**INTRAARTERIAL CHEMOTHERAPY.** Intraarterial infusion of chemotherapeutic agents delivered in the neoadjuvant setting, concurrent with radiotherapy, or as salvage treatment for recurrent disease has generated interest for some years because of the distinct arterial supply to the central pelvis.<sup>362,390,391 and 392</sup> A number of drugs have been used in small pilot studies, but 5-FU and cisplatin have been the most popular in this setting. Unfortunately, this technique is difficult and invasive, the toxicity reported in some series has been substantial, and the results have been variable in several small series of patients. However, occasional optimistic reports have maintained some interest in this approach, particularly for concurrent intraarterial chemotherapy and irradiation.

### Stage IVB

Patients who present with disseminated disease almost always have incurable disease. The care of these patients must emphasize palliation of symptoms with appropriate pain medications and localized radiotherapy. Tumors may respond to chemotherapy, but responses are usually short.

**SINGLE-AGENT CHEMOTHERAPY.** Many drugs have been studied for their activity in patients with recurrent or metastatic carcinoma of the cervix. Approximately 20 have yielded response rates (partial and complete) of at least 15% and may be of therapeutic value ( [Table 36.2-11](#) ).<sup>363,393,394,395,396,397,398,399,400,401,402,403,404,405,406,407,408,409,410,411,412,413,414,415,416,417,418,419,420,421,422,423,424,425,426,427,428 and 429</sup>

Drug	Response Rate* (%)
Cyclophosphamide <sup>393,394</sup>	36/203 (18%)
Chlorambucil <sup>395,396</sup>	11/44 (25%)
Ethosuximide <sup>397,398</sup>	25/102 (25%)
Capecitabine <sup>399</sup>	7/36 (19%)
Biochanin A <sup>400,401,402</sup>	47/189 (25%)
Melphalan <sup>403</sup>	4/30 (13%)
Carboplatin <sup>404</sup>	37/176 (21%)

Interferon <sup>419</sup>	20/142 (14%)
Hexamethylmelamine <sup>420</sup>	12/68 (18%)
Ramona <sup>421</sup>	5/28 (18%)
Tegaserod <sup>422</sup>	8/45 (18%)
Podofilox <sup>423,424</sup>	17/68 (25%)

**TABLE 36.2-11.** Cytotoxic Drugs Active Against Squamous Cell Carcinoma of the Cervix (Response Rate <sup>≥</sup>15%)

Several of the platinum compounds have been evaluated in greater detail. Cisplatin has been studied in a variety of doses and schedules.<sup>409,411,412</sup> These studies have demonstrated activity of the drug at a dose of 50 mg/m<sup>2</sup> given intravenously at a rate of 1 mg/min every 3 weeks. Although there appears to be a small but statistically significant increase in the response rate with a doubling of the dose to 100 mg/m<sup>2</sup>, this has not resulted in a detectable improvement in the rates of progression-free or overall survival. More prolonged infusion of the same dose over 24 hours yields a similar response rate with less nausea and vomiting, although the development of more effective antiemetic agents reduces the clinical importance of this observation. The response rates with other platinum compounds (i.e., carboplatin and iproplatin) are lower than those observed with cisplatin, which remains the platinum compound of choice for patients with cervical carcinomas.

Ifosfamide has been studied as a single agent in patients with recurrent cervical cancer in at least five phase II trials.<sup>399,402,403,405,430</sup> Response rates ranged between 33% and 50% in three studies that were conducted in patients who had received no previous chemotherapy.<sup>399,403,405,430</sup> However, the response rates were much lower in two phase II trials that included patients who had received prior systemic chemotherapy, with only three partial responses (8%) in 36 patients.<sup>399,402</sup>

**COMBINATION CHEMOTHERAPY.** Most reports of combination chemotherapy for carcinoma of the cervix have described small, uncontrolled phase II trials of drug combinations that have included at least some agents with known activity. Although response rates have varied widely, data from these phase II studies provide no firm evidence that any of the studied combinations are superior to single-agent therapy for patients with disseminated or recurrent cervical cancer.<sup>431</sup> However, combinations based on ifosfamide and cisplatin and those based on 5-FU and cisplatin have attracted significant interest and deserve further discussion.

Several small phase II studies have evaluated treatment with combinations of ifosfamide and either cisplatin or carboplatin in patients who had not received prior radiotherapy. Response rates for these combinations ranged between 50% and 62% ( [Table 36.2-12](#) ).<sup>404,432,433 and 434</sup> A number of investigators have combined bleomycin with ifosfamide and a platinum compound. Three studies that included patients who had not had prior radiotherapy reported response rates of 65% to 100%.<sup>435,436 and 437</sup> Reports of treatment with these drugs in previously irradiated patients have yielded mixed but generally lower response rates of between 13% and 72%.<sup>434,435,436,437 and 438</sup>

**TABLE 36.2-12.** Platinum-Containing Chemotherapy Combinations Used to Treat Cervical Carcinomas: Contrast between Results in Patients Treated before or after Pelvic Irradiation

Combinations of cisplatin and continuous infusion 5-FU,<sup>439,440</sup> and<sup>441</sup> cisplatin and paclitaxel,<sup>442</sup> or cisplatin and vinorelbine<sup>443</sup> also produce high response rates in previously untreated patients. Again, response rates decrease significantly if patients have had previous irradiation.<sup>440,444</sup>

In 1996, the GOG<sup>445</sup> reported results of a large prospective randomized trial comparing cisplatin alone with cisplatin plus ifosfamide and cisplatin plus mitolactol in patients with advanced or recurrent cervical cancers. The addition of ifosfamide to cisplatin improved the response rate (33% vs. 19%,  $P = .02$ ) and progression-free survival rate (4.6 vs. 3.2 months,  $P < .05$ ), but was associated with significantly greater toxicity (leukopenia, peripheral neuropathy, renal toxicity, and encephalopathy) and did not significantly improve the overall median survival. The addition of mitolactol did not improve the response rate or survival duration. Other phase III randomized trials that are ongoing or have been completed recently will evaluate the benefit of adding bleomycin to cisplatin and ifosfamide and will test the addition of paclitaxel or topotecan to cisplatin.

**PALLIATIVE RADIOTHERAPY.** Localized radiotherapy can provide effective pain relief for symptomatic metastases in bone, brain, lymph nodes, or other sites. A rapid course of pelvic radiotherapy can also provide excellent relief of pain and bleeding for patients who present with incurable disseminated disease.<sup>446,447</sup> and<sup>448</sup>

### Special Problems

#### TREATMENT OF LOCALLY RECURRENT CARCINOMA OF THE CERVIX.

**After Radical Surgery.** Patients should be evaluated for possible recurrent disease if a new mass develops; if, in irradiated patients, the cervix remains bulky or nodular or cervical cytologic findings are abnormal 3 months or more after irradiation; or if symptoms of leg edema, pain, or bleeding develop after initial treatment. The diagnosis must be confirmed with a tissue biopsy, and the extent of disease should be evaluated with appropriate radiographic studies, cystoscopy, proctoscopy, and serum chemistry studies before treatment is administered.

The treatment of choice for patients who have an isolated pelvic recurrence after initial treatment with radical hysterectomy alone is aggressive radiotherapy. Treatment for patients with an isolated central recurrence is similar to that for patients with a primary carcinoma of the vagina. Most patients are treated with external-beam radiotherapy with or without brachytherapy. Implants may need to be inserted under laparoscopic or laparotomy guidance. Pelvic wall recurrences are often treated with external-beam irradiation alone, although intraoperative therapy may contribute to local control in selected patients.<sup>449,450</sup> and<sup>451</sup> Reported survival rates usually range between 20% and 40% for patients treated with radical radiotherapy.<sup>452,453,454</sup> and<sup>455</sup> Patients with central recurrence usually have a better prognosis than those with pelvic wall recurrence. Ijaz and colleagues<sup>452</sup> reported a survival rate of 69% 5 years after radical radiotherapy for 16 patients who had isolated vaginal recurrences that did not involve the pelvic wall. Only 18% of patients who had recurrences that were fixed to the pelvic wall or that involved pelvic lymph nodes survived 5 years. Several authors have reported significantly lower salvage rates for patients with locally recurrent adenocarcinoma.<sup>452,456</sup> Thomas and colleagues<sup>457</sup> reported encouraging results in a group of patients treated with radiation and concurrent chemotherapy, but further studies will be needed to determine whether this approach is superior to radiotherapy alone.

**After Definitive Irradiation.** In some cases, patients who have an isolated central recurrence after radiotherapy can be cured with surgical treatment. Because the extent of disease may be difficult to evaluate and the risk of serious urinary tract complications from pelvic surgery is high after high-dose radiotherapy, surgical salvage treatment usually requires a total pelvic exenteration. Less extensive operations, such as radical hysterectomy or anterior exenteration, are reserved for selected patients with small tumors confined to the cervix or lesions that do not encroach on the rectum, respectively.<sup>458,459</sup> and<sup>460</sup>

Tumor involvement of the pelvic sidewall is a contraindication to exenteration but may be difficult to assess if there is extensive radiation fibrosis. The triad of unilateral leg edema, sciatic pain, and ureteral obstruction almost always indicates unresectable disease on the sidewall. Although advanced age is usually considered a contraindication to pelvic exenteration, Matthews and colleagues<sup>461</sup> reported a 5-year survival rate of 46% and an operative mortality of 11% for selected patients who underwent exenteration at the age of 65 years or older compared with a 5-year survival rate of 45% and an operative mortality of 8.5% for younger patients. In all cases, preparation for total pelvic exenteration must involve careful counseling of the patient and family regarding the extent of surgery and postoperative expectations.

The operation begins with a thorough inspection of the abdomen for evidence of intraperitoneal spread or disease in the pelvic sidewall or paraaortic lymph nodes. Despite careful preoperative evaluation, approximately 30% of operations are aborted intraoperatively.<sup>462</sup> Frozen section biopsies are done of suspicious areas. If the biopsy findings are negative, the surgeon proceeds to remove the bladder, rectum, vagina, uterus, ovaries, fallopian tubes, and all other supporting tissues in the true pelvis. A urinary conduit, a transverse or sigmoid colostomy, and a neovagina are created.

Postoperative recuperation may take as long as 3 months. The surgical mortality is less than 10%, with most postoperative complications and deaths related to sepsis, pulmonary thromboembolism, and intestinal complications such as small bowel obstruction and fistula formation.<sup>463,464</sup> Gastrointestinal complications may be reduced by using unirradiated segments of bowel and by closing pelvic floor defects with omentum, rectosigmoid colon, or myocutaneous flaps.<sup>267</sup> Advances in low colorectal anastomosis and techniques for creating continent urinary reservoirs have improved the quality of life for selected patients.<sup>465,466</sup> and<sup>467</sup>

The 5-year survival rates for patients who undergo anterior or total pelvic exenteration are 33% to 60% and 20% to 46%, respectively.<sup>459,465,468,469</sup> and<sup>470</sup> Several groups are exploring the role of intraoperative irradiation to treat patients with recurrent disease that involves the pelvic wall.<sup>449,450</sup> and<sup>451</sup> However, patients with bulky central disease, positive lymph nodes, or 1 year or less between initial treatment and exenteration have a poor prognosis.<sup>469</sup>

**TREATMENT AFTER SIMPLE HYSTERECTOMY WITH UNSUSPECTED INVASIVE CANCER.** Every patient who undergoes a planned hysterectomy should be carefully screened to rule out invasive cervical cancer before the procedure.<sup>471</sup> However, whenever an unexpected diagnosis of invasive cancer is made in a hysterectomy specimen, the patient should be immediately referred for additional treatment because pelvic radiotherapy produces excellent pelvic disease control rates and survival rates for most patients in this setting.<sup>472,473,474</sup> and<sup>475</sup>

Patients may be classified according to the extent of disease at the time of referral for posthysterectomy treatment into the following groups: (1) microinvasive cancer, (2) tumor confined to the cervix with negative surgical margins, (3) positive surgical margins but no gross residual tumor, (4) gross residual tumor by clinical examination documented by biopsy, and (5) patients referred for treatment more than 6 months after hysterectomy (usually for recurrent disease).<sup>472</sup> In a report of the results of radiotherapy in 123 patients, Roman et al.<sup>475</sup> reported survival rates of 79% and 59% for patients in groups 2 and 3, respectively. In contrast, the survival rate for 30 patients with gross disease (groups 4 and 5) was 41% ( $P = .0001$ ).

Patients with less than 3 mm of invasion without lymph-vascular invasion usually require no treatment after simple hysterectomy. Patients with more extensive involvement who have negative margins require 45 to 50 Gy of pelvic radiotherapy to treat the pelvic nodes and paracolpal tissues. Most clinicians follow this with

vaginal intracavitary therapy, delivering an additional vaginal surface dose of 30 to 50 Gy. Patients with positive margins may benefit from a somewhat higher dose of external-beam irradiation through reduced fields designed to include the region at highest risk (e.g., parametria, posterior bladder wall). Patients in groups 3 and 4 reported in the series by Roman and colleagues<sup>475</sup> were usually treated with 65 Gy of external-beam therapy with or without intracavitary therapy. The role of interstitial therapy in this setting is not well documented.

## CARCINOMA OF THE CERVICAL STUMP

Although supracervical hysterectomy was once a popular treatment for benign uterine conditions, enthusiasm for the procedure has declined since the 1950s and it is rarely performed today. As a result, carcinomas of the cervical stump are less common than they once were and are usually seen in elderly women. Tumors are usually subclassified as coincidental tumors (diagnosed within 2 years of supracervical hysterectomy) or true cervical stump carcinomas (diagnosed less than 2 years after hysterectomy). Tumors classified as coincidental were probably present at the time of supracervical hysterectomy and are said to have a relatively poor prognosis, although the number of cases in most series is small.

The natural history, staging, and workup of cervical stump carcinomas are the same as for carcinomas of the intact uterus. If possible, the cervix should be probed at the beginning of treatment to determine the length of the uterine canal. MRI may be an important aid to treatment planning in these patients.

Patients with stage IA1 disease may be treated with simple trachelectomy, and selected stage IA2 or small stage IB tumors may be treated with radical trachelectomy and pelvic lymph node dissection. However, most patients are treated with irradiation alone using a combination of external-beam therapy and brachytherapy.

The altered geometry and short uterine canal in these patients complicate treatment planning. However, in most cases the endocervical canal is 2 cm or longer and, after a course of external-beam irradiation, patients can be adequately treated with intracavitary therapy. The endocervical canal is usually loaded with 20 to 30 mgRaEq of cesium, depending on the length of the endocervical canal, and vaginal ovoids are loaded according to their diameter and position. Remote afterloading systems provide somewhat greater flexibility in source loading. If the endocervical canal cannot accommodate any sources, a boost dose may be delivered to the tumor with interstitial therapy, transvaginal irradiation, or reduced fields of external-beam irradiation. However, brachytherapy should be used whenever possible. Barillot et al.<sup>476</sup> reported a survival rate of 81.5% for patients treated with combined brachytherapy and external-beam irradiation versus 38.5% for those treated with external-beam irradiation alone. Several authors have advocated interstitial therapy, using techniques described for apical vaginal carcinomas, for patients with bulkier lesions. Vaginal ovoids alone rarely deliver an adequate dose to the cervix.

Most investigators have reported survival rates similar to those for patients with carcinomas of the intact cervix. In a series of 263 patients, Miller and colleagues<sup>477</sup> reported survival rates of 91%, 77%, and 40% for patients with stage I, II, and III tumors, respectively. Similar survival rates have been reported in other large series.<sup>476,478,479</sup> Miller and colleagues<sup>477</sup> reported a somewhat higher complication rate for cervical stump carcinomas than for carcinomas of the intact cervix, but others have not observed this difference.<sup>476,479</sup>

## CARCINOMA OF THE CERVIX DURING PREGNANCY

Estimates of the incidence of invasive cervical cancer during pregnancy range from 0.02% to 0.9%.<sup>480,481</sup> Estimates of the incidence of pregnancy in patients with invasive cervical cancer usually range between 0.5% and 5.0%. Hacker and colleagues<sup>480</sup> reported an incidence of cervical carcinoma *in situ* of 0.013% in pregnant women.

Diagnosis is often delayed because bleeding is erroneously attributed to pregnancy-related complications. All pregnant patients should have a careful pelvic examination and Pap smear at their first antenatal visit. Any suspicious lesion should be biopsied. If the Pap smear result is positive for malignant cells and the diagnosis of invasive cancer cannot be made with colposcopy and biopsy, a diagnostic conization may be necessary. Because conization subjects the mother and fetus to complications, it should be performed only in the second trimester and only in patients with inadequate colposcopy and strong cytologic evidence of invasive cancer. Conization in the first trimester of pregnancy is associated with an abortion rate of up to 33%.<sup>480,482</sup> Conservative conization under colposcopic guidance may reduce the risk.<sup>483</sup>

It appears to be safe to delay definitive treatment of patients with carcinoma *in situ* or stage IA disease until the fetus has matured.<sup>480,481,484</sup> Patients with less than 3 mm of invasion and no LVSI may be followed to term and delivered vaginally. A vaginal hysterectomy may be performed 6 weeks after childbirth if further childbearing is not desired. Patients with 3 to 5 mm of invasion and those with LVSI may also be followed to term. The infant may be delivered by a cesarean section, which is followed immediately by modified radical hysterectomy and pelvic lymph node dissection.<sup>485</sup>

Patients with more than 5 mm of invasion should be treated as having frankly invasive carcinoma of the cervix. Treatment depends on the stage of gestation and the wishes of the patient. Modern neonatal care affords a 75% survival rate for infants delivered at 28 weeks of gestational age and 90% for those delivered at 32 weeks. Fetal pulmonary maturity can be determined by amniocentesis, and prompt treatment can be instituted when pulmonary maturity is documented. It is probably wise to avoid delays in therapy of more than 4 weeks whenever possible although this guideline is controversial.<sup>481,482,486</sup> For most women with stage IB1 tumors, the recommended treatment is classic cesarean section followed by radical hysterectomy with pelvic lymph node dissection. There should be a thorough discussion of the risks and options with both parents before any treatment is undertaken.

