 childhood ALL patients treated in trials of the Children's Cancer Study Group between 1972 and 1988, the risk of developing a second malignancy was increased 6.9-fold as compared with the general population. <sup>230</sup> The associated 10- and 15-year cumulative risks were 1.5% and 2.5%, respectively. In a multicenter Italian study including 1664 ALL patients, the relative risk of all second cancers was 13.6, with cumulative risks of 2.6% and 4.5%, respectively, at 10 and 15 years since the completion of initial treatment. <sup>231</sup> In both studies, the largest excess was observed for central nervous system tumors, with relative risks of 22 <sup>230</sup> and 52. <sup>231</sup> Most brain tumors were high-grade astrocytomas or glioblastomas, and all occurred in children who had previously received radiotherapy, mostly cranial irradiation with doses ranging from 18 to 24 Gy. A study of 1612 patients with ALL from St. Jude Children's Research Hospital, with long-term follow-up data (median follow-up, 16 years), demonstrated an excess of high-grade gliomas during early follow-up (up to 10 years after diagnosis), whereas an increased risk of low-grade brain tumors was observed at later follow-up intervals. <sup>232</sup> The risk of developing a brain tumor was significantly increased with increasing cranial radiation dose, with 20-year cumulative risks of 1.0%, 1.7%, and 3.2% for patients who received radiation doses of 10 to 21 Gy, 21 to 30 Gy, and 30 Gy or more, respectively.

During the 1990s, prophylactic cranial radiotherapy has been largely replaced by intrathecal methotrexate. The number of intrathecal methotrexate administrations was not related to the risk of brain tumors, <sup>232</sup> but few children treated without cranial radiation were followed for more than 15 years. In two studies, <sup>230,232</sup> risk of central nervous system tumors was significantly higher in children 5 years of age or younger at first treatment.

Several very large studies of ALL survivors have reported negligible risks of AML after chemotherapy regimens that contain cyclophosphamide, anthracyclines, or both. <sup>230,231,233</sup> In contrast, very high risks of AML have been reported for children treated with epipodophyllotoxin-containing regimens. Pui and associates <sup>97</sup> were the first to report on the risk of AML in 734 children with ALL who received maintenance treatment according to different schedules of epipodophyllotoxin administration at St. Jude Children's Research Hospital. AML developed in 21 children, with an overall cumulative risk of 3.8% at 6 years follow-up. The schedule of epipodophyllotoxin treatment appeared to be a crucial factor in determining AML risk. Patients who received weekly or twice-weekly doses of teniposide (with or without etoposide), were at an approximately 12 times greater risk of AML than patients treated only during remission induction, or every 2 weeks during maintenance treatment. Several subgroups of patients in this study were exposed to other potentially leukemogenic factors, such as cyclophosphamide and cranial irradiation. The strongest evidence that the excess risk of AML was due to epipodophyllotoxin treatment came from comparing two subgroups that differed only in schedule of epipodophyllotoxin administration. Among 84 patients who received epipodophyllotoxins weekly, the risk of AML was clearly and significantly increased (12.4% at 6 years; 95% CI, 6.1% to 24.4%) compared with 148 patients who received the agents every other week (1.6% at 6 years; 95% CI, 0.4% to 6.1%;  $P = .01$ ). Cumulative dose did not show enough variation within the study groups to reliably assess its effect. Compelling evidence for a causal link between epipodophyllotoxin therapy for ALL and the development of AML was also provided by Winick and associates. <sup>234</sup>

Elevated risk of AML also has been reported after a number of other childhood malignancies, especially lymphomas. <sup>57,62,105,223,235,236</sup> Two case-control studies addressed the effects of radiation dose and amount of chemotherapy on the risk of AML in children treated for various malignancies. <sup>18,105</sup> A significant dose-response relationship between total dose of alkylating agents and AML risk was observed in both studies. The Late Effects Study Group <sup>18</sup> found no association between leukemia risk and radiation dose to active bone marrow. In contrast, using similar methods of estimating bone marrow dose, Hawkins and colleagues <sup>105</sup> observed a highly significant trend, with an approximately 20-fold increased risk for patients receiving 15 Gy or more (compared to patients not treated with radiotherapy). These discrepant results may be explained by differences between the studies in the pattern of first cancers and in therapeutic practices. It is possible that the patients in the British study received lower radiation doses to larger volumes of bone marrow, which, for a specified dose, might result in less cell kill and a greater susceptibility to leukemogenic transformation. <sup>105</sup> The case-control study in the United Kingdom <sup>105</sup> included ten cases of secondary AML after epipodophyllotoxin treatment, mostly for pediatric NHL. It is of interest that, at much lower cumulative doses than used in the St. Jude Children's Research Hospital study, <sup>97</sup> a steep increase in AML risk was noted with increasing dose of epipodophyllotoxins. Another striking difference between the two studies was that the strong dose-response relationship in the British study was observed for regimens in which the epipodophyllotoxins were given less frequently than weekly.

The Cancer Therapy Evaluation Program of the National Cancer Institute has developed a monitoring plan to better quantify the risk of AML after epipodophyllotoxin treatment. Smith and colleagues <sup>106</sup> reported results for patients included in trials that used epipodophyllotoxins at low (less than 1.5 g/m<sup>2</sup>), moderate (1.5 to 2.9 g/m<sup>2</sup>), or higher (3 g/m<sup>2</sup> or more) cumulative etoposide doses. The 6-year cumulative risks for AML (including MDS) with the low, moderate, and higher cumulative dose groups were 3.3% (based on eight AML cases in 451 patients), 0.7% (based on four AML cases in 1270 patients), and 2.2% (based on five AML cases in 570 patients), respectively. This result does not appear to provide support for a cumulative-dose effect for the leukemogenic activity of the epipodophyllotoxins, at least not within the cumulative-dose range and with the treatment schedules encompassed by the monitoring plan (cumulative etoposide dose of 5.0 g/m<sup>2</sup> or less, on daily times 2-to 5 schedules). A limitation of this study, however, is that the three treatment strata according to cumulative etoposide dose also differed with respect to other cytotoxic drugs received, primary tumor, and age. These differences and the administration of radiotherapy were not accounted for in the analysis. <sup>93</sup> Smith and associates <sup>106</sup> suggested that the much larger AML risk observed in earlier investigations might be due to the higher cumulative epipodophyllotoxin doses used in those studies (as high as 9 to 19 g/m<sup>2</sup>) <sup>97,234,235</sup> or, alternatively, to their schedule of weekly or twice-weekly administration. This intermittent exposure schedule, which is not commonly used in current treatment regimens, has been associated with increased leukemogenicity *in vitro*. <sup>237</sup> In view of several inconsistencies between the studies conducted to date, final conclusions regarding the leukemogenicity of different epipodophyllotoxin-based regimens cannot yet be drawn.

Hawkins and associates <sup>61</sup> addressed the quantitative relationship between radiation dose, alkylating agent therapy, and risk of bone sarcoma in a case-control study within a British cohort of 13,175 3-year survivors of childhood cancer. Risk of bone cancer was strongly increased in all follow-up intervals beyond 3 years, with no apparent trend of increasing or decreasing relative risks up to 25 years after diagnosis of primary cancer. As in an earlier study, <sup>19</sup> no increased risk was observed for radiation doses to the site of the bone tumor of less than 10 Gy. At more than 10 Gy, risk for bone sarcoma rose sharply with increasing radiation dose, with a relative risk of 93 for patients who received 30 to 50 Gy as compared to those not treated with radiation. At higher radiation doses, however, the risk appeared to decline somewhat (Table 55.7-7). Such a downturn in relative risk at very high doses was also observed in a smaller case-control study of osteosarcoma after childhood cancer <sup>238</sup> but was not found in the large case-control investigation nested in the LESG cohort. <sup>19</sup> In the latter study, Tucker and colleagues <sup>19</sup> showed that the pattern of

risk increase in relation to radiation dose was similar in patients treated for retinoblastoma and those treated for other initial malignancies. Thus, although patients with retinoblastoma have a higher intrinsic risk for sarcoma development, their relative responses to radiation treatment do not appear to be different from patients with other childhood cancers. Importantly, the study by Hawkins and colleagues<sup>61</sup> also showed that the relative risk of bone sarcoma increases with increasing cumulative exposure to alkylating agents, even after adjustment for radiation therapy (see [Table 55.7-7](#)). It is clear, however, that the effect of radiotherapy on sarcoma risk is stronger than that of chemotherapy. An association between chemotherapy and risk of bone sarcoma also has been observed in other studies<sup>19,91,238,239</sup>; an effect of alkylating chemotherapy on sarcoma risk in the absence of radiotherapy was found only in the LESG study.<sup>19</sup> Comparative studies of children and adults irradiated for Hodgkin's disease have shown that children experience a much higher relative risk of developing bone sarcomas than adults, probably because of greater radiosensitivity of growing bone.<sup>12,62</sup>

Radiation Dose, cGy	Number of Patients		Relative Risk (95% CI) Adjusted for Alkylating Agent Exposure	P Value

**TABLE 55.7-7.** A Case-Control Study of Second Primary Bone Cancer in Relation to Radiation Dose and Cumulative Exposure to Alkylating Agents

The risk of thyroid cancer after radiotherapy for childhood malignancies was assessed in the LESG cohort.<sup>60</sup> High relative risks compared with general population rates were observed for thyroid malignancies after treatment of neuroblastoma (RR, 350), Wilms' tumor (RR, 132), and Hodgkin's disease (RR, 67). The relative risk increased significantly with time since treatment throughout the observation period (more than 20 years). In a case-control study, radiation dose to the thyroid was estimated for 23 thyroid cancer cases and 89 matched controls. Radiation doses of 2 Gy or more carried 13 times greater risk than doses of less than 2 Gy ( $P < .05$ ). Because all patients with thyroid cancer had been exposed to at least 1 Gy of radiation to the thyroid, the risk associated with doses less than 2 Gy could not be reliably determined in this study. However, the investigators estimated that the risk associated with doses of 2 Gy or more was increased approximately 130-fold compared to nonirradiated patients.<sup>60</sup> Unexpectedly, the dose-response relationship was more or less flat at radiation doses beyond 2 Gy; even at doses as high as 60 Gy, no decrease in thyroid cancer risk was observed. A pooled analysis of seven large studies of thyroid cancer after various radiation exposures demonstrated that the risk decreases significantly with increasing age at exposure and is highest for persons with radiation exposure before age 5 years.<sup>59</sup>

In conclusion, survivors of childhood cancer are at substantially elevated risk to develop new malignancies. The magnitude of this risk depends on the type of the initial malignancy, because some childhood cancers, such as bilateral retinoblastoma, carry a high intrinsic risk for second cancer occurrence. Long-term survival after various types of childhood cancer has become possible through therapies introduced from the early 1970s onwards. Consequently, the growing population of cured patients is just beginning to enter the ages at which adult cancers typically occur, so the full spectrum of second malignancies has not yet been encountered. It is therefore imperative that survivors of childhood cancer be carefully monitored to assess the long-term risks of various types of second cancers. Bone sarcoma has consistently been identified as the second malignancy for which the excess risk is highest. Of much interest is the potential interaction between genetic susceptibility and treatment in second cancer development. The leukemogenic potential of epipodophyllotoxin-containing regimens that vary in cumulative dose and schedule of administration should continue to be rigorously assessed. As quantitative risk information from more studies becomes available, it will be possible to carefully weigh the benefits derived from epipodophyllotoxin treatment against the risks. Second cancers among survivors of childhood cancer are associated with a poor prognosis.<sup>97,230,232,240,241</sup> Hence, the need is pressing to develop therapeutic strategies with less oncogenic potential, without compromising the excellent cure rates that have been achieved.

## CONCLUSION

The results described in this chapter have multiple clinical implications. Knowledge of risk factors for second malignancy has made it possible to identify patient groups at high risk of developing second cancers due to treatments that they received in the past. Whenever effective screening methods are available, these should be implemented in the patients' follow-up program to improve their survival after diagnosis of second malignancy. In some cases, preventive strategies (e.g., smoking cessation) may reduce substantially the risk of developing a treatment-related cancer. The issue of treatment-induced second cancers must always be viewed in relation to the sometimes dramatic improvement in survival rates for patients with various malignancies. The risks associated with various treatments should be weighed carefully against the consequences of not using such treatments. Clinical research should focus on the development of therapeutic regimens with less carcinogenic potential. However, the arbitrary alteration of a successful therapy to mitigate second cancer risk is unwarranted. It is of the utmost importance that changes in therapy to reduce the risk of late complications be made only in the context of carefully designed clinical trials that evaluate whether the overall efficacy of treatment is maintained.

For many cancer treatments, the long-term effects on second malignancy risk are not yet known. In addition, new therapies are being introduced continuously, and the associated risks of late sequelae must be evaluated. Whenever possible, future studies of second cancer risk should incorporate investigations at the molecular level. Results of these laboratory analyses may clarify the influence of genetic susceptibility on treatment-related risk and contribute important data for the elucidation of mechanisms underlying drug- and radiation-induced carcinogenesis.

## NEUROTOXICITY

### VINCRIStINE , VINBLASTINE, AND VINOReLBINE

The first drug class to be recognized as having neurotoxicity was the vinca alkaloids, especially vincristine. Vincristine is unique among the antitumor agents in that neurotoxicity is the sole dose-limiting problem. The neurologic injury can occur in the peripheral, central, or autonomic nervous systems. <sup>1,2</sup>

The most common and initial manifestations of neurotoxicity are depression of the deep tendon reflexes and paresthesias of the distal extremities. The Achilles' tendon reflexes and the fingertips are the usual respective initial sites of abnormalities. Loss of the tendon reflexes is usually asymptomatic. The paresthesias commonly progress proximally as vincristine therapy is continued and may involve the entire hands or feet. Despite the presence of peripheral paresthesias, vibration sense, position sense, pinprick sensation, and two-point discrimination are generally unaffected.

Motor dysfunction and gait disorders are initially manifested as lower extremity weakness. Footdrop may ensue, and if vincristine is continued, weakness to the point of paraparesis may develop. However, when vincristine and corticosteroids are administered together, steroid myopathy often occurs and causes similar symptoms of weakness, which should not be ascribed to vincristine neurotoxicity and result in a dose modification of the wrong drug. <sup>3</sup> Patients with hereditary neuropathies are especially prone to the additive effects of vincristine neuropathy. <sup>4</sup> Severe bone pain (especially in the mandible) may occur acutely a few hours after drug administration but usually subsides after a few days. <sup>5</sup>

Cranial nerves may be affected and cause ophthalmoplegia and facial palsy. Toxicity to the parasympathetic nervous system is manifested by constipation and difficult micturition, which can progress to paralytic ileus and bladder atony. Autonomic neuropathy can produce orthostatic hypotension (which can be symptomatic or clinically silent <sup>6</sup>) and erection/ejaculatory dysfunction. <sup>7</sup> Other rare, but severe, neurotoxic manifestations observed from vincristine include cortical blindness <sup>8</sup> and laryngeal nerve (with vocal cord) paralysis, <sup>9</sup> resulting in dysphonia and even aphonia.

Neurotoxicity from the vinca alkaloids, especially vincristine, is both an individual dose and a cumulative dose phenomena. The usual practice in adults is to limit an individual dose of vincristine to 2 mg. Studies of higher vincristine dosing <sup>7</sup> have shown a very high rate of neurotoxicity. No effective prevention or treatment has been developed except to stop therapy and wait for neurologic recovery. The neuropathy symptoms may persist as long as 3 or 4 years after cessation of therapy, but they usually wane to a point where they are no longer troublesome to the patient. <sup>10</sup> Empiric vitamin therapy is ineffective. Intestinal dysfunction from autonomic neuropathy may be improved by metoclopramide therapy. <sup>11</sup>

Vincristine binds to the B subunit of tubulin, causing disruption of microtubule function in neuronal axons. Electrophysiologic studies indicate distal axonal dysfunction, and nerve conduction testing shows sensory nerves are most affected with a reduced amplitude of nerve action potentials. Histologic changes are generally those of axonal degeneration.

The vincristine analogues vinblastine and vinorelbine also have neurotoxicity potential. The primary dose-limiting toxicity of both vinblastine and vinorelbine is myelosuppression, and neurotoxicity is less common than that occurring from vincristine. The form and range of neurotoxicity manifestations from these analogues are similar to those of vincristine, and again, the degree of dysfunction is related to both individual and cumulative drug doses. However, vinblastine and vinorelbine seem to produce more autonomic effects, resulting in severe constipation and paralytic ileus. <sup>12</sup>

Concurrent use of two neurotoxic agents has been reported to cause enhanced neurotoxicity or no such toxicity, depending on the drug involved. The combination of vinorelbine and cisplatin seems not to increase the incidence or severity of neuropathy. <sup>13</sup> However, when vinorelbine is used either in combination with, or sequentially after, paclitaxel, there is more potential for severe neuropathy. <sup>14,15</sup> In addition, the combination of vincristine and a granulocyte growth factor may precipitate a severe neuropathy involving primarily the legs. <sup>16</sup>

### CISPLATIN AND OXALIPLATIN

Although nephrotoxicity is a major and cumulative dose-limiting toxicity of cisplatin, neurotoxicity is also a common problem and can be dose-limiting for both single and cumulative doses, but primarily the latter. <sup>17,18,19</sup> and <sup>20</sup> Cisplatin-induced neuropathy can be manifested as sensory peripheral neuropathy, Lhermitte's sign, autonomic neuropathy, grand mal or focal seizures, encephalopathy, transient cortical blindness, retrobulbar neuritis, and retinal injury. <sup>17,21,22</sup>

The incidence of neurotoxicity ranges up to 100%, depending on individual and cumulative drug dose, treatment duration, concurrent or prior neurotoxic drugs used, the presence of other medical conditions, and possibly gender (women being more sensitive). <sup>17,18</sup> A cumulative cisplatin dose of 300 to 500 mg/m<sup>2</sup> is the range in which toxicity most often occurs. <sup>17,20</sup>

Peripheral neuropathy similar to that induced by vincristine is the most common form of cisplatin neurotoxicity. Vincristine produces initial paresthesias in the fingers, whereas cisplatin most often affects the toes and feet.<sup>23</sup> Loss of the Achilles' tendon reflexes is an early sign, and continued treatment leads to sensory ataxia and loss of proximal deep tendon reflexes and vibration sense. Although muscle cramps are a common symptom, motor function is usually not affected.

The pathophysiology of cisplatin neurotoxicity is not known, but it is probably related to the accumulation of inorganic platinum within neurons, which may be irreversible. An autopsy study<sup>24</sup> of platinum concentrations and histopathologic changes in the dorsal root ganglia of cisplatin-treated patients demonstrated a correlation of the tissue level of platinum with neuronal histologic changes and clinical neurotoxicity.

Treatment is discontinuation of therapy, but neurotoxic symptoms may last for months after cisplatin therapy is discontinued. The electrophysiologic test abnormalities may last for several years and perhaps indefinitely. The symptoms and signs may even progress despite discontinuing treatment.<sup>25</sup> Amitriptyline has been used as treatment for the neuropathies related to use of antitumor agents, but no clinical trials in this clinical setting evaluating efficacy in double-blind fashion have been performed. Because treatment of neurotoxicity is of limited benefit, prevention using protective agents has been extensively explored.<sup>26</sup> Amifostine, a nephrotoxicity protectant, also provides significant protection against peripheral neuropathy when used in conjunction with cisplatin.<sup>27</sup> Dimesna is a new drug with exceptional promise as a neuroprotective agent and is in advanced clinical development for this indication.<sup>28</sup>

Concurrent use of cisplatin with paclitaxel has demonstrated an enhanced potential for neurotoxicity, although variability exists, probably related to the drug doses and schedules employed. At the doses of these two drugs that are commonly used, more than 50% of patients may develop neuropathy, and this problem is often dose-limiting.<sup>29,30</sup> When patients receiving this drug combination are closely monitored, neurotoxicity may be evident after just two cycles in nearly all cases.<sup>30</sup>

Neuropathy is the most common toxicity of the cisplatin analogue oxaliplatin, and cumulative neurotoxicity is usually dose-limiting. The manifestations are peripheral sensory neuropathy and muscle cramps similar to that of cisplatin, but pharyngolaryngeal dysesthesias (presenting as dyspnea and dysphagia) are a unique symptom seen with this drug.<sup>31</sup> These neuropathic problems may be triggered by touching cold surfaces (finger paresthesias) or drinking cold liquids (pharyngolaryngeal symptoms). Most patients have a nearly full recovery within 6 months after discontinuing therapy.<sup>32</sup>

## CYTARABINE

Cytarabine is administered both intravenously and intrathecally, and both routes can produce neurotoxicity. Manifestations include cerebellar dysfunction, seizures, generalized encephalopathy, peripheral neuropathy, necrotizing leukoencephalopathy, spinal myelopathy, basal ganglia necrosis, and pseudobulbar palsy.<sup>33</sup>

The highest incidence (15% to 37%) occurs in patients receiving high-dose cytarabine therapy (i.e., more than 1 g/m<sup>2</sup> in multiple doses).<sup>33,34</sup> The toxicity is generally acute and not related to cumulative drug doses, in contrast to neuropathy associated with cisplatin and vincristine. Risk factors for neurotoxicity are age older than 50 years, drug dose, prior cytarabine treatment, and renal dysfunction.<sup>33,35</sup>

Cerebellar effects (dysarthria, ataxia, and dysmetria) are the most common form of neurotoxicity. These symptoms often occur within days of first treatment and are accompanied by headache, altered mentation, memory loss, and somnolence. Seizures have rarely occurred. Peripheral neuropathy can also occur but is rare. Symptoms range from a purely sensory neuropathy to sensorimotor polyneuropathies in a glove-stocking distribution.<sup>33</sup> The neuropathy can even progress to a quadriplegia, with ventilatory support being necessary.<sup>36</sup> Intrathecal cytarabine can produce an ascending myelopathy.<sup>37</sup> All of these neurologic abnormalities (even the peripheral neuropathy) can progress to coma and death.<sup>33,35,38</sup>

Recovery from the neurologic effects usually occurs within a few days after discontinuing cytarabine therapy. There is no known treatment. Serial radiographic studies of the brain have shown improvement in cerebellar abnormalities after discontinuing treatment,<sup>39</sup> but progressive atrophy may also occur after a few months and is associated with persistent symptoms.<sup>40</sup> Instances<sup>41</sup> have been reported of ascending myelopathy with paraplegia from intrathecal cytarabine in which complete recovery took place within 1 hour after onset.

The mechanism of such neurotoxicity is not known. When high drug doses are used, cytotoxic concentrations of cytarabine reach the cerebrospinal fluid, but parent drug and metabolites are cleared more slowly from spinal fluid than blood, a likely explanation for the dose relationship of this toxicity.<sup>42</sup> Neuron function and survival appears to be inhibited by cytarabine through blocking of an essential deoxynucleoside.<sup>43</sup> Why the Purkinje cells of the cerebellum are particularly prone to injury from intravenous cytarabine, even in experimental animals,<sup>44</sup> is unknown.