Patients with stage II to IV tumors and some patients with bulky stage IB cervical cancers should be treated with radiotherapy. If the fetus is viable, it is delivered by classic cesarean section and radiotherapy is begun postoperatively. If the pregnancy is in the first trimester, external-beam irradiation can be started with the expectation that spontaneous abortion will occur before the delivery of 40 Gy. In the second trimester, a delay of therapy may be entertained to improve the chances of fetal survival. If the patient wishes to delay therapy, it is important to ensure fetal pulmonary maturity before delivery is undertaken.

Compared with other cervical cancer patients, those with cervical cancer during pregnancy have slightly better overall survival because an increased proportion have stage I disease. The diagnosis of cancer in the postpartum period tends to be associated with a more advanced clinical stage and a corresponding decrease in survival. However, studies differ in their conclusions about whether pregnancy has an independent influence on the prognosis of patients with cervical cancer.<sup>481,487,488</sup> Patients who are diagnosed with invasive cervical cancer shortly after a vaginal delivery appear to be at risk for recurrence in the site of their episiotomy. At least 13 cases demonstrating this unusual pattern of failure have been reported.<sup>489,490 and 491</sup>

## CARCINOMA OF THE VAGINA

Carcinomas of the vagina are rare, accounting for only approximately 2% to 3% of gynecologic malignancies.<sup>492,493</sup> According to FIGO, cases should be classified as vaginal carcinomas only when "the primary site of the growth is in the vagina."<sup>494</sup> A tumor that is limited to the urethra should be classified as a primary urethral cancer, and a tumor that has extended from the vulva to involve the vagina should be classified as a primary vulvar cancer. Also, according to FIGO, any tumor that has extended to the cervical portio and has reached the area of the external os should be classified as a cervical carcinoma. For this reason, in patients with an intact uterus, it is probable that many tumors that originated in the apical vagina are actually classified as cervical cancers. This may explain why a large percentage (30% to 50%) of patients diagnosed with vaginal carcinoma have had a prior hysterectomy (preventing classification of their tumors as primary cervical cancers).<sup>495,496,497 and 498</sup>

More commonly, the vagina is a site of metastasis or direct extension from tumors originating in other genital sites, such as the cervix or endometrium, or from extragenital sites, including the rectum and bladder.

## EPIDEMIOLOGY

Vaginal intraepithelial neoplasia (VAIN) often accompanies CIN and is thought to have a similar etiology.<sup>499</sup> VAIN lesions are more often seen in the upper third of the vagina and may be either extensions from adjacent areas of CIN or separate lesions.<sup>500</sup> Kalogirou and associates<sup>501</sup> found 41 cases of VAIN in 993 patients followed with cytologic examination and colposcopy after hysterectomy for CIN. Most VAIN lesions were in the upper vagina, particularly in the vault angles of the suture line.

Because the vagina does not have a transformation zone of immature epithelial cells susceptible to HPV infection, HPV-induced vaginal lesions are thought to arise in areas of squamous metaplasia that develop during healing of mucosal abrasions caused by coitus, tampon use, or other trauma.<sup>499</sup> Invasive vaginal carcinoma has also been associated with chronic irritant vaginitis, particularly that caused by chronic use of a vaginal pessary.<sup>502</sup> Schraub et al.<sup>503</sup> reported that 80% of vaginal cancers arising in patients who used pessaries were in the posterior fornix or posterior wall of the vagina. Investigators have also reported an association between vaginal carcinoma and infection with HPV similar to that found for invasive cervical cancer.<sup>502,504</sup> Ikenberg and colleagues<sup>504</sup> found HPV DNA in 10 of 18 patients with invasive vaginal cancer.

Pride and colleagues<sup>505</sup> suggested that pelvic irradiation might be a predisposing factor in some cases. However, viral and other risk factors independent of the mode of treatment undoubtedly place some of these patients at risk for multiple primary tumors. In a review of 301 patients with vaginal cancer, Chyle and associates<sup>495</sup> found that 56 had a prior history of carcinoma *in situ* of the cervix, 22 had a history of invasive cervical cancer, and two had prior *in situ* carcinomas of the vagina.

Primary invasive carcinoma of the vagina is predominantly a disease of elderly women, with 70% to 80% of cases presenting in women older than 60 years.<sup>494</sup> However, FIGO data<sup>494</sup> suggest that the age of peak incidence may have decreased since the early 1960s, when the highest incidence was among women in their 80s. Except for clear cell carcinomas, which are associated with maternal diethylstilbestrol (DES) exposure, invasive vaginal carcinomas are extremely rare in women younger than 40 years.<sup>494,506</sup>

In 1971, Herbst and colleagues<sup>507</sup> first reported a highly significant association between clear cell carcinomas of the vagina and maternal ingestion of DES during pregnancy. This led to the establishment of a registry to gather information about cases of clear cell carcinoma in the United States. The peak number of DES-associated cases occurred in 1975, when 33 were reported to the registry.<sup>508</sup> The peak risk period for exposed women in the United States is between the ages of 15 and 22 years; the youngest patient reported was 7 years old. The oldest patient reported so far was 42 years old at diagnosis, but the risk to women older than 40 years is still unknown because women in the first exposed cohort are just reaching their fifth decade. Because only approximately 1 of every 1000 women exposed to DES *in utero* develops clear cell carcinoma,<sup>509</sup> investigators have tried to define other risk factors for development of the disease. The risk of clear cell carcinoma has been associated with initiation of DES early during pregnancy, a maternal history of early miscarriage, and premature birth.<sup>508,510</sup> Sharp and Cole<sup>510</sup> found a correlation between adolescent obesity in exposed girls and the development of vaginal clear cell carcinoma. Infection with HPV may be a cofactor in some cases.<sup>511</sup> Among 14 cases of clear cell carcinoma studies by Waggoner and colleagues,<sup>511</sup> three contained HPV 31 DNA; ten of the remaining HPV-negative tumors had p53 protein detected by immunohistochemistry, suggesting a mutation of *p53*.

Although the risk of clear cell carcinoma of the vagina is small in DES-exposed women, 45% of these patients have areas of vaginal adenosis, and 25% have structural abnormalities of the uterus, cervix, or vagina. Fortunately, awareness of the risks of *in utero* DES exposure has led to a dramatic reduction in the use of high doses of estrogen to prevent miscarriage, and the number of young women who need to be followed for this problem is declining. There is as yet no evidence that DES-exposed women are at risk for malignancies other than clear cell carcinoma.<sup>512</sup>

## NATURAL HISTORY AND PATTERN OF SPREAD

Approximately 50% of vaginal cancers arise in the upper third of the vagina.<sup>495,498,506,513</sup> Although Plentl and Friedman<sup>513</sup> reported that tumors arise more commonly on the posterior wall, more recent reviews have reported a more even distribution of lesions arising on the anterior, posterior, and lateral walls.<sup>495,498</sup> Tumors may exhibit an exophytic or ulcerative, infiltrating pattern of growth.

Tumors may invade directly to involve adjacent structures such as the urethra, bladder, and rectum. Despite the proximity of these structures, fewer than 10% of vaginal cancers are found to be stage IVA at presentation.<sup>494,498,506,514</sup> However, extensive infiltration of the suburethra or rectovaginal septum is common and frequently influences treatment planning. Vaginal cancers may also spread laterally to the paravaginal space and pelvic wall. Although tumors arising in the vagina undoubtedly can spread superiorly to involve the cervix and uterus, this usually leads to their classification as cervical cancers, according to FIGO convention.

The vagina is supplied with a fine anastomosing network of lymphatics in the mucosa and submucosa. Despite the continuity of lymphatic vessels within the vagina, Plentl and Friedman<sup>515</sup> found a regular pattern of regional drainage from specific regions of the vagina. The lymphatics of the vaginal vault communicate with those of the lower cervix, draining laterally to the obturator and hypogastric nodes. The lymphatics of the posterior wall anastomose with those of the anterior rectal wall, draining to the superior and inferior gluteal nodes. The lymphatics of the lower third of the vagina communicate with those of the vulva and drain either to the pelvic nodes or with the vulvar lymphatics to the inguinofemoral lymph nodes. Plentl and Friedman summarized their description of the lymphatic drainage of the vagina with the comment that, except for the lateral external iliac group, all lymph nodes of the pelvis may at one time or other serve as primary sites of regional drainage for vaginal lymph.<sup>515</sup>

Few data are available concerning the incidence of spread of vaginal cancer to the pelvic lymph nodes. In a review of early reports, Plentl and Friedman<sup>515</sup> quoted an overall incidence of positive nodes of 21%. More recent studies suggest that the incidence of positive pelvic nodes in patients with stage II disease is at least 25% to 30%, emphasizing the importance of regional treatment for these patients.<sup>516,517</sup> Inguinal node metastases generally occur only in patients whose tumors involve the lower third of the vagina.<sup>495,514</sup>

The most frequent site of hematogenous metastasis is the lung. Less frequently, vaginal cancers may metastasize to liver, bone, or other sites.<sup>494,495</sup>

## PATHOLOGY

Eighty percent to 90% of primary vaginal malignancies are squamous cell carcinomas.<sup>492,494</sup> Grossly, these tumors may be nodular, ulcerative, or exophytic plaques of any size. Histologically, they are similar to squamous tumors from other sites. Approximately one-third of these tumors are keratinizing, and more than one-half are nonkeratinizing, moderately differentiated lesions.

Verrucous carcinoma is an uncommon variant of squamous cell carcinoma that presents as a warty, fungating mass.<sup>518</sup> Histologically, verrucous carcinoma is composed of large papillary fronds covered by dense keratin. Its deep margin creates a pushing border of well-oriented rete ridges. This tumor rarely metastasizes but can extensively infiltrate into surrounding tissues, including the rectum and coccyx. Wide surgical excision is the treatment of choice in this situation.

Approximately 5% to 10% of primary vaginal neoplasms are adenocarcinomas, although the incidence may vary with the proportion of women in the population who were exposed to DES *in utero*.<sup>492,494,507</sup> Clear cell carcinomas of the vagina are usually polypoid but may have tubulocystic or solid patterns. Adenocarcinomas not associated with DES exposure occur primarily in postmenopausal women. The differential diagnosis of adenocarcinoma occurring in the vagina is often difficult, as it must be distinguished from metastatic tumors originating in other sites.<sup>519</sup> Histologic patterns include clear cell, mucinous, adenosquamous, papillary, and undifferentiated. It has been hypothesized that these tumors may arise in foci of adenosis, from mesonephric rests, or from foci of endometriosis in the vagina.<sup>520,521</sup>

Primary small cell carcinomas of the vagina are rare; fewer than 20 cases have been reported in the literature.<sup>522,523</sup> and <sup>524</sup> They are histologically indistinguishable from neuroendocrine small cell carcinomas of the lung or cervix and like these tumors may coexist with squamous or adenocarcinoma elements.

Primary vaginal melanomas represent approximately 3% of primary vaginal cancers and fewer than 20% of genital melanomas.<sup>492,494</sup> Primary vaginal melanomas are thought to arise from melanocytes in areas of melanosis or atypical melanocytic hyperplasia.<sup>525</sup> They usually originate in the lower third of the vagina and occur at a mean age of 55 years, with an age range of 22 to 83 years. They tend to have a poorer prognosis than vulvar melanomas, with 5-year survival rates of 15% to 20% after treatment with surgery, radiation, or both.<sup>526,527</sup>

Approximately 3% of vaginal cancers are sarcomas; approximately two-thirds of these are leiomyosarcomas, but endometrial stromal sarcomas, malignant mixed Müllerian tumors, and other types have been reported.<sup>528</sup> Embryonal rhabdomyosarcoma (sarcoma botryoides) is a highly malignant sarcoma that occurs in children up to 6 years of age. This tumor usually forms soft nodules that fill and protrude from the vagina. The prognosis for children with this tumor has improved with the use

of multimodality therapy including surgery, chemotherapy, and radiation. <sup>529</sup>

## DIAGNOSIS, CLINICAL EVALUATION, AND STAGING

Most patients with VAIN and approximately 10% to 20% of patients with invasive disease are asymptomatic at presentation; in these cases carcinoma is usually diagnosed during investigation of an abnormal Pap smear result. Colposcopic evaluation in the case of abnormal cytologic findings should always include a detailed examination of the entire vagina and cervix, even when there is an obvious cervical lesion, because patients can present with multiple areas of abnormality. Women who have persistent positive Pap smear results after treatment of CIN should be examined carefully for VAIN.

Approximately 50% to 60% of patients with invasive cancer present with abnormal vaginal bleeding, frequently after coitus or vaginal douching. Patients may also present with complaints of vaginal discharge, a palpable mass, dyspareunia, or pain in the perineum or pelvis. <sup>506,530,531 and 532</sup>

According to FIGO, the rules for clinical staging of patients with carcinoma of the vagina are the same as those for clinical staging of patients with cervical cancer. <sup>494</sup> The workup should include careful examination of the cervix and vagina and bimanual examination. All patients should have chest roentgenography, complete blood count, and biochemical profile. Cystoscopy and ureteroscopy are strongly recommended for patients with large tumors or tumors involving the anterior vaginal wall. Proctoscopy is indicated for lesions involving the posterior vaginal wall. A barium enema or skeletal films may also be needed in selected cases. The kidneys should be localized and the rare case of hydronephrosis ruled out with either classical intravenous pyelography or a pyelography obtained with a CT scan. However, it should again be emphasized that the FIGO rules for clinical staging prohibit the use of other information obtained from CT, MRI, lymphangiography, or surgical staging to change clinical stage even though these studies may aid in the determination of disease extent.

The FIGO categories for staging of vaginal cancers are listed in [Table 36.2-13](#).<sup>494</sup> Because this is a clinical staging system, the classification of lesions as stage I or II is probably subjective. In general, thin (less than 0.5 cm), relatively exophytic tumors tend to be classified as stage I, and thicker, infiltrating tumors and those with obvious paravaginal nodularity tend to be classified as stage II. Perez and colleagues <sup>514</sup> use a modification of the FIGO system that distinguishes tumors that infiltrate the parametrium (stage IIB) from those with paravaginal submucosal extension only (stage IIA). They reported a 5-year survival rate of 55% for patients whose tumors were classified as stage IIA versus 35% for those whose tumors were classified as stage IIB. <sup>514</sup>

Stage 0	Carcinoma in situ, intraepithelial carcinoma.
Stage I	The carcinoma is limited to the vaginal wall.
Stage II	The carcinoma has involved the subvaginal tissues but has not extended onto the pelvic wall.
Stage III	The carcinoma has extended onto the pelvic wall.
Stage IV	The carcinoma has extended beyond the true pelvis or has clinically involved the mucosa of the bladder or rectum. Bulbous edema as such does not permit a case to be allotted to stage IV.
Stage IVA	Spread of the growth to adjacent organs, direct extension beyond the true pelvis, or both.
Stage IVB	Spread to distant organs.

**TABLE 36.2-13.** International Federation of Gynecology and Obstetrics Clinical Staging of Carcinoma of the Vagina

FIGO does not specify how tumors should be classified when the inguinal nodes are clinically positive. The stage descriptions state that tumors that have spread beyond the true pelvis should be classified as stage IVB, but many clinicians ignore inguinal node status in assigning stage and thus generate confusion in the literature on this subject. The American Joint Committee on Cancer<sup>533</sup> has suggested a TNM staging system that classifies patients with unilateral inguinal metastases as N1 (stage III) and those with bilateral nodes as N2 (stage IVA), but this system is rarely used. Patients with inguinal metastases are sometimes cured with locoregional treatment; Kucera and Vavra<sup>530</sup> report uncorrected 5-year survival rates of 29% for patients with clinically suspicious inguinal nodes and 44% for patients with clinically negative groins.

## PROGNOSTIC FACTORS

The rates of local control, distant metastasis, and survival in vaginal carcinoma are all correlated strongly with tumor stage ( [Table 36.2-14](#) ).<sup>495,506,514,530,532,534,535,536 and 537</sup> Tumor size also appears to be an important predictor of outcome. Chyle and colleagues <sup>495</sup> reported a higher rate of local and distant failure for tumors larger than 5 cm in diameter; Kirkbride and associates<sup>506</sup> reported a significantly better survival rate for patients with tumors smaller than 4 cm in diameter; and Stock and colleagues<sup>498</sup> reported better survival when disease was limited to one-third of the vaginal canal.

**TABLE 36.2-14.** Carcinoma of the Vagina: Survival Rates According to Clinical Stage

Most investigators have been unable to find a correlation between tumor site and outcome. <sup>495,506,514,530,532,534,535</sup> However, Chyle and colleagues<sup>495</sup> reported higher rates of local recurrence and overall relapse in patients with posterior wall lesions, and Kucera and Vavra <sup>530</sup> reported a better survival rate for patients whose tumors involved the upper third of the vagina. Tumors that involve the entire vagina tend to have a poorer prognosis, probably reflecting the larger size of these lesions. <sup>495,530</sup> Exophytic tumors may have a better prognosis than those with infiltrating or necrotic lesions. <sup>514</sup> Investigators disagree about the influence of histologic grade and type on outcome. Several investigators have reported a correlation between increasing grade of squamous carcinomas and recurrence, <sup>495,538,539</sup> whereas others have found no correlation. <sup>497,505,540</sup> Chyle and coinvestigators<sup>495</sup> reported significantly poorer survival and local control rates for patients with adenocarcinoma, but other investigators<sup>506,517,540</sup> found no difference in outcome for patients with squamous carcinomas or adenocarcinomas.

## TREATMENT

### Stage 0

Patients with only HPV infection or VAIN 1 do not require treatment. These lesions often regress spontaneously, are frequently multifocal, and recur quickly after attempts at ablative therapy. VAIN 2 is usually treated by laser ablation. However, VAIN 3 is more likely to harbor an invasive lesion. Hoffman and colleagues <sup>499</sup> reported finding occult invasion in upper vaginectomy specimens from 9 (28%) of 32 patients who had surgery for VAIN 3. It has been recommended that VAIN 3

lesions located in dimples of the vaginal cuff of older patients be locally excised before definitive treatment to rule out occult invasion. <sup>541</sup>

VAIN 3 lesions that have been adequately sampled to rule out invasion can be treated with laser ablation. Cryosurgery should not be used in the vagina because the depth of injury cannot be controlled and inadvertent injury to the bladder or rectum may occur. Superficial fulguration with electrosurgical ball cautery may be used under colposcopic control, with the epithelial tissue wiped away as it is ablated to allow observation of the depth of destruction. Local excision is an excellent method of treatment for small upper vaginal lesions. Rarely, total vaginectomy is required for extensive VAIN 3 lesions. The vagina should then be reconstructed with a split-thickness skin graft. However, this aggressive treatment should not be used for VAIN 2.

Although progression of stage 0 lesions to invasive disease is uncommon, the risk is sufficient to warrant close follow-up of patients treated for VAIN. In a review of 136 cases of carcinoma *in situ* of the vagina, Benedet and Saunders<sup>542</sup> found only four cases (3%) that progressed to invasive cancer with up to 30 years of follow-up. Cheng and colleagues<sup>543</sup> reported four cases of invasive cancer that developed in 35 patients who were followed after wide local excision for VAIN.

VAIN can also be treated effectively with intracavitary radiotherapy, <sup>495,506,514</sup> but this treatment is usually reserved for patients with multifocal, multiply recurrent disease or high operative risk. Treatment is usually delivered using <sup>137</sup>Cs loaded in a plastic vaginal cylinder 3 to 4 cm in diameter. Chyle et al. <sup>495</sup> reported a 17% recurrence rate at 10 years in 37 patients treated with a vaginal surface dose of 70 to 80 Gy. Perez et al. <sup>514</sup> reported only one recurrence (5%) in 20 patients treated with a vaginal surface dose of 60 to 70 Gy. The single vaginal recurrence was distal to the region treated with brachytherapy, and the authors emphasize the importance of treating the entire vagina to avoid marginal recurrences. More recently, some authors have reported results using fractionated high-dose-rate intracavitary therapy to treat VAIN. MacCloud and colleagues<sup>544</sup> reported control of VAIN 3 in 11 of 14 patients followed for 36 to 115 months after treatment; in these patients, the vaginal surface was treated with a total dose of 34 to 45 Gy in four to ten fractions. One patient had progression to invasive disease. The authors observed no severe complications with this treatment. However, Ogino and colleagues<sup>545</sup> reported adhesive vaginitis and rectal bleeding in two patients treated to the entire vagina with a less conservative fractionation schedule.

### Stage I

Radiotherapy is often the treatment of choice for stage I disease because if surgery is used, total vaginectomy or even exenteration may be needed to obtain satisfactory resection margins. However, surgery has a definite role in selected cases. <sup>498</sup> Early tumors that involve the upper posterior vagina can be removed with a radical hysterectomy and partial vaginectomy (if the uterus is *in situ*) or with a radical upper vaginectomy (if the patient has had a prior hysterectomy) and bilateral pelvic lymphadenectomy. Some surgeons advocate broader indications for surgical treatment of stage I disease. <sup>498,517</sup> Stock and associates<sup>498</sup> reported a 5-year disease-free survival rate of 56% for 15 patients with stage I disease treated with surgery alone (local excision, partial vaginectomy, or radical vaginectomy). One patient in whom disease recurred had successful salvage treatment with irradiation, and two patients who received postoperative irradiation were cured of their disease. Among six patients in the series of Stock et al. who<sup>498</sup> were treated with definitive irradiation, the disease-free survival rate was 80%; one patient in whom disease recurred had successful salvage treatment with pelvic exenteration. For patients with a prior history of pelvic irradiation, radical surgery (usually pelvic exenteration) is indicated and is often curative.

Disease-specific survival rates for patients with stage I disease treated with definitive irradiation range from 75% to 95%. <sup>495,514,530,532,546</sup> Selected patients with small, superficial tumors may be treated with brachytherapy alone. Perez et al. <sup>514</sup> achieved pelvic tumor control in 22 (88%) of 25 selected patients with stage I disease treated with brachytherapy alone. They recommended a dose of 60 to 70 Gy calculated 5 mm beyond the plane of the implant or vaginal mucosa (vaginal surface dose of 80 to 120 Gy). Thicker stage I tumors should be treated with a combination of external-beam irradiation and brachytherapy with an aim to deliver 40 to 50 Gy to the pelvic nodes and 70 to 75 Gy to the tumor.

### Stage II

Because investigators rarely define their criteria for distinguishing stage I from stage II disease or for selecting patients for various treatments, different institutional experiences cannot be easily compared. Reported disease-specific survival rates range from 50% to 80%. Data suggest that most patients with stage II disease require treatment with a combination of external-beam irradiation and brachytherapy. Perez and colleagues <sup>514</sup> achieved pelvic tumor control in only 4 (36%) of 11 selected patients with stage II tumors treated with brachytherapy alone, compared with 54 (67%) of 81 patients treated with a combination of external-beam irradiation and brachytherapy. Chyle et al. <sup>495</sup> reported a local recurrence rate (in the vagina) of 11% in 18 patients treated with brachytherapy (usually interstitial implant) alone, but did not report the rate of pelvic wall relapse in this patient subset.

Brachytherapy should be tailored to the volume and distribution of the tumor and its response to external-beam irradiation. For tumors that flatten to less than 5 mm in thickness, the dose to the vagina may be boosted using intracavitary sources in a vaginal cylinder. Because the thickness of apical vaginal tumors may be difficult to assess in patients who have had a hysterectomy, an examination under anesthesia is often needed to determine whether intracavitary therapy will cover the tumor adequately. Transvaginal ultrasound or MRI may also be helpful in treatment planning. When the uterus is intact, tumors high in the posterior fornix can often be treated with a tandem and ovoids. Larger tumors usually require a boost with interstitial therapy or additional external-beam irradiation. Most authors emphasize the importance of brachytherapy in the treatment of vaginal cancer. <sup>514,532,546</sup> However, brachytherapy must be designed to treat the entire vaginal tumor. Chyle and colleagues<sup>495</sup> argue that tumors that cannot adequately be covered with brachytherapy can often be cured with external-beam irradiation alone using carefully designed shrinking fields. They reported three (11%) vaginal recurrences in 28 patients with stage II disease treated with external-beam irradiation alone, compared with 12 (21%) recurrences in 58 patients treated with combined external-beam irradiation and brachytherapy.

Selected patients with stage II disease may be cured with radical surgery. <sup>498</sup> However, total radical vaginectomy or pelvic exenteration is often required to remove the tumor, and results with radical surgery do not appear better than those achieved with radiotherapy alone. Primary radical surgery is usually indicated for patients who have previously had pelvic radiotherapy.

### Stages III and IVA

Most authors report disease-specific survival rates of between 30% and 50% for patients with stage III disease and between 15% and 30% for patients with stage IVA disease. <sup>495,506,514,530</sup> Stage III and IVA tumors are usually bulky, highly infiltrative lesions involving most or all of the vagina as well as the pelvic wall, bladder, or rectum. The extent of these tumors and the proximity of critical normal tissue structures make their management a formidable technical challenge. Pelvic recurrence rates are high in most series; the risk of distant metastasis is also relatively high, although distant relapse is often accompanied by locoregional recurrence.

All patients require treatment with external-beam irradiation. Most authors advocate the use of brachytherapy whenever possible. However, Chyle and colleagues <sup>495</sup> reported a fairly high rate of freedom from relapse (47% at 10 years) in a series of patients with stage III disease in which the majority of patients (40 of 55) were treated with external-beam irradiation alone. Brachytherapy is undoubtedly an important part of disease management in some patients. However, in some cases interstitial therapy does not provide adequate coverage of tumors that are large and intimately associated with critical structures. In these cases, it may be appropriate to place greater emphasis on external-beam treatment.

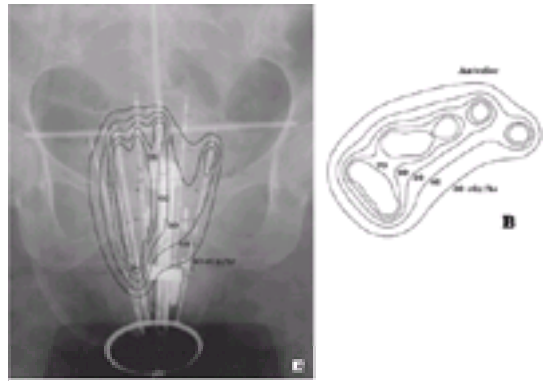

For selected patients with stage IVA disease who are in otherwise good medical condition, a pelvic exenteration with vaginal reconstruction using a gracilis myocutaneous flap or rectus abdominis myocutaneous flap may be the treatment of choice, particularly if a rectovaginal or vesicovaginal fistula is present. <sup>465,516,547</sup>

**RADIOTHERAPY TECHNIQUE.** External-beam fields must include the primary lesion and the regional lymph nodes. Fields should be individualized according to the primary site. Radiopaque markers placed at the distal edge of the tumor help to define the lower border, which often includes a portion of the introitus. Treating the patient in an open (frog-leg) position can often reduce the severity of vulvar cutaneous reactions.

When tumors involve the lower third of the vagina, pelvic fields should be enlarged to include at least the medial inguinal lymph nodes. When four fields are used to treat the pelvis, care must be taken to cover all the draining lymph nodes. Lateral fields should adequately cover posterior perirectal nodes, particularly when the primary lesion involves the posterior vaginal wall.

Intracavitary brachytherapy is of little value in the treatment of locally advanced vaginal cancers because the dose falls off rapidly from the surface of a vaginal cylinder. In general, the dose at a 5-mm depth is only 50% to 65% of the dose at the vaginal surface. Interstitial brachytherapy can provide better coverage of thick

vaginal tumors. Vaginal implants can be inserted free-hand, a technique that requires experience but permits excellent control of the position of sources with respect to the vaginal surface and rectal mucosa, which can be palpated as the needles are positioned ( Fig. 36.2-10). Vaginal implants may also be positioned using a perineal template. This technique provides a more homogeneous dose distribution because it facilitates parallel positioning of sources, but the template interferes somewhat with the brachytherapist's ability to monitor the placement of needles with respect to the rectal and vaginal mucosa. When tumors involve the vaginal apex in patients who have had a hysterectomy, laparoscopic or laparotomy guidance may be needed to ensure accurate needle placement.

**FIGURE 36.2-10.** Interstitial implant of a squamous carcinoma involving the anterior and right lateral wall of the vagina. Needles were placed transperineally, while the position of the needles was monitored by fingers in the vagina and rectum. A plastic cylinder in the vagina displaced uninvolved tissues away from the needles, which were loaded with iridium 192 sources. Needles were placed and sources were selected to deliver a somewhat higher dose to the thickest portion of the tumor on the right lateral wall of the vagina. Isodose contours represent the dose rates (in cGy/h) delivered to tissues in a coronal plane at the approximate center of the implant (A) and in a transverse plane through the center of the implant (B).

Several authors have reported a correlation between higher doses of radiation and lower rates of pelvic recurrence. <sup>514,532,540</sup> Chyle and associates<sup>495</sup> did not report a significant correlation between tumor dose and outcome. However, dose-response analyses can be misleading because the total dose of radiation prescribed for a vaginal tumor is often influenced by its size, extent, and initial response to irradiation, all of which determine the feasibility of delivering high-dose brachytherapy. When good brachytherapy coverage of the tumor can be accomplished, an effort should be made to treat the tumor to a dose of 75 to 85 Gy. When brachytherapy is not possible, some patients may be cured with external-beam irradiation alone using shrinking pelvic fields to deliver a tumor dose of 60 to 66 Gy. Treatment can usually be completed in less than 6 to 7 weeks and should not be protracted unnecessarily. Lee and colleagues<sup>546</sup> reported a significantly lower pelvic recurrence rate in patients whose entire treatment course was completed in 9 weeks or less.

**COMPLICATIONS OF RADIOTHERAPY.** The close proximity of the bladder and rectum makes them vulnerable to damage when invasive vaginal cancers are treated with radiotherapy. In their review of 301 patients treated with definitive irradiation, Chyle and colleagues<sup>495</sup> reported a 19% actuarial incidence of serious complications at 20 years (the crude complication rate was 13%). The most frequent complications were fistulae (ten patients); rectal ulceration, proctitis, or stricture (ten patients); urethral stricture (six patients); vaginal ulceration or necrosis (eight patients); and small bowel obstruction (seven patients). Others have reported similar major complication rates.<sup>496,506,514,530,540</sup> There have been no comprehensive studies of vaginal function in women with vaginal cancer treated with radiotherapy. Kirkbride and colleagues<sup>506</sup> reported that 45 of 128 irradiated patients in their study had vaginal stenosis. The severity of vaginal morbidity is probably related to the damage to vaginal mucosa and submucosa from tumor infiltration, ulceration, and infection; the age and menopausal status of the patient; and the radiation dose and the amount of vaginal tissue treated to high doses.

### **Vaginal Clear Cell Carcinoma**

The treatment of vaginal clear cell carcinoma is similar to that of squamous cell carcinoma. However, most women with vaginal clear cell carcinoma are young, so an effort should be made to preserve vaginal and ovarian function whenever possible. Conventional treatments for stage I and II disease include radical hysterectomy, vaginectomy, and lymphadenectomy with formation of a neovagina using a split-thickness skin graft, and radical radiotherapy. Senekjian and colleagues<sup>548</sup> reported on the use of local therapy alone in 43 patients with stage I disease who were reported to the Registry for Research on Hormonal Transplacental Carcinogenesis. Patients treated with local excision alone had a recurrence rate of more than 40% at 10 years. However, 17 patients who were treated with local irradiation (brachytherapy or transvaginal orthovoltage cone irradiation) with or without local excision had a 10-year recurrence rate of less than 10%. Of 41 assessable patients treated with local therapy in Senekjian and colleagues' <sup>548</sup> report, eight had had 15 pregnancies and 12 live births. Retroperitoneal lymphadenectomy may be indicated when local treatment is considered for stage I lesions, which are reported to have an overall rate of pelvic lymph node metastases of 17%.<sup>549</sup> When larger or more advanced lesions are treated with whole pelvic irradiation, ovarian transposition should be considered before radiotherapy.

The overall actuarial 10-year survival rate for patients treated for vaginal clear cell carcinoma is 79%. The survival rates for patients with stage I and II tumors are 90% and 80%, respectively.<sup>548,550,551</sup> Most recurrences occur within 3 years of initial therapy. However, recurrences have been reported to occur as many as 10 to 20 years after treatment.<sup>552,553</sup> Approximately one-third of relapses are first detected at distant sites, most commonly the lungs or extrapelvic lymph nodes.

**ROLE OF CHEMOTHERAPY.** Because primary vaginal carcinomas are rare, few reports have specifically addressed the role of chemotherapy in the treatment of this disease. Chemotherapeutic management is usually based on extrapolations from experience with the treatment of carcinomas of the cervix. For this reason, patients who have metastatic or recurrent vaginal carcinoma that is no longer amenable to locoregional treatment are sometimes treated with cisplatin-based chemotherapy even though the efficacy of this treatment is not well documented in the literature. Thigpen and colleagues<sup>554</sup> reported one complete and no partial responses in 16 patients with vaginal cancers treated with cisplatin 50 mg/m<sup>2</sup> every 3 weeks. In another GOG study, no responses were observed in 16 patients treated with etoposide for advanced vaginal cancers.<sup>555</sup> Reports of the use of neoadjuvant chemotherapy or concurrent chemoradiation are anecdotal.<sup>556,557</sup> and <sup>558</sup> However, vaginal carcinoma resembles cervical carcinoma in its location, pattern of spread, histologic appearance, relationship to HPV infection, and response to radiotherapy. It may therefore be reasonable to extrapolate from randomized trials demonstrating a benefit from concurrent chemoradiation in patients with locally advanced cervical cancer<sup>229,230,232,559</sup> to justify a similar approach in selected patients with high-risk invasive vaginal cancers.