## IFOSFAMIDE

Ifosfamide and cyclophosphamide have similar chemical structures, but ifosfamide induces neurotoxicity (as it does nephrotoxicity), whereas cyclophosphamide does not. Acute symptoms are visual and auditory hallucinations, vivid dreams, logorrhea, incontinence, dizziness, palilalia, confusion, perseveration, agitation, personality changes, somnolence, cerebellar and cranial nerve dysfunction, hemiparesis, seizures, coma, and occasionally death.<sup>45,46,47</sup> and <sup>48</sup> Peripheral neuropathy and extrapyramidal abnormalities, such as myoclonus and muscular spasticity, also have been reported. The onset is acute up to 5 days after beginning ifosfamide, and recovery usually occurs within a few days after discontinuing therapy. Memory and affect disorders may occasionally persist. No cumulative-dose neurotoxic effects have been reported, but re-treatment with ifosfamide may again precipitate the same acute toxicity manifestations.

Significant neurotoxic abnormalities occur in approximately 10% of patients treated with ifosfamide. The incidence varies depending on how carefully patients are monitored for this problem, the ifosfamide dose and method of administration used, and the presence of various risk factors. Such risk factors are low serum albumin, any degree of renal dysfunction, prior administration of cisplatin (probably resulting in subclinical renal dysfunction), poor performance status, the presence of central nervous system tumor, and age (children being more susceptible than adults).<sup>45,48,49</sup> High doses may accentuate symptoms of an underlying mild neuropathy and cause severe and painful paresthesias.<sup>50</sup> For unknown reasons, oral administration of ifosfamide has more neurotoxic potential than the intravenous route.<sup>51</sup>

The etiology of this neurotoxicity is probably multifactorial and is due to one or more metabolites of ifosfamide that are produced in high quantities.<sup>52</sup> Cyclophosphamide may not produce neurotoxicity because metabolites with encephalopathic potential are a minor component of its degradation. Effective treatment (besides discontinuing the ifosfamide) has been intravenous diazepam<sup>53</sup> and methylene blue.<sup>52,54</sup> Such treatment can produce dramatic reversal of the neurotoxic manifestations. Means of prevention include a continuous infusion schedule of drug administration and concurrent use of methylene blue.<sup>54</sup>

## 5-FLUOROURACIL

5-Fluorouracil (5-FU) has been known to cause neurotoxicity since the earliest clinical trials were conducted with this drug. Cerebellar dysfunction with findings of gait ataxia, nystagmus, dysmetria, and dysarthria is the most common form of neurotoxicity, but confusion, somnolence, seizures, coma, and peripheral neuropathy also have been observed.<sup>55,56</sup> and <sup>57</sup> The incidence is approximately 5%, and it may occur with any of the administration schedules in common use. Neurotoxicity from this drug is acute in onset, and a cumulative-dose effect has not been observed. It is now common practice to administer leucovorin in combination with 5-FU to enhance antitumor activity. Leucovorin may itself be the etiology<sup>58</sup> of some of the instances of seizures occurring in conjunction with administration of these two drugs.

The combination of 5-FU and levamisole may produce a multifocal leukoencephalopathy manifested by agitation, confusion, short-term memory loss, diplopia, cerebellar dysfunction, and expressive aphasia.<sup>59</sup> Magnetic resonance imaging of the brain shows multiple, enhanced, white matter lesions (sometimes ring-enhanced) in the cerebrum, and histologic examination shows focal demyelination. Such toxicity has not been reported when 5-FU has been used alone, but it has occurred with use of levamisole alone.<sup>60</sup> Therefore, the levamisole in this adjuvant therapy combination is probably the most culpable in producing these cerebral effects.

The etiology of 5-FU neurotoxicity is not well understood. 5-FU metabolites have been shown to have neuropathic action in experimental animals.<sup>61</sup> However, it may also be due to parent drug, and not metabolites, because patients have been reported who developed severe toxic symptoms due to a genetic deficiency of the initial enzyme necessary for catabolizing 5-FU.<sup>62</sup> Patients with complete or partial deficiency of this enzyme, dihydropyrimidine dehydrogenase, appear particularly subject

to 5-FU toxicity of all kinds including neuropathy.

## METHOTREXATE

Neurotoxicity from methotrexate can manifest as meningeal irritation, transient paraparesis, or encephalopathy. When the drug is administered intrathecally (IT), it can cause headache, nausea and vomiting, lethargy, nuchal rigidity, and other features of meningeal irritation.<sup>63</sup> A subacute set of abnormalities include paraparesis, hemiparesis, somnolence, cranial nerve dysfunction, cerebellar symptoms, and seizures, which can develop days to several weeks after therapy. Such encephalopathy symptoms may occur more commonly when both IT and intravenous high-dose methotrexate are administered.<sup>64</sup> When IT methotrexate is given repetitively (especially if it is administered via an intraventricular device), progressive necrotizing leukoencephalopathy may develop. Although acute onset with resultant death has occurred,<sup>65</sup> the usual symptoms include initial memory loss with occasional later progression to severe dementia, gait disturbance, dysphasia, and seizures.<sup>66</sup> Even if serious neuropathy does not occur, subtle cognitive deficits may develop months to years later, especially in children.<sup>67</sup> Risk factors for such problems are cranial irradiation, presence of neoplastic cells in the spinal fluid, and cumulative drug dose. The neurotoxic effect is probably a direct consequence of high drug dose concentrations in the cerebrospinal fluid.

Intravenous methotrexate also can produce encephalopathy, especially if high doses and leucovorin rescue are used.<sup>68</sup> The manifestations and risk factors are similar to those of IT methotrexate. The neurologic dysfunction may be acute and transient or delayed in onset with personality changes. Magnetic resonance imaging can show white matter abnormalities in asymptomatic patients that are probably subclinical manifestations of neurotoxicity.<sup>69</sup> However, it has been argued that such findings do not necessarily correlate with subsequent intellectual dysfunction and therefore may be inconsequential.<sup>70</sup> Treatment consists of active hydration to facilitate methotrexate clearance and leucovorin to circumvent the enzyme inhibition of methotrexate.

It has been postulated that this toxicity arises from methotrexate-related impairment of synthesis of neurotransmitters and accumulation of adenosine and homocysteine.<sup>71</sup> Based on this hypothesis that the neurotoxicity is related to brain accumulation of adenosine, aminophylline (an adenosine receptor antagonist) has been used successfully to reverse the neurologic effects of methotrexate.<sup>72</sup>

## PACLITAXEL AND DOCETAXEL

The two analogues paclitaxel and docetaxel cause neurotoxicity similar to that of cisplatin and vincristine in the form of a peripheral neuropathy that can be a treatment-limiting effect.<sup>73,74,75,76</sup> and <sup>77</sup> The clinical manifestations are glove-stocking or perioral paresthesias and/or burning pain, loss of vibration sense, loss of deep tendon reflexes, Lhermitte's sign, and orthostatic hypotension. Motor dysfunction in the form of both proximal and distal extremity weakness also has been observed.<sup>78</sup> However, it is impossible to determine how much taxane-associated myopathy might be due to the antitumor drug and how much to the intermittent, but large, doses of corticosteroids that are used concurrently with the taxanes to minimize the risk of hypersensitivity reactions. Transient scintillating scotomata and visual deficits due to optic neuropathy<sup>79</sup> and encephalopathy<sup>80</sup> in the form of confusion and behavioral changes also have been reported. A possible risk factor for initiating or enhancing the neural dysfunction from these drugs is an underlying neuropathy from other conditions such as diabetes mellitus and ethanol abuse.<sup>73</sup> However, one study<sup>81</sup> has shown that patients with diabetes may be treated with standard doses of paclitaxel, and they do not develop neurotoxicity to a greater degree than expected.

Both a single-dose and cumulative-dose relationship is noted for paclitaxel. Single doses of more than 175 mg/m<sup>2</sup> given at 3-week intervals produce a higher rate of neurotoxicity than lesser doses, and at 250 mg/m<sup>2</sup>, neurotoxicity is dose-limiting in as many as 70% of patients.<sup>74</sup> When paclitaxel is given weekly in 1-hour infusions, severe neurotoxicity occurs at doses of more than 100 mg/m<sup>2</sup>.<sup>82</sup> Cumulative dosing also increases the frequency of neurotoxicity, but there is no neurotoxic dose threshold. Depending on the drug dose used, the onset of these problems can be within a few days of receiving the first dose or after several cycles of therapy. A docetaxel dose of 100 mg/m<sup>2</sup> also induces mild to moderate neurotoxic symptoms in as many as 50% of patients after five cycles of therapy.<sup>76,77</sup> A cumulative docetaxel dose of 400 mg/m<sup>2</sup> can produce severe symptoms and electrophysiologic changes in nerves,<sup>77</sup> but as with paclitaxel, there is no threshold dose. Concurrent or prior use of other neurotoxic agents (cisplatin,<sup>30,83,84</sup> oxaliplatin,<sup>85</sup> or vinorelbine<sup>14</sup>) enhances the risk and degree of neurotoxicity manifestations from both of the taxanes.

The mechanism of taxane neurotoxicity is likely a drug effect on neuronal microtubules, causing axonal degeneration and demyelination. Neurometric testing demonstrates decreased nerve conduction velocities and absent sural nerve action potentials from both taxanes.<sup>73,76,77</sup>

The only effective treatment, as with the other neurotoxic antitumor agents, is discontinuing therapy and allowing the symptoms to wane over time (which they usually, but not always, do). Amitriptyline may or may not help with symptom relief. With this toxicity being so prevalent and often dose-limiting with these two potent antitumor agents, development of an efficacious neuroprotectant is a high priority. Amifostine has not demonstrated efficacy as a neurotoxicity protectant for paclitaxel.<sup>86</sup> Dimesna is a new agent in clinical development as a protectant for both paclitaxel-induced<sup>87</sup> and cisplatin-induced<sup>28</sup> neurotoxicity.

## ALTRETAMINE (HEXAMETHYLMELAMINE)

Altretamine (hexamethylmelamine) causes a variety of peripheral and central nervous system toxicities. Peripheral neuropathy is the most common form and manifests as paresthesias, hyperesthesia, hyporeflexia, and diminished proprioception.<sup>88</sup> Central nervous effects are confusion, dysphagia, personality changes, ataxia, somnolence, seizures, respiratory dyskinesia, and parkinsonian tremors.<sup>88</sup>

Neurotoxicity is related to both individual and cumulative doses. Intermittent dosing schedules help reduce this side effect. The incidence varies depending on the dose but can be as high as 40%. Altretamine can be safely administered to patients who have been treated previously with cisplatin, but if significant cisplatin neuropathy is present, the neurotoxic manifestations may worsen.<sup>89</sup>

## PROCARBAZINE

Neurotoxicity from procarbazine has been known since it was first used clinically.<sup>90</sup> Both central and peripheral neurotoxicity symptoms can occur. Cerebral symptoms predominate and consist of lethargy, depression, confusion, hallucinations, agitation and, rarely, psychosis. Extremity paresthesias and depressed deep tendon reflexes are the manifestations of peripheral neuropathy.

Procarbazine is most commonly used in combination with the vinca alkaloids, so it is difficult to determine which agent is causing peripheral neuropathy symptoms. The incidence of neuropathy induced by procarbazine alone is 20% or less. It is much higher when procarbazine and vincristine are used concurrently. Treatment is discontinuation of therapy. Cerebral symptoms usually resolve promptly, but peripheral neuropathy may last for weeks to months.

## ALDESLEUKIN (INTERLEUKIN-2)

The biologic antitumor agent aldesleukin (interleukin-2) has many toxicities precipitated by increased vascular permeability. Neurotoxicity in the form of hallucinations, disorientation, agitation, combativeness, seizures, and coma may also occur.<sup>91,92</sup> A neurotoxic manifestation unique to this drug is carpal tunnel syndrome, which appears to be a consequence of interstitial edema (due to the vascular leak), causing pressure on the median nerve.<sup>93</sup>

## FLUDARABINE , CLADRIBINE, AND PENTOSTATIN

When fludarabine was tested in phase I and II trials, central nervous toxicity was so severe that the studies had to be closed prematurely. Altered mental status, photophobia, amaurosis, generalized seizures, dementia, spastic or flaccid paralysis, quadriparesis, and coma occurred at doses of more than 90 mg/m<sup>2</sup> given for 5 to 7 days.<sup>94</sup> Despite discontinuing therapy, some patients had progressive neurologic abnormalities and died. At autopsy, leukoencephalopathy was present in the occipital lobes. Because such severe toxicity is clearly dose-related, the recommended fludarabine dose is 25 mg/m<sup>2</sup> daily for 5 days at monthly intervals. This dose usually causes no more than mild and uncommon (incidence of approximately 15%) neurotoxicity symptoms, but sporadic cases of severe (and even fatal) neurotoxicity have occurred, some of which even developed a few months after fludarabine therapy was stopped.<sup>95,96</sup> and <sup>97</sup>

Both cladribine and pentostatin can cause severe, and fatal, neurotoxicity when administered at doses producing marked myelosuppression. The manifestations are

similar to those of fludarabine.<sup>96</sup> However, like fludarabine, drug doses in the range recommended for usual therapy produce only rare instances of severe neurotoxicity.<sup>95</sup>

## OTHER AGENTS

Table 55.8-1 lists other antitumor drugs that can produce neurotoxicity and categorizes them based on the risk for this effect. The manifestations are similar to those described for the individual drugs. Certain ones (e.g., busulfan<sup>96</sup>) produce problems such as seizures only when very high doses are administered in the stem cell transplantation setting, even despite the use of prophylactic anticonvulsant medication.

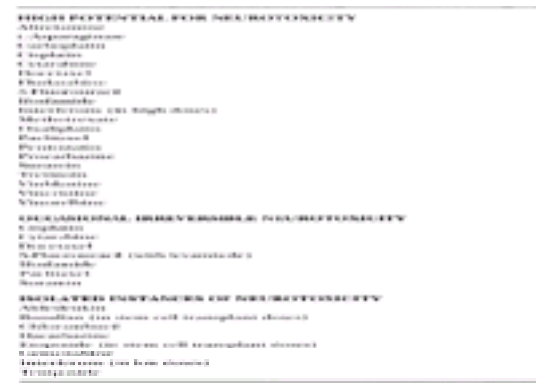

TABLE 55.8-1. Antitumor Agents That Cause Neurotoxicity

## NEPHROTOXICITY

The kidneys are the elimination pathway of many antitumor drugs and their metabolites and, therefore, are vulnerable to injury. The entire anatomic pathway from glomerulus to distal tubule is at risk, depending on the drug involved. The symptoms vary from an asymptomatic rise in serum creatinine or mild proteinuria to acute renal failure with anuria requiring dialysis.

### CISPLATIN AND CARBOPLATIN

The nephrotoxicity of cisplatin has been well known since it was first used clinically in the early 1970s. This obstacle to its clinical use has been so profound that several thousand cisplatin analogues have subsequently been synthesized in hopes of finding a less nephrotoxic compound with equivalent antitumor efficacy. A means of avoiding nephrotoxicity by forcing diuresis and enhancing cisplatin excretion was first reported in 1977.<sup>98</sup> This seminal work allowed safer use of this drug with its wide spectrum of antitumor efficacy.

Cisplatin renal toxicity is dose-related, cumulative, and manifested primarily by a decrease in the glomerular filtration rate, which is clinically approximated by increases in the serum creatinine and decreases in the creatinine clearance. Single drug doses of less than 50 mg/m<sup>2</sup> usually cause little renal injury, but higher doses require aggressive hydration, otherwise abrupt, irreversible renal failure may ensue.<sup>100</sup> Hydration reduces cisplatin concentration and the time it is in contact with the tubular epithelium, which helps to limit the tubular injurious effect of the drug. The hydration used most successfully is normal saline because the high chloride inhibits cisplatin hydrolysis in the tubules, which seems to add to the nephrotoxicity-protection effect of diuresis. Mannitol also is used to enhance diuresis, but no evidence indicates that mannitol is necessary. Concurrent use of furosemide to enhance diuresis further is unnecessary and may even be harmful, as it was in animal experiments.<sup>101</sup> A urine output of at least 100 mL/hour for 2 to 4 hours before and 4 to 6 hours after cisplatin doses of 50 to 75 mg/m<sup>2</sup> reduces, but does not eliminate, nephrotoxicity. More intensive hydration schedules are necessary when higher cisplatin doses are used.

The pathologic lesion of cisplatin nephrotoxicity is seen primarily in the proximal and distal tubules but also may involve the collecting ducts, whereas the glomeruli are unaffected.<sup>102</sup> The extent of tubular injury helps to explain why electrolyte abnormalities, such as hyponatremia and hypomagnesemia, are so common after cisplatin administration.<sup>103,104</sup> The hypomagnesemia is symptomatic only in approximately 10% of patients, but it can last months to years after completing therapy.<sup>105</sup> Magnesium supplementation in conjunction with cisplatin administration can minimize, but does not eliminate, hypomagnesemia.<sup>106</sup> The hyponatremia has been reported to cause persistent orthostatic hypotension.<sup>104</sup>

The mechanism of the tubular injury is not fully understood. It is not simply the tubular handling of a heavy metal, because the *trans* isomer of cisplatin is not nephrotoxic. Cisplatin produces DNA intrastrand cross-links as one of its mechanisms of antitumor effect, and the same effect perhaps occurs on DNA in tubule cells, causing defects in tubular (especially proximal) resorption.

A variety of substances have been evaluated for minimizing cisplatin nephrotoxicity in the hope that the cumbersome process of hydration can be circumvented. These include sodium thiosulfate, amifostine, probenecid, diethyldithiocarbamate, superoxide dismutase, hypertonic saline, glutathione, bismuth compound, and mesna.<sup>107</sup> Only one of these many compounds (amifostine) has provided sufficient protective benefits to become accepted for routine use. Amifostine demonstrated statistically significant protection against cisplatin-induced nephrotoxicity<sup>27,108</sup> and is now marketed for this indication. However, amifostine has its own toxicities that can be an obstacle to convenient use, such as hypotension and nausea and vomiting. One simple technique for nephrotoxicity protection besides hydration is to administer cisplatin in the evening to take advantage of circadian rhythm effects that have been shown to reduce renal injury,<sup>109</sup> although this timing may be impractical in the outpatient setting. A final measure of protection is to be certain that renal function is normal by performing a pretreatment 24-hour, measured creatinine clearance. A result of less than 70 mL/min, especially in patients older than 60 years of age, may preclude cisplatin use without a significant risk of nephrotoxicity.<sup>110</sup> In addition, other renal tubular toxins, such as aminoglycoside antibiotics, should be avoided whenever possible to prevent additive tubular damage.

Carboplatin was synthesized as a cisplatin alternative with less nephrotoxicity and without a requirement of hydration for safe administration. It is definitely less nephrotoxic, but it is not free of potential for renal injury, especially in patients who have previously received nephrotoxins, or when given in high doses in the stem cell transplantation setting.<sup>111,112</sup> Carboplatin-related renal dysfunction is usually detectable only by means of sensitive kidney function tests, such as urine tubular enzyme excretion or glomerular filtration rate, and is transient.<sup>113,114</sup> The serum creatinine and creatinine clearance are rarely affected.

Life-threatening hemolytic-uremic syndrome has been reported as a rare form of acute renal dysfunction related to cisplatin and carboplatin.<sup>115,116</sup> Many of the reported instances related to cisplatin have involved combined use of cisplatin and bleomycin,<sup>117</sup> so it is unclear which drug is most culpable in initiating this fulminant toxicity.

### MITOMYCIN

The capacity of mitomycin to produce renal toxicity has been known for many years, and it can be life-threatening. The clinical manifestations vary from a chronic, progressive rise in serum creatinine to fulminant onset of microangiopathic hemolytic anemia (MAHA). The latter problem has been reported in a large number of anecdotal cases,<sup>118,119</sup> but in one study of adjuvant therapy with mitomycin, a 10.7% incidence occurred.<sup>120</sup> It was also observed<sup>121</sup> in 10% of patients treated with a combination of mitomycin and tamoxifen, and the authors of this study suggested some interaction between the two drugs might have contributed to the development of this toxicity.

The MAHA toxicity is cumulative dose-related, but even only several mitomycin doses can initiate it. It also can develop a few months after mitomycin has been discontinued.<sup>118,122</sup> The risk of developing MAHA increases when the cumulative mitomycin dose exceeds 60 mg.<sup>122</sup>

The clinical presentation of MAHA is an abrupt and often severe hemolytic anemia that usually precedes the renal dysfunction by 1 or 2 weeks. The peripheral blood

smear shows schistocytes, and thrombocytopenia becomes apparent as renal failure develops. Other manifestations are rash, fever, arterial hypertension, central neurologic dysfunction, pericarditis, interstitial pneumonitis, pulmonary hemorrhage, hematuria, and proteinuria. <sup>118,122</sup> A high rate (65%) of patients have noncardiogenic pulmonary edema. <sup>122</sup> A prominent feature is the fact the MAHA is often precipitated or worsened by blood transfusions, suggesting that blood product administration should be avoided as much as possible when treating patients with mitomycin. The outcome is often (more than 50% of the time) death, despite vigorous treatment, although a few long-term survivors (who have persistent mild renal dysfunction) have been reported. <sup>122,123</sup>

Treatment includes hemodialysis and plasmapheresis. The most successful treatment has been plasma perfusion over filters containing staphylococcal protein A, a method of extracting circulating immune complexes. <sup>124</sup>

The pathogenesis of this acute nephropathy is not certain. When injected directly into the renal arteries of rats, mitomycin caused glomerular endothelial damage, <sup>125</sup> and increases in vascular endothelial cell markers in plasma have been observed in patients who developed MAHA related to mitomycin. <sup>126</sup> This vascular injury probably activates platelets and leads to fibrin thrombi deposition in the microvasculature of the kidney, thus initiating renal dysfunction and a mechanical shearing of red blood cells with resultant hemolysis.

## METHOTREXATE

When methotrexate is administered in conventional oral or intravenous doses, nephrotoxicity is only an occasional problem. If high doses with folinic acid rescue are used, acute nephrotoxicity can pose a greater danger.

Methotrexate is excreted rapidly in the urine whether it is administered orally or parenterally. Both the parent compound and the major metabolite, 7-hydroxymethotrexate, are filtered by the glomeruli and actively secreted by the tubules. At physiologic pH, the drug is fully ionized, but in acidified form (pH less than 5.7), the parent drug and main metabolite are less ionized and may precipitate. During urinary excretion, drug precipitation occurs as the urine is concentrated and acidified in the tubules. The solubility of 7-hydroxymethotrexate is only one-fourth that of the parent drug, thus providing further potential for drug precipitation within tubules and resultant acute renal dysfunction.