## **CARCINOMA OF THE VULVA**

### **EPIDEMIOLOGY**

Invasive vulvar carcinoma is a rare disease that accounts for approximately 4% of gynecologic cancers.<sup>1,560</sup> In the United States, invasive vulvar cancer occurs with an average annual age-adjusted incidence rate of 1.2 cases per 100,000 woman-years.<sup>561</sup> The median age of patients diagnosed with invasive vulvar cancer is approximately 65 to 70 years; the incidence peaks in women older than 75 years at approximately 20 per 100,000.<sup>560,561</sup> and <sup>562</sup> In contrast, vulvar intraepithelial neoplasia (VIN) tends to occur in younger women; the median age of women diagnosed with VIN is 45 to 50 years. Although investigators have not demonstrated an overall increase in the incidence of invasive vulvar cancer, studies in the United States and Europe suggest that the incidence of VIN has more than doubled since the early 1970s.<sup>561,563,564</sup> This increase has been particularly marked in women younger than 55 years.<sup>561,563</sup> The relatively stable incidence of invasive cancer despite a steady increase in patients diagnosed with VIN could suggest that the etiologic factors for the two conditions are different, that diagnostic procedures have improved, or that effective treatment of VIN has prevented a significant increase in the incidence of invasive disease.

Evidence that HPV may play a role in the pathogenesis of cervical cancer has led investigators to look for HPV infection in patients with vulvar neoplasms. Eighty percent to 90% of VIN lesions contain HPV 16 or other HPV types. However, although more than 90% of invasive cervical cancers are associated with HPV, only 30% to 50% of invasive vulvar carcinomas are associated with evidence of HPV infection.<sup>565,566,567,568</sup> and <sup>569</sup>

Epidemiologic, histopathologic, and viral data suggest that patients with invasive squamous cell carcinomas of the vulva can be divided into at least two groups whose tumors may have different etiologies: one that is associated with HPV infection and one that is not.<sup>561,566,568,570,571</sup> HPV-positive tumors tend to occur in younger women

(35 to 55 years), are often associated with VIN, are frequently multifocal, and tend to form less keratin than do HPV-negative tumors. Patients with HPV-positive tumors are also more likely to have CIN and to have the risk factors typically associated with cervical cancers (multiple sexual partners, early age at first intercourse, low socioeconomic status, and cigarette smoking).<sup>571,572 and 573</sup> In contrast, HPV-negative tumors usually occur in older women (55 to 85 years), are often associated with vulvar inflammation or lichen sclerosis (but rarely with VIN), are generally unifocal, and are usually well differentiated with exuberant keratin formation.<sup>566,567,568 and 569</sup> Although a number of investigators have reported this distinct grouping of patients with vulvar cancer, others have found greater overlap.<sup>570,574,575</sup>

Several investigators have reported a high incidence of p53 mutations in HPV-negative tumors.<sup>576,577 and 578</sup> Lee and colleagues<sup>576</sup> found missense mutations of p53 in four (44%) of nine HPV-negative tumors but in only one (8%) of 12 HPV-positive tumors. They postulated that alteration in p53 activity, either through point mutations or through E6-mediated loss of p53 function in HPV-infected cells, could be important in the development of vulvar neoplasms.

## NATURAL HISTORY AND PATTERN OF SPREAD

The female external genitalia include the mons pubis, labia majora, labia minora, clitoris, vestibular bulb, vestibular glands (including Bartholin's glands), and vestibule of the vagina. Together, these structures form the vulva. The region between the posterior commissure of the labia and the anus is termed the *gynecologic perineum*. Approximately 70% of vulvar squamous carcinomas involve the labia majora or minora, most frequently the labia majora.<sup>579,580 and 581</sup> Approximately 15% to 20% involve the clitoris, and a similar proportion involve or arise in the perineum. In approximately 10% of cases, the lesion is too extensive to permit determination of the original site, and in approximately 5% of cases, the lesion is multifocal. Vulvar tumors may extend locally to invade adjacent structures, including the vagina, urethra, and anus; advanced vulvar tumors may invade adjacent pelvic bones.

A rich network of anastomosing lymphatics that frequently crosses the midline drains the vulva. Even minimally invasive vulvar tumors may spread to regional lymph nodes (Table 36.2-15).<sup>579,582,583,584 and 585</sup> In most cases, initial regional metastasis is to the superficial inguinal lymph nodes that are located between Camper's fascia and the fascia lata; tumors may then metastasize secondarily to the deep femoral lymph nodes located along the femoral vessels and then to the pelvic lymph nodes (Fig. 36.2-11).<sup>580,586</sup> However, metastases have been reported to the deep femoral lymph nodes without involvement of the superficial inguinal lymph nodes, especially from carcinomas of the clitoris and Bartholin's glands.<sup>580,586,587 and 588</sup> Theoretically, tumors involving the clitoris can also spread directly to the obturator nodes through lymphatics that follow the dorsal vein of the clitoris, although evidence of this route is rarely seen in practice. Despite the extensive anastomosis of lymphatics in the region, metastasis of vulvar carcinoma to contralateral lymph nodes is uncommon in patients with well-lateralized T1 lesions.<sup>541</sup>

Depth of Invasion (mm)	Patients with Positive Lymph Nodes (Total % of Patients)				
	≤0.1	0.1-1.0	1.1-1.0	1.1-5.0	>5

FIGURE 36.2-11. Inguinal-femoral lymph nodes. (From Hacker NF. Vulvar cancer. In: Hacker NF, Moore JG, eds. *Essentials of obstetrics and gynecology*. Philadelphia: WB Saunders, 1992:618, with permission.)

The lungs are the most common sites of hematogenous metastasis.

## PATHOLOGY

As classified by the International Society for the Study of Vulvar Disease, nonneoplastic epithelial disorders of the vulva (previously termed *vulvar dystrophies*) include lichen sclerosis, squamous hyperplasia, and other dermatoses.<sup>589</sup> Approximately 10% of these lesions have cellular atypia and are termed VIN. Histologically, VIN is characterized by disruption of the normal epithelial architecture, varying degrees of cytoplasmic and nuclear maturation, and giant cells with abnormal nuclei.<sup>570,590</sup> VIN lesions are assigned a grade from one to three according to their degree of maturation. Invasive cancers have been associated with two types of VIN.<sup>570</sup> The most common VINs contain nuclear atypia throughout the epithelial layers and are frequently associated with HPV. These lesions are sometimes subdivided into warty and basaloid types, which have greater and lesser degrees of differentiation, respectively.<sup>570</sup> In the second subset of VINs, atypia is largely confined to the basal layers of the epithelium. These lesions tend to occur in older women and are not usually associated with HPV but are commonly adjacent to areas of lichen sclerosis or hyperplasia. Buscema and Woodruff<sup>591</sup> estimated that approximately 4% of patients treated for VIN develop a subsequent invasive cancer.

Paget's disease of the vulva, a rare intraepithelial lesion located in the epidermis and skin adnexa, accounts for 1% to 5% of vulvar neoplasms. Histologically, vulvar Paget's disease is characterized by large, pale, mucopolysaccharide-rich cells that are positive for periodic acid-Schiff. Electron microscopic studies have suggested that Paget's cells derive from apocrine cells in the stratum germinativum of the epidermis.<sup>592</sup> Paget's disease usually occurs in postmenopausal women, who often present with symptoms of vulvar pruritus and discomfort.<sup>593</sup> Grossly, Paget's lesions appear eczematoid or, when extensive, may be raised and velvety with persistent weeping.<sup>594</sup> Approximately 5% to 10% of newly diagnosed Paget's lesions are associated with underlying adenocarcinoma arising locally in a vulvar vestibular gland or skin appendage or from a distant site such as the breast or rectum.<sup>593</sup> It has been suggested that Paget's disease with underlying adenocarcinoma represents a different process than other types of intraepithelial Paget's disease because the other types rarely progress to invasive adenocarcinoma.<sup>595</sup>

The term *microinvasive carcinoma of the vulva* should be used with caution. The methods and criteria used to define microinvasive carcinoma of the cervix cannot be applied to carcinoma of the vulva. Stromal invasion by vulvar carcinomas is not measured in a uniform manner, and strict criteria for the diagnosis of microinvasive vulvar cancer have not been defined. VIN is not routinely seen adjacent to invasive vulvar cancer, and the transition from normal tissue to invasive cancer can be abrupt. Elongated rete pegs may extend 6 mm or more from the basement membrane and are sometimes misconstrued as invasive cancer. The International Society of Gynecologic Pathologists recommends that the depth of stromal invasion be measured vertically from the most superficial basement membrane to the deepest tumor. Tumor thickness is defined as the distance between the granular layer of epidermis and the deepest tumor. Lymph node metastases from tumors less than 1 mm in depth or thickness are extremely rare (see Table 36.2-15).<sup>579,582,583 and 584</sup> For this reason, FIGO now includes a stage IA subcategory in its staging system for

tumors that invade less than 1 mm ([Table 36.2-16](#)).<sup>560</sup> However, the risk of inguinal lymph node metastasis rises steeply as the depth of invasion exceeds 1 mm.

Stage I	Lesions 2 cm or less in size confined to the vulva or perineum (T1). <sup>a</sup> No nodal metastases (N0).
Stage IA	Lesions 2 cm or less in size confined to the vulva or perineum and with stromal invasion no greater than 1.0 mm. <sup>b</sup> No nodal metastases.
Stage IB	Lesions 2 cm or less in size confined to the vulva or perineum and with stromal invasion greater than 1.0 mm. <sup>b</sup> No nodal metastases.
Stage II	Tumor confined to the vulva, perineum, or both, or more than 2 cm in the greatest dimension (T2). No nodal metastases (N0).
Stage III	Tumor of any size with adjacent spread to the lesser urethra, vagina, or both, or the anus (T3), and/or unilateral regional node metastases (N1).
Stage IVA	Tumor involves any of the following: upper urethra, bladder mucosa, rectal mucosa, pelvic bone (T4), and/or bilateral regional node metastases (N2).
Stage IVB	Any distant metastasis, including pelvic lymph nodes (M1).

<sup>a</sup>Equivalent tumor, node, metastasis (TNM) groupings according to the TNM Committee of the International Union Against Cancer are indicated in parentheses.<sup>560</sup>  
<sup>b</sup>The depth of invasion is defined as the measurement of the tumor from the epithelial-stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.  
 (Reprinted from ref. 560, with permission.)

**TABLE 36.2-16.** International Federation of Gynecology and Obstetrics Staging of Carcinoma of the Vulva (1994)

More than 90% of invasive vulvar cancers are squamous cell carcinomas. Atypical keratinization is the hallmark of invasive vulvar cancer. Most squamous carcinomas are well differentiated, but mitoses may be noted.<sup>596</sup> Approximately 5% of vulvar cancers are anaplastic carcinomas that may consist of large immature cells, spindle sarcomatoid cells, or small cells. Vulvar carcinomas consisting of small cells may resemble small cell anaplastic carcinomas of the lung or Merkel's cell tumors and have demonstrated an aggressive biologic behavior in the few reported cases.<sup>597,598</sup> and <sup>599</sup> Verrucous carcinoma is a rare, very well-differentiated form of vulvar carcinoma that usually presents in the fifth or sixth decade of life as a large, locally invasive lesion.<sup>598</sup> On microscopic examination, the tumor has a papillary, exophytic appearance; tumor cells retain a normal appearance of maturation and demonstrate minimal atypia. Even with extensive local invasion, lymph node metastasis from verrucous carcinoma is rare.

The diagnosis of Bartholin's gland carcinoma is based on clinical findings of a tumor arising in the anatomic location of Bartholin's glands and on the histologic appearance. Biopsy of a tumor arising from a Bartholin's gland usually reveals adenocarcinoma, but squamous cell carcinomas, transitional cell carcinomas (arising from the duct and histologically indistinguishable from transitional cell carcinoma of the bladder), and adenoid cystic carcinomas have also been reported.<sup>588</sup>

Rare cases of primary mammary adenocarcinoma of the vulva have been reported, presumably arising in aberrant mammary tissue occurring along the embryonic milk line.<sup>600</sup> Other rare carcinomas that may occur in the vulva include basal cell carcinomas<sup>601</sup> and sebaceous carcinomas.<sup>602</sup>

Malignant melanomas of the vulva account for approximately 2% to 4% of primary vulvar malignancies and 1% to 3% of melanomas arising in women.<sup>603,604</sup> Vulvar melanoma occurs most frequently in women older than 60 years of age, but 10% to 20% of vulvar melanomas occur in women younger than 40 years.<sup>604</sup> Approximately 50% of vulvar melanomas involve the labium majus, but tumors may also arise on the labium minus, clitoris, or perineum.<sup>604,605</sup> and <sup>606</sup> In a large Swedish series, 57% of vulvar melanomas were of the mucosal lentiginous type, 22% were nodular, and 16% were superficial spreading or lentiginous.<sup>606</sup> Most investigators have reported a correlation between depth of invasion or Breslow thickness and outcome.<sup>605,607,608</sup> However, because the vulvar epithelium sometimes lacks a well-developed papillary dermis, which makes it difficult to assign Clark's levels of invasion, Chung and colleagues proposed a modification of the Clark system that is often used to categorize patients with vulvar melanoma.<sup>609,610</sup> Other factors that have been associated with a poorer prognosis are ulceration, clinical amelanosis, and older age.<sup>607</sup> Diagnosis is made by biopsy of any suspicious pigmented or nonpigmented lesion, particularly if it is nodular or indurated or has a perilesional halo.

Vulvar sarcomas constitute 1% to 2% of vulvar malignancies and include leiomyosarcomas, rhabdomyosarcomas, angiosarcomas, neurofibrosarcomas, and epithelioid sarcomas. The prognosis appears to depend on three main determinants: lesion size, tumor contour, and mitotic activity. Lesions greater than 5 cm in diameter with infiltrating margins, extensive necrosis, and more than five mitotic figures per ten high-power fields are the most likely to recur after surgical resection.<sup>611,612</sup>

## DIAGNOSIS, CLINICAL EVALUATION, AND STAGING

Patients with VIN may complain of vulvar pruritus, irritation, or a mass, but up to 50% of these patients are asymptomatic at the time of diagnosis.<sup>613,614</sup> Patients with invasive vulvar cancer usually complain of a vulvar mass and chronic vulvar pruritus. Advanced lesions may bleed and are often exquisitely tender.

Because VIN can have many manifestations, any new vulvar lesion should be biopsied. Once the diagnosis of VIN has been established, the entire vulva, cervix, and vagina should be carefully examined because patients often have multifocal or multicentric involvement.<sup>613,614</sup> and <sup>615</sup> Colposcopic examination may help to define the extent of disease.

Diagnosis of invasive vulvar lesions requires a wedge biopsy of the lesion with surrounding skin and with underlying dermis and connective tissue so the pathologist can adequately evaluate the depth of stromal invasion. This procedure can usually be performed in the physician's office under local anesthesia. Excisional biopsy is preferred for lesions smaller than 1 cm in diameter.

Patients with invasive disease require additional evaluation for regional and metastatic disease. All patients with invasive disease require a careful physical examination including a detailed pelvic examination, chest radiography, and biochemical profile. Cystoscopy and proctoscopy should be performed in patients with advanced lesions or with tumors that are near the urethra or anus, respectively. Patients who complain of bone pain or who have tumor fixed to pelvic bones should have appropriate skeletal radiography. CT or MRI scans can be obtained to evaluate deep inguinal and pelvic lymph nodes for possible regional metastasis.