Acute methotrexate nephrotoxicity produces abrupt renal insufficiency. The serum creatinine rises rapidly, and costovertebral angle pain (from renal swelling) may occur. Dehydration, oliguria, and even anuria may develop.

Methotrexate-induced renal insufficiency is primarily a physical process of tubular drug precipitation. It can be largely prevented by methods designed to hinder this precipitation of drug in the tubules: hydration and urine alkalinization. <sup>127</sup> Whenever a drug dose high enough to require leucovorin rescue is being given, the urine should be kept alkaline (pH higher than 8) with sodium bicarbonate administration, and a urine output of 100 mL/hour should be maintained. Serial serum methotrexate levels should be monitored until the drug concentration declines to  $10^{-8}$  molar or less, 24 to 48 hours after administration. <sup>127</sup>

If methotrexate clearance is impaired by renal dysfunction already present or initiated by concurrently administered drugs, nephrotoxicity can develop or be enhanced. For example, prior therapy with cisplatin may contribute to methotrexate nephrotoxicity, <sup>128</sup> and concurrent administration of nonsteroidal antiinflammatory drugs may engender serious, and even fatal, renal dysfunction from methotrexate. Indomethacin, ketoprofen, diclofenac, and naproxen all have been reported to intensify renal dysfunction from methotrexate, whether it is being given in high doses <sup>129</sup> or low doses. <sup>130</sup> This enhanced toxicity is probably mediated by a reduction in methotrexate clearance caused by the concurrent drug administration.

Sequential hemodialysis and charcoal hemofiltration <sup>131</sup> have been used as treatment of acute nephrotoxicity from high methotrexate doses. A highly successful therapy has been administration of a combination of thymidine, leucovorin, and the recombinant form of the bacterial enzyme carboxypeptidase G<sub>2</sub>, <sup>132</sup> which quickly converts methotrexate to a harmless metabolite. Both thymidine and carboxypeptidase are available on a compassionate-use basis from the National Cancer Institute for treating this life-threatening toxicity. <sup>132</sup>

## STREPTOZOCIN , CARMUSTINE, AND LOMUSTINE

Streptozocin has the most potential for nephrotoxicity in the nitrosourea drug class, and renal damage is its dose-limiting toxicity. <sup>133</sup> Prolonged drug administration increases the risk of such toxicity, and most patients eventually display it if therapy continues.

The kidneys are the major excretion pathway for both parent drug and its metabolites, the probable main factor in the pathogenesis of the nephrotoxicity. Streptozocin injury occurs in both the glomeruli and tubules (primarily the proximal), where histologic changes have been observed, but the mechanism is unknown. Hyperphosphatemia and proteinuria are early indicators of renal effect. Renal tubular acidosis is a frequent occurrence, manifested by glycosuria, acetonuria, hyperchloremia, and aminoaciduria. <sup>133</sup> If streptozocin is discontinued, these findings usually resolve. A rising serum creatinine is a later, and sometimes irreversible, finding. Hydration and diuresis during therapy have occasionally minimized the renal dysfunction. <sup>134</sup>

The other two nitrosoureas in wide clinical use (carmustine and lomustine) are much less nephrotoxic. Carmustine usually causes interstitial pneumonitis toxicity before it affects the kidneys. Lomustine has produced only rare instances of nephrotoxicity when unusually large cumulative doses have been administered. <sup>135</sup>

## IFOSFAMIDE

Cyclophosphamide and ifosfamide are analogues with similar chemical structures. Both produce the metabolite acrolein, which can cause hemorrhagic cystitis during urinary excretion. Despite their similarities in chemical structure, toxicity, and antitumor efficacy, they differ significantly in their ability to cause nephrotoxicity. Cyclophosphamide produces no renal toxicity of any clinical consequence, whereas ifosfamide initiates a variety of renal abnormalities that may in some instances result in death or irreversible renal failure requiring chronic hemodialysis or renal transplantation, especially in children who are at higher risk for this problem. <sup>136,137</sup> Hypotheses regarding the mechanism of ifosfamide nephrotoxicity and why cyclophosphamide does not have such effect have been formulated based on the differences in metabolism of these two drugs (ifosfamide produces much more chloroacetaldehyde) and the unique effect of ifosfamide on proximal renal tubule cells. <sup>138,139</sup>

Initial clinical studies of ifosfamide showed that single high doses could precipitate acute tubular necrosis and renal failure within a few days of administration. This severe toxicity was one reason a fractionated dose schedule was developed for this drug. Administration over 5 consecutive days reduced both renal and bladder toxicity, but the most effective measure for reducing urinary tract problems was the development of mesna as a means of protection against the drug-induced cystitis. Mesna is now a standard accompaniment to ifosfamide use, but it limits the cystitis, *not* the nephrotoxicity. <sup>140</sup> There is no known means of preventing ifosfamide renal toxicity.

The incidence of renal toxicity varies from 5% up to 30%. Besides young age (especially younger than 5 years), <sup>137</sup> risk factors are drug dose (cumulative doses of more than 60 g/m<sup>2</sup>), unilateral nephrectomy, prior renal irradiation, presence of retroperitoneal masses, and prior cisplatin treatment. <sup>141,142 and 143</sup> Clinical manifestations include tubular dysfunction, Fanconi's syndrome, and a rising serum creatinine. The tubular injury is indicated by aminoaciduria, glycosuria, renal tubular acidosis, hypokalemia, proteinuria, and phosphaturia with hypophosphatemia. <sup>138</sup> These abnormalities can even result in renal rickets and growth retardation, which require long-term therapy. <sup>137,141,144</sup> Once acute renal dysfunction from this drug becomes evident, it may or may not be reversible, so frequent monitoring of renal and tubular function during ifosfamide therapy is important, with prompt treatment when dysfunction occurs. <sup>138</sup> Progression to renal failure is generally not a problem in children, <sup>144</sup> but such failure may occur in adults, even with only moderate cumulative doses of ifosfamide. <sup>145</sup> Renal abnormalities may not become evident until long after ifosfamide therapy has been completed. <sup>146</sup>

## OTHER AGENTS

[Table 55.8-2](#) lists the antitumor agents that have been reported to cause renal injury. They are categorized by the risk of such toxicity from those drugs with an occasional anecdotal report to those with high risk for severe damage.

HIGH POTENTIAL FOR NEPHROTOXICITY
Adriamycin (doxorubicin-D)
Asparaginase
Cisplatin
Carboplatin
Fluorouracil
Methotrexate (in high doses)
Mitomycin
Streptozocin
Thioguanine
AGENTS WITHOUT NEPHROTOXICITY
L-Asparaginase
Dacarbazine
OCCASIONAL IRREVERSIBLE NEPHROTOXICITY
Cisplatin
Fluorouracil
Carboplatin
Fluorouracil
Hydroxyurea
Levamisole
Mitomycin
Streptozocin
ISOLATED INSTANCES OF NEPHROTOXICITY
Cyclophosphamide
D-Mercaptopurine
Methotrexate (in low doses)

**TABLE 55.8-2.** Antitumor Agents That Cause Nephrotoxicity

Not only can individual drugs cause nephrotoxicity, but combinations of agents can occasionally precipitate serious reactions, such as hemolytic uremic syndrome from cisplatin and bleomycin.<sup>117</sup> In addition, the intensive doses of chemotherapy used in conditioning for stem cell transplantation can induce hemolytic uremic syndrome with an acute or delayed onset and sometimes fatal outcome.<sup>147</sup>

## HEPATOTOXICITY

A number of antitumor agents cause hepatic toxicity (Table 55.8-3). This toxicity takes three main forms: hepatocellular dysfunction and chemical hepatitis, venoocclusive disease (VOD), and chronic fibrosis.

HIGH POTENTIAL FOR HEPATOTOXICITY
L-Asparaginase
Cytarabine
Methotrexate (in high doses)
Methotrexate (in low doses)
Streptozocin
HIGH POTENTIAL FOR HEPATOTOXICITY WITH HIGH DOSES
Busulfan
Carboplatin
Cyclophosphamide
Dactinomycin
Etoposide
Mitomycin
OCCASIONAL IRREVERSIBLE HEPATOTOXICITY
Busulfan (in high doses)
Carboplatin (in high doses)
Cytarabine
Dactinomycin
Methotrexate
Mitomycin
ISOLATED INSTANCES OF HEPATOTOXICITY
Dactinomycin
Hydroxyurea
Levamisole (in low doses)
D-Mercaptopurine
Streptozocin
Vincristine

**TABLE 55.8-3.** Antitumor Agents That Cause Hepatotoxicity

## HEPATOCELLULAR DYSFUNCTION

Hepatocellular dysfunction usually is caused by a direct effect of either the parent drug or a metabolite and is an acute event. Serum hepatic enzymes rise as cellular damage occurs. Fatty infiltration and cholestasis may occur as the toxic effect progresses. Hepatic metastases, viral hepatitis, and drugs administered for other therapeutic purposes (e.g., antiemetics) can cause similar enzymatic abnormalities. Thus, the clinical picture, appropriate laboratory or radiologic studies, and the pattern of abnormal liver function tests must be analyzed to identify the cause of the hepatic changes.

The drugs most likely to cause enzymatic abnormalities are L-asparaginase, carmustine in high doses, cytarabine, dactinomycin, etoposide, levamisole in combination with 5-FU, 6-mercaptopurine, methotrexate in high doses, streptozocin, and vincristine. These drugs can cause rises in the serum glutamic-oxaloacetic transaminase, serum glutamic-pyruvic transaminase, and serum bilirubin.

L-Asparaginase causes the widest spectrum of liver abnormalities and has the highest incidence of hepatotoxicity. It produces changes in liver enzymes and in hepatic protein synthesis, resulting in low plasma levels of albumin, lipoproteins, and clotting factors. Prolongation of the prothrombin and thrombin times occurs as a result. Fatty metamorphosis is commonly seen, and these changes may persist for several months after discontinuing treatment.<sup>148</sup>

The combination of levamisole and 5-FU, used as adjuvant therapy for colon cancer, also frequently produces reversible hepatic enzyme and serum bilirubin changes.<sup>149</sup> These abnormalities are due to fatty infiltration of the liver, and in some cases the degree of liver abnormality may be sufficient to mimic liver metastases on radiographic studies.<sup>150</sup>

Cytarabine hepatotoxicity is a common event in the treatment of acute leukemia, especially when high doses are used.<sup>151</sup> Because patients with acute leukemia are subject to transfusion-related hepatitis and receive a variety of potentially hepatotoxic drugs, it is always difficult to establish cytarabine as the sole hepatotoxin. However, hyperbilirubinemia developing in temporal relation to cytarabine administration, accompanied by histologic abnormalities on liver biopsy, has confirmed the hepatotoxicity potential of this drug.<sup>152</sup>

6-Mercaptopurine has been known since the 1950s to cause hepatotoxicity, which may even be rarely fatal.<sup>153</sup> Intrahepatic cholestasis is the most common abnormality, and liver function usually returns to normal with discontinuation of therapy.

Hepatic dysfunction from dactinomycin may occur in up to 10% of patients with Wilms' tumor treated with this drug, but it is very uncommon when used for treatment of other malignancies. Hepatomegaly, enzyme abnormalities, and jaundice may occur.<sup>154</sup> Fever is also common, and thrombocytopenia may occur. Most cases appear to be associated with Wilms' tumors occurring in the right kidney, so the tumor mass effect present in the liver region may play a precipitating role in this toxic manifestation.<sup>155</sup>

## VENOOCCLUSIVE DISEASE

VOD results from blockage of venous outflow in the small centrilobular and sublobular hepatic vessels. Antitumor drugs known to produce this form of hepatotoxicity are cytarabine, cyclophosphamide, dacarbazine, 6-mercaptopurine, mitomycin, and 6-thioguanine. In addition, high doses of busulfan, carmustine, cyclophosphamide, and mitomycin given in the stem cell transplantation setting can cause VOD.

The clinical features of VOD are painful hepatomegaly, ascites, peripheral edema, marked elevations in serum enzymes and bilirubin, and hepatic encephalopathy. The onset is often abrupt, occurring during the first posttransplant week, and the clinical course is fulminant. It is caused by damage to endothelial cells, sinusoids, and hepatocytes in the area of the liver surrounding the central vein.<sup>156</sup> Thrombosis is precipitated, causing ischemia and hepatocellular necrosis. A component of hepatocellular injury may also be directly related to the high doses of drugs and not mediated by thrombosis. VOD occurring in the transplantation setting may be irreversible and lead to death with multiorgan failure in 25% to 50% of the patients developing it.<sup>156</sup> All of the drugs reported to induce VOD at high doses have been alkylating agents. This situation may not be because of any unusual tendency of alkylating agents to cause VOD, but rather to the fact that these are the drugs used in very large doses in the stem cell transplantation setting.

Conventional doses of certain antitumor agents (e.g., dacarbazine, 6-mercaptopurine, 6-thioguanine) can also cause hepatic VOD. Dacarbazine has been most frequently implicated in this form of hepatotoxicity, but only sporadic cases have been reported, both from dacarbazine alone and in combination with other drugs.<sup>157</sup> Why only some patients develop this life-threatening complication of dacarbazine is unknown. It may be some sort of idiosyncratic or hypersensitivity reaction.

## CHRONIC FIBROSIS

Methotrexate used for cancer treatment can produce acute and reversible hepatocellular injury and elevation of serum enzymes. The intermittent dosing schedules seem to obviate any chronic hepatotoxicity from this drug. However, long-term use of methotrexate for the treatment of nonmalignant disease (e.g., rheumatoid arthritis) poses a hazard for the development of irreversible hepatic fibrosis.<sup>158</sup> Because patients with autoimmune diseases may already have underlying liver abnormalities, methotrexate may not be the sole etiologic factor in the development of this chronic toxicity.

## HYPERSENSITIVITY REACTIONS

Most of the available antitumor agents can produce hypersensitivity reactions, and a substantial minority cause such reactions in 5% or more of patients treated. Several drugs (e.g., L-asparaginase and the taxanes) cause hypersensitivity reactions that are frequent enough to be a major treatment-limiting toxicity. Most of the other antitumor drugs produce such reactions only sporadically. The mechanism of these reactions is often unknown or evaluated only in a single patient. Premedication regimens designed to prevent or minimize reactions from the taxanes and a new formulation of L-asparaginase (pegaspargase) created to minimize reactions from this drug have been successful in reducing the frequency and severity of this toxicity.

L-Asparaginase produces hypersensitivity reactions in 10% to 20% of patients treated, which can be immediate and life-threatening, with all the components of anaphylaxis. This high rate is related to the fact L-asparaginase is a polypeptide of bacterial origin, displaying multiple antigenic sites that can stimulate production of immunoglobulin E (IgE) or other immunoglobulins. These immunoglobulins can then mediate an acute anaphylactic reaction.

The clinical manifestations are typical of type I reactions, with acute onset of wheezing, pruritus, rash, angioedema, extremity pain, agitation, and hypotension.<sup>159,160</sup> The mechanism of L-asparaginase reactions appears to be mediated by an IgE antibody in at least some cases. Complement activation also occurs, perhaps induced by specific IgG or IgM antibodies. A number of factors increase the risk for hypersensitivity reactions, including a history of atopy or other drug allergy, prior L-asparaginase therapy (including even several years previously), high drug doses, and the intravenous route of administration. Intramuscular administration often reduces the severity of reactions,<sup>161</sup> but they can still occur and may do so several hours after the drug is given. Concurrent treatment with prednisone and vincristine (for the acute leukemia being treated) also appears to reduce the risk of reactions.<sup>159</sup>

No reliable method has been found that can indicate who will have a reaction to any dose of L-asparaginase. Intradermal skin testing may give either false-negative or false-positive results, and test doses of the drug are valueless.<sup>159</sup> Therefore, one must approach each dose of L-asparaginase as the one that could initiate a hypersensitivity reaction and be prepared to treat it. Antianaphylaxis medication must be at hand, and the patient should be observed for approximately 1 hour after the drug is administered.

When a hypersensitivity reaction occurs with the *Escherichia coli* source of L-asparaginase, one can substitute the *Erwinia chrysanthemia* form and continue therapy without a loss of efficacy of this important drug for the treatment of acute lymphoblastic leukemia.<sup>160</sup> This drug form is immunologically distinct and appears to have a lower degree of immunogenicity. Patients may still sustain a hypersensitivity reaction from the substitute, but most (more than 75%) do not and can complete the planned therapy.<sup>160</sup> Precautions for treating anaphylaxis are necessary no matter the origin of the L-asparaginase. A third form of L-asparaginase (pegaspargase<sup>162</sup>) provides another alternative for the patient who is reactive to either of the other asparaginases. This form is a conjugate of polyethylene glycol with the enzyme. It may be the least immunogenic of all three forms of this drug, but hypersensitivity reactions are still possible. Because this drug has a prolonged serum half-life compared to the other two, it is administered only once or twice per week.

Paclitaxel has high potential for initiating a hypersensitivity reaction, and because of this fact, it is necessary to administer prophylaxis therapy before each dose.<sup>163</sup> The Cremophor EL excipient used to maintain solubility of paclitaxel has long been suspected of being the initiator of these reactions. When docetaxel was first evaluated in clinical trials, it was assumed that premedication to prevent hypersensitivity reactions was unnecessary, because docetaxel is formulated with Tween 80 (instead of Cremophor EL), and thus reactions would be unlikely to occur. This assumption proved incorrect, because docetaxel can initiate reactions with the same manifestations and with approximately the same frequency (5%) as paclitaxel.<sup>164</sup> The signs and symptoms can occur even despite premedication, although the intensity may be diminished.<sup>164</sup> The etiology appears to be either the two taxanes themselves or that Cremophor EL and Tween 80 are equally capable of causing reactions, with the former explanation being more likely. The mechanism of these reactions has not been well studied. Although a few reported cases have occurred from later drug cycles,<sup>165</sup> the fact that they most often (more than 70% of the time) occur with the first drug dose<sup>163,164</sup> suggests a nonimmunologic mechanism.

The clinical manifestations are those of any type I hypersensitivity reaction and include bronchospasm and wheezing, agitation, chest and back pain, rash, angioedema, and hypotension. The onset is usually within minutes of starting a drug infusion, and even very small drug doses are capable of initiating a reaction. A form of apparent hypersensitivity that may be delayed in onset is pulmonary infiltrates typical of a hypersensitivity pneumonitis that may either resolve spontaneously or after corticosteroid therapy.<sup>166</sup>

To prevent or assuage these reactions, paclitaxel is usually infused over 1 to 3 hours. Infusion in any interval shorter than 1 hour may precipitate an unacceptable frequency of reactions.<sup>167</sup> Premedication with corticosteroids and antihistamines is standard procedure. Docetaxel is given over 1 hour, and premedications must also be used. Such measures reduce the frequency and perhaps the intensity of reactions but do not fully prevent them.

A number of other chemotherapeutic agents (Table 55.8-4) are known to produce hypersensitivity reactions in at least sporadic instances. Most of these reactions have the features of a type I hypersensitivity, whether mediated by IgE or nonimmunologically. Hemolytic anemia (a type II reaction) is an uncommon form of such toxicity. Some drugs, such as procarbazine and methotrexate, may produce acute episodes that are typical of a type III reaction and cause interstitial pneumonitis and vasculitis.

HIGH POTENTIAL FOR HYPERSENSITIVITY REACTIONS

## VASCULAR TOXICITY

Four main forms of vascular toxicity are produced by cancer chemotherapeutic agents: VOD, thrombotic microangiopathy with hemolytic uremic syndrome, venous or arterial thrombosis, and vascular ischemia (involving cerebral, myocardial, or extremity arterial vessels).<sup>168</sup> VOD of hepatic vessels (see the section [Venooclusive Disease](#)) and microangiopathy (see the section [Mitomycin](#)) were discussed earlier in this chapter.

Venous thrombosis in association with metastatic cancer has long been recognized (Trousseau's syndrome). Chemotherapeutic agents can also induce venous thrombosis in the form of extremity thromboses and pulmonary emboli, even in the absence of demonstrable metastatic cancer.<sup>169,170</sup> Although they are less common, thromboses of cerebral, coronary, and extremity arteries can also be initiated by chemotherapy, again in the absence of demonstrable cancer.<sup>171,172</sup> These events are not limited to one form of cancer. They have occurred in a variety of cancers as disparate as stage II breast cancer, testicular cancer, and lymphomas. One drug associated with such thrombotic episodes more than others is cisplatin,<sup>173</sup> and a combination of chemotherapy with tamoxifen seems to produce a higher rate of such thrombotic episodes than either one alone.<sup>170</sup>

Arterial ischemia without thrombosis can be induced by chemotherapy in major coronary or cerebral vessels and in the small vessels of the extremities. Myocardial ischemia and infarction occur in patients who receive continuous infusions of 5-FU, and precipitous heart failure and sudden death have occurred.<sup>174</sup> Such events may occur in patients who have no known underlying coronary vessel disease, and they develop a few days after the start of the first infusion of 5-FU. The pathogenesis seems to be induction of coronary spasm by 5-FU, but the physiologic mechanism is not known. Anginal symptoms are often a precursor, which can be relieved by discontinuing the 5-FU therapy. Raynaud's phenomenon occurs as a chronic toxicity in approximately 40% of young men treated with cisplatin-bleomycin regimens for testicular cancer.<sup>175</sup> Cigarette smoking increases the risk for this toxicity. Clinical manifestations are painful digits and paresthesias, which may last indefinitely for years after the chemotherapy is completed. The mechanism appears to be vasospasm, without thrombosis, in the terminal arterioles of the fingers due to impaired smooth muscle function.<sup>176</sup> Bleomycin is the most likely etiology of this toxicity, because it can cause Raynaud's phenomenon when administered alone.<sup>177</sup> In similar fashion to causing vasoconstriction in coronary arteries, a continuous infusion of 5-FU may also engender digital arterial spasm and Raynaud's phenomenon.<sup>178</sup>

## INTRODUCTION

Advances in the diagnosis and treatment of cancer, coupled with advances in our understanding of the anatomy, physiology, pharmacology, and psychology of pain perception, have led to improved care of the patient with pain of malignant origin.<sup>1</sup> Specialized methods of cancer diagnosis and treatment provide the most direct approach to treating cancer pain by treating the cause of the pain. However, before the introduction of successful antitumor therapy, when treatment of the cause of the pain has failed, or when injury to bone, soft tissue, or nerve has occurred as a result of therapy, appropriate pain management is essential. Patients with cancer are managed most effectively by a multidisciplinary approach, using the expertise of a wide range of health care professionals. The goal of pain therapy for patients receiving active treatment is to provide them with sufficient relief to tolerate the diagnostic and therapeutic approaches required to treat their cancer. For patients with advanced disease, pain control should be sufficient to allow them to function at a level they choose and to die relatively free of pain.<sup>2</sup> The management of the symptom of pain is only one component of a broad palliative care approach for cancer patients.<sup>3</sup> Control of other symptoms, treatment of psychological distress, and attention to the religious, spiritual, and existential dimensions of the patient's illness experience should be concurrently addressed to maintain the patient's quality of life throughout the cancer illness course from diagnosis to death.<sup>4</sup>

## EPIDEMIOLOGY

Existing studies based on numerous national and international surveys and World Health Organization (WHO) estimates suggest that moderate to severe pain is

experienced by one-third of cancer patients receiving active therapy and by 60% to 90% of patients with advanced disease.<sup>5,6,7,8</sup> and <sup>9</sup> There are 17 million new cases of cancer diagnosed worldwide each year and 5 million cancer deaths, accounting for large numbers of patients who suffer from cancer pain.<sup>9</sup> Pain associated with direct tumor involvement is the most common cause of cancer pain, occurring in as many as 85% of patients reported from a pain service study, to 65% from an outpatient cancer center pain clinic survey.<sup>5</sup> Bone pain is the most common type, with tumor infiltration of nerve and hollow viscus as the second and third most common pain locations. Cancer therapy causes pain in approximately 15% to 25% of patients receiving chemotherapy, surgery, or radiation therapy. Three percent to 10% of patients with cancer have pain caused by non-cancer-related problems, with pain syndromes reflecting the common causes of pain in the general population.

Patients with cancer often have multiple causes of pain and multiple sites of pain.<sup>6</sup> Based on a variety of survey data, up to one-third of patients had more than one pain and 81% of patients reported two or more distinct pain complaints; 34% reported three pains. Cross-cultural studies from India, Thailand, Vietnam, Germany, France, Taiwan, the Philippines, and China report a similar prevalence of cancer pain in patients in active therapy and advanced disease.<sup>10,11</sup> and <sup>12</sup>

Studies have focused not only on the prevalence of pain but on its intensity, degree of pain relief, and the effect of pain on quality of life in patients with various cancers including lung, colon, ovarian, and pancreatic cancers.<sup>13,14</sup> and <sup>15</sup> In one study of lung and colon cancer ambulatory patients, the median pain duration was 4 weeks and the average pain intensity was moderate. Ninety percent experienced pain more than 25% of the time, and 50% reported that pain interfered moderately or more with their general activity or work.<sup>13</sup> In the Netherlands, 60% of all outpatients seen at an oncology clinic were in pain and 20% of this group reported moderate to severe pain.<sup>16</sup> In a 1999 survey of cancer outpatients, Weber and Huber reported inadequate documentation of pain severity, opioid dose, and rescue doses, observing that lack of documentation is a significant barrier to providing effective pain control.<sup>17</sup> Cleeland et al., in a study of patients who were followed by the Eastern Cooperative Oncology Group, reported that 56% of patients reported moderate to severe pain 50% of the time.<sup>18</sup> Numerous studies point out the fact that pain is prevalent in ambulatory patients, as well as hospitalized patients, and compromises function in approximately one-half of the patients who experience it.

A series of studies have focused on the seriously ill and nursing home cancer population and have identified a high prevalence of pain in these populations. The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments showed that 50% of adults who die in the hospital experience moderate to severe pain in the last 3 days of life.<sup>19</sup> A study of 4000 elderly nursing home residents with cancer revealed that 24%, 29%, and 38% of those over age 85, 74 to 84, and 65 to 74, respectively, reported daily pain.<sup>20</sup> Twenty-six percent in daily pain did not receive any medication. Those over 85 who reported pain were most likely to receive no analgesic.<sup>20</sup>

Such studies have led to an assessment of the factors that influence the prevalence of cancer pain. Primary tumor type is one factor. Tumors that commonly metastasize to bone such as breast or prostate have a higher incidence of pain (60% to 80%) as compared with patients with lymphoma and leukemia. Stage of disease is a contributing factor, with increasing pain prevalence with disease progression. For example, less than 15% of patients with nonmetastatic disease report pain. Tumors that occur in close proximity to neural structures also have a greater incidence of pain. Patient variables such as anxiety, depression, and history of previous substance abuse influence the patient's report and experience of pain.<sup>21</sup>

Several studies have detailed the characteristics of patient populations followed by pain services and palliative and hospice care programs, providing further data on the magnitude of the cancer pain problem.<sup>18,22,23,24,25,26</sup> and <sup>27</sup> A 10-year experience of a German anesthesiology-based pain service associated with a palliative care program reported on the course of treatment of 2118 patients over a period of 140,478 treatment days.<sup>27</sup> Table 56.1-1 lists the primary tumors and pain localization etiology and type of pain syndrome. In their survey, gastrointestinal and head and neck cancers were the most common types, with the majority (85%) caused by tumor involvement. Pain intensity data were collected through the course of treatment. Eighty-two percent of patients had moderate to very severe pain at the beginning of treatment, with only 7% reporting such high intensity at the completion of treatment.

**TABLE 56.1-1.** Sites of Cancer Pain and Localization, Etiology, and Type of Pain Syndromes

Several studies have also addressed the epidemiology and ethnography of pain treatment. In a study to assess the effect of a comprehensive medical and neurologic evaluation of pain in the cancer patient, 64% of patients had a lesion newly identified by the pain consultant.<sup>28</sup> Of note, more than 50% were neurologic in origin and, in 19% of patients further anticancer therapy combined with analgesic approaches were recommended. Further studies have observed that neurologic lesions make up a substantial portion of painful lesions in the cancer population. In a prospective study of neurologic symptoms, neurologic diagnoses, and primary tumors in all patients with a history with systemic cancer referred to Memorial Sloan-Kettering Cancer Center Neurology Consultation Service, the three most common symptoms in 851 patients were back pain (18.2%), altered mental status (17.1%), and headache (15.4%).<sup>28</sup> The most common neurologic diagnosis was brain metastases (15.9%), followed by metabolic encephalopathy (10.2%), pain associated with bone metastases only (9.9%), and epidural extension or metastases of tumor (8.4%).<sup>29</sup>

In studies of patients with far-advanced disease cared for in palliative care programs, pain is the most common physical symptom. Of note, pain treatment significantly reduced this symptom but several other prominent symptoms including anxiety, fatigue, weakness, anorexia, nausea and vomiting, and dyspnea were less effectively managed.<sup>30</sup> This observation supports the critical need to evaluate, prioritize, and treat all symptoms to improve cancer pain patients' quality of life.

## DEFINITION AND TYPES OF CANCER PAIN

### DEFINITION OF PAIN

The definition of pain proposed by the International Association for the Study of Pain is “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.”<sup>31</sup> Because pain is a subjective complaint, there is no definitive way to distinguish pain occurring in the absence of tissue damage from pain resulting from such damage. Pain as a somatic delusion or masked depression is rare in cancer patients and the presence of pain usually implies a pathologic process.

### ANATOMY AND PHYSIOLOGY OF PAIN

Extensive investigations over the last 30 years have expanded our knowledge of ascending and descending central nervous system pathways that process and modulate nociceptive information. These advances provide a scientific rationale for the use of new and improved methods of cancer pain treatment.<sup>1,32,33</sup> and <sup>34</sup> A brief review of the neuroanatomy, physiology, and pharmacology of pain provides a background for the later discussions of specific drug, anesthetic, and neurosurgical approaches. Detailed information now supports the theory that activation of peripheral receptors in both superficial and deep structures as well as viscera by mechanical and chemical stimuli excites afferent discharges. Nonnociceptive messages are transmitted through rapidly conducting A-beta fibers and nociceptive information is signaled through slowly conducting A-delta and C-fiber afferents. The receptor endings of A-delta fibers most often respond to one sensory stimulus, whereas most C-fiber receptors are multimodal and respond to multiple high-threshold stimuli. These primary sensory afferents have their cell bodies in the dorsal root ganglion, and their axons enter the spinal cord via the dorsal root. The synaptic connections of these primary afferents with the corresponding second-order nociceptive neurons in the spinal dorsal horn are the initial site of processing for sensory information and act as a relay in transmitting noxious signals to the central

nervous system.<sup>34,35</sup>

They ascend or descend from one or two segments in Lissauer's tract and synapse in specific lamina in the dorsal horn, lamina I and lamina II. Evidence suggests that myelinated nociceptors project to lamina I and V and unmyelinated nociceptors to lamina II and possibly lamina I, and nonnociceptive myelinated afferents project to only deep lamina. The dorsal horn is a critical site for modulating sensory input. Sensory transmission is mediated through excitatory amino acids (EAAs), predominantly glutamate.<sup>36</sup> The EAA aspartate and the neuropeptides substance P and calcitonin gene-related peptide are also involved. Excitatory synaptic transmission from the primary afferent is also modulated by the N-methyl-D-aspartate (NMDA) receptor as well as non-NMDA receptors.<sup>34</sup> Following EAA-NMDA receptor interaction, intracellular calcium influx and mobilization of intracellular calcium lead to subsequent changes in second messenger systems. One second messenger system activated following EAA-NMDA receptor interaction is the generation of nitric oxide via the enzyme nitric oxide synthase. There is also an increase in transcription of immediate early gene c-fos, which may regulate the subsequent expression of endogenous opioid genes, preproenkephalin and preprodynorphin. NMDA receptor activation initiates and maintains central sensitization and the component known as *windup*. These phenomena are manifestations of persistent signaling from primary sensory afferents. Central sensitization is thought to be the major mechanism underlying neuropathic pain and accounts for the hyperpathia and enlarged cutaneous receptor fields that occur following nerve injury.

At the level of the second-order neurons in the dorsal horn, sensory processing occurs through interactions among neurochemical transmitters released by primary afferents including gamma-aminobutyric acid, glycine, adenosine, bombesin, cholecystokinin, dynorphin, enkephalin, neuropeptide Y, neurotensin, substance P, somatostatin, and vasoactive intestinal polypeptide.

Several ascending pathways arise from these second-order neurons and decussate in the central gray of the spinal cord to become the neospinothalamic and paleospinothalamic tracts. These tracts project to discrete regions of the thalamus and cortex. The neospinothalamic pathway subserves pain intensity and localization, whereas the phylogenetically older paleospinothalamic pathway subserves the arousal and emotional component of pain. Descending pathways, the most important of which originate from the periaqueductal gray nuclei of the midbrain, synapse in the raphae magnus nucleus of the medulla. From this nucleus a medial pathway, the dorsal longitudinal fasciculus, projects to the dorsal horn to modulate pain transmission. This pathway represents an important descending inhibitory pathway. A more laterally placed descending pathway from the locus ceruleus to the dorsal horn also plays a role on pain modulation at the spinal cord level.

Opiate receptors, stereospecific binding sites on the end of free nerve endings that bind exogenous opioids, are localized in the ascending and descending pain pathways. These receptors mediate the multiple pharmacologic effects of the opioid analgesics. Subpopulations of opioid receptors including high-affinity and low-affinity  $\mu$  receptors and  $\kappa$ ,  $\delta$  and  $\sigma$  receptors are localized to specific areas of the brain and spinal cord. More recently, several opioid receptor subtypes have been cloned and quantitative changes in the messenger RNA for these receptors determined in experimental models. The cloning of these subtypes of receptors that mediate different pharmacologic effects and then are located in specific cerebral and spinal sites offers the possibility of developing new analgesics targeted for specific receptors.<sup>37</sup> For example,  $\mu$  receptors modulate predominantly supraspinal analgesia, whereas  $\delta$  and  $\kappa$  receptors are important in modulating analgesia at the spinal cord level. The periaqueductal gray region in the midbrain and dorsal horn in the spinal cord are rich in these receptors and are the supraspinal and spinal sites that mediate opioid analgesia. The use of brainstem stimulation and the administration of opioid analgesics directly into the cerebrospinal fluid bathing the selective opioid sites in animals and cancer patients with pain are procedures based on this knowledge.<sup>38</sup> Pain transmission at the spinal cord level can be inhibited by the direct application of morphine, and these studies have led to the use of spinal opioid analgesia in clinical pain states.<sup>39,40</sup> There is now increasing information about the molecular basis of opioid tolerance development. A variety of NMDA receptor antagonists have been demonstrated both to attenuate and to reverse experimental opioid analgesic tolerance.<sup>41</sup> Therefore, the confluence of NMDA receptors in pain transmission and their role in the development of tolerance have provided new insights into the role of opioid receptors in analgesia.

These advances in our understanding of pain modulatory systems and their neuroanatomic and neuropharmacologic correlates have had a major effect on the management of patients with pain. A better understanding of the molecular biology of both nociceptive and neuropathic pain is facilitating the wide application of a variety of agents including the NMDA antagonists, calcium channel agonists and antagonists, and topical and local systemic anesthetics and opioids.<sup>34,35</sup>

## TYPES OF PAIN

Three types of pain have been described based on the neuroanatomy and the neurophysiology of pain pathways: somatic, visceral, and neuropathic pain. Each type results from activation and sensitization of nociceptors and mechanoreceptors in the periphery by either mechanical (tumor compression or infiltration) or chemical (epinephrine, serotonin, bradykinin, prostaglandin, histamine, and so forth) stimuli.

### SOMATIC PAIN

When nociceptors are activated in cutaneous or deep tissues, somatic pain results, typically characterized by a dull or aching but well-localized pain. Metastatic bone pain, postsurgical incisional pain, and myofascial and musculoskeletal pain are common examples of somatic pain.

### VISCERAL PAIN

Visceral pain results from activation of nociceptors from infiltration, compression, extension, or stretching of the thoracic, abdominal, or pelvic viscera. This typically occurs in patients with intraperitoneal metastases and is common with pancreatic cancer. This type of pain is poorly localized; is often described as deep, squeezing, and pressure-like; and when acute is often associated with significant autonomic dysfunction, including nausea, vomiting, and diaphoresis. Visceral pain is often referred to cutaneous sites that may be remote from the site of the lesion (e.g., shoulder pain with diaphragmatic irritation). It may be associated with tenderness in the referred cutaneous site. Increasing data have demonstrated the role of  $\kappa$  opioid receptors in modulating visceral pain.<sup>42</sup>

### NEUROPATHIC PAIN

Neuropathic pain results from injury to the peripheral or central nervous system as a consequence of tumor compression or infiltration of peripheral nerves or the spinal cord, or from chemical injury to the peripheral nerve or spinal cord caused by surgery, radiation therapy, or chemotherapy. Examples of neuropathic pain include both metastatic and radiation-induced brachial and lumbosacral plexopathies, chemotherapy-induced peripheral neuropathies, paraneoplastic peripheral neuropathies, and postmastectomy, postthoracotomy, and phantom limb pain.<sup>34,43</sup> Pain from nerve injury is often severe and is described as burning or dysesthetic, with a vice-like quality. The pain is typically most common in the site of sensory loss and may be associated with hypersensitivity to nonnoxious (allodynia) and noxious stimuli. Intermittently, patients complain of paroxysms or burning or electric shock-like sensations. The latter symptoms result from the phenomenon of central sensitization.

These three types of pain may occur alone or combined in the same patient. These different types of pain account for different responses to drug and nondrug approaches. For instance, the nonsteroidal antiinflammatory drugs (NSAIDs) reduce chemical activation of nociceptors peripherally (e.g., bone pain), whereas anesthetic approaches suppress the pain transmission in peripheral nerves. Management of both somatic and visceral pain suggests that these types of pain respond to a wide variety of approaches. The management of neuropathic pain is more complicated: Changes in the peripheral nervous system and the central nervous system make this type of pain less responsive to a wide variety of pharmacologic, anesthetic, and neurosurgical approaches.

Evidence suggests that most cancer patients have both somatic and visceral pain, with neuropathic pain representing 15% to 20% of the significant pain problems in this population.<sup>1,32</sup> Certain adjuvant drugs appear to be more appropriate in the management of neuropathic pain; these issues are discussed in a later (see [Adjuvant Analgesics for Neuropathic Pain](#)).

## TEMPORAL ASPECTS OF PAIN

### ACUTE PAIN

Acute pain is characterized by a well-defined temporal pattern of pain onset, generally associated with subjective and objective physical signs and with hyperactivity of the autonomic nervous system. These signs provide the physician with objective evidence that substantiates the patient's complaint of pain. Acute pain is usually

self-limited and responds to treatment with analgesic drug therapy and to treatment of its precipitating cause. It can be further subdivided into subacute and episodic. Subacute pain comes on over several days, often with increasing intensity, and represents a pattern of progressive pain symptomatology. Episodic or intermittent pain occurs during confined periods of time on a regular or irregular basis. All of the pains in this category of acute pain have associated autonomic hyperactivity.

## CHRONIC PAIN

Chronic pain is the persistence of pain for more than 3 months, with a less well-defined temporal onset. The autonomic nervous system adapts, and chronic pain patients lack the objective signs common to those with acute pain. Chronic pain leads to significant changes in personality, lifestyle, and functional ability. Treatment of chronic pain in the cancer patient is especially challenging because it requires a careful assessment of not only the intensity of the pain but its broad multidimensional aspects.<sup>21</sup> Evidence suggests that the persistence of pain plays a major negative role in the quality of life of patients with pain and cancer.

Investigators have developed a nomenclature to describe a series of specific pains in cancer patients with both acute and chronic pain states. *Baseline pain* is the average pain intensity experienced for 12 or more hours during a 24-hour period. *Breakthrough pain* is a transient increase in pain to greater than moderate intensity occurring on a baseline pain of moderate intensity or less. In a study of 70 adult inpatient cancer patients, 65% reported breakthrough pain.<sup>44</sup> The median number of reported pains was four, with a wide range. Most pains had a rapid onset and a brief duration. Breakthrough pain has a diversity of characteristics. Some authors have detailed the prevalence of such transitory flares of pain.<sup>45</sup> In a study of 613 consecutive cancer patients, 39% reported transitory flares that were severe or worse in 92% of patients. There were no correlations with gender, age, tumor site, stage, and therapy. The pain was somatic in 39%, visceral in 22%, and neuropathic in 36%. In this and other series, the transitory increase in pain marks the onset or worsening of pain at the end of the dosing interval or the regularly scheduled analgesic. In other patients, it is caused by an action of the patient, referred to as *incident pain*; sometimes the incident pain has a nonvolitional precipitant, such as flatulence. Most breakthrough or transitory pains are thought to be associated with a known malignant cause from direct tumor infiltration. Clinical trials with an oral transmucosal fentanyl preparation have focused attention on the clinical management of such episodes of worsening pain.<sup>46</sup>

## INTENSITY OF PAIN

Pain may also be defined on the basis of intensity, but there are limitations to a concept of pain based solely on intensity. Specific categoric scales of pain intensity have been used in which patients are asked to describe their pain as mild, moderate, severe, or excruciating.<sup>47</sup> Visual analog scales (VAS) have also been used. These are often a 10-cm line anchored on either end by two points, signifying *no pain* and *worst possible pain*. The patient is asked to mark the intensity of the pain on the line. Numeric scales are also commonly used, asking patients to rate their pain between 1 (no pain) and 10 (worst possible pain). These scales have their limitations, but they are part of a series of validated instruments that include a measure of pain intensity as one of the components of the pain experience to be defined.<sup>47</sup> In a study of physicians' and nurses' understanding of the language to describe pain, there was a close correlation among them of the level of intensity meant by the terms *ache*, *hurt*, or *pain*.<sup>48</sup> Although health care professionals may understand the common language of pain, there is an enormous discrepancy between their assessment and the patient's report of pain, particularly when the patient reports pain as moderate or severe. They compared the ratings of pain severity by patients with those by physicians and found that patients tended to rate their pain as more intense than did physicians. In a study by Grossman and associates, the cancer patients' report of pain and the physicians' concurrent observation had a close correlation when patients reported mild pain.<sup>49</sup> However, when patients reported moderate to severe pain, the correlation of the nurse, house officer, and oncology fellow differed significantly from that of the patient: The concordance dropped from 78% for patients with mild pain to 20% for those with moderate to severe pain.

## MEASUREMENT OF PAIN

These problems in communication about pain intensity strongly support the argument that multiple dimensions of the pain experience should be used to assess it adequately. Several validated instruments for pain measurement attempt to look at it in a multidimensional nature. The use of such methods can provide rapid evaluation in clinical settings of the major aspects of the pain experienced by cancer patients. Growing evidence suggests that they should be integrated into clinical trials and should be available for use on a routine basis to better define the pain symptomatology and to study the effect on pain by various treatment approaches.

### BRIEF PAIN INVENTORY (BPI)

The Wisconsin Brief Pain Questionnaire (BPI) is a self-administered, easily understood, brief method to assess pain.<sup>50</sup> It addresses the relevant aspects of pain (history, intensity, location, and quality) and the pain's ability to interfere with the patient's activities and helps to provide an understanding of its cause. The history of pain and its relation to the patient's disease are assessed initially. If the patient admits to pain in the last month, he or she answers questions about current manifestations of pain. If the patient has no pain, he or she skips to the end of the questionnaire to complete demographic information. For patients with pain, a human figure drawing is provided for the patient to shade the area corresponding to the pain. Patients are asked to rate their pain at its worst, usual pain, and pain now. The pain scales consist of numbers from 0 to 10; 0 is labeled *no pain* and 10 is labeled *pain as bad as you can imagine*. Patients are asked to report the medications or treatments they receive for pain, the percent relief that these medications or treatment provide, and their belief about the cause of their pain. Finally, they are asked to rate how much the pain interferes with their mood, relations with other people, and functional ability (walking, sleeping, working, enjoying life). All patients, including those without pain, are asked for basic demographic information about marital status, education, occupation, spouse's occupation, and months since diagnosis.

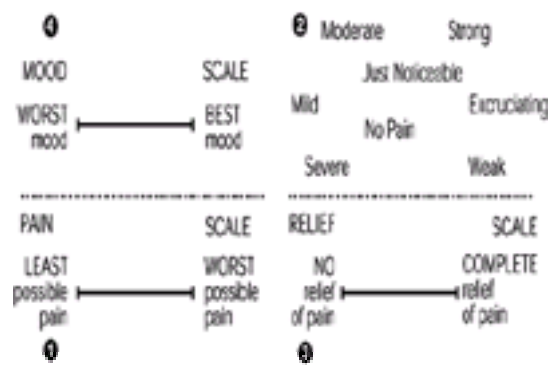

This inventory has been translated into numerous languages and has been used to assess pain in cancer patients in such diverse settings as Vietnam, Mexico, the Philippines, China, and the University of Wisconsin Cancer Center. Data from these studies suggest that cancer pain patients from widely different cultural and linguistic backgrounds respond in a similar fashion to rating the severity of their cancer-related pain and the interference caused by the pain.