In 1983, FIGO adopted a clinical TNM staging system for vulvar cancer. This system was based on a clinical assessment of the primary tumor and regional lymph nodes. However, several studies have demonstrated poor correlation between clinical assessment of the inguinal lymph nodes and pathologic findings.<sup>251,616,617</sup> In a study of 588 patients with tumors that invaded 5 mm or deeper, Homesley and colleagues<sup>616</sup> reported that although 93% of patients with fixed or ulcerated nodes had metastatic tumor, 24% of those with clinically negative nodes had inguinal lymph node metastases and 24% of patients with suspicious but mobile nodes had negative findings at lymphadenectomy. In 1988 the FIGO staging system was modified to incorporate the more accurate information gained from surgical assessment of regional lymph nodes. The staging system was revised again in 1994 to create a separate stage IA for minimally invasive lesions (see [Table 36.2-16](#)).<sup>560</sup>

## PROGNOSTIC FACTORS

The risk of regional metastases of vulvar carcinoma and the prognosis for cure after treatment are correlated with a number of clinical and pathologic features. Clinical tumor diameter is strongly predictive of outcome and has been incorporated in the FIGO staging system ([Table 36.2-17](#); see [Table 36.2-16](#)). Other factors that have consistently been correlated with outcome include depth of invasion, tumor thickness, and the presence or absence of LVSI.<sup>251,616,618,619</sup> and <sup>620</sup> These features tend to be correlated with one another, and all are predictive of lymph node metastasis. More than 75% of patients with LVSI have positive inguinal nodes.<sup>582,616,621</sup> Studies of the relationship between tumor grade and outcome have drawn varying conclusions, possibly reflecting the inconsistent criteria used to grade vulvar tumors.<sup>259,582,616,617,621,622</sup> Other factors that tend to be associated with prognosis include the amount of keratin, the mitotic rate, and the tumor growth pattern.<sup>582,618,623,624</sup> Aneuploid tumors appear to have a poorer prognosis than diploid tumors, but ploidy tends to be correlated with other prognostic factors and may not be an independent predictor of outcome.<sup>625,626</sup> Several authors have reported that tumors containing HPV DNA have a poorer prognosis than HPV-negative tumors.<sup>565,569</sup> Some investigators have reported a worse prognosis for patients aged 70 years or older, whereas others have found no correlation between prognosis and age.<sup>579,616,622,623</sup>

Tumor Diameter (cm)	No. of Positive Groin Nodes									
	None		One		Two Unilateral		Two Bilateral		Total	
	No.	Survival (%)	No.	Survival (%)	No.	Survival (%)	No.	Survival (%)	No.	Survival (%)

\*These patients had an undetermined number of positive nodes and/or ipsilateral ilioacinar node disease.  
(Adapted from ref. 631)

**TABLE 36.2-17.** Relative Survival by Tumor Diameter and Surgical Groin Node Status

Prognosis is strongly correlated with the presence and number of inguinal node metastases (see [Table 36.2-17](#)). In a study of 586 patients treated in two GOG trials, Homesley and colleagues<sup>619</sup> reported 5-year survival rates of 91% for patients with negative inguinal lymph nodes and 75%, 36%, and 24%, respectively, for patients with one or two, three or four, or five or six positive nodes. None of the 16 patients with seven or more nodes involved with tumor survived. Patients with bilateral node involvement had a survival rate of 25%, compared with 71% for those with unilateral node involvement. The authors did not state whether patients with bilateral nodal disease had a poorer prognosis than did patients with a similar number of unilateral metastases. Homesley and colleagues<sup>627</sup> reported that patients with pelvic node metastases had a particularly poor survival rate: Among patients treated with surgery alone, 3-year survival rates were 23% for patients with pelvic node metastases versus 73% for patients with only inguinal node involvement. For this reason, FIGO has categorized tumors that have spread to the pelvic nodes as stage IV. However, it should be remembered that most of these series include patients who did not receive postoperative irradiation. It is not possible from available data to define the prognosis of patients who received multidisciplinary treatment for vulvar cancer metastatic to pelvic lymph nodes.

In 1995, van der Velden and colleagues<sup>628</sup> published a detailed study of nodal prognostic factors in 71 patients with inguinal node metastases from vulvar carcinomas. Patients with extranodal spread or more than two positive nodes received adjuvant radiotherapy to an unspecified dose. The most powerful predictor of outcome in their study was extranodal tumor extension: 28 (63%) of 44 patients with extranodal tumor died of disease versus three (14%) of 22 without this finding. In Cox regression analysis, none of the other factors studied (tumor size, number of nodes, FIGO stage, nodal size, degree of nodal replacement, laterality) added to the predictive power of extranodal extension. Orioni and colleagues reported similar findings in a series of 53 patients with positive nodes.<sup>629</sup>

Studying the relationship between surgical margins and tumor recurrence, Heaps and colleagues<sup>618</sup> reported no local failures in 91 patients whose closest tumor margin (deep or at the skin surface) was 8 mm or more in the fixed specimen. Ten (43%) of 23 patients with margins of 4.8 mm or less experienced a local recurrence, as did 8 (62%) of 13 patients with margins between 4.8 mm and 8.0 mm.

## TREATMENT

The traditional operative approach to invasive carcinoma of the vulva, radical *en bloc* resection of the vulva and inguinofemoral nodes, was developed at the beginning of the twentieth century, was popularized during subsequent decades, and remained the standard of care until the early 1980s.<sup>630,631 and 632</sup> Radiotherapy was thought to have little role in the treatment of vulvar cancer. Although this surgical approach achieved 5-year survival rates of 60% to 70%, the surgery caused significant physical and psychological complications, and patients with multiple positive nodes continued to have a poor prognosis. In 1981, Hacker and colleagues<sup>633</sup> demonstrated that a less morbid surgical approach, operating through separate vulvar and groin incisions, achieved cure rates similar to those achieved with the traditional radical vulvectomy. Since then, there has been a continuing trend toward less radical surgery for early-stage disease. In addition, prospective and retrospective studies have established the role of radiotherapy in the curative management of locoregionally advanced disease.

### Preinvasive Disease (Vulvar Intraepithelial Neoplasia)

After invasive carcinoma has been excluded by a sufficient number of excisional biopsies, the treatment of VIN should be as conservative as possible. Focal lesions can be simply excised. Multiple lesions can be excised separately or, if confluent, with a larger single excision. This approach is generally well tolerated and provides material for histologic assessment. When there is more extensive VIN, the lesions can be vaporized with a CO<sub>2</sub> laser. This method may provide an alternative to more extensive operations but does not yield a specimen for histologic inspection.

Extensive, diffuse VIN may require a wider excision, particularly if the lesion involves the perianal skin. These lesions are sometimes treated with a partial vulvectomy of the superficial skin (called *skinning vulvectomy*). Whenever possible, the vulvar skin should be sutured primarily, but a split-thickness skin graft is sometimes needed to close the defect.

VIN often recurs at or near the margins of resection, even when the histopathologic analysis demonstrates that the initial lesions were completely resected. Presumably this phenomenon reflects the multifocal nature of the condition.<sup>615</sup> In fact, VIN can recur within the donor skin from split-thickness grafts.<sup>541</sup>

### T1 and T2

Invasive vulvar tumors can usually be treated effectively without the complications of *en bloc* radical vulvectomy and inguinal node dissection. Today, most gynecologic oncologists advocate an individualized approach to early invasive vulvar carcinomas.<sup>583,634,635,636,637 and 638</sup> Overall 5-year disease-specific survival rates for stage I (T1N0M0) and stage II (T2N0M0) disease are approximately 98% and 85%, respectively.<sup>619</sup>

Most T1 and selected T2 lesions can be controlled locally with a radical wide local excision. A wide and deep excision of the lesion is performed, with the incision extended down to the inferior fascia of the urogenital diaphragm. An effort should be made to remove the lesion with a 2-cm margin of normal tissue in all directions unless this would require sacrifice of the anus or urethra. The surgical defect is closed in two layers. Small T1 lesions that invade 1 mm or less can be managed with local resection alone because the risk of regional spread is small (see [Table 36.2-15](#)). Patients with more invasive tumors must also have surgical or radiation treatment of the inguinal nodes as discussed here.

Larger T2 tumors may require radical vulvectomy to obtain acceptable tumor clearance with negative margins. *En bloc* resection of the vulva and inguinal nodes was once believed to be necessary to prevent recurrences in the soft tissue intervening between the vulva and regional nodes; however, most surgeons now perform the operation through separate vulvar and groin incisions. Although recurrences have been reported in this *tissue bridge*, these appear to be rare, and the risk of complications is significantly decreased when separate incisions are used.<sup>633,637,638,639 and 640</sup>

Wound seroma is the most common acute complication of radical vulvectomy and inguinal node dissection, occurring in approximately 15% of cases.<sup>583,635</sup> Other acute complications include urinary tract infection, wound cellulitis, temporary anterior thigh anesthesia from femoral nerve injury, thrombophlebitis, and, rarely, pulmonary embolus.<sup>583,627,635,637,639</sup> The most common chronic complication is leg edema, but this risk has decreased from approximately 30% to 15% with the use of separate groin incisions.<sup>638</sup> Other chronic complications including genital prolapse, urinary stress incontinence, temporary weakness of the quadriceps muscle, and introital stenosis. Rare late complications include pubic osteomyelitis, femoral hernia, and rectoperineal fistula. These risks are less when separate incisions are used and are further reduced when radical local excision of the primary lesion is done instead of radical vulvectomy.<sup>635,638,641,642</sup>

### T3 and T4

Primary tumors that involve the anus, rectum, rectovaginal septum, or proximal urethra pose a difficult problem because adequate surgical clearance can be obtained only by combining a pelvic exenteration with radical vulvectomy and bilateral groin node dissection. Although some patients may be cured with this ultraradical surgery, the risks of acute and long-term complications of the procedure are substantial.<sup>643,644 and 645</sup> For this reason, a number of investigators have explored the use

of combined surgery and irradiation to spare critical structures in patients with locally advanced disease.

In some cases, patients with T3 tumors that minimally involve the external urethra or anus can undergo initial vulvectomy without sacrifice of major organ function if close margins are accepted near critical structures. Postoperative radiotherapy can then be delivered to prevent local recurrence. <sup>646,647</sup> and <sup>648</sup> Although local recurrences are frequently successfully controlled with additional surgery, Faul and colleagues <sup>649</sup> reported an overall 5-year survival rate of only 40% after the first local recurrence and emphasized the importance of achieving local control. These authors reported a significant reduction in the local failure rate (from 58% to 16%) when tumors that were within 8 mm of the operative margins were irradiated after surgery. <sup>649</sup> In such cases, the vulva may be treated with opposed anterior and posterior photon fields (if the inguinal regions also require treatment) or with an appositional perineal electron beam. <sup>648,650</sup> The vulva should receive a total dose of 50 to 65 Gy depending on the proximity of disease to the surgical margin.

In the early 1980s, several investigators <sup>651,652,653,654</sup> and <sup>655</sup> reported results of preoperative radiotherapy in small series of patients with locally advanced disease. These reports indicated that modest doses of radiation (45 to 55 Gy) produced dramatic tumor responses in some patients with T3 and T4 disease, permitting organ-sparing surgery without sacrifice of tumor control. Hacker and colleagues <sup>654</sup> reported that four of eight patients with T3 to T4 tumors treated preoperatively with 44 to 54 Gy had no residual tumor in the vulvectomy specimen and that seven of these eight had local control of their disease. More recently, investigators have emphasized the use of concurrent chemoradiation in this setting.

### Chemotherapy in Locoregionally Advanced Disease

To reduce the need for morbid ultraradical surgery and to improve locoregional control rates, a number of investigators have explored combinations of chemotherapy with radiation and surgery in patients with locally advanced vulvar carcinoma. <sup>556,656,657,658,659,660,661,662,663,664,665,666,667</sup> and <sup>668</sup> Most studies have used combinations of cisplatin, 5-FU, and mitomycin C, extrapolating from the high response rates observed with use of this treatment for locally advanced carcinomas of the cervix and head and neck and from studies that have demonstrated the efficacy of these drugs as radiosensitizers in the treatment of carcinomas of the anus. Treatment schedules usually include a 4- to 5-day infusion of 5-FU combined with one of the other two drugs, with this course repeated every 3 to 4 weeks ( [Table 36.2-18](#)). Studies have usually included small numbers of patients with advanced local or regional disease. However, most investigators have observed impressive responses that often appear to be better than would be expected with radiation alone. Randomized trials have not been done and may be difficult to perform because of the small number of patients with locally advanced vulvar cancer. However, trials that demonstrated improved local control and survival when concurrent cisplatin-containing chemotherapy was added to radiation treatment of cervical cancers <sup>229,230,232</sup> and improved colostomy-free survival when mitomycin C and 5-FU were added to radiation treatment of anal cancer <sup>669</sup> suggest that this approach may be also be useful treatment of women with vulvar cancer.

Investigator	No. of Patients	Chemotherapy	Radiation Therapy (Gy)	No. with Resection of Primary Local Disease after Radiation Therapy + Surgery	Follow-up (mo)

 \*Mean patient age, 65 years (range 53-75 years).

**TABLE 36.2-18.** Concurrent Chemoradiotherapy in the Management of Locally Advanced or Recurrent Carcinoma of the Vulva

Only one study has investigated the role of neoadjuvant chemotherapy in the treatment of locally advanced vulvar cancer. Benedetti-Panici and colleagues <sup>670</sup> treated 21 patients with stage IVA vulvar cancers with two to three cycles of cisplatin, bleomycin, and methotrexate followed by radical surgery. Two (10%) of 21 patients had partial responses of their vulvar tumors, and 14 (67%) had partial responses of regional nodes. Ninety percent of the tumors were considered operable, but the 3-year survival rate was only 24%.

Caution is warranted in designing aggressive treatment protocols for patients with vulvar cancers, who typically are elderly and often have concurrent medical problems. Serious pulmonary toxicity has been observed in a number of patients treated on studies that included bleomycin. <sup>664,668,671</sup> In the largest published series of patients treated with mitomycin C and 5-FU, hematologic tolerance was acceptable, but the administered dose of mitomycin C was somewhat lower than that generally used in the treatment of anal cancers. <sup>666</sup>

### Treatment of Regional Disease

Effective regional treatment is the single most important factor in the curative management of early vulvar cancer. Although patients with vulvar recurrences can often have their disease successfully controlled with additional local treatment, patients who suffer inguinal recurrences are rarely curable.

All patients with primary tumors that invade more than 1 mm must have their inguinal nodes treated. Traditional management includes a bilateral radical inguinal lymph node dissection. Today, this is usually performed through separate groin incisions. An ellipse of skin is removed 1 cm below and parallel to the groin crease. <sup>633</sup> The incision is extended down to the fascia lata and 2 cm above the inguinal ligament to remove the inguinal nodes. The saphenous vein is tied off, the fascia lata is split, and the femoral nodes are dissected. A suction drain is placed, and the wound closed in two layers.

At one time, pelvic node resection was also performed in all patients with invasive vulvar cancer. When subsequent studies demonstrated that pelvic node metastases were found only in patients with clinically suspicious or multiple positive inguinal nodes, use of the procedure was limited to patients determined intraoperatively to have positive inguinal nodes. <sup>672,673</sup> and <sup>674</sup>

Then, in 1986, Homesley and colleagues <sup>627</sup> published results of a randomized, prospective study that compared pelvic node resection with inguinal and pelvic irradiation in patients with inguinal node metastases from carcinoma of the vulva. All patients were initially treated with radical vulvectomy and inguinal lymphadenectomy. Patient randomization was done intraoperatively after frozen section evaluation of the inguinal nodes. This trial was closed prematurely, after 114 eligible patients had been entered, when interim analysis revealed a survival advantage for the radiation treatment arm (  $P = .03$ ). The difference was most marked for patients with clinically positive or multiple histologically positive groin nodes ( [Fig. 36.2-12](#)). For patients with two or more positive nodes, the 2-year survival rates were 63% and 37% for the radiotherapy and pelvic node resection groups, respectively. Analysis of failure patterns reveals that the largest difference between treatment groups was in the number of inguinal failures ( [Fig. 36.2-13](#)). With the publication of this study, most practitioners abandoned routine pelvic node dissection, and postoperative radiotherapy became standard for most patients with inguinal node metastases.

**FIGURE 36.2-12.** Survival rates of 114 patients with invasive squamous cell carcinoma of the vulva who were entered on a Gynecologic Oncology Group protocol in which patients with positive groin nodes after radical vulvectomy and bilateral inguinal lymphadenectomies were randomly assigned to receive pelvic lymph node dissection or postoperative irradiation to the pelvis and inguinal nodes ( $P = .004$ ). (From ref. 627, with permission.)

**FIGURE 36.2-13.** Sites of recurrence in 114 patients with invasive squamous cell carcinoma of the vulva who were entered on a Gynecologic Oncology Group protocol in which patients with positive groin nodes after radical vulvectomy and bilateral inguinal lymphadenectomies were randomly assigned to receive pelvic lymph node dissection or postoperative irradiation to the pelvis and inguinal nodes. (From ref. 627, with permission.)

Most of the serious acute and subacute complications of radical vulvectomy are related to the lymph node dissection, although these risks have decreased somewhat with the use of separate groin incisions.<sup>674,675,676</sup> and <sup>677</sup> Complications include wound disruption or infection in 50% to 75% of cases, chronic lymphedema in 20% to 50%, and a perioperative mortality of 2% to 5%. Patients who undergo vulvectomy without inguinal node dissection have significantly shorter hospital stays and fewer complications.<sup>674,675,677</sup>

Although radical inguinal lymphadenectomy has historically been considered the treatment of choice for regional management of invasive vulvar carcinoma, several retrospective studies have suggested that regional radiotherapy may be an effective and less morbid way of preventing recurrence in patients with clinically negative groins. In a review of 91 patients who had elective treatment of the inguinal nodes for cancers with primary drainage to the inguinal nodes, Henderson and colleagues<sup>678</sup> observed only two recurrences after treatment with 45 to 50 Gy over 5 weeks, and both of these occurred outside the treatment fields. In a retrospective review of 42 patients with invasive vulvar carcinomas, Petereit and colleagues<sup>675</sup> found no difference in the groin recurrence rate for patients with clinically negative inguinal nodes treated with radical lymphadenectomy or radiotherapy, even though the irradiated patients in their series had more advanced primary tumors. The complications of treatment, including lymphedema, wound separation, and infection, and the length of hospitalization were greater for patients who had had lymphadenectomy. Leiserowitz and colleagues<sup>679</sup> reported no groin recurrences in 23 patients with locally advanced, clinically N0 vulvar cancers after prophylactic treatment of the groins with concurrent chemoradiation.