### MCGILL PAIN QUESTIONNAIRE

The McGill Pain Questionnaire (MPQ) is an extensively used pain assessment instrument that produces scores on four empirically derived dimensions, as well as several summary scores.<sup>51</sup> The instrument consists of 78 adjectives that cluster in 20 categories. Within each category, the adjectives are arranged in order of intensity from low to high. The categories are divided into four dimensions: sensory, affective, evaluative, and miscellaneous. The patient is asked to choose one adjective from each applicable category that describes an aspect of his or her current pain, and the score for each dimension is obtained by adding the rank values of the selected adjectives. A total summary score is derived by adding the scores across the four dimensions, and a total word count is also obtained. Finally, a rating of present pain intensity is made on a five-point scale. Studies with this instrument have demonstrated that the factors derived reflect specific sensory qualities and combined emotional and sensory dimensions. This tool has also been used to assess distinct score profiles according to the nature of pain. For instance, patients with acute pain tend to use more sensory words, but patients with chronic pain tend to use more affective and reaction word subgroups. The MPQ offers a methodologic approach to assess the sensory, affective, and evaluative components of pain, but it may be more difficult and cumbersome for patients to understand and complete and may be limited by its language constraints.

### MEMORIAL PAIN ASSESSMENT CARD

The Memorial Pain Assessment Card (MPAC) (Fig. 56.1-1) was initially developed by the Analgesic Studies Section of the Memorial Sloan-Kettering Cancer Center to assess the relative potency of new and standard analgesic drugs. In that context, this method was found repeatedly to be a valid, reliable, efficient, and sensitive measure.<sup>52</sup> The MPAC consists of three VAS that measure pain intensity, pain relief, and mood, and a set of pain severity descriptors adapted from the Tursky rating scale. The card is 8.5 by 11 inches and is folded in the middle so that the four sides can be quickly presented to the patient. Three sides are imprinted with the 100-mm long VAS scale; the fourth side is the set of Tursky adjectives. The pain intensity VAS is anchored by the terms *least possible pain* and *worst possible pain*. The patient is asked to place a mark along the line to indicate his or her subjective judgment of pain intensity. The score on this and the other VAS is obtained by measuring in millimeters the distance between the left end of the line and the patient's mark. The Tursky pain adjective scale is a categorical measure of pain intensity. Eight intensity descriptors, ranging from *no pain* to *excruciating*, are printed in a random arrangement and the patient is asked to circle the adjective that describes his or her subjective experience of pain severity. Side 3 of the MPAC is a pain-relief VAS. Patients are asked to indicate with a mark the degree of pain reduction they experience after the most recent intervention, which is usually the administration of an analgesic drug. On side 4 the VAS measures the subjective experience of mood; on this side patients are asked to rate their current feeling, from *worst* to *best*. The instructions for administration of these scales are simple and readily understood, and an experienced patient can complete the four ratings in less than 20 seconds.

**FIGURE 56.1-1.** Memorial Pain Assessment Card, front (1 and 4) and back (2 and 3) sides. The card is folded along the broken line, and each measure is presented to the patient separately, in the numbered order. (1) Visual analog scale (VAS) of pain intensity; (2) modified Tursky pain descriptors scale; (3) VAS pain relief; (4) VAS mood. (From ref. 52, with permission.)

The MPAC has been compared with the MPQ, the Profile of Mood States Questionnaire (a standardized self-report instrument that measures six dimensions of mood, reflecting degree and type of psychological distress), the Hamilton Rating Scale for Depression (an interviewer-rated scale evaluating the presence and severity of 17 symptoms typical of clinical depression), and the Zung Anxiety Scale (a standardized self-report scale that reports the presence and severity of various symptoms of anxiety). The MPAC and the MPQ both provide reasonably equivalent assessments of the intensity dimension of pain. However, the evaluative scales of the MPQ did not correlate significantly with any of the measures of the MPAC, suggesting that the cognitive judgmental dimension of pain may be independent of the experiences of intensity, relief, and mood. None of the MPQ subscales correlated significantly with the VAS ratings of mood and pain relief.

These observations have led to the conclusion that the VAS mood scale on the MPAC represents a much more global assessment of general psychological distress rather than a specific pain-related affect. This would suggest that the MPAC provides a broader assessment of the patient by its use of the mood scale, whereas the MPQ has a more narrow focus of simply representing pain-related emotional distress. What was particularly impressive was that in the use of any of the available scales, patients could differentiate pain and mood when they were explicitly asked. The perceptions of pain intensity and pain relief have different weights as components of psychological distress. The existence of such distinctions has important clinical and theoretical significance. Although the perception of pain intensity was found to contribute significantly to subjective distress, the perception of inadequate pain relief was a more important factor. The MPAC provides valid, multidimensional information for the evaluation of pain and distress in cancer patients. It can distinguish pain intensity from pain relief and from global suffering, and it can be used to study the subtle interactions of these factors. With repeated administration it has now been demonstrated to be valid, reliable, easy to use, and nondisruptive. The MPAC and the BPI are the tools recommended for use in the clinical evaluation of individual patients and as an outcome measure in clinical trials.<sup>53</sup>

### MEMORIAL SYMPTOM ASSESSMENT SCALE

The Memorial Symptom Assessment Scale (MSAS) is a validated, patient-rated measure that provides multidimensional information about a diverse group of common symptoms.<sup>53</sup> Thirty-two physical and psychological symptoms are characterized in terms of intensity, frequency, and distress. The MSAS provides a Global Distress Index (MSAS-GDI), a ten-item subscale that reflects global symptom distress and separate subscales that measure physical (MSAS-Phys) and psychological (MSAS-Psych) symptom distress, respectively. Ongoing studies have confirmed its value in patients with various types of cancer, and studies of its reliability and validity with repeated administration are currently under way. The use of the MSAS allows the concurrent measurement of pain with various other symptoms, psychological distress, and psychological factors and represents overall a useful, patient-accepted method to measure the multidimensional issues facing cancer patients with pain.<sup>53</sup> Newer studies have identified the usefulness of a short form for rapid assessment.<sup>54</sup>

### QUALITY IMPROVEMENT GUIDELINES FOR THE TREATMENT OF CANCER PAIN

The American Pain Society Quality of Care Committee has strongly advocated pain measurement as an integral part of any continuous quality-improvement program.<sup>55</sup> They have argued that such quality-improvement programs should include five key elements: (1) ensuring that a report of unrelieved pain raises a red flag that attracts clinicians' attention; (2) making information about analgesics convenient where orders are written; (3) promising patients responsive analgesic care and urging them to communicate pain; (4) implementing policies and safeguards for the use of modern analgesic technologies; and (5) coordinating and implementing these measures. They have argued formally for there to be methods in place to chart and display patients' self-reported pain in a way that makes it highly visible and facilitates regular review by members of the health care team. Such information should be incorporated in the patient's permanent record. [Figure 56.1-2](#) is an example of recording pain data as a fifth vital sign to be available on a page at the front of the patient's record. Unrelieved pain then should be a red flag that promptly turns attention to the problem. National programs have supported the development of broad institutional programs to improve pain management. The Veterans Administration has instituted a quality-improvement program in a wide effort to include pain as the fifth vital sign. The Joint Commission on Accreditation of Hospitals has similarly adopted clear guidelines for hospitals to improve pain management. Both of these programs, although not specifically focused on the cancer patient, are evidence of a broad commitment to reduce the barriers to effective pain management at institutional levels by instituting routine quality indicators of pain management. DuPen and colleagues have focused attention on the need to improve outpatient pain management, and through the use of a specific algorithm and nurse and chart reminders have demonstrated improved pain management for outpatient cancer patients using a specific algorithm.<sup>56</sup>

### CLASSIFICATION OF PATIENTS WITH CANCER PAIN

Five types of cancer pain patients can be identified, exemplifying the distinctions between acute and chronic pain ( [Table 56.1-2](#)). Although these categories are fluid, they serve as a useful preamble for discussion of the specific therapeutic approaches to the management of cancer patients.

- 
- I. Patients with acute cancer-related pain
    - a. Associated with the diagnosis of cancer
    - b. Associated with cancer therapy (surgery, chemotherapy, or radiation)
  - II. Patients with chronic cancer-related pain
    - a. Associated with cancer progression
    - b. Associated with cancer therapy (surgery, chemotherapy, or radiation)
  - III. Patients with preexisting chronic pain and cancer-related pain
  - IV. Patients with a history of drug addiction and cancer-related pain
    - a. Actively involved in illicit drug use
    - b. In methadone maintenance program
    - c. With a history of drug abuse
  - V. Dying patients with cancer-related pain
- 

**TABLE 56.1-2.** Types of Patients with Pain from Cancer

### GROUP I: ACUTE CANCER-RELATED PAIN

Group I, patients with acute cancer-related pain, can be subdivided further according to etiology.

#### GROUP IA: TUMOR-ASSOCIATED PAIN

For group IA patients, with tumor-associated pain, pain is the major symptom prompting medical consultation and the diagnosis of cancer. In addition, pain has a special significance as the harbinger of the patient's illness. Recurrent pain during the course of the illness or after successful therapy has the immediate implication of recurrent disease. Defining the cause of the pain may present a diagnostic problem, but effective treatment of its cause (e.g., radiation therapy for bone metastases) is usually associated with dramatic pain relief in most patients.

#### GROUP IB: PAIN ASSOCIATED WITH CANCER THERAPY

Group IB patients have postoperative pain, pain secondary to oral ulceration from chemotherapy, or myalgias secondary to corticosteroid withdrawal. The cause of the pain is readily identifiable, and its course is predictable and self-limiting ( [Table 56.1-3](#)). These patients do not represent difficult diagnostic problems. Pain treatment directed at the cause of the pain is used to manage the transient symptoms. These patients endure significant pain for the promise of a successful outcome.

**TABLE 56.1-3.** Cancer-Related Acute Pain Syndromes

### GROUP II: CHRONIC CANCER-RELATED PAIN

Group II patients, those with chronic cancer-related pain, represent difficult diagnostic and therapeutic problems, in contrast to patients with acute cancer-related pain. They can be divided for discussion purposes into two groups: those with chronic pain from tumor progression, and those with chronic pain related to cancer treatment. Both groups share the characteristic of a pain symptom that has persisted for more than 3 months.

#### GROUP IIA: CHRONIC PAIN FROM TUMOR PROGRESSION

In patients with chronic pain associated with progression of disease (e.g., patients with carcinoma of the pancreas, metastatic melanoma to bone, or Pancoast's syndrome), the pain escalates in intensity secondary to tumor infiltration of adjacent bone, nerve, or soft tissue. Combinations of antitumor therapy, analgesic drug therapy, anesthetic blocks, and behavioral approaches are all applied with varying degrees of success. Psychological factors play a significant role in this group of patients, in whom palliative cancer therapy may be of little value and is physically debilitating. The sense of hopelessness and fear of impending death may further add to and exaggerate the pain complaint; pain then becomes an aspect of the global *suffering* component.<sup>57</sup> Identifying both the pain and the suffering component is essential to the development of adequate therapy for these patients. Management approaches must be directed to controlling the pain and identifying and developing treatment strategies for each of the components of the patient's symptoms and psychological distress. Analgesic therapy combined with a wide range of alternative approaches is necessary to provide adequate analgesia. Such patients are appropriate candidates for palliative care programs to address the broader aspects of symptom management and psychological support.<sup>2,4,58</sup>

#### GROUP IIB: CHRONIC PAIN ASSOCIATED WITH CANCER THERAPY

Group IIB includes patients with chronic pain associated with cancer therapy, such as patients who develop pain after mastectomy, thoracotomy, or limb amputation (phantom limb). The nature of pain in these patients is secondary to nerve injury (neuropathic pain) with the development of a traumatic neuroma. Treatment of the pain for these patients is limited by the lack of available methods to remove the cause of the pain. Again, treatment is directed at the symptoms, not the cause. These patients closely parallel those in the general population with chronic intractable pain syndromes. Psychological factors play a significant role in how these patients adapt to and function with chronic pain. Defining this group is imperative: Identifying the cause of the pain as not directly related to tumor markedly alters the patient's therapy, prognosis, and psychological state. Each of the primary modalities of cancer therapy is associated with a series of specific chronic pain syndromes with characteristic pain patterns and clinical presentations ( [Table 56.1-4](#), [Table 56.1-5](#), and [Table 56.1-6](#)). Although it is consoling to both the patient and the physician to realize that the pain does not represent recurrent or progressive disease, the persistence of the pain is a constant reminder of the previous diagnosis of cancer.

---

**POSTCHEMOTHERAPY PAIN SYNDROMES**

- Chronic painful gastrointestinal neuropathy
- Recurrent necrosis of distal or proximal limb
- Pharyngitis associated with intravenous infusion

**CHRONIC PAIN ASSOCIATED WITH HORMONAL THERAPY**

- Gynecomastia with hormonal therapy for prostate cancer

**CHRONIC POSTSURGICAL PAIN SYNDROMES**

- Postmastectomy pain syndrome
- Postradical neck dissection pain
- Postthoracotomy pain
- Postoperative frozen shoulder
- Phantom pain syndromes
  - Phantom limb pain
  - Phantom breast pain
  - Phantom nerve pain
  - Phantom bladder pain
- Scalp pain
- Postmyeloid patch: thorax myalgia

**CHRONIC POSTRADIATION PAIN SYNDROMES**

- Pharyngitis
- Radiation-induced brachial and lumbosacral plexopathies
- Radiation-induced gastrointestinal nerve masses
- Chronic radiation myelopathy
- Chronic radiation necrosis and proctitis
- Burning geostasis syndrome
- Chronic radionecrosis

**TABLE 56.1-6. Causes of Brachial Plexopathy in Patients with Breast Cancer: Distinguishing Clinical Features**

In these patients, all approaches aimed at maintaining the patient's functional status should be used. Alternative methods of therapy, in contrast to drug therapy, represent the major management approach. This group of patients with neuropathic pain is increasing in number and accounts for 15% to 25% of patients referred to a medical pain clinic.

**GROUP III: PREEXISTING CHRONIC PAIN AND CANCER-RELATED PAIN**

Group III includes patients with a history of chronic nonmalignant pain who develop cancer and pain. Psychological factors play a significant role in this group of patients, whose psychological and functional status is already compromised by their chronic nonmalignant pain state. These patients are at high risk of developing further functional incapacity and escalating chronic pain symptoms. However, their history should not be used in a punitive way to minimize or deny their complaints. Identifying this group of patients as a high-risk group helps to improve their psychological assessment and intervention.

**GROUP IV: PATIENTS WITH A HISTORY OF DRUG ADDICTION AND PAIN**

Group IV includes patients with a history of drug addiction who have cancer-related pain. Three subgroups can be identified: patients actively involved in illicit drug use and drug-seeking behavior, those receiving methadone in a maintenance program, and those who have not used drugs for several years. Undertreatment with analgesic drugs occurs most commonly in this group of patients. Assessment of reported pain by physicians and nurses is colored by the fact that the pain symptoms are confused with drug-seeking behavior. Attention to the medical and psychological needs of these patients requires individualized assessment and consultation with experts in drug-related problems. The first subgroup represents a major management problem, straining the most tolerant of medical care systems. Pain in the other two subgroups is readily managed, with the recognition that the psychological stresses consequent to the pain and cancer may place the patient at a high risk for recidivism. There is increasing expertise to address the need of this patient population with experts in addiction medicine and cancer pain working together to provide a coordinated system of care.<sup>59</sup>

**GROUP V: DYING PATIENTS WITH PAIN**

In dying patients in pain, diagnostic and therapeutic considerations are directed at maintaining the patient's comfort. This group is identified separately from group II patients, because the psychological factors further compound adequate pain management. The issues of hopelessness and coping with death and dying become more prominent, and the suffering component must be addressed.<sup>57,60,61</sup> Inadequate control of pain in the dying patient exacerbates the suffering component and demoralizes the family and the caregivers, who feel that they have failed in treating the patient's pain at a time when adequate treatment may matter the most. Rapid escalation of analgesic drug therapy, usually by the parenteral route (intravenous, subcutaneous, or transdermal), and amelioration of psychological symptoms should be attempted. The risk-to-benefit ratios in analgesic approaches become less of an issue when the goal of pain therapy is the patient's comfort. It is now widely recognized that it is the role and the responsibility of the physician to treat pain and suffering in this population of patients. Defined guidelines for the care of the dying have been published.<sup>2,61,62</sup> Good physician-patient communication, which include issues of truth telling and the assault of truth; respect for patients' religious, cultural, and spiritual needs; and clearly defining goals of care can improve the care of this population of patients.<sup>58</sup>

**COMMON PAIN SYNDROMES**

Pain in the cancer patient results from direct tumor infiltration and from the various cancer treatments and can occur unrelated to the cancer and cancer therapy. [Table 56.1-3](#), [Table 56.1-4](#), and [Table 56.1-5](#) list the common acute and chronic pain syndromes that occur in patients with cancer. These lists are a compendium of various sources, but serve to summarize the broad and now well-recognized pain syndromes that occur often uniquely in this population of patients.<sup>32,33,64,65</sup>

**CLINICAL ASSESSMENT OF PAIN**

Certain general principles should be followed in evaluating cancer patients who complain of pain. Lack of attention to these general principles is the major cause for misdiagnosis of a specific pain syndrome. Adequate assessment is a critical component for defining the appropriate therapeutic strategy for each patient. The general principles are presented here:

- Believe the patient's complaint of pain.
- Take a careful history of the patient's pain complaint.
- Evaluate the patient's psychological state.
- Perform a careful medical and neurologic examination.
- Order and personally review the appropriate diagnostic studies.

Treat the pain to facilitate the appropriate workup.  
Reassess the patient's response to therapy.  
Individualize the diagnostic and therapeutic approaches.  
Clearly define the goals of care.  
Discuss advance directives with the patient and the family.

## **BELIEVE THE PATIENT'S COMPLAINT OF PAIN**

Critical to the management of the patient with cancer pain is the establishment of a trusting relationship with the physician. The complaint of pain is a symptom, not a diagnosis. Pain perception is not simply a function of the amount of physical injury sustained by the patient, but is a complex state determined by multiple factors. The diagnosis of a specific pain syndrome and a complete understanding of the patient's psychological state is not always made during the initial evaluation. In fact, it may take several weeks to define its nature because of the lack of radiologic or pathologic verification. It may take a similar period to fully comprehend each patient's psychological makeup. Numerous examples in the assessment of patients with pain and cancer highlight the limitation of the diagnostic process. It is not uncommon for patients with tumor infiltration of the brachial plexus from either lung or breast cancer to have pain for several weeks or months before the onset of objective radiologic and neurologic findings. A comprehensive evaluation involves taking a careful history; performing a detailed medical, neurologic, and psychological evaluation; developing a series of diagnosis-related hypotheses; and ordering the appropriate diagnostic studies.

## **TAKE A CAREFUL HISTORY OF THE PATIENT'S PAIN COMPLAINT**

A careful history of the patient's pain complaint should include the patient's description of site of pain, quality of pain, exacerbating and relieving factors, temporal pattern, exact onset, associated symptoms and signs, interference with activities of daily living, effect on the patient's psychological state, and response to previous and current analgesic therapies. Multiple pain complaints are common in patients with advanced disease and must be ranked and classified.

## **EVALUATE THE PATIENT'S PSYCHOLOGICAL STATE**

The patient's current level of anxiety and depression must be clarified and his or her past history of such symptoms must be defined. Knowledge of the patient's previous psychiatric history and need for past hospitalization for psychiatric care helps to clarify the patient's potential psychological risk. Information on how the patient has handled previous painful events may provide insight into whether the patient has demonstrated chronic illness behavior or has a past history of a chronic pain syndrome. It is important to know about a personal or family history of alcohol or drug dependence, to understand why the patient may be fearful or refuse to take opioid drugs.

Because each patient has his or her own understanding of the meaning of pain, it is useful to have the patient elaborate this meaning. <sup>21,57,63,66</sup> Does he or she think it represents recurrent tumor, or is he or she convinced it is simply arthritis? Evidence suggests that when patients have a clear understanding of the meaning of their pain as representing recurrent tumor, they have increased psychological distress.

The importance of defining the psychological makeup of the patient with pain is supported by a variety of studies that have focused on the effect of suffering in patients with pain. <sup>2,57</sup> Psychological factors play a significant role in accounting for the differences in pain experiences in cancer patients. A series of psychiatric syndromes have been described for cancer patients, with depression occurring in as many as 25% of patients. <sup>21</sup> The depression presents either as an acute stress response or as a major depression. Awareness of the common psychiatric syndromes when evaluating the pain complaint expands the physician's understanding of such a complaint.

Although it is critical to know as much as possible about each patient with pain, some information may not be readily available in the first interview; in some instances it may never be available because of the lack of intellectual competence on the patient's part to define clearly the various components of the pain complaint. It is often necessary to verify the history from a family member who may provide information that the patient is unable or unwilling to provide. The family may be more objective in assessing a disability of a patient who underreports his or her symptoms. Similarly, in a patient who is a poor historian, the family member may be able to provide essential information that may alter the diagnostic approach. All attempts should be made to compile a careful history and define the medical, neurologic, and psychological profile of the pain complaint.

It is also useful to define for the patient the goal of treatment. Some patients may have unreasonable expectations for adequate pain control, whereas others fail to critically consider the various options available to them. Before starting any new procedure, review carefully with the patient the risks and benefits to provide them with their expectation of the potential outcome of the therapeutic approach. As patients become more active in defining advance directives and as they focus on the quality of life, it is critical to ask patients to define what they would do if the pain were intractable or intolerable. <sup>67</sup> Did the patient have a family member who died a painful death? From our experience, patients who have had such an experience are particularly fearful of their own deaths. Does the patient have suicidal thoughts or a pact with a family member? Does the patient have a family history of suicide? Does the patient have drugs in reserve or a gun in the house that he or she might use in desperation? <sup>67</sup> In a study by Chochinov et al., pain alone did not correlate with patients' suicidal ideation. <sup>68</sup> Significant depression appeared to be the major correlating factor, although pain clearly played a role in the development of depression in some patients. This series of questions allows patients to discuss openly their fears of death and their intention to take matters into their own hands rather than trust the health care professional. Such open discussions can allow the physician to better define for the patient the options for care and to reassure the patient of the physician's commitment to care. Because patients rarely offer this information unless requested, it is critical to develop specific questions that can be readily integrated into the initial history taken by the physician. Discussing with the patient how they would die and engaging the patient in a discussion of his or her concerns and wants can address the commonly heard quote of patients, "I have never died before, how do I do it?"

## **PERFORM A CAREFUL MEDICAL AND NEUROLOGIC EXAMINATION**

A medical and neurologic examination helps provide the necessary data to substantiate the history. It also provides a direct assessment of the cognitive status of the patient. Knowledge of the referral patterns of pain and the common cancer pain syndromes can direct the examination. The commonly described pain syndromes in cancer patients associated with a postmastectomy pain syndrome can readily be defined as separate from tumor infiltration of the brachial plexus <sup>5,66</sup> (see [Table 56.1-6](#)).

The physical and neurologic examination allows the physician to visually inspect and palpate the site of pain and to look for the associated physical and neurologic signs that might help to better define the nature of the pain symptom. Defining the degree of motor or sensory changes can help define the specific site in the nervous system that may be involved. Similarly, in patients with sensory loss, the presence of allodynia and hyperesthesia can further define the nature of the sensory problem and define a neuropathic pain syndrome. Moreover, the degree of muscle spasm, gait instability, and impaired coordination can only be fully assessed by such an evaluation.

## **ORDER AND PERSONALLY REVIEW THE APPROPRIATE DIAGNOSTIC STUDIES**

Diagnostic studies confirm the diagnosis and define in patients with metastatic disease the site and extent of tumor infiltration. Computed tomography and magnetic resonance imaging (MRI) are the most useful diagnostic procedures in evaluating cancer patients with pain. <sup>70</sup> The positron emission tomography scan is increasingly being used to further define tumor and to differentiate tumor from radiation injury. The bone scan is a useful screening device and is more sensitive for demonstrating abnormalities in the bone before changes appear on plain radiography. However, a negative bone scan does not rule out bony metastatic disease, nor does a positive bone scan confirm the diagnosis of metastatic tumor. In patients with collapsed vertebral bodies, an MRI can distinguish osteoporotic from tumor-induced bony changes. The physician should review the results personally with the radiologist to correlate any pathologic change with the site of pain.

Evaluation of the extent of metastatic disease may help to discover the relation of the pain complaint to possible recurrent disease. The use of tumor markers such as carcinoembryonic antigen, CA 125, CA 15-3, and prostate-specific antigen can be useful in a patient in whom recurrent tumor is suspected. In certain pain syndromes the presence of recurrent disease is closely associated with the onset of pain (e.g., in the appearance of late postthoracotomy pain syndrome in a patient after initial resolution of the postoperative pain).

## TREAT THE PAIN TO FACILITATE THE APPROPRIATE WORKUP

No patient should be evaluated inadequately because of a significant pain problem. Early management of the pain while investigating the source markedly improves the patient's ability to participate in the necessary diagnostic procedures. [Table 56.1-7](#) lists the reasons for a pain consultation at Memorial Sloan-Kettering Cancer Center. During the initial evaluation of the pain complaint, early consideration of the use of alternative methods of pain control, including anesthetic and neurosurgical approaches, should be considered (e.g., the temporary use of a local anesthetic via an epidural catheter to manage sacral pain).

Reason for Referral <sup>a</sup>	No. of Referrals
Uncontrolled chronic pain despite analgesic therapy	73
Excessive side effects without adequate analgesia	24
Difficulties in assessment	22
Uncontrolled acute pain despite analgesic therapy	12
Change route of opioid administration	8
Concerns regarding drug-seeking behavior or possibility of addiction	8
Excessive side effects with adequate analgesia	5
Manage persistent route of drug administration	2
Concern that the patient's analgesic regimen involves too many pills	2
Concern that pain is disproportionate for extent of disease	1
Concern that patient is using excessive opioid therapy	1

<sup>a</sup>Physicians were asked to record one or more reasons for referral. The three reasons that were never cited included uncontrolled pain in a patient not on analgesic therapy, concern that the patient is receiving too many drugs, or concern that the treatment is too expensive.  
(From ref. 26, with permission.)

**TABLE 56.1-7.** Reasons for Referral to the Pain Service (n=100)

## REASSESS THE PATIENT'S RESPONSE TO THERAPY

Continual reassessment of the response of the patient's pain complaint to the prescribed therapy provides the best method to validate the initial diagnosis as correct. If relief is less than predicted or if the pain worsens, reassessment of the treatment approach or a search for a new cause of the pain should be considered. A common example is the patient with epidural cord compression who develops a second block proximal to the one being radiated, with neurologic signs mimicking the original one.<sup>71</sup>

## INDIVIDUALIZE THE DIAGNOSTIC AND THERAPEUTIC APPROACH

Evaluation of the patient must be closely linked to the patient's level of function, ability to participate in the diagnostic workup, willingness to undergo the necessary diagnostic approaches, objective evidence that treatment approaches may be beneficial, and life expectancy. Careful judgment is required to select diagnostic approaches that will have a direct effect on the choice of the therapeutic strategy or will answer a specific question. The random use of diagnostic procedures in these patients, particularly those with advanced cancer and significant pain, is inappropriate because it may have an adverse effect on their quality of life. Open discussion with the patient about the need for assessment as well as the therapeutic options is critical to allow the patient to be part of the decision-making process. In some patients, diagnostic procedures such as MRI are inappropriate because they simply confirm the existence of a disease for which no treatment is available or for which the treatment would be a major surgical procedure (e.g., vertebral body resection) that would be inappropriate for a dying patient. Patient refusal of evaluation or treatment must be respected when the physician has fully explained the options and is convinced that the patient has an accurate understanding of the implications of no further workup or treatment.<sup>72</sup>

## DISCUSS ADVANCE DIRECTIVES WITH THE PATIENT AND FAMILY

When developing approaches for treatment, there must be an open discussion about advance directives so that the physician has a clear understanding of the patient's goal for therapy or his or her ambivalence in developing a therapeutic strategy. The physician must have unconditional positive regard for the patient, placing the control of symptoms of pain and treatment of psychological distress in the highest regard. Knowledge of the patient's decisions about resuscitation, living wills, and symptom management should he or she become incompetent improves the physician's ability to appropriately and humanely care for the dying patient with advanced disease.<sup>61</sup> In a study of Memorial Sloan-Kettering Cancer Center patients evaluated by the Pain and Palliative Care Service, patients reported reluctance to discuss end-of-life care issues with their physicians, preferring to discuss their concerns with family and friends.<sup>73</sup> Such data emphasize the need for education of families in the continuum of cancer care including issues of pain management and the role of sedation in patients whose lives are ending.

## MANAGEMENT OF CANCER PAIN

The management of cancer pain incorporates treatment of the primary disease with analgesic drug therapy and aesthetic, neurosurgical, rehabilitative, psychological (cognitive behavioral), and psychiatric methods. Individualizations of the treatment strategy and titration to effective pain relief are the hallmarks of this therapeutic approach. Increasing sophistication in the use of analgesic drugs, coupled with advances in research on the underlying mechanisms of pain, have provided the scientific rationale for the more effective use of standard analgesic drug therapy (nonopioid, opioid, and adjuvant drugs), including the use of novel routes of drug administration (transdermal and transmucosal), the use of novel methods (bisphosphonates and calcitonin for bone pain, antidepressants and anticonvulsants for neuropathic pain), and the indication for the use of anesthetic, neurosurgical, psychological, and psychiatric approaches concurrently applied in the overall continuum of care.

Pain management is only one aspect of a broad palliative care approach, but it serves as a model for the scientific rigor and clinical trials that have defined cancer pain treatment as a specific strategic focus. The full impact of such a comprehensive approach has not been fully determined. From data evaluating the use of analgesic drug therapy to cancer pain alone, 70% to 90% of patients report adequate analgesia. Studies from various pain services, hospices, and palliative care programs report results as high as 95% of patients receiving effective analgesia.

To develop appropriate outcome assessment methods and to provide a basis for comparison of treatment strategies, Bruera and Wantanabe have developed the Edmonton Staging System for cancer pain, patterning it to the various staging systems for different primary tumors. Stage I (good prognosis), stage II (intermediate prognosis), and stage III (poor prognosis) are based on five prognostic features, including the presence or absence of neuropathic pain, incident pain, psychological distress, rapid tolerance development, and a history of drug addiction or alcohol abuse.<sup>74</sup> This methodology, in preliminary studies, has been validated as a way to compare different patient populations with different primary tumors in clinical trials and outcome assessments of cancer pain therapy.<sup>75</sup>

## ANALGESIC DRUG THERAPY

Numerous guidelines for the management of cancer pain have been issued by various organizations and researchers.<sup>3,76,77</sup> All of these guidelines have emphasized that analgesic drug therapy is the mainstay of treatment and have focused on the aims of drug therapy to achieve adequate pain relief safely within an acceptable time frame, minimize side effects of treatment, and provide ongoing analgesic therapy by the most convenient and least noxious means available. More recently, detailed descriptions of the decision-making process implemented during the treatment of patients with pain have provided further data on the rationale and outcomes of specific decisions and have detailed a series of principles in the selection of opioid drug and route of administration.<sup>26,78</sup> In the following section, guidelines for the rational use of analgesics in the management of cancer pain are detailed. These guidelines are based on clinical pharmacologic principles, clinical trials, available metaanalyses of analgesic studies, and the clinical experience developed by the Pain Service at Memorial Sloan-Kettering Cancer Center. [Table 56.1-7](#) lists the reasons why patients with pain were referred to an inpatient consultation service at Memorial Sloan-Kettering Cancer Center. These reasons for referral point out the complexity that has now developed in providing individualized pharmacotherapy for patients with pain. These data also point out the need for physicians and nurses to be knowledgeable in the use of these guidelines to provide patients with effective analgesia. These data, from 100 consecutive inpatients who were referred over a 14-week period to Memorial Sloan-Kettering Cancer Center Pain Service had 158 reasons for referral.<sup>26</sup> The two most common reasons were uncontrolled chronic pain, which occurred in 73 patients, and excessive side effects without adequate analgesia, despite analgesic therapy, which occurred in 24 patients. The most common reasons included difficulties in pain assessment and poorly controlled acute pain. At the time of initial evaluation, 77 patients had a pain intensity of 7 out of

10, and 18 patients had a pain intensity of 4 to 6 out of 10. After initial evaluation by the Pain Service physicians, the therapeutic intent of analgesic therapy was to provide comfort and function for 87 patients and comfort only for 13 patients. Comfort and function were the therapeutic intent of analgesic therapy for 75 of the patients discharged (92%) and comfort only for 17 patients who died (94%). After initial evaluation, the Pain Service physicians changed the opioid drug, the route of administration, or both for 58 patients. Of 42 patients whose regimens were not changed, 17 were discharged, 3 died, and 22 required subsequent changes in either drug or route of administration. In short, a total of 80 patients required changes in opioid therapy before death or discharge. Sixty-four patients required more than one change in therapy. Forty-four patients required one or more changes, and 20 patients required two or more changes. These data are particularly important to point out the complexity of analgesic drug therapy in this population of patients. Side effects were problematic in providing patients with a balance between adequate analgesia and excessive side effects. It is critical, then, that the goals of care for an individual patient be recognized and help provide the essential context for therapeutic decision making. When patients prioritize optimal comfort and function equally, the therapeutic attempt is to achieve an adequate degree of relief without compromising cognitive and physical function. When comfort is the overriding goal of care, there is a willingness to use whatever analgesic therapy is necessary to achieve relief, even if function is diminished in the process. To achieve the goal of care as comfort and function, substantial effort is necessary to optimize a balance between relief and side effects through dose adjustment, sequential trials of opioid drugs, coadministration of adjuvant medications, and the use of spinal analgesic techniques. Increasing attention has focused on the need to switch patients from one opioid to another. Several studies have outlined the need for opioid rotation and substitution.<sup>78,79,81 and 82</sup>

In the following section, detailed guidelines for the rational use of analgesics in the management of cancer pain are provided ( Table 56.1-8). The use of drug therapy should be within the armamentarium of any physician or nurse who cares for patients with pain in cancer. Similarly, the integration of some of the psychological and psychiatric approaches should be widely available. The use of specific anesthetic and neurosurgical techniques will often require the services of trained medical personnel who have clinical experience in managing cancer pain, but such approaches may require referral to a specialty center.

**TABLE 56.1-8. Guidelines for the Rational Use of Analgesics in the Management of Cancer Pain**

**WORLD HEALTH ORGANIZATION THREE-STEP ANALGESIC LADDER**

As part of a global program of WHO, the Cancer and Palliative Care Unit has created a Cancer Pain Relief Program, and through a series of expert panels, has developed guidelines for the treatment of cancer pain.<sup>7,83,84</sup> This program has achieved a broad international consensus, based on the concept that analgesic drug therapy is the mainstay for the majority of patients with cancer pain. As previously stated, field testing of the WHO guidelines, in conjunction with clinical experience, has shown that 70% to 90% of cancer patient's pain can be controlled using a simple and inexpensive method described as the *three-step analgesic ladder*.<sup>83</sup> This approach is based on the use of a combination of nonopioid, opioid, and adjuvant drugs, titrated to the individual needs of the patient according to the severity of pain and its pathophysiology ( Tables 56.1-9, Table 56.1-10, and Table 56.1-11). Implementation of the analgesic guidelines, assurance of drug availability (specifically opioids), the education of health care professionals, and designating cancer pain as a priority for all national cancer control programs are the major goals of the WHO effort.<sup>84</sup>

Class/Drug	Indication	Starting Oral Dose (mg and Range) 24 h	Comments
<b>Nonopioid analgesics</b>			
<b>Nonsteroidal anti-inflammatory drugs</b>			
Aspirin	Subacute and acute pain, low pain	60, 60-300	Use together with aspirin, paracetamol and benzocaine effects, avoid combination with corticosteroids
Acetaminophen	Like aspirin	60, 60-300	Lower gastrointestinal effects, no effect on platelet function, no significant antitumor effect
Diapiridol	Like aspirin	60, 100-400	Higher analgesic potential than aspirin, lower gastrointestinal and benzocaine effects than aspirin
Choline magnesium salicylate	Like aspirin	100, 100-400	Antitumor effect and analgesic effect, similar to aspirin without benzocaine effects
Propyfenone	Like aspirin	20, 20-40	Like diapiridol
Mefenamic acid	Like aspirin	20, 20-300	Longer duration of action than diapiridol, higher analgesic potential than aspirin
Syringic acid	Like aspirin	20, 20-30	Like mefenamic acid

**TABLE 56.1-9. Nonopioid Analgesic Drugs in the Management of Cancer Pain**

Drug*	Intermediate (mg)	Goal (mg)	Half-life (h)	Duration of Action (h)
Codeine	150	200	2-5	2-4
Dihydrocodeine	15	200	2-5	2-4
Oxycodone	15	30	2-5	2-4
Propoxyphene	50	100	2-5	2-4
Morphine	10	30 (equianal dose)	2-5	3-4
Hydrocodone	1.5	7.5	2-5	2-4
Methadone	10	20	15-200	6-8
Meprobamate	75	300	2-5	2-4
Oxycodone	1	10 (per rectum)	2-5	3-4
Lorazepam	2	4	12-15	6-8
Fentanyl (transdermal)	0.1	—	1-2	1-2
Fentanyl (transdermal) (equi)	—	—	—	66-72
Fentanyl (transdermal)	—	—	1-2	1-2

\*Oxycodone, hydrocodone, and morphine available in dose-release preparations.  
 †Transdermal fentanyl, 100 µg/h; morphine, 4 mg/h.

**TABLE 56.1-10. Opioid Drugs Commonly Used in Cancer Pain Management**

*(This table content is illegible due to low resolution in the provided image.)*

The opioid analgesics, of which morphine is the prototype, vary in potency, efficacy, and adverse effects. These drugs produce their analgesic effects by binding to discrete opiate receptors in the peripheral and central nervous systems. This group also includes a series of heterogeneous substances with varying chemical structures. In contrast to the nonopioid analgesics, opioid analgesics, at least the opioid pure agonist, do not appear to have a ceiling effect (i.e., as the dose is escalated on a log scale, the increment in analgesia is linear to the point of loss of consciousness). There are also series of drugs that are pure antagonists (i.e., they block the effect of morphine at the receptor). The drug most commonly used in clinical practice is naloxone, which is used to reverse respiratory depression and other complications associated with opioid overdose.

Effective use of the opioid drugs requires the balancing of the most desirable effects of pain relief with the undesirable effects of nausea, vomiting, mental clouding, sedation, constipation, tolerance, and physical dependence. These undesirable effects impose a practical limit on the dose useful for a particular patient and have led to the concept of opioid responsiveness (see [Principles of Opioid Drug Therapy](#), later in this chapter).

The use of opioids in the management of cancer pain remains a controversial issue.<sup>85,86</sup> and <sup>87</sup> Some of the controversies include their role in the management of neuropathic pain, which has been suggested for the *opioid resistant*, the specific choice of opioid drug, the use of sequential trials of opioids, routes of administration, development of tolerance, economic factors influencing these controversies, and the concern that opioids are agents of physician-assisted suicide and euthanasia.<sup>93,94,95</sup> and <sup>96</sup> When appropriate, these controversies are addressed in the following discussion of the principles of opioid drug therapy.

## PRINCIPLES OF OPIOID DRUG THERAPY

### START WITH A SPECIFIC DRUG FOR A SPECIFIC TYPE OF PAIN

As defined by the three-step analgesic ladder, the specific drug chosen is dependent in part on the degree of pain intensity. As previously noted, cancer patients commonly have multiple sites and types of pain. It has been suggested that neuropathic pain, which accounts for 10% to 20% of pain problems that are difficult to manage, is opioid resistant, and that opioid drugs should not be used in this population.<sup>86</sup> Studies in cancer patients with both nociceptive and neuropathic pain, as well as controlled studies in nonmalignant neuropathic pain, demonstrate the variable responsiveness of neuropathic pain to opioid analgesics.<sup>88</sup> The concept of a continuum of opioid responsiveness, rather than an all or none quantal phenomenon, has been clearly observed. *Opioid responsiveness* is defined as the degree of analgesia achieved during dose escalation to either intolerable side effects or adequate analgesia. Patient characteristics, pain-related factors, as well as drug-selective effects influence this variable response.

A wide range of adjuvant analgesics has been suggested to provide analgesia alone or in combination with opioid drug therapy, and there are specific adjuvants for bone pain and neuropathic pain. Not only pain intensity and type of pain dictate the choice of a specific drug, but also the patient's prior opioid exposure, history of allergy, and history of side effects.

The WHO Cancer Pain Guidelines designated morphine as the drug of choice in its Cancer Pain Relief Program. The choice was based on practical, not scientific, considerations. The introduction of the WHO program rapidly demonstrated the limited availability of morphine worldwide for oral treatment of chronic cancer pain.<sup>97</sup> Morphine consumption worldwide is now used as an indicator of the success of the WHO Cancer Pain Relief Program. For example, in Japan following a nationwide program to improve cancer pain management, a 17-fold increase in morphine consumption has been reported. The expanded use of morphine, combined with new formulations and new information about the analgesic activities of its metabolites, focuses renewed attention on its clinical pharmacology with recognition of morphine-6-glucuronide (M6G) as an active metabolite.<sup>98</sup> Human studies have shown that M6G is analgesic in humans and appears in the plasma and cerebrospinal fluid of patients receiving morphine systemically.<sup>99</sup> In renal dysfunction, M6G has an increased elimination half-life and decreased clearance, confirming a true delay in elimination of the compound, leading to an increase in the M6G to morphine ratio during chronic therapy.<sup>100</sup> Adverse effects (nausea and respiratory depression) have been attributed to plasma concentration of the metabolite, particularly in patients with renal failure.<sup>101</sup> However, attempts to correlate M6G to morphine ratio or M6G to M3G ratio with side effects such as cognitive impairment or myoclonus have not been possible.<sup>102,103</sup> Various factors may influence the levels of both M6G and M3G, including route (increased M6G following oral administration), age (increased M3G and M6G if greater than 70 years), male sex (decreased morphine and M6G plasma concentrations), concurrent use of tricyclic antidepressants (increased M3G), and use of ranitidine (increased morphine). Controlled-release oral morphine is currently available in a wide range of doses from 50 to 200 mg for every 8-, 12-, and 24-hour administration. These preparations provide comparable analgesia with immediate release forms and offer increased convenience, improved compliance, and a reduction in duration of pain.

The increasing need for a wide range of opioids to manage cancer pain has led to the wide use of a series of alternative opioids to morphine, including hydromorphone, oxycodone, oxymorphone, and levorphanol, all congeners of morphine. Hydromorphone has poor oral availability and a short half-life. It is highly soluble and available in a high-potency parenteral form (10 mg/mL), making it a useful choice for chronic subcutaneous administration. Because of its short half-life, it is commonly used in the elderly patient. Myoclonus has been reported following high doses possibly due to accumulation of its metabolites (3-O methyl or a 6-glucuronide).<sup>104</sup> When compared in a double-blind trial of patient-controlled analgesia, no differences in analgesia or side effects were noted between morphine and hydromorphone. Although cognitive performance was poorer in the hydromorphone group, patients reported better mood as compared with morphine.<sup>105</sup> Hydromorphone is available in slow-release preparations.

Oxycodone, which is commonly used at a 5-mg dose in the second step of the WHO analgesic ladder, can also be used in the third step at higher doses. It is now available in a slow-release preparation.<sup>106</sup> Its half-life is approximately 3 to 4 hours. Oxymorphone is its active metabolite. Oxymorphone is currently only available by the intravenous and rectal routes and serves as an alternative to morphine and its other congeners. Oxymorphone has less of a histamine effect and may be of use in those patients who complain of headache or itch following other opioid administration.

Levorphanol has good bioavailability but a long plasma half-life (12 to 16 hours). It should be used cautiously because with repeated administration, accumulation may occur.

The role of methadone in cancer pain also remains controversial.<sup>79,80,81</sup> and <sup>82</sup> Methadone represents a second-line drug for cancer pain patients who have had prior exposure to opioids. It is a relatively inexpensive oral analgesic, but its name has negative connotations for cancer patients who view methadone as a drug used to treat addicts. The bioavailability of methadone is higher than that of morphine (85% vs. 35%, respectively). Its analgesic potency also differs with a parenteral to oral ratio of 1:2 in contrast to 1:6 with morphine. Moreover, the plasma half-life of methadone is 17 to 24 hours, with reports of up to 50 hours in some cancer patients, but with a duration of analgesia of only 4 to 8 hours. Significant adverse effects have been reported in cancer patients receiving methadone by various routes. The discrepancy between analgesic duration and plasma half-life of methadone have made it a difficult drug to use in the naïve patient because of the need for careful titration.

A number of case reports have highlighted the possible greater analgesic potency of methadone than the often quoted 1:1 equivalency with morphine.<sup>79,80,81</sup> and <sup>82</sup> Studies of interindividual differences in response to opioid analgesics demonstrate dramatically reduced doses of methadone required to produce analgesia in patients chronically taking morphine or hydromorphone. Several authors have shown marked reductions in the equianalgesic dose of methadone when patients with either uncontrolled pain or extreme side effects were switched. These clinical survey studies suggested up to a 75% reduction in the methadone equianalgesic dose. In the only perspective study, Ripamonti et al. developed a specific dose ratio based on the patient's morphine doses.<sup>80</sup> For patients on 30 to 90 mg of morphine, the dose ratio is 4:1; for those on 90 to 300 mg daily, the dose ratio is 6:1; and for those on 300 mg or more, the dose ratio is 8:1. Bruera et al. developed a similar ratio for hydromorphone based on survey data.<sup>79</sup> In patients receiving more than 330 mg of hydromorphone, the dose ratio is 1.6:1; and less than 300 mg, the dose ratio is 0.95:1.