In 1992 the GOG reported the results of a trial that randomly assigned patients with clinically negative inguinal nodes to receive inguinal node irradiation or radical lymphadenectomy (followed by inguinopelvic irradiation in patients with positive nodes) after resection of the primary tumor.<sup>677</sup> The study was closed after entry of only 58 patients, when an interim analysis demonstrated a significantly higher rate of inguinal recurrence and death in the irradiated group. The authors concluded that lymphadenectomy was the superior treatment, although the morbidity rate of lymphadenectomy was greater than that of groin irradiation. However, the radiotherapy techniques used in this study have since been criticized. CT scans were not consistently obtained to verify the position and size of inguinal nodes. Patients were treated with anterior appositional fields, the dose was prescribed at a depth of 3 cm, and the use of electrons (usually 12 meV) was emphasized. This method of treatment can lead to significant underdosage of the inguinofemoral nodes, which frequently extend to a depth of more than 5 to 8 cm.<sup>680,681</sup> Because of these criticisms, the study's results and the role of radiation in the primary management of clinically negative inguinal nodes remains controversial.

Some surgeons have tried to reduce surgical complications by reducing the extent of lymph node dissections. Burke and colleagues<sup>641</sup> reported four (5%) groin recurrences in 74 patients with T1 to T2 tumors treated with wide local excision and superficial inguinal lymphadenectomy (unilateral or bilateral depending on the location of the tumor). In a prospective study of patients with favorable primary lesions (T1, less than or equal to 5 mm thick, no LVSI), the GOG<sup>682</sup> reported nine (7%) inguinal recurrences in 121 patients who had negative findings on ipsilateral superficial inguinal lymphadenectomy. A number of investigators have explored the use of intraoperative lymphatic mapping to identify a *sentinel* node that would predict the presence or absence of regional metastases.<sup>683,684,685</sup> and <sup>686</sup> Preliminary studies suggest that a sentinel node can be identified in most patients. Further study will be needed to determine whether this procedure can be used to more accurately identify patients who can be successfully treated without the morbidity of radical regional treatment.

### Treatment of Metastatic Disease

A number of reports document the use of single-agent chemotherapy in patients with metastatic or recurrent squamous cell carcinomas of the vulva. Several anecdotal reports published in the 1970s suggest that bleomycin may be an active agent, but the response rate has not yet been documented in a prospective phase II trial, and the optimal dose and schedule have not been determined.<sup>687,688</sup> and <sup>689</sup> Single-agent phase II studies of cisplatin, etoposide, mitoxantrone, and piperazinedione have failed to document any objective responses.<sup>555,690</sup> Data on the use of combination chemotherapy in this setting are anecdotal, and no series includes more than nine patients. In the absence of reliable data specific to carcinoma of the vulva, clinicians often use combinations that have had some activity in the treatment of cervical cancer. However, there are as yet few data to indicate that chemotherapy can provide effective palliation for patients with metastatic or recurrent vulvar carcinoma that is not amenable to locoregional treatments.

## ENDOMETRIAL CARCINOMA

### CLINICAL OVERVIEW

Tumors of the uterine fundus comprise the most common group of gynecologic malignancies. Annual incidence figures for the United States have remained stable at approximately 36,000 cases during the 1990s. Deaths from disease occur in 6000 women per year.<sup>1</sup> The large proportion of survivors with these cancers reflects a disease course characterized by early onset of symptoms and well-established diagnostic guidelines. Nevertheless, women with high-risk or advanced disease have a poor prognosis and account for the most uterine cancer deaths.<sup>2</sup>

A general classification of uterine fundal cancers is provided in [Table 36.3-1](#). Approximately 90% of tumors arise within the epithelium of the uterine lining and are categorized as endometrial carcinomas. Within this group, 90% of cancers are typical endometrial adenocarcinomas.<sup>3</sup> The typical endometrial carcinomas are further subdivided into three architectural grades based on the percentage of solid tumor growth: Grade 1 cancers have identifiable endometrial glands and are well differentiated ([Fig. 36.3-1](#)), whereas grade 3 tumors demonstrate a solid growth pattern and are poorly differentiated.<sup>4</sup> Rare cell types, including papillary serous carcinoma, clear cell carcinoma, papillary endometrioid carcinoma, and mucinous carcinoma, account for the remaining 10% of cases. Adenosquamous carcinomas are now classified as typical endometrial adenocarcinomas with squamous differentiation. In general, all of these uncommon cell types are associated with a later age of onset, greater risk for extrauterine metastases, and poorer prognosis when compared with typical grade 1 adenocarcinomas.<sup>5,6,7,8,9,10,11,12,13 and 14</sup>

Tumor Type	Approximate Frequency (%)
Epithelial tumors (endometrioid, papillary endometrioid, papillary serous, clear cell, mucinous)	90
Mesenchymal tumors (endometrial stromal sarcoma, leiomyosarcoma, other nonspecific sarcomas)	5
Mixed tumors (malignant mixed Müllerian, adenosarcoma)	3
Secondary tumors (metastasis, direct local extension: cervix, ovary, colon)	2

**TABLE 36.3-1.** Classification of Uterine Fundal Cancer

**FIGURE 36.3-1.** Adenocarcinomas of the endometrium are graded on the basis of their architectural pattern. A complex, branching, glandular pattern without solid areas, as seen in this photomicrograph, is characteristic of grade 1 cancers.

### EPIDEMIOLOGY

The normal endometrium is a hormonally responsive tissue. Estrogenic stimulation produces cellular growth and glandular proliferation, which is cyclically balanced by the maturational effects of progesterone.<sup>15</sup> Abnormal proliferation and neoplastic transformation of the endometrium has been associated with chronic unopposed exposure to estrogenic stimulation. It is currently believed that estrogen-associated endometrial cancers progress through a premalignant stage described as *atypical adenomatous hyperplasia*. This phase is characterized by increases in gland number and complexity as well as cytologic atypia. Although serial observations of women with adenomatous hyperplasia are scarce, it is estimated that at least one-third of such cases progress to carcinoma.<sup>16</sup>

The best-recognized risk factors for the development of endometrial carcinoma can be related to chronic estrogen exposure. These include oral intake of exogenous estrogen (without progestins), estrogen-secreting tumors, low parity, extended periods of anovulation, early menarche, and late menopause.<sup>17,18,19,20,21,22,23,24 and 25</sup>

Pregnancy represents a 9-month period of relatively intense progesterone stimulation by the placenta. Consequently, women with multiple pregnancies have a lower risk of endometrial lesions on the basis of this protective hormonal effect. Both menarche and menopause are commonly associated with absent or irregular ovulation, so women who experience early onset or late cessation of ovarian function are more likely to have additional estrogenic exposure.<sup>26</sup> Morbidly obese women also have a greater risk of endometrial cancer, presumably because their adipocytes are able to convert androstenedione of adrenal origin to estrone, a weak circulating estrogen.

Epidemiologic studies have consistently identified women with diabetes mellitus and hypertension as having an increased risk of endometrial carcinoma. This risk remains independent of other known factors in multivariate analyses. It has not been possible to connect these relatively common medical conditions to the “estrogenic hypothesis” of endometrial carcinogenesis. Epidemiologic risk factors for endometrial cancer are listed in [Table 36.3-2](#).

Factors	Relative Risk
<b>CHRONIC ESTROGENIC STIMULATION</b>	
Estrogen replacement (no progestin)	2-12
Early menarche/late menopause	1.5-4.0
Nulliparity	2-3
Anovulation	ND
Estrogen-producing tumors	ND
<b>DEMOGRAPHIC CHARACTERISTICS</b>	
Increasing age	4-6
Caucasian race	2
High socioeconomic status	1.3
European/North American country	2-3
Family history of endometrial cancer	2
<b>ASSOCIATED MEDICAL ILLNESS</b>	
Diabetes mellitus	2
Gallbladder disease	3.7
Obesity	2-4
Hypertension	1.5
Prior pelvic radiotherapy	6
ND, no data.	

Table compiled from multiple sources.

**TABLE 36.3-2.** Epidemiologic Risk Factors for Endometrial Carcinoma

There is extensive current interest in the potential connection between long-term tamoxifen use as adjuvant therapy for women with breast cancer and the development of endometrial cancers. Although primarily an estrogen antagonist, tamoxifen also has some agonist properties. The diagnosis of endometrial cancer among a few women taking tamoxifen on the National Surgical Adjuvant Breast and Bowel Project trial has raised concerns about the safety of such therapy.<sup>27</sup> Some pathology reviews of tamoxifen-associated endometrial tumors have identified a preponderance of poor-prognosis tumors, whereas others have noted a majority of low-risk lesions.<sup>28,29,30,31,32</sup> and <sup>33</sup> A confounding variable is the known increased risk of endometrial tumors in women with breast cancer.<sup>34</sup> This issue is complex and evolving. On the basis of current information, it seems reasonable to conclude that (1) if an association between tamoxifen and endometrial carcinoma exists, the overall risk is small compared with the risk of recurrent breast cancer, and (2) women receiving long-term tamoxifen therapy should be monitored carefully for uterine abnormalities. Ultrasonic assessment of the contour and thickness of the endometrium is frequently used to monitor such patients, but its value is unproven. Certainly, any woman with abnormal vaginal bleeding should be evaluated promptly by biopsy. Exposure to adjuvant tamoxifen therapy should be limited to 5 years. The development of new selective estrogen receptor modulators that do not have stimulatory effects on the endometrium should eliminate all such risk for women who may benefit from antiestrogen therapy.

### NATURAL HISTORY AND ROUTES OF SPREAD

Endometrial carcinoma is a disease of postmenopausal women. The average age at diagnosis is usually about 60 years. Women with high-risk tumors, such as grade 3 adenocarcinoma, papillary serous carcinoma, and clear cell carcinoma, tend to be slightly older. All endometrial lesions originate in the glandular component of the uterine lining. Their initial growth forms a polypoid mass within the uterine cavity ( [Fig. 36.3-2](#)). This tumor mass is friable and often contains areas of superficial necrosis. Consequently, postmenopausal bleeding is the hallmark symptom for more than 90% of patients. Because most women and their physicians recognize that this as an ominous finding, prompt diagnosis is common.

**FIGURE 36.3-2.** Endometrial cancers develop as polypoid lesions that gradually expand to fill the uterine cavity. This well-differentiated tumor involves both the anterior and posterior uterine walls throughout the entire fundus. Scattered areas of superficial necrosis give rise to the hallmark symptom of postmenopausal bleeding.

With further growth, the primary tumor may extend to involve a greater proportion of the endometrial surface and ultimately extend to the lower uterine segment and cervix. Invasion into the myometrium occurs simultaneously. The uterus has a rich and complex lymphatic network. Channels draining the superior portion of the fundus parallel the ovarian vessels and empty into the paraaortic lymph nodes in the upper abdomen. Lymphatics from the middle and lower portions of the uterus travel through the broad ligaments to the pelvic nodes. A few small lymphatic vessels course through the round ligaments to the superficial inguinal nodes. As a result of this extensive network, nodal metastases can occur at any level and in any combination.<sup>35</sup>

Tumors that penetrate the uterine serosa may directly invade adjacent tissues, such as the bladder, colon, or adnexae, or they may exfoliate into the abdominal cavity to form implant metastases. Small tumor fragments may also gain access to the peritoneal cavity by traversing the fallopian tubes. However, the clinical importance of this potential mechanism of spread is uncertain. Hematogenous dissemination is observed but uncommon. Sites of distant spread include lung, liver, bone, and brain.

### DIAGNOSIS AND PRETHERAPY EVALUATION

A diagnosis of endometrial carcinoma should be considered in postmenopausal women with any vaginal bleeding, perimenopausal women with heavy or prolonged bleeding, and premenopausal women with abnormal bleeding patterns who are obese or oligo-ovulatory. Although a formal dilatation and curettage has been the standard technique for diagnosis, outpatient endometrial biopsy has replaced it in most situations.<sup>36,37</sup> and <sup>38</sup> A correctly performed endometrial biopsy includes an adequate amount of tissue obtained from multiple passes through the uterus, and it has a diagnostic accuracy equivalent to that of surgical curettage under anesthesia. Operative sampling may be necessary in unusual patients, such as those with cervical stenosis, inadequate outpatient biopsy, or inability to tolerate an outpatient examination and procedure. Asymptomatic women with endometrial cancer occasionally have abnormal glandular components detected by routine cervical cytology ([Fig. 36.3-3](#)). Because the Papanicolaou (Pap) smear is designed to sample the cervical epithelium, this method of diagnosis is uncommon. Fewer than 50% of women with known endometrial cancer have an abnormal Pap smear.<sup>39,40</sup>

**FIGURE 36.3-3.** This photomicrograph shows two small tissue fragments demonstrating the typical features of adenocarcinoma. Although not universally seen, such findings are sometimes identified on routine cervical cytology specimens and lead to the diagnosis of endometrial cancer in an asymptomatic woman.

Endometrial carcinoma is a surgically treated and staged tumor. Consequently, the focus of the pretreatment evaluation is on the detection of unresectable disease and a determination of operative risk. For patients with disease that is clinically limited to the uterus by physical examination, a straightforward evaluation that includes laboratory studies, a chest radiograph, and an electrocardiogram is adequate. A serum CA-125 assay should be considered in women with high-risk histologic types because it may be predictive of occult extrauterine disease and may be useful as a tumor marker.<sup>41,42 and 43</sup> More sophisticated imaging studies such as ultrasound, computed tomography, intravenous pyelography, and magnetic resonance imaging rarely provide information that is not determined after surgical exploration. These studies should be reserved for patients with advanced disease or prohibitive surgical risks. Many women with endometrial cancer are elderly and have associated medical conditions, particularly obesity, diabetes, and hypertension. The pretreatment medical evaluation should be individualized based on findings obtained from the medical history and general physical examination.

### RISK FACTORS

Histopathologic risk factors have been extensively evaluated since the late 1970s.<sup>44,45,46,47,48 and 49</sup> For convenience, these can be grouped into uterine and extrauterine categories. Major prognostic factors associated with the uterine component of the tumor are grade or cell type, depth of myometrial invasion, and tumor extension to the cervix. Less important are extent of uterine cavity involvement,<sup>50</sup> lymph–vascular space invasion,<sup>51</sup> and tumor vascularity. Obviously, women whose tumors have spread beyond the uterus have a poorer prognosis. The major extrauterine risk factors are adnexal metastases, pelvic or paraaortic lymph node spread, positive peritoneal cytology, peritoneal implant metastases, and distant organ metastases.

A detailed analysis of nearly 1000 patients has been presented by the Gynecologic Oncology Group (GOG).<sup>49</sup> The relative risks for the various histologic factors evaluated in that study are summarized in [Table 36.3-5](#). The risk for developing recurrent disease was greatest in women whose tumors had metastasized to pelvic or paraaortic lymph nodes, demonstrated gross intraperitoneal spread, or contained unequivocal lymph–vascular space invasion. Not surprisingly, an exceptionally high incidence of recurrence was noted in cases with two or more risk factors. Based on the findings of this and other surgical staging trials, the International Federation of Gynecology and Obstetrics (FIGO) adopted a surgical staging system for uterine fundal cancers in 1988.<sup>4</sup>

Positive Risk Factor	Frequency of Recurrence*			Comment
	Radical Therapy	No Radical Therapy	Total (%)	
Specific factor				
Pelvic node	4/36 (11%)	0/1 (0%)	5/38 (13%)	
Adnexa node	0/7	0/5	0/12 (0%)	
Adnexa	1/9	0/5	1/14 (7%)	
Cervix invasion	1/3	0/2	1/5 (20%)	
Coagula	1/2 (20%)	0/4	1/6 (16%)	1/4 with implants only
CE	0/9	0/4	0/13 (0%)	0/2 with implants only
Subserosa/ovary	0/10 (0%)	1/9 (11%)	1/19 (5%)	0/4 with implants only
Total				
One factor	21/139 (15%)	12/96 (12%)	33/135 (24%)	1/10 with implants only
Two factors	25/98 (26%)	6/18 (33%)	31/116 (27%)	0/2 with implants only
Three or more factors	18/42 (43%)	11/31 (35%)	29/73 (40%)	

CE, epithelial cell space invasion; P, pelvic node; A, adnexa; C, cervix; CO, coagula; O, ovary; S, subserosa; I, implant metastases.

 †Some groups of patients with one positive factor did not have sufficient follow-up. Eighteen patients with two or more positive factors did not have sufficient follow-up.  
 ‡Data not all with primary.

**TABLE 36.3-5.** Frequency of Recurrence in Patients with Positive Risk Factors

In addition to the more classic histologic risk factors, several studies have examined archival specimens to evaluate a number of potential molecular markers. Data suggesting a prognostic role for DNA ploidy, S-phase fraction, oncogenes, tumor suppressor genes, AgNOR, and nuclear morphometric features should be considered preliminary.<sup>52,53,54,55,56,57,58 and 59</sup> Further prospective study in larger numbers of fresh tissue specimens may lead to a refinement of risk assessment. This would be particularly useful if it permitted the identification of the small percentage of otherwise low-risk patients who are destined to develop recurrent disease. Data reported by Lim and colleagues<sup>60</sup> suggest that this approach is possible using ploidy and p53 overexpression as markers.

Some women have a genetic predisposition for endometrial cancer. Endometrial tumors are a component of some of the cancer family syndromes identified and evaluated by Lynch and colleagues.<sup>61,62</sup> Within these unique families, the risk of developing endometrial cancer may approach 50%. However, cancer syndromes account for relatively few cases of endometrial carcinoma overall. Endometrial cancer is also more common in women with a previous cancer of the breast, colon, or ovary. Dual neoplasms may occur simultaneously or metachronously. The time interval between the diagnosis of the two neoplasms may be as long as 10 years.<sup>34</sup>

### STAGING

Before 1988, uterine fundal cancers were staged clinically. The clinical staging system stratified patients with early disease on the basis of a fractional biopsy specimen from both the endocervix and the endometrium as well as the depth of the uterine cavity and physical examination ([Table 36.3-3](#)). These techniques for assessment of disease volume and spread were found to be erroneous in as many as one-third of cases when compared with histopathologic findings at the time of laparotomy.<sup>63,64</sup> In addition, women with small-volume disease in retroperitoneal nodes or the peritoneal cavity were rarely identified during clinical staging. The clinical system was abandoned because the accumulating data from surgical staging reports was more accurate and allowed stratification of similar risk groups for adjuvant and adjunctive therapy trials. Consequently, the surgical staging system approved at the 1988 FIGO meeting is currently used for most patients with uterine fundal cancers ([Table 36.3-4](#)). Risk factors incorporated into this system include depth of myometrial invasion, tumor extension to the cervix, tumor spread to adnexal organs, peritoneal cytology, retroperitoneal lymph node metastases, and spread to abdominal or distant sites. The clinical staging criteria have been retained for patients who do not undergo surgical exploration as a part of their initial treatment. Patients in this group are those with obviously advanced cancers who would not benefit from tumor resection by hysterectomy and those with medical conditions that preclude an operative procedure.

Stage	Description
I	The tumor is limited to the uterine fundus.
IA	The uterine cavity measures 8 cm or less.
IB	The length of the uterine cavity is greater than 8 cm.
II	The tumor extends to the uterine cervix.
III	The tumor has spread to the adjacent pelvic structures.
IV	There is bulky pelvic disease or distant spread.
IVA	Tumor invades the mucosa of the bladder or rectosigmoid.
IVB	Distant metastases are present.

\*International Federation of Gynecology and Obstetrics, 1971.

**TABLE 36.3-3.** Clinical Staging of Uterine Fundal Tumors<sup>a</sup>

Stage	Description
I	The tumor is confined to the uterine fundus.
IA	The tumor is limited to the endometrium.
IB	The tumor invades less than one-half of the myometrial thickness.
IC	The tumor invades more than one-half of the myometrial thickness.
II	The tumor extends to the cervix.
IIA	Cervical extension is limited to the endocervical glands.
IIB	The tumor invades the cervical stroma.
III	There is regional tumor spread.
IIIA	The tumor invades the uterine serosa or adnexa, or there is positive peritoneal cytology.
IIIB	Vaginal metastases are present.
IIIC	The tumor has spread to pelvic or paraaortic lymph nodes.
IV	There is bulky pelvic disease or distant spread.
IVA	Tumor invades the mucosa of the bladder or rectosigmoid.
IVB	Distant metastases are present.

\*International Federation of Gynecology and Obstetrics, 1989.

**TABLE 36.3-4.** Surgical Staging of Uterine Fundal Tumors<sup>a</sup>

## TREATMENT OF PRIMARY DISEASE

### Surgical Resection and Operative Staging

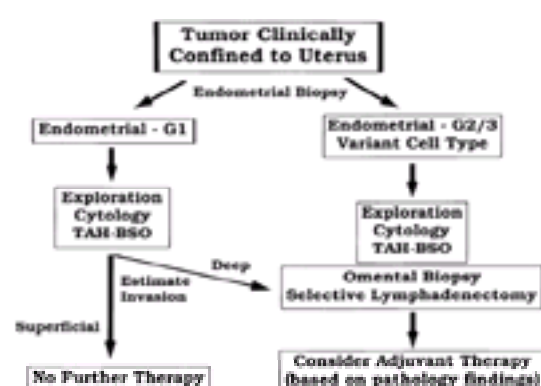

Resection of the primary tumor by total abdominal hysterectomy and bilateral salpingo-oophorectomy is the mainstay of therapy for uterine cancers.<sup>65</sup> Because endometrial cancer originates in the fundus, adequate surgical margins can usually be achieved by simple extrafascial hysterectomy. Salpingo-oophorectomy is recommended because the ovary is a relatively common site of occult metastasis and because most women are already postmenopausal and no longer have hormonal function from the organ. Removal of the uterus is curative treatment for most stage I cases. The more extensive radical hysterectomy has been recommended for selected patients with gross tumor involvement of the cervix.<sup>66,67</sup> However, combined therapy, using both external-beam pelvic irradiation and extrafascial hysterectomy, is more frequently used in such cases.<sup>68,69,70,71</sup> and <sup>72</sup> The increased expansion of endoscopic surgery has permitted its application in endometrial cancer. The staging portion of the operation is performed endoscopically followed by a transvaginal hysterectomy. Among surgical teams skilled in these techniques, the results appear to be equivalent to those obtained by open laparotomy.<sup>73</sup> Some evidence also suggests that aggressive cytoreduction may improve survival in women with extrauterine disease.<sup>74</sup>

The surgical staging system for uterine fundal tumors identifies certain histopathologic prognostic features for stage and substage assignment but does not define a specific surgical approach required to accomplish staging. The additional operative procedures associated with surgical staging produce a small, but definite, increase in operative risk. Most reported complications are related to organ injury during biopsy or hemorrhage from vascular injury during node sampling.<sup>75,76</sup> and <sup>77</sup> Patients who have extensive intraperitoneal staging procedures also have a greater risk of bowel injury if they receive postoperative external irradiation.<sup>78</sup>

Who should undergo surgical staging? Some advocate an extended staging procedure for all women with endometrial cancer. Our approach has been to limit surgical staging to patients at risk for occult disease spread. We routinely perform staging procedures in women with grade 2 or 3 adenocarcinomas and those with variant histologic tumor types. This group typically represents approximately one-third of cases. For patients with grade 1 adenocarcinoma, we estimate the depth of myometrial invasion intraoperatively by making a visual estimate<sup>79</sup> and evaluating a frozen section (Fig. 36.3-4). Extended staging procedures are only performed when significant myometrial invasion (more than 50%) is identified. Using this stratified approach to surgical staging minimizes surgical risk for patients with low-risk tumors while maximizing the chance for detecting occult extrauterine disease in those patients at risk (Fig. 36.3-5).

**FIGURE 36.3-4.** The depth of myometrial invasion can be estimated by visually examining a cut section of the uterine wall taken at the level of the tumor. A clear line distinguishes polypoid tumor growth from myometrium in this surgical specimen. The accuracy of intraoperative visual estimates can be enhanced by using frozen section analysis in selected cases.

**FIGURE 36.3-5.** Schematic representation of a staging algorithm. Patients with grade 1 (G1) typical endometrial adenocarcinoma have an exploratory laparotomy with peritoneal cytology, total abdominal hysterectomy (TAH), and bilateral salpingo-oophorectomy (BSO). The depth of myometrial invasion and extension to the cervix

are evaluated intraoperatively. Those with low-risk features have no further therapy, whereas those with high-risk features undergo an extended staging operation. All patients with grade 2 or 3 (G2/3) endometrial tumors and those with variant histologic types (papillary serous, papillary endometrioid, clear cell) undergo an extended staging procedure.

An equally important question is what procedures constitute an adequate staging effort. After the collection of cytology specimens and completion of the hysterectomy, the staging assessment is focused on two general areas—the peritoneal cavity and the retroperitoneal lymph nodes. Many gynecologic oncologists have adopted a staging approach similar to that used for women with epithelial ovarian carcinoma. Evaluation of the peritoneal cavity begins with a careful visual and palpatory inspection. Abnormal areas from peritoneal or serosal surfaces are biopsied. In the absence of obvious disease spread, random biopsies from multiple peritoneal sites are obtained. Cytology or histology samples, or both, are also taken from the diaphragm. A portion of the omentum is removed. When we examined our peritoneal staging procedures in a group of at-risk women, we found that occult peritoneal spread is relatively uncommon.<sup>80</sup> Although directed biopsy of palpably suspicious areas often detected metastatic disease, random biopsies were rarely positive. Peritoneal cytology and omental biopsy, coupled with directed biopsy from abnormal sites, provided accurate and reliable information regarding intraperitoneal disease.

The lymphatic drainage of the uterine fundus is complex. Cancers may access either the pelvic or paraaortic nodes, and occasionally the inguinal nodes, on either side. Consequently, detecting retroperitoneal lymph node spread is a potentially difficult problem. Various techniques for lymph node evaluation have been proposed, including palpation with biopsy of abnormal nodes, single lymph node biopsy, selective lymphadenectomy, and full node dissection.<sup>81,82</sup> and <sup>83</sup> We believe that a systematic and selective approach to lymphadenectomy reliably detects occult metastases and accurately portrays the true lymph node status.<sup>84</sup> More limited approaches are clearly less accurate. Kilgore and colleagues' suggestion that complete lymphadenectomy may carry a therapeutic advantage deserves further investigation.<sup>85</sup>

The primary goal of surgical staging is to provide an accurate assessment of disease spread at the time therapy is initiated. For patients with tumors confined to the uterus, those in the low-risk subgroup (grade 1 tumor with superficial myometrial invasion) are adequately treated by hysterectomy alone. Fortunately, such cases account for most women with endometrial cancer. Women with tumors demonstrating high-risk features have an incidence of recurrent disease of 25% to 40% and are excellent candidates for adjuvant therapy trials. Patients with more advanced disease warrant additional postoperative adjunct treatment.

### Radiotherapy

**HISTORICAL PERSPECTIVE.** Within a few years of Marie Curie's discovery in 1895, radium was used to treat uterine cancers. Early reports of pathologic complete responses to radiation, encouraging survival rates with combined treatment, and the reduction of postoperative vaginal recurrences fueled enthusiasm for combined treatment.<sup>86,87</sup> By the 1950s, preoperative irradiation followed by hysterectomy had become standard treatment for early-stage endometrial cancer in the United States and other countries, although a few clinicians argued the advantages of selective postoperative irradiation.<sup>88,89</sup> The development of megavoltage radiotherapy in the 1950s reduced the risk of pelvic irradiation and increased the use of this modality to prevent pelvic recurrences. In more recent years, clinicians increasingly have come to appreciate the value of operative findings as a guide to the selection of adjuvant treatment. Because preoperative irradiation has never been proven to be more effective than tailored postoperative radiation therapy, its use has declined in favor of treatment with initial surgery.<sup>65,90,91</sup> Moreover, although radiation therapy has been clearly demonstrated to reduce the rate of pelvic disease recurrence after hysterectomy, the influence of adjuvant irradiation on the survival rate of patients with endometrial carcinoma has never been clearly determined. As a result, investigators continue to disagree about the role that adjuvant radiotherapy should play in the management of uterine carcinomas.

Several factors have made it difficult to study the value of adjuvant treatment. Because most newly diagnosed endometrial carcinomas are clinically confined to the uterus, with cure rates of 80% to 90% after treatment with hysterectomy alone, the margin for improvement is small. To detect any advantage from adjuvant treatment, studies must have many patients or must be confined to subgroups that are at high risk for recurrence. The influences of physicians' biases on the selection of patients for adjuvant treatment have limited the value of retrospective studies. Retrospective experiences are also difficult to compare because of changes that have been made in the classification systems for staging and grading neoplasms and the relatively recent recognition of special high-risk histologic subtypes. For these reasons, the selection of treatment is based primarily on clinicians' understandings of the risk factors for recurrence and the natural history of the disease, impressions gained from inconclusive studies, and physician or patient preference.

**PREOPERATIVE IRRADIATION.** The primary goal of preoperative intracavitary irradiation is to prevent vaginal recurrences. Bedwinek et al.<sup>92</sup> observed an inverse correlation between the dose of intracavitary treatment and the incidence of distant metastases in their patients, but other investigators have not confirmed this result. Intrauterine applicators are usually loaded with 35 to 40 mgRaEq of cesium and left in place for approximately 72 hours for a total exposure of 3500 to 4000 mgRaEq-hr. Vaginal applicators are loaded to deliver 60 to 70 Gy to the surface of the apical vagina over the same period. Inserting additional sources in the form of Heyman or Simon capsules may increase the dose to the fundus. After this dose of radiation, hysterectomy can be safely performed within 2 to 3 days.<sup>93,94</sup> Immediate hysterectomy is usually preferred because important prognostic information about the depth of tumor infiltration is retained. Although the popularity of preoperative irradiation has declined, some groups still support its use for patients with grade 2 or 3 tumors. Preoperative irradiation is not indicated for patients with grade 1 tumors that are clinically confined to the uterus, because low-grade carcinomas are usually superficial and have a very low risk of recurrence after treatment with hysterectomy alone.

The theoretical arguments for preoperative irradiation are strongest for patients with uterine cancers that grossly involve the cervix, because preoperative intracavitary techniques deliver a greater dose to the paracervical tissues than is possible with postoperative vaginal irradiation. Combined preoperative external-beam and intracavitary irradiation may be indicated for patients with nonserous tumors that extensively infiltrate the cervix. However, when external-beam irradiation is given preoperatively, hysterectomy should be delayed 4 to 6 weeks.

Because radiation therapy has been used to treat high-risk endometrial carcinoma for many years, few unselected series of patients treated with surgery alone have been reported. In early series, overall vaginal recurrence rates were as high as 15% to 25%.<sup>87,95</sup> However, changes in the staging of disease and methods of reporting results make it difficult to relate these results to current experience. A few authors have reported much lower vaginal recurrence rates after surgery alone and have suggested that the wide range of reported local recurrence rates may, in part, reflect variations in surgical technique that influence the risk of tumor cell implantation.<sup>96,97</sup>

Most data suggest that irradiation reduces the incidence of vaginal recurrence from 10% to 15% to less than 5% for patients with high-risk disease. In a compilation of series published between 1967 and 1973, Jones<sup>87</sup> reported an overall incidence of vaginal recurrences of 4.6% in patients treated with preoperative radium compared with 10.6% in patients treated with surgery alone. Subsequent series reported vaginal relapse rates of 0% to 5% for patients with clinical stage I disease treated with preoperative intracavitary irradiation ( [Table 36.3-5](#) ).<sup>93,94,97,98,99,100,101,102</sup> and <sup>103</sup> However, these results cannot be compared with the recurrence rates of patients not treated with radiation because, in nearly all studies, patients who had a higher risk of recurrence were selected to receive combined treatment ( [Table 36.3-6](#) ).

**TABLE 36.3-6.** Rates of Vaginal Recurrence for Patients Treated with Hysterectomy for Endometrial Carcinoma

**POSTOPERATIVE REGIONAL IRRADIATION.** For many years, the only prospective randomized study that had evaluated the benefit of postoperative pelvic irradiation was one conducted at the Norwegian Radium Hospital and published in 1980.<sup>104</sup> Patients with clinical stage I adenocarcinomas underwent total abdominal hysterectomy and bilateral salpingo-oophorectomy. Those proven to have metastases at laparotomy were excluded from the study, but no consistent surgical evaluation was performed. The remaining 540 patients received 60 Gy with brachytherapy to the surface of the apical vagina and were then randomized either to receive 40 Gy of pelvic radiotherapy or no further treatment.

Although patients who received pelvic irradiation in this study had a lower rate of pelvic recurrences, there was no significant improvement in overall disease-specific survival. The data suggested that the survival rate of patients with deeply invasive grade 3<sup>104</sup> tumors may be improved with radiotherapy, but the number of patients in this subset was small, and the result was not statistically significant. The authors suggested that regional irradiation may have failed to improve the survival rate because patients whose pelvic disease was controlled recurred instead at distant sites. However, local control appeared to be most improved for patients with tumors that deeply invaded the myometrium, whereas the higher rate of distant metastases was seen primarily in irradiated patients with superficial or no muscle invasion. However, although the Norwegian study is one of the largest published series of patients with endometrial cancer, few patients with high-risk disease and relatively few disease-related deaths were reported. As a result, the study was unable to demonstrate or rule out moderate differences in survival rates between patient subgroups.