In general, a good rule is to reduce the calculated equianalgesic dose by 75% and titrate the patients to effective pain relief. These reports have pointed out the need to use one-fourth to one-third the equianalgesic dose of methadone when switching from other opioids to this regimen. This observation relates in part to significant incomplete cross-tolerance with methadone and other factors that have not been fully assessed. Methadone can be administered by a variety of routes, but the subcutaneous route is associated with adverse effects including cutaneous hypersensitivity.<sup>107</sup> Due to its long half-life, some offer the suggestion that methadone be used on a every 8 to 12 hour basis, whereas others have demonstrated analgesic efficacy and safety in acute 3- to 4-hour dosing intervals. Ongoing studies are attempting to elucidate better the clinical pharmacology of methadone to facilitate its broader use.

Meperidine is a drug that should not be used chronically in the management of patients with cancer pain. Meperidine has a poor parenteral to oral ratio (1:4). It is

available in oral and intramuscular routes but repetitive intramuscular administration is associated with local tissue fibrosis and sterile abscess. Repetitive dosing of meperidine (greater than 250 mg/d) can lead to normeperidine accumulation, an active metabolite that can produce central nervous system hyperexcitability.<sup>108</sup> This hyperirritability is characterized by subtle mood effects followed by tremors, multifocal myoclonus, and occasional seizures. It occurs most commonly in patients with renal disease, but can also occur following repeated administration in patients with normal renal function. Naloxone does not reverse meperidine-induced seizures and its use in meperidine toxicity is controversial; there have been some case reports that the use of naloxone has precipitated generalized seizures in individual patients. In rare instances, central nervous system toxicity characterized by hyperpyrexia, muscle rigidity, and seizure have been reported following the administration of a single dose of meperidine to patients receiving treatment with monoaminoxidase inhibitors.

With the development of a novel transdermal patch, fentanyl is an opioid analgesic used effectively in cancer pain patients for management of both acute and chronic pain.<sup>109</sup> The half-life of fentanyl is 1 to 2 hours. Its relative potency compared with parenteral morphine is 1 to 20 in intolerant acute pain patients. In chronic cancer pain, relative potency comparisons have not been fully established but the common dosing guideline is that 4 mg of intravenous morphine is equivalent to 100 µg of intravenous fentanyl. The uniqueness of this preparation facilitates the management of patients who are unable to take drugs by mouth by providing them with continuous opioid analgesia. Patches are currently available in 25 to 100 µg/h doses. Fentanyl can also be used as an anesthetic premedication, as well as intravenously and epidurally for pain control. Oral transmucosal formulations have demonstrated effectiveness in breakthrough pain in cancer patients.<sup>45</sup> Fentanyl (Actiq) is available in a range of dosages from 200 to 1600 µg. Twenty-five percent of the preparations in a lozenge formulation in a stylet is absorbed transmucosally over a 15-minute period and an additional 25% is absorbed via the gastrointestinal tract over the following 90 minutes. Onset of relief occurs in 5 minutes. Oral transmucosal fentanyl citrate in dose titration trials is shown to be safe and effective with the effective dose being a variable requiring titration in the majority of patients.

## KNOW THE EQUIANALGESIC DOSE OF THE DRUG AND ITS ROUTE OF ADMINISTRATION

Knowing the equianalgesic dose can ensure more appropriate drug use. Lack of attention to these differences in drug dose is the most common cause of undermedication of pain patients. These doses have been derived from assessment of the relative analgesic potency of a drug. *Relative potency* is the ratio of the doses of two analgesics required to produce the same effect. Estimates of relative potency allow calculation of the equianalgesic dose, which provides the basis for selecting the appropriate dose when switching drugs or route of administration of the same drug. The values in [Table 56.1-10](#) are based on studies in which 10 mg of morphine was the standard dose.<sup>110</sup> The equianalgesic dose is the recommended starting dose, with the optimal dose for each patient determined by dose adjustment. There is now evidence to suggest that relative potency may differ in single-dose and repeated dose studies. For example, for morphine, a 1:6 relative analgesic potency ratio should be used for patients with acute pain, whereas a 1:2 or 1:3 ratio in patients treated with repeated doses on a chronic basis is more appropriate. For methadone, the equianalgesic dose ratios vary with the degree of prior exposure as previously discussed.<sup>80</sup>

## ADMINISTER ANALGESICS REGULARLY AFTER INITIAL TITRATION

Medication should be given regularly in order to maintain the plasma level of the drug above the minimum effective concentration for pain relief. In the initial titration, patients should be advised to take their medication as needed to determine their total 24-hour requirements. This is also the time frame for reaching the steady-state level of drug, which depends on the drug's half-life. For morphine, steady state can be reached in 24 hours; with methadone it may take up to 5 to 7 days to reach steady state. In patients on a fixed schedule, rescue medications equivalent to one-half of the standing dose should be available to patients for breakthrough pain.

Continuous intravenous and subcutaneous opioid infusions to manage both acute and chronic cancer pain are commonly used with a patient-controlled analgesic pump programmed to the patient's need with a set *lock-out time* to prevent overdosing. This method of drug administration is especially useful to manage patients with breakthrough pain. It is a significant advance in facilitating adequate titration of analgesics in chronic cancer patients, allowing discharge to home and hospice settings.

## GEAR THE ROUTE OF ADMINISTRATION TO THE PATIENT'S NEEDS

Various methods of drug delivery of opioids have been developed in an attempt to maximize pharmacologic effects and minimize side effects. Most patients require at least two routes of drug administration, and 20% need up to four approaches during the course of their cancer pain treatment, from diagnosis to death.

The oral route is preferable and easy. Orally administered drugs have a slower onset of action, delayed peak time, and longer duration of effect; drugs given parenterally have a rapid onset of action but a shorter duration of effect. Slow-release preparations of morphine, hydromorphone, and oxycodone allow more convenient dosing of cancer pain patients every 8 to 12 hours or 24 hours.

For cancer pain management by the sublingual route, these are drugs that are well absorbed sublingually including both fentanyl and methadone.<sup>111</sup> As discussed there is now an oral transmucosal fentanyl citrate preparation that has been widely studied for the management of breakthrough pain and is absorbed transmucosally.

For the rectal route, oxymorphone, hydromorphone, and morphine are available in suppository form. Oxymorphone suppositories produce analgesia equivalent to 10 mg of parenteral morphine. Slow-release oxycodone and morphine preparations have also been demonstrated to be effective rectally and ongoing studies with rectal methadone suggest that this drug is well absorbed by the rectal route.

The transdermal route is a convenient way to deliver a potent short-acting opioid on a continuous basis. Drug is released through the skin patch at a nearly constant amount per unit time with a concentration gradient from patch to skin. Serum fentanyl concentrations increase and steady-state levels are approached at 12 to 24 hours.<sup>109</sup> After patch removal, the drug persists in the skin, with falling blood levels over 24 hours. In calculating the equianalgesic dose, 4 mg of intravenous morphine is equivalent to 100 µg of fentanyl transdermally. Innovative transdermal delivery systems are in development, which include systems for immediate-dose delivery using iontophoresis and drug reservoirs. Iontophoresis is the transfer of ionic solutes through biologic membranes under the influence of an electric field. It offers an alternative system for parenteral administration and has been shown to allow for comparatively rapid achievement of fentanyl dose levels using a transdermal system.<sup>112</sup>

Various parenteral routes include intermittent and continuous subcutaneous, intravenous, epidural, intraventricular, and intrathecal infusions. The use of intermittent and continuous subcutaneous infusions is most useful in patients who cannot tolerate oral analgesics because of gastrointestinal obstruction or intractable nausea and vomiting and do not have intravenous access. The usefulness of this technique has been demonstrated using morphine, heroin, hydromorphone, levorphanol, and fentanyl. Methadone by this route is associated with the development of a cutaneous hypersensitivity syndrome.<sup>107</sup>

Patient-controlled analgesic pumps designed to infuse continuously but with options for bolus administration are connected to a 27-gauge butterfly needle that the patient can insert into a new subcutaneous site every third to sixth day. Limited pharmacokinetic studies have demonstrated that systemic absorption of the drug from subcutaneous sites at steady state has an 87% bioavailability with hydromorphone, for example.<sup>112</sup>

Intermittent and continuous intravenous infusions are used if intravenous access is available and more commonly in the patient who is hospitalized. Specific guidelines for the use of continuous infusions have been developed.<sup>113</sup>

Intermittent and continuous epidural and intrathecal opioid infusions are based on the demonstration of opioid receptors in the dorsal horn of the spinal cord and the availability of opioid drugs to suppress noxious stimuli at the spinal cord level.<sup>34,35</sup> Localized selective analgesia is produced without motor or sensory blockade. The pharmacokinetics of epidural opioid administration demonstrate that there is significant systemic uptake after epidural injection, comparable with an intramuscular injection of the same drug and dose. However, distribution of the drug directly into the cerebrospinal fluid is 10 to 100 times greater. Existing studies demonstrate that approximately 10% of cancer patients use this approach to maximize analgesia and minimize side effects. This technique is commonly used in patients who have mixed nociceptive neuropathic pain syndromes and in whom combinations of local anesthetics and opioids are administered epidurally.

Rarely, intraventricular opioid infusion has been used to manage patients with pain in the cervical and craniofacial region from tumor infiltration.<sup>114</sup> Doses between 1.0 and 7.5 mg/24 hours have been used and patients have reported 70% excellent results. At present, there is not a clear indication that this intraventricular route offers special advantages over systemic opioids.<sup>114</sup>

## USE A COMBINATION OF DRUGS

The use of a combination of drugs enables a physician to increase analgesic effects without escalating the opioid dose. Combinations that produce additive analgesic effects include an opioid plus a nonopioid, an opioid plus an antihistamine (100 mg of intramuscular hydroxyzine), and an opioid plus an amphetamine (10 mg of intramuscular dextroamphetamine).<sup>115,116 and 117</sup> Trials with opioids combined with dextromethorphan demonstrate additive analgesia and such combinations are now under study for their role in cancer pain patients.<sup>118</sup>

## ANTICIPATE AND TREAT SIDE EFFECTS

The side effects of the opioid analgesics often limit their effective use. The most common side effects are sedation, respiratory depression, nausea, vomiting, constipation, and multifocal myoclonus and seizures.

Sedation and drowsiness vary with the drug and dose and may occur after both single and repeated administration. They are mediated through activation of opiate receptors in the reticular formation and diffusely throughout the cortex. Management of these effects includes reducing the individual drug dose but prescribing the drug more frequently, or switching to an analgesic with a shorter plasma half-life. Amphetamine, methylphenidate, and caffeine can be used to counteract these sedative effects.<sup>116,117,119</sup> It is important to discontinue all other drugs that might exacerbate the sedative effects of the opioid analgesic, including a wide variety of medications such as cimetidine, barbiturates, and other anxiolytic medications.

Respiratory depression is the most serious adverse effect of the opioid drugs. It occurs most commonly after short-term administration of an opioid and is usually associated with other signs of central nervous system depression, including sedation and drowsiness. The opioid-agonist drugs act on brainstem respiratory centers to produce, as a function of dose, increasing respiratory depression to the point of apnea. Tolerance to this effect develops rapidly with repeated drug administration, thereby allowing prolonged use without significant risk of respiratory depression.

Respiratory depression can be reversed by giving the short-acting opioid antagonist naloxone (suggested dose, 0.4 mg/mL). Repeated administration, including an intravenous drip, may be necessary to prevent respiratory arrest in such patients. In patients receiving opioids for prolonged periods who develop respiratory depression, diluted doses of naloxone (0.4 mg in 10 mL of saline) should be titrated carefully to prevent the precipitation of severe withdrawal symptoms while reversing the respiratory depression. A useful dosing normogram for continuous intravenous infusion of naloxone has been developed in which two-thirds of the initial bolus is started on an hourly basis and titrated against the patient's symptoms.<sup>120</sup>

In some patients the use of naloxone to reverse drug-induced respiratory depression can be dangerous. An endotracheal tube should be placed in the comatose patient before giving naloxone to prevent aspiration from excessive salivation and bronchial spasm induced by naloxone administration. In patients receiving meperidine over a longer period, naloxone may precipitate seizures by lowering the seizure threshold and by allowing the convulsant activity of the active metabolite, normeperidine, to become evident. In this instance, special attention must be given to the potential seizure effect of naloxone. If naloxone is used, diluted doses, slow titration, and appropriate seizure precautions are advised. There is insufficient clinical evidence to make more specific recommendations. If respiratory support can be effected by other means (i.e., continuous stimulation to maintain the patient's wakefulness), such an approach may place the patient at less risk and clearly in less discomfort.

The opioid analgesics produce nausea and vomiting by an action limited to the medullary chemoreceptor trigger zone. The incidence of nausea and vomiting is markedly increased in ambulatory patients. Tolerance develops to these side effects with repeated administration. Nausea with one drug does not mean that all drugs will produce it.<sup>121</sup> Switching to alternative opioid analgesics or using an antiemetic together with the opioid analgesic are ways to obviate this effect. Lack of controlled trials to identify a specific first-line agent has supported the practice of using sequential trials of agents beginning with prochlorperazine (Compazine) concurrently with the opioid to clarify a useful regimen. Droperidol has also been noted to be effective in opioid-induced nausea and vomiting.

Constipation results from the action of these drugs at multiple sites in the gastrointestinal tract and in the spinal cord to produce a decrease in the intestinal secretions and peristalsis, resulting in a dry stool and constipation. When opioid analgesics are started, a regular bowel regimen, including cathartics and stool softeners, should also be instituted. Several bowel regimens have been suggested because of their specific ability to counteract the effects of the opioid drugs, but none has been studied in a controlled way.<sup>122</sup> Anecdotal surveys suggest that doses far above those used for routine bowel management are needed, that senna derivatives are effective, and that careful attention to dietary factors along with the use of a bowel regimen can reduce patient complaints dramatically. Tolerance to this effect develops over time, but relatively slowly. Oral naloxone has been shown to be effective in treating constipation, but its use is variable depending on the degree of opioid exposure of the patient.<sup>123</sup>

Multifocal myoclonus may occur with high doses of all of the opioid drugs. Multifocal myoclonus and seizures have been reported in patients receiving multiple doses of meperidine (250 mg or more per day), although signs and symptoms of central nervous system hyperirritability may occur with toxic doses of all the opioid analgesics. In a series of cancer patients receiving meperidine, accumulation of the active metabolite normeperidine was associated with these neurologic signs and symptoms. However, in a similar group of cancer patients with pain, subtle mood effects were noted after meperidine administration, which suggests a spectrum of central nervous system effects. Management of this hyperirritability includes discontinuing the meperidine, using intravenous diazepam if seizures occur, and substituting morphine to control the persistent pain. Because the half-life of normeperidine is 16 hours, it may take 2 or 3 days for the signs of central nervous system hyperirritability to clear completely. Meperidine is contraindicated in patients with chronic renal disease, but these complications noted in cancer pain occurred in patients with normal renal function.<sup>108</sup> Morphine and hydromorphone at high doses produce myoclonus, which has not been directly associated with their known active metabolite such as M6G and hydromorphone-6-glucuronide. In dying patients with myoclonus, the use of benzodiazepines or barbiturates has been reported anecdotally to suppress this sign, improving the patient's comfort.

Opioid hyperexcitability and hyperalgesia have been reported with the use of increasing opioid doses by the parenteral acute and epidural routes. It has most often been observed in patients on high doses of morphine and hydromorphone and is characterized by uncontrolled pain, hypervigilance, total body hyperalgesia, and allodynia. It is best managed by rapid dose reduction and substitution with an alternative opioid such as methadone. The mechanism of action is unclear.<sup>103</sup>

In animal studies with morphine it is thought to be related to M3G, which in animals is associated with allodynia and hyperalgesia following intracerebroventricular administration. This action of M3G is mimicked by strychnine, a glycine agonist. Glycine mediates postsynaptic inhibition on dorsal horn neurons. It is suggested that high doses of morphine or its metabolites may act via a spinal antiglycinergic effect, reducing postsynaptic inhibition causing allodynia and myoclonus.

## MANAGE TOLERANCE

The earliest sign of the development of tolerance is the patient's complaint that the duration of effective analgesia has decreased. For reasons not yet understood, the rate of development of tolerance varies greatly among cancer patients. Some demonstrate tolerance within days of initiating opioid therapy; others remain controlled for many months on the same dose. Studies in an outpatient clinic population, a hospitalized population, and a home care population revealed three patterns of drug use: those who rapidly increase their opioid requirements, those who stabilize at one dose for several weeks or months, and those who decrease or eliminate opioids.<sup>124</sup> Increased opioid requirements are most commonly associated with disease progression rather than tolerance alone. With the development of tolerance, increases in the frequency of the dose of the opioid are required to provide continued pain relief. Because the analgesic effect is a logarithmic function of the dose of opioid, a doubling of the dose may be needed to restore full analgesia. There appears to be no limit to the development of tolerance, and with appropriate dose adjustments patients can continue to obtain pain relief. Cross-tolerance among the opioid analgesics is not complete; therefore, it is advantageous to change to an alternative opioid, selecting half the predicted equianalgesic dose as the starting dose.

The use of analgesic combinations can reduce the amount of opioid required. Similarly, the use of bolus or continuous epidural local anesthesia in patients with perineal pain can dramatically reduce the need for systemic opioids and reverse tolerance.

## TAPER DRUGS SLOWLY

The long-term administration of opioid analgesics is associated with the development of physical dependence, a state in which the sudden cessation of the opioid analgesic produces signs and symptoms of withdrawal: agitation, tremors, insomnia, fear, marked autonomic nervous system hyperexcitability, and exacerbation of

pain. Slowly tapering the dose of the opioid analgesic prevents such symptoms. The appearance of abstinence symptoms from the time of drug withdrawal is related to the elimination half-life for the particular drug. The type of abstinence syndrome similarly varies with the drug. For example, with morphine, withdrawal symptoms occur within 6 to 12 hours after drug cessation. Reinstating the drug in doses of approximately 25% of the previous daily dose suppresses these symptoms.

## ANTICIPATE COMPLICATIONS

Overdose with opioid analgesics occurs either intentionally, when a patient takes an excessive amount of drug in a suicide attempt, or unintentionally, when the recommended dosage accidentally produces excessive sedation and respiratory depression. In both instances, the complication can be treated effectively with naloxone. Intentional overdose in cancer patients occurs rarely, and concern for this is overemphasized. Overdose in patients previously stabilized on a opioid regimen for cancer pain rarely is caused by drug intake alone. More commonly, it is the medical deterioration of the patient with a superimposed metabolic encephalopathy. Egel studied the use and misuse of naloxone and identified that sedation was the most common reason for naloxone use.<sup>125</sup> Of note, in this study of naloxone use in 34 patients over 1 year in a cancer center, 71% of patients had a medical reason other than opioid dose escalation as an explanation for the change in medical condition prompting naloxone use. Following naloxone administration, 64% of patients experienced significant side effects; 42% had increased pain and 14% had increased agitation. Patients were given intravenous boluses of 0.4 mg of naloxone rather than titrated with diluted naloxone as has been recommended.<sup>126</sup> Reducing the opioid drug dosage and carefully assessing the patient's metabolic status usually provide the differential diagnosis. Patients who have taken an unintentional drug overdose should be scrutinized carefully to rule out other causes of excessive sedation, confusion, or respiratory depression. In such cases a reversal of these effects with naloxone is more therapeutic than diagnostic.

Psychological dependence or addiction is characterized by a concomitant behavioral pattern of drug abuse evidenced by craving a drug for other than pain relief and overwhelming involvement in the use and procurement of the drug. This is a state distinct from tolerance and physical dependence, which are responses to the pharmacologic effects of long-term opioid administration. The profound fear of causing psychological dependence plays a major role in a physician's reluctance to prescribe opioid analgesics, particularly in cancer patients in the early phase of their disease. Patients may share this fear, consistently taking less analgesic drug than is effective to control their pain. Increasing evidence suggests that cancer patients with pain can take opioid analgesics for prolonged periods but can discontinue such drugs when adequate pain relief is achieved from other approaches. In almost all instances, dramatic escalation of drug intake is associated with progression of disease and subsequent death. Few patients with cancer and pain become psychologically dependent on the drugs and participate in drug-seeking and illicit drug use. Careful evaluation of patients who might be at risk for this complication is necessary, but such concern should not be punitive to the patient with severe cancer pain.

Out-of-control aberrant drug taking among oncology patients with or without a prior history of substance abuse represents a serious and complex clinical occurrence. Passik and Portenoy have developed guidelines to manage such patients.<sup>59</sup> The most difficult situations present themselves in the patient who is actively abusing illicit or prescription drugs or alcohol while concurrently receiving medical therapies. Such patients need a multidisciplinary approach usually focused on a harm-reduction concept that attempts to enhance social support for the patient to maximize treatment compliance. Passik and Portenoy have outlined a series of approaches to maximize a number of strategies for promoting compliance, including the consideration of a written contract between the team and patient, the inclusion of spot urine toxicology screens to assess compliance, set expectations regarding attendance in clinic, and the patient's management of medication supplies. It is often most useful to see the patient on a regular basis, often every several days, and to limit prescribing of opioids to that basis until the patient has demonstrated his or her willingness to be compliant and to follow an appropriate drug regimen. Other approaches include the use and encouragement for the patient to attend a 12-step program and to engage the patient's family members and friends to further bolster social support and functioning. Such approaches can be helpful on an outpatient basis, but on an inpatient basis when patients demonstrate manipulative behaviors in the inappropriate use of medication, direct discussion with the patient about the drug use in an open manner is a first step. Providing the patient with a private room near the nurses' station to monitor the patient and discourage attempts to leave the hospital for purchase of illicit drugs and requiring visitors to check in with the nursing staff before visitation are additional steps. As well, the use of daily urine specimens is another method to evaluate compliance. Underlying all of this is the attempt to provide the patient with a supportive environment that respects the patient's pain symptomatology and serious medical illness and attempts to limit harm to the patient or others by the aberrant drug use and behaviors.

## ADJUVANT DRUGS

Adjuvant drugs are used to enhance opioid analgesia, provide analgesia for certain types of pain (e.g., neuropathic pain, bone pain, and visceral pain), and treat opioid side effects or other symptoms associated with pain.<sup>127</sup> They are an integral part of the WHO three-step analgesic ladder. Because of the lack of well-defined guidelines for their use, sequential drug trials are necessary to identify the most useful drug and dose titration to find a safe effective dose. [Table 56.1-11](#) lists the commonly used adjuvants and their therapeutic categories.

### *Adjuvants to Enhance Analgesia*

Adjuvants to enhance analgesia have been previously discussed in the section on combinations of drugs (see [Use a Combination of Drugs](#), earlier in this chapter). Acetaminophen, NSAIDs, hydroxyzine, and dextromethorphan have been demonstrated to provide additive analgesia to patients chronically receiving opioids.

### *Adjuvant Analgesics for Neuropathic Pain*

The common neuropathic pain syndromes in patients with cancer include injury to peripheral nerves and plexus by tumor invasion, chemotherapy, surgery, or viral agents. Depending on the intensity of pain, nonopioid and opioid analgesics are the first-line agents. However, as previously discussed, there is evidence to suggest that such neuropathic pains are less responsive to nonopioid and opioid approaches. Some of the commonly used adjuvant drugs for managing this population of patients are described in the following sections.

### *Antidepressants*

The tricyclic antidepressants may be the most useful group of psychotropic drugs used in pain management.<sup>128,129</sup> Their analgesic effects are mediated by enhancement of serotonin activity. Data from controlled trials indicate that both the tertiary amine tricyclic antidepressants (amitriptyline, doxepin, imipramine and clomipramine), and the secondary amine compounds (desipramine and nortriptyline) have analgesic effects. More recently, one of the serotonin selective reuptake inhibitors, paroxetine, has also been shown to have analgesic properties in patients with neuropathic pain.<sup>130</sup> These drugs have been reported to be effective in treating continuous dysesthesias, as well as intermittent lancinating dysesthetic pain. The doses used for analgesia are far below those needed to produce an antidepressant effect. The analgesic properties of these drugs appear to occur independent of their mood-altering effects. Patients should be started on low doses of 10 to 25 mg and titrated up to achieve adequate analgesia in a 2- to 4-week trial. Blood levels should be measured to determine both patient compliance and drug absorption, because of wide individual variation. Patients who are unable to tolerate amitriptyline, or who are predisposed to its sedative, anticholinergic or hypotensive effects, should be considered for a trial with a secondary amine tricyclic antidepressant, or a serotonin selective reuptake inhibitor such as paroxetine. In the management of cancer patients with pain, the antidepressant drugs are the first-line therapeutic approach for neuropathic pain, and every attempt should be made to provide the patient with a several-week trial before discontinuing these drugs.

### *Anticonvulsants*

The role of anticonvulsants in the management of patients with neuropathic pain is based, in part, on the fact that the mode of action is to stabilize membranes and alter sodium and calcium influx.<sup>130,131</sup> Many patients with neuropathic pain complain of paroxysmal, brief lancinating pains. To date, clinical experience with the anticonvulsants has been positive. The drugs most commonly used include gabapentin, carbamazepine, phenytoin, valproate, and clonazepam. Gabapentin is considered the first-line anticonvulsant to manage neuropathic pain. Controlled trials in diabetic neuropathy, postherpetic neuralgia, and acquired immunodeficiency syndrome neuropathy demonstrate the effectiveness of this agent in reducing pain. Doses range from 900 to 1800 mg/d.<sup>131</sup> The major drug side effect is sedation. Patients should be started at 300 mg/d and rapidly titrated to 900 mg. Pain relief up to 30% to 50% of patients has been suggested. Clinical studies with carbamazepine demonstrate efficacy, but the utility of this drug in the cancer population is limited by its potential to produce bone marrow suppression, particularly leukopenia. The dosing guidelines used for the treatment of seizures are suggested in managing neuropathic pain. Each of the drugs should be initiated at low doses and gradually titrated upward. There is anecdotal experience to suggest that using intravenous loading doses of phenytoin for patients in an acute crisis with severe lancinating pain may be of clinical value. Gabapentin was not effective in drug trials in neuropathic pain. Both valproate and clonazepam have been reported anecdotally to be useful in neuropathic pain, but these are considered third-line agents in this patient population. Currently, there are no data to relate the plasma level and pain relief with any of these drugs. As previously stated, sequential trials are necessary to identify the most useful agent. With the use of baclofen, which is generally well tolerated, doses should begin at 5 mg two or three times a day, with titrations upward, with the highest reported doses between 100 to 150 mg/d titrated

to the individual responses of the patient.<sup>132</sup>

### **Local Anesthetics**

The use of both brief intravenous local anesthetic infusions (lidocaine), as well as maintenance oral anesthetic drugs, have demonstrated some efficacy in the management of chronic neuropathic pain, particularly in those patients with both lancinating and continuous dysesthesias. Mexiletine is the oral local anesthetic for which there are pilot data to support its analgesic efficacy.<sup>133</sup> The initial dose of mexiletine is low, at 150 mg/d, with gradual upward dose titration. Electrocardiograms should be monitored at higher doses, and blood levels of mexiletine may be useful to prevent toxicity. Currently, there are no good data available to predict what patient might respond to the use of oral local or intravenous anesthetics, as have been done in the use of brief local anesthetic infusions to determine control of cardiac arrhythmias.

Epidural local anesthetics (bupivacaine, lidocaine) have been most widely used to manage neuropathic pain either alone or in combination with opioid. Alternatively, the use of brief intravenous infusions of lidocaine may be helpful in patients who have an opioid-refractory continuous dysesthesia that has not responded to an antidepressant or anticonvulsant.<sup>134</sup> These drugs clearly serve as a second-line approach, with individualized therapy the rule.

**CUTANEOUS LOCAL ANESTHETICS.** The use of cutaneous anesthesia has been suggested to be most helpful in patients who have significant allodynia and marked hyperesthesia. The use of the topical application of a local anesthetic, such as a eutectic mixture of local anesthetics, has been demonstrated to be efficacious in patients with postherpetic neuralgia.<sup>135</sup> The cream should be applied under an occlusive dressing, to increase skin penetration and augment analgesic efficacy. The use of high-concentration lidocaine (5% and 10%) has also been reported to be effective in this population of patients.<sup>136</sup>

### **Corticosteroids**

A series of controlled and uncontrolled surveys have demonstrated that the use of chronic corticosteroid therapy to reduce pain in patients with breast and prostate cancer improves quality of life.<sup>7c,137,138</sup> In a controlled study of corticosteroid use in patients with far-advanced disease, transient improvement in appetite, analgesia, and mood were noted, but they were not sustained after the initial effect.<sup>139</sup> The major indications for corticosteroid use include refractory neuropathic pain, bone pain, pain associated with capsular expansion or duct obstruction, and headache due to increased intracranial pressure. In certain cancer pain syndromes, such as epidural cord compression, 85% of patients receiving 100 mg of dexamethasone as part of their radiation therapy protocol reported significant pain relief associated with marked reduction in analgesic requirements.<sup>7c</sup> Similarly, in patients with tumor infiltration of the brachial and lumbosacral plexus, corticosteroids provided additive analgesic effects. The risk of adverse effects associated with corticosteroid therapy varies with the duration. Long-term use may be associated with gastrointestinal toxicity and acute psychosis. A wide range of doses have been suggested, including doses of 30 mg/d in patients with prostate cancer, which was effective in providing improved quality of life and reduced pain. As stated, with epidural cord compression, initial doses of 100 mg with maintenance doses of 16 mg have been associated with effective analgesia. In our experience, the use of 16 mg as a loading bolus and rapid titration to lower doses of approximately 4 mg/d is one approach commonly used in the refractory chronic pain patient with advanced disease.

### **Other Adjuvant Drugs**

There are a wide variety of other drugs that have been used to manage neuropathic pain, including benzodiazepines, neuroleptics, a  $\alpha_2$ -adrenergic agonist drugs, NMDA antagonists, and peptides. Of the benzodiazepines, clonazepam is commonly used in patients with lancinating or paroxysmal pain.<sup>140</sup> The use of these drugs must be balanced with their potential for somnolence and cognitive impairment. They serve as second- to third-line therapy in patients who have not responded to antidepressant or anticonvulsant drug therapy. Of the neuroleptics, pimozide has been reported to be analgesic in patients with trigeminal neuralgia.<sup>141</sup> Methotrimeprazine has been demonstrated to have analgesic properties comparable with morphine.<sup>142</sup> This drug has sedative, anxiolytic, and antiemetic properties and is commonly used in patients who have excessive opioid side effects. It provides analgesia by a nonopioid mechanism.

Coadministration of these drugs with opioids can often be effective in patients with neuropathic pain. Of the  $\alpha_2$ -adrenergic agonist drugs, clonidine has been demonstrated to be analgesic in controlled trials.<sup>143</sup> It can be used by either the oral or transdermal route and has been reported to be specifically effective in patients with dysesthetic pain, who demonstrate sympathetic hyperactivity. Following intrathecal administration, clonidine was reported to improve pain in patients with intolerable neuropathic pain. Dextromethorphan and ketamine are two commercially available NMDA antagonists. Both have been shown to have analgesic effects in controlled studies.<sup>144,145</sup> The mechanism of action relates to the fact that the NMDA receptor reduces the development of the windup phenomenon, which occurs as a result of changes in the response of central dorsal horn neurons with neuropathic pain. Case reports have suggested that dextromethorphan has been beneficial in selected patients, although a controlled trial of low-dose dextromethorphan had negative results.<sup>145</sup> The drug may be initiated at doses of 40 to 60 mg daily and gradually escalated. Doses of 1 g have been administered safely, at least in the short-term. Studies of dextromethorphan combined with opioids demonstrated added analgesia, suggesting an opioid-sparing effect of the drug. The use of ketamine infusions have been previously well established to produce analgesia, and they have been reintroduced into clinical use as brief infusions for the management of patients with refractory neuropathic pain. Further studies are necessary to demonstrate the safety and efficacy of these treatment approaches in long-term management for chronic neuropathic pain. Oral ketamine in case reports has demonstrated efficacy in cancer patients with pain uncontrolled by other approaches.

Calcitonin has been reported to provide analgesia in patients with sympathetically maintained pain and in the management of acute phantom pain.<sup>146</sup> The mechanism underlying these analgesic effects is unknown, but it has suggested the empiric use of calcitonin in patients with refractory neuropathic pain. The clinical, anecdotal literature suggests that patients be treated initially with a low dose, after initial skin testing to rule out hypersensitivity to this agent, with gradual escalation to a range of 100 to 200 IU/d. Its use chronically has not been assessed, and further studies are necessary to define its place in the treatment of patients with neuropathic pain.

### **Adjuvants for Bone Pain**

Metastatic disease to bone is the most common cause of pain in patients with cancer. Analgesic drug therapy is commonly used to manage the pain during the initial treatment with either chemotherapy or radiation therapy. Numerous investigators have identified a management approach for bone pain, which includes the use of specific surgical palliative approaches, radiotherapeutic approaches, hormonal therapies, and bone resorption inhibitors. Multifocal metastatic bone disease that is refractory to routine treatments may benefit from the use of a series of agents, including the bisphosphonate compounds, gallium nitrate, calcitonin, and strontium 89. The current bisphosphonates most widely studied for the treatment of bone pain include pamidronate and clonidronate.<sup>147,148 and 149</sup> Pamidronate is usually administered as a brief infusion in a starting dose of 60 to 120 mg. Analgesia, if it occurs, usually appears within days, but may accrue for many weeks with repeated infusions. In two studies patients receiving pamidronate in doses of 30 to 60 mg every 2 weeks showed relief of pain in 30% to 60% of patients. Bisphosphonates' analgesic effect appears to be dose dependent. Current recommendations include a regimen of intravenous pamidronate, 60 mg every 2 weeks for at least two or three treatments. If no response, therapy can be discontinued. If effective, a biweekly regimen can be continued. A study of pamidronate, 120 mg intravenously, versus placebo in patients with painful bone metastases revealed a correlation between analgesic response and collagen cross-links suggesting such peptide cross-links may be used to select those patients more likely to achieve improvement in pain with bisphosphonate therapy. The major indication of these drugs is to prevent skeletal morbidity, with data in breast cancer patients and patients with multiple myeloma showing efficacy in reduction of fractures and reduction in bone pain. Clonidronate may be administered orally and has been demonstrated to be efficacious in patients with breast cancer and multiple myeloma.

Calcitonin has also been reported anecdotally to be useful in patients with malignant bone pain, but the appropriate dose and dosing frequency have not been well defined.<sup>150</sup> Gallium nitrate has also been used with some efficacy in patients with metastatic bone pain, but the limited experience has not well defined the appropriate dosing guidelines, and nephrotoxicity has been reported.<sup>151</sup> Strontium 89 is a bone-seeking radiopharmaceutical, recognized as useful in the treatment of bone pain secondary to metastatic disease.<sup>152,153</sup> It is indicated in patients with refractory multifocal pain due to osteoblastic lesions who have a life expectancy greater than 3 months, who have sufficient bone marrow reserve (i.e., a platelet count above 60,000 and a white blood cell count above 2400), and for whom there is no further planned myelosuppressive chemotherapy. The onset of effect is slow and may require several weeks, with peak effects at 2 to 3 months. Bone marrow suppression is the major adverse effect, with irreversible thrombocytopenia.

The selection of any one of these treatments in metastatic bone pain needs to be individualized, with evidence that both the bisphosphonates and strontium 89 have clearly demonstrated efficacy in certain patients.

## Adjuvants to Treat Side Effects

Nausea and vomiting, confusion, sedation, and constipation are common opioid-induced side effects. The use of drugs to manage these have been previously discussed (discussed earlier, in [Anticipate and Treat Side Effects](#)). The use of caffeine, methylphenidate, and dextroamphetamine have all been demonstrated in clinical trials to reduce opioid-induced sedation. Haloperidol is the treatment of choice to manage hallucinations and agitated delirium in patients receiving opioid analgesics. The use of bowel regimens to manage depressed gastrointestinal motility have also been discussed.

## PSYCHOLOGICAL APPROACHES

Psychological approaches should be an integral part of the care of the cancer patient with pain. A series of psychological variables contribute to the cancer pain experience and suffering, such as perception of control, the meaning of pain, fear of death, depressed mood, and hopelessness. The level of psychological distress experienced by each patient varies depending on personality, coping ability, social support, and medical factors. Pain has a profound effect on levels of emotional distress, and psychological factors such as depression and anxiety intensify the pain experience. Measures of emotional disturbance have been reported to be predictors of pain in advancing later stages of cancer. The incidence of pain, depression, and delirium increases with high levels of physical debilitation in advanced disease. Approximately 25% of all cancer patients experience severe depressive symptoms, with the prevalence increasing to 77% in those with advanced illness. Uncontrolled pain is a major factor in cancer suicide.<sup>21</sup>

Various psychological interventions have been advocated for patients with cancer pain. Optimal treatment is multimodal and requires pharmacologic, psychotherapeutic, and cognitive-behavioral approaches. The roles of the psychiatrist, psychologist, and social worker in cancer pain management are well described in the literature.

The goals of short-term psychotherapy are to provide emotional support, continuity, and information and to assist patients in adapting to the crisis. Communication skills are of paramount importance for patient and family, particularly about pain and analgesic issues. The needs of the patient and family must be addressed. Psychotherapy in the cancer pain setting is primarily nonanalytic and focuses on current issues and exploration of reactions to cancer, which often provides insight into other life issues. Group interventions may also be helpful.

A specialized approach called cognitive-behavioral therapy has been used to treat pain disorders, including cancer pain.<sup>154</sup> This approach uses short-term therapeutic interventions based on theoretically and empirically derived principles that can be adapted to each patient's problems and needs. It includes a set of systematic mental and behavioral techniques designed to modify specific emotional, behavioral, and social problems as well as the global experience of pain and distress. Its major goal is to enhance the sense of personal control or self-efficacy. In a multidisciplinary approach to cancer pain, not every patient needs referral for this therapy, but it is useful if all members of the pain team follow a cognitive-behavioral model. Because cognitive-behavioral therapy is a commonsense psychological approach consisting of specific techniques, it can be learned and practiced by any interested clinician, nurse, or social worker who can gain practical training in the use of these techniques and apply them effectively.

Various intervention methods have been developed and are arbitrarily divided into behavioral and cognitive methods for discussion purposes. These approaches must be targeted to each patient's needs.

Behavioral techniques include ways to modify physiologic pain reactions and pain behaviors. Relaxation training can be used by all caregivers who manage patients with pain and cancer. Its mechanism of action includes the reduction of muscle tension, and it can provide the patient with a sense of improved self-control and a calming diversion of attention, breaking the associated pain-anxiety-tension cycle. Techniques range from simple deep-breathing exercises to more specialized methods of biofeedback and hypnosis. Contingency management is another behavioral approach designed to modify dysfunctional pain behaviors and replace them with *well* behaviors.

Cognitive techniques are designed to modify dysfunctional mental processes or to teach adaptive coping strategies. Cognitive coping and cognitive modification are approaches in which distraction, focusing, and perception and interpretation of the meaning of pain are assessed.

## ANESTHETIC AND NEUROSURGICAL APPROACHES

Anesthetic and neurosurgical approaches are most effective in treating patients with well-defined localized pain. [Table 56.1-12](#) and [Table 56.1-13](#) outline the indications for their use. Approximately 10% to 20% of cancer pain patients require these approaches, together with pharmacologic approaches, to provide adequate analgesia.

Site	Procedure	Indications
<b>NEUROABLATIVE PROCEDURES</b>		
Trigeminal	Radiofrequency	Useful to relieve and neuropathic pain from sensory afferents of the oral and facial trigeminal nerves.
Spinal cord	Spinal cord stimulation	Useful to relieve neuropathic pain from brachial, cervical, and lumbosacral plexus and peripheral neuropathy.
	Cordotomy	Useful to relieve pain from the chest and lower extremities. Spinal cord stimulation and cordotomy may be used for pain control.
	Neurolytic	Useful to relieve pain from the chest and lower extremities. Neurolytic agents may be used for pain control.
Brachial plexus	Neurolytic	Useful to relieve pain in the shoulder and regional areas.
Thoracic	Neurolytic	Useful to relieve neuropathic pain in the chest and lower extremities.
Celiac	Celiac ganglion neurolytic	Useful through a minimally invasive approach for diffuse pain.
Perineur	Perineur neurolytic	Useful to pain control of bone metastases in radiation-dependent areas, breast, and prostate.
<b>NEUROSTIMULATORY PROCEDURES</b>		
Regional nerve	Transcutaneous and percutaneous electrical nerve stimulation	Useful to relieve painful dysesthesia from sensory afferents of nerve or trauma (eg, neuropathy).
Spinal cord	Spinal cord stimulation	Useful to relieve neuropathic pain in the chest, abdomen, and lower extremities.
Thalamic	Thalamic stimulation	Useful to relieve neuropathic pain in the chest, abdomen, or lower extremities.

**TABLE 56.1-13.** Neuroablative and Neurostimulatory Procedures for Relief of Pain from Cancer

In a prospective study, Ventafridda and colleagues evaluated two groups of patients for 3 months who presented with intractable cancer pain not responsive to specific anticancer therapies.<sup>22</sup> One group was treated with sequential pharmacologic approaches using the analgesic ladder. The second group was treated with a multimodal approach of analgesic therapy followed by the use of neurolytic blocks or chronic spinal opioid administration. Patients treated with neurolytic procedures combined with pharmacologic therapy showed a statistically significant degree of greater pain relief than those treated with drugs alone by the third week of therapy. However, by 6 weeks, there was no statistical difference between the two groups. Complete pain relief without the need for analgesic drug therapy persisted to 3 months in 29% of the patients who received spinal opiates, 25% treated with celiac ganglion neurolytic block, 24% with percutaneous cordotomy, 12% with chemical rhizotomy, and 7% with gasserian thermorhizotomy. This study demonstrated that although analgesic therapy is the mainstay of treatment, anesthetic and neurosurgical procedures provide an important, but limited, contribution to adequate analgesia. Cherny et al. reported that 17% of patients in a prospective study of 100 cancer patients involved at Memorial Sloan-Kettering Cancer Center were evaluated for anesthetic and neurosurgical approaches with 10% requiring such approaches. One study assessed attitudes of oncologists toward interventional cancer pain treatments. Eighty-one percent of oncologists reported patient referral to pain specialists, yet their familiarity with intrathecal therapy was low, with only 46% referring patients for intrathecal therapy in the previous 6 months, citing the invasive nature of device placement as a drawback by 42% of physicians.<sup>26</sup>

Several factors are important in selecting the appropriate procedure for each patient. Because diffuse pain problems are common in cancer patients and most of the procedures are useful for well-defined localized pain, the role of these approaches is limited at best. Further complicating their use is the limited number of professionals who have expertise in these procedures. As patients become more cognizant of their disease and treatment options, they are often hesitant to undergo neurodestructive procedures. Patients often consider their pain to be an important marker for their disease and are frightened of the potential, although unlikely, complications of these procedures. As a result, these procedures are often performed late in the illness, and full evaluation of their effectiveness and duration of action is limited by the patient's overriding medical problems.

These procedures are often not very effective in managing neuropathic pain, except for the use of local anesthetics, and are most helpful in managing most types of somatic and visceral pain. However, cancer patients often have a mixed somatic, visceral, and neuropathic pain syndrome. We advocate early consideration for the use of some of these anesthetic and neurosurgical procedures in patients to improve their quality of life through adequate pain management.

## LOCAL ANESTHETICS

Anecdotal reports and several controlled studies support the use of cutaneous, subcutaneous, intravenous, intrapleural, and epidural local anesthetics in the management of patients with somatic, visceral, and neuropathic pain.<sup>37</sup>

Intravenous lidocaine should be considered as both a diagnostic and therapeutic approach in patients with neuropathic pain.<sup>155</sup> If such patients obtain an analgesic response, a trial of oral mexiletine or the use of continuous subcutaneous lidocaine should be considered to determine whether prolonged relief may be possible. Although no studies have confirmed that the response to lidocaine predicts a response to mexiletine for pain, a comparable predictive value exists in the cardiac literature, in which intravenous lidocaine's effectiveness in controlling ventricular arrhythmias predicts the usefulness of mexiletine for this same disorder.

Brose and Cousins reported the use of continuous subcutaneous infusions in two patients with cancer-related neuropathic pain, advocating this approach as an alternative in patients who do not respond to standard opioid and adjuvant treatments as well as anesthetic approaches for neuropathic pain.<sup>134</sup>

Intrapleural local anesthetics have been used for acute pain in the chest wall and have been adapted for the management of chronic cancer pain.<sup>156</sup> A subcutaneously tunneled intrapleural catheter offered long-term relief of right upper quadrant pain from hepatic metastases in a patient with significant pain from tumor infiltration of the liver. This novel method offers an alternative approach for patients with local regional pain in the pleural and abdominal regions.