Several studies that document 80% to 90% survival rates for patients with high-risk disease treated with postoperative radiotherapy provide indirect evidence of the efficacy of regional irradiation.<sup>49,105,106,107,108,109,110</sup> and <sup>111</sup> Carey and colleagues<sup>111</sup> reported an 81% 5-year relapse-free survival rate for 157 patients with clinical stage I disease and high-risk features (deep myometrial invasion, grade 3, adenosquamous histology, or cervical involvement) who were prospectively treated with a standardized treatment protocol. The local recurrence rate was 29% in 28 patients who refused recommended pelvic radiotherapy compared with 4% in those who received the treatment as per protocol ( $P = .03$ ). Overall recurrence rates (29% vs. 16%) were not significantly different. In another prospective phase II trial, Piver and Hempling<sup>108</sup> reported a 5-year survival rate of 88% in 41 patients who received postoperative pelvic radiotherapy for deeply invasive or grade 3 tumors that were surgically staged with a finding of negative paraaortic nodes. Only one patient had disease recurrence within the radiation treatment field. Kucera et al.<sup>107</sup> reported a survival rate of 88% for 229 patients who had infiltration of the outer one-third of the myometrium or grade 2 or 3 tumors that involved the middle third. This survival rate was not significantly different from that of 376 patients who had more favorable tumors treated with hysterectomy and vaginal irradiation alone (91%). The GOG reported a 70% projected 5-year survival rate in 63 patients who had metastases to the pelvic nodes without paraaortic node involvement.<sup>49</sup> Of these studies, only one (that by Carey and colleagues<sup>111</sup>) excluded patients with papillary serous neoplasms from the analysis. Because the tendency of serous tumors to recur intraperitoneally is not adequately addressed with local treatment, their inclusion in studies of adjuvant pelvic irradiation tends to obscure its possible benefit to patients with high-risk endometrioid tumors.

The GOG completed a randomized trial comparing surgery with surgery plus pelvic radiation therapy in 448 women with intermediate risk endometrial adenocarcinoma.<sup>112</sup> The dose of pelvic radiation was 50.4 Gy, and brachytherapy was not used in either arm. All patients underwent complete surgical staging and only those with FIGO stage IB, IC, or occult stage II disease were eligible. With a median follow-up of 56 months, the estimated 2-year progression-free interval was 96% for patients who received adjuvant radiation therapy versus 88% for those treated only with surgery ( $P = .004$ ). Disease recurred in the pelvis in three patients treated with adjuvant radiation and in 17 patients treated with surgery alone. Overall survival rates for patients treated with or without adjuvant radiation were 96% and 89%, respectively, at 36 months; this difference was not statistically significant ( $P = .09$ ). This study clearly confirms the ability of postoperative irradiation to reduce local recurrence, although some of this reduction may have been achievable with brachytherapy alone. Opponents of adjuvant irradiation argue that survival was not improved by adjuvant treatment. However, follow-up of this study is still incomplete, and the inclusion of patients with very favorable (e.g., stage IB, grade 1) tumors may dilute a survival benefit to remaining patients (if it exists).

These studies suggest that pelvic radiotherapy is indicated for patients with endometrioid or mucinous tumors that are confined to the pelvis and have features that predict a high risk of recurrence in the pelvis. The potential benefit of treatment should be carefully balanced against the risk of complications, particularly for patients with a history of pelvic infection, multiple abdominal surgical procedures, or severe diabetes mellitus. Patients whose tumors invade the myometrium by more than 50% or involve the cervical stroma, lymph-vascular spaces, or pelvic lymph nodes are at highest risk for pelvic recurrence and are usually treated with external-beam radiation to the true pelvis. Other risk factors may be used to select treatment for tumors with intermediate risk factors (e.g., grade 2 tumors invading to the middle third of the myometrium). Schink et al.<sup>113</sup> reported that tumors measuring less than 2 cm in diameter rarely involved pelvic nodes, whereas those involving the entire uterine cavity had a high risk of pelvic nodal involvement and disease recurrence even when the outer half of the myometrium was not invaded. Patients with intermediate risk factors in the uterus who have had extensive nodal dissections without demonstration of nodal involvement are less likely to benefit from regional irradiation, particularly in view of the possible increased risk of late complications in patients who have had staging lymphadenectomies.<sup>114,115</sup> and <sup>116</sup>

Pelvic radiotherapy is usually delivered using a four-field technique or anteroposterior opposed fields with 15 to 20 MV photons to a total dose of 40 to 50 Gy. Serious complications are observed in 2% to 5% of patients who receive this treatment, but complications may be greater for patients who have had a staging lymphadenectomy.<sup>114,115</sup> and <sup>116</sup> Corn and colleagues<sup>116</sup> also reported a correlation between external-beam irradiation and the risk of complications. Some clinicians give additional intracavitary irradiation to the vaginal cuff after pelvic radiotherapy, although investigators disagree about the benefit of this treatment. Bliss and Cowie<sup>117</sup> reported a lower vaginal recurrence rate (10% vs. 0%) in patients who had intracavitary irradiation added to external-beam irradiation, but gastrointestinal toxicity was also increased. In contrast, Randall et al.<sup>118</sup> reported no difference in local control or complication rates when the vaginal cuff received an intracavitary radiation boost. Several authors<sup>117,119,120</sup> have reported increased complication rates when an intracavitary boost was added to 45 to 50 Gy of external-beam radiotherapy to the pelvis; however, these groups tended to give relatively high doses (more than 50 Gy) or rapid dose rates (more than 70 cGy/hr) to the vaginal surface.

**EXTENDED-FIELD IRRADIATION.** Extended-field irradiation appears to be effective treatment for patients with nonserous endometrial cancer metastatic to paraaortic nodes. Between 30% and 50% of patients survive 5 years with this treatment (Table 36.3-7).<sup>49,121,122,123,124,125,126,127</sup> and <sup>128</sup> Survival rates are not clearly different for patients with gross or microscopic nodal involvement.<sup>125,129</sup> In their review of 50 patients, Corn et al.<sup>124</sup> reported a lower rate of recurrence in paraaortic lymph nodes in patients who had had a lymph node dissection in addition to extended-field irradiation. However, multivariate analysis suggested that the risk of recurrence was not significantly decreased by combined treatment. In another study, Onda and colleagues<sup>128</sup> reported a 5-year survival rate of 75% for 20 patients treated with lymphadenectomy followed by cisplatin-containing chemotherapy and extended-field irradiation. Further study is needed to determine whether this excellent survival rate is reproducible.

**TABLE 36.3-7.** Survival Rate of Patients Treated with Extended-Field Irradiation for Endometrial Carcinoma Metastatic to Paraaortic Lymph Nodes

**WHOLE ABDOMINAL IRRADIATION.** The poor prognosis of uterine papillary serous carcinomas and their tendency to spread and recur intraabdominally have led radiation oncologists to explore the value of treatment with whole abdominal irradiation. The 68% abdominal recurrence rate reported by Greven et al.<sup>130</sup> in patients with pathologic stage III papillary serous or clear cell carcinomas after treatment with pelvic or extended-field radiotherapy demonstrate why smaller radiation fields are usually inadequate for this disease. Although whole abdominal radiotherapy is accepted by many clinicians as a standard treatment for papillary serous

carcinoma, there are as yet only anecdotal reports supporting its efficacy. <sup>123,131,132</sup> Potish<sup>123</sup> reported long-term survival in five (57%) of nine patients who had intraperitoneal spread from uterine papillary serous carcinoma at diagnosis, and Malipeddi et al. <sup>131</sup> reported survival durations of 102 to 133 months in five of ten patients treated with whole abdominal irradiation. Three of the patients who survived more than 5 years had been diagnosed with pathologic stage IIIA disease. Treatment techniques are similar to those used to treat patients with primary ovarian carcinomas.

Some authors have advocated the use of whole abdominal irradiation for patients with tumors of other histologic subtypes. <sup>133</sup> The number of patients treated in these series is insufficient to determine whether the treatment is better than locoregional irradiation or even whether it is beneficial. Most studies suggest that intraabdominal dissemination is an uncommon pattern of spread in patients with nonserous histologic subtypes, even when malignant cells are seen in peritoneal washings taken at the time of hysterectomy. Although some have advocated whole abdominal irradiation to treat patients with positive peritoneal cytology, there is little evidence that this finding predicts a pattern of intraabdominal recurrence in patients with the more common endometrioid subtypes of endometrial carcinoma. Thus, treatment directed specifically at the positive cytology may not be warranted. <sup>134</sup>

The GOG is comparing whole abdominal radiation therapy with chemotherapy (cisplatin and doxorubicin) for patients with FIGO (1988) stage III and IV disease (less than 2 cm residual).<sup>133</sup> This study will be of particular interest for its comparison of the two treatments in patients with papillary serous tumors, although it will also include patients with nonserous stage III tumors for whom the risk of intraabdominal dissemination is probably small.

**POSTOPERATIVE VAGINAL IRRADIATION.** Some patients with minimally invasive grade 2 or noninvasive grade 3 tumors have a significant risk of vaginal recurrence despite a relatively low risk of pelvic node metastases. Implantation of tumor cells in the vaginal cuff incision may be an important mechanism of recurrence in these cases.

Postoperative intracavitary irradiation appears to be a very effective method of preventing vaginal cuff recurrences. Calais et al. <sup>101</sup> reported no differences between the survival and vaginal recurrence rates of patients treated with preoperative or postoperative intracavitary radiation. Reported rates for central recurrence range from 0% to 5% for patients treated with postoperative intracavitary irradiation alone, with the variation partly reflecting the different selection criteria used by various groups.<sup>87,98,99,101,107,108,111,135,136</sup>

A variety of different types of intracavitary applicators have been used to treat the vaginal cuff. Radioactive sources are usually placed in vaginal ovoids or in a plastic dome-shaped vaginal cylinder. The arrangement of sources and shape of the cylinder are designed to deliver a homogeneous dose to the apical vaginal surface. Additional sources may be used to treat the mid-vagina if desired. Because the dose of radiation decreases rapidly to approximately 50% to 60% of the surface dose at a depth of 0.5 cm beneath the vaginal mucosa, the dose to adjacent normal tissues is substantially less than the vaginal surface dose.

In the past, radiation was usually administered at low dose rates. Typically, the apical one-third to one-half of the vaginal surface was treated to a total dose of 60 to 70 Gy (30 to 40 Gy at 0.5 cm depth) at a dose rate of 90 to 100 cGy/hr (50 to 60 cGy/hr at 0.5 cm depth). With this treatment, most investigators report a risk of major complications of approximately 1% to 2%.<sup>98,103,104,108,119</sup> The complication rates tend to be higher with higher total doses and when more than one-half of the vaginal length is treated, although this has not been studied rigorously.

Today, fractionated high dose-rate intracavitary irradiation is increasingly being used as an alternative to low dose-rate irradiation to treat the vaginal cuff. This approach is more convenient for the patient and the physician and less costly than inpatient low dose-rate irradiation. <sup>137</sup> The use of high dose-rate brachytherapy has been less controversial in this setting than in the treatment of primary cervical cancer because only a modest dose of radiation is needed to prevent tumor recurrence in the vagina and because placement of the vaginal cylinder requires little manipulation and no sedation.

There is no clear consensus about the ideal dose or fractionation schedule for high dose-rate vaginal brachytherapy. Sorbe and Smeds <sup>135</sup> compared four fractionation schemes—4 × 9.0 Gy, 5 × 6.0 Gy, 6 × 5.0 Gy, and 6 × 4.5 Gy, prescribed at a tissue depth of 1.0 cm—in 404 patients who received intracavitary irradiation alone (without external-beam irradiation) after hysterectomy. The rates of acute and late complications were strongly correlated with fraction size. Eighty-eight percent of patients treated with 4 × 9.0 Gy had significant late rectal complications. Because the authors prescribed treatment at 1.0-cm depth, the total dose and dose per fraction at the mucosal surface were much higher than the specified dose.

Most authors have recommended more conservative fractionation schemes. Treatment is usually prescribed at the surface or 5 mm beneath the mucosa. When the dose is prescribed at 5 mm beneath the mucosa, it should be remembered that the rectal mucosa will receive a total dose (and dose per fraction) that is similar to the prescribed dose. In some reports, investigators have recommended a number of fractionation schemes including, for example, 6 × 6 Gy, <sup>138</sup> 3 × 7 Gy,<sup>139</sup> 4 × 8.5 Gy,<sup>140</sup> and 2 × 16.2 Gy,<sup>141</sup> with doses specified at the vaginal surface. All have reported vaginal recurrence rates of less than 1.5% for patients with relatively favorable tumors.

**RADIOTHERAPY ALONE.** Although hysterectomy is the primary treatment of most endometrial carcinomas, radiotherapy alone is also an effective treatment that is sometimes indicated for patients who are medically inoperable or who have unresectable disease. Most authors report disease-specific survival rates of 75% to 85% and local recurrence rates of 10% to 20% for patients with clinical stage I to II disease treated with radiation alone. Prognosis is usually correlated with clinical stage and histologic grade. <sup>142,143,144,145,146,147</sup> and <sup>148</sup> Kupelian et al. <sup>146</sup> found that the survival rate of patients with papillary serous tumors was significantly poorer than that for patients with other histologic types of endometrial cancer. However, the disease-specific survival rate of 43% was not obviously different from that commonly reported for treatment of this tumor with hysterectomy alone.

Some authors recommend treatment with a combination of external-beam and intracavitary irradiation. <sup>144,147,148</sup> However, very good local control and survival rates also have been reported after treatment with brachytherapy alone. <sup>145,146</sup> Patients who have low-grade tumors that do not expand the uterus are probably effectively treated with intracavitary irradiation alone. Patients with large uterine cavities, cervical involvement, or grade 3 tumors may benefit from a course of external-beam irradiation before intracavitary treatment.

Brachytherapy must cover the uterine fundus adequately when treatment will not include a hysterectomy. A single uterine tandem with increased activity in the highest source may be sufficient for patients who have a very small uterine cavity. A number of applicator systems, such as the Heyman capsule or Simon afterloading systems, have been devised to improve the dose to the fundus in patients with larger uterine cavities. Both of these afterloading systems are used to pack the uterine cavity with radium or cesium sources to expand the dose distribution to the fundus. In some cases, two tandems can be placed in the right and left cornua of the uterus and loaded to achieve the desired distribution. Magnetic resonance imaging may be helpful in planning treatment.

Several groups have reported results of treatment with high dose-rate intracavitary radiation for patients with inoperable endometrial cancer. <sup>149,150</sup> and <sup>151</sup> In the largest of these series, Knocke and colleagues<sup>150</sup> reported results for 280 patients, most of whom had clinical stage I to II disease. Treatment appeared to be well tolerated, but the local recurrence rates were somewhat higher than those reported from earlier series. In particular, local control rates for patients with clinical stage IB and II tumors were only approximately 60%. This rate may possibly reflect a suboptimal distribution to the uterine fundus from the single-channel tandem applicator used in their treatments. Nguyen and Peterit<sup>151</sup> reported good uterine disease control rates (88%) but a high rate of perioperative morbidity and two perioperative deaths in 36 patients treated with high dose-rate brachytherapy for clinical stage I disease. Although this approach may offer advantages over low dose-rate brachytherapy for selected patients who are deemed medically inoperable, sedation may still be required to optimize applicator insertion. Deep venous thrombosis, a possible complication of prolonged bed rest during low dose-rate applications, can also be encouraged by prolonged lithotomy positioning for high dose-rate procedures. <sup>151,152</sup> Whatever method of brachytherapy is used, these patients should only be treated by experienced brachytherapists in a well-controlled environment with adequate monitoring and emergency medical support.

## **Systemic Adjuvants**

### **HORMONES.**

*Historical Background.* The original observations by Kelley and Baker <sup>153</sup> documenting the responsiveness of metastatic endometrial adenocarcinoma to progestogens encouraged the organization of the Endometrial Surgical Adjuvant Study Group in 1965, the forerunner of the GOG. This group's initial trial failed to demonstrate an effect of medroxyprogesterone acetate (MPA) on recurrences after surgical treatment of stage I endometrial cancer. <sup>154</sup> Nevertheless, it stimulated the interest of gynecologic oncologists in collaborative clinical trials and led directly to a grant application in support of GOG activities that began in May 1971. More recent studies

have focused on the role of adjuvant progestogens on higher risk populations with stage I or clinically occult stage II cancer.

*Adjuvant Hormonal Studies.* Progestogens have been widely used to treat metastatic endometrial cancer. Although no adjuvant effect of MPA was shown in the initial randomized study, optimistic results were obtained using adjunctive progestogens in women with stage I endometrial cancer compared retrospectively with patients treated only with local modalities.<sup>155,156</sup> Subsequent randomized studies, however, again failed to demonstrate survival differences.<sup>157,158</sup> and <sup>159</sup> Accordingly, some have argued for performing clinical trials on a better-selected population—for example, those with a greater chance of recurrence or with features that might render them more responsive to progestogens. However, such selection criteria produce the paradox that higher-risk tumors are less likely to be hormone responsive. Subset analyses have documented an unfavorable relative survival in “receptor-poor” versus “receptor-rich” stage I endometrial cancer treated with MPA. Studies have been initiated in Germany comparing higher doses of MPA (1000 mg orally daily) with tamoxifen and with observation in patients with stage I cancer and with nonrandomized use of MPA in women with stage II disease. However, because no fully published results from such newer adjuvant therapy trials have appeared, adjuvant hormonal therapy can only be recommended in the context of clinical trials. Similarly, nonrandomized experience with progestogens given as induction therapy before, or in lieu of, surgery in patients with preinvasive or minimally invasive disease, or in patients who are poor surgical risks, attests to their biologic activity but does not represent an established indication.<sup>160</sup>

In addition to the use of adjuvant progestogens alone, a large Italian study of women with FIGO stage I cancers randomized patients with invasion beyond one-third of the myometrium to either external radiation or external irradiation plus MPA. No differences were seen among arms.<sup>158</sup>

**CYTOTOXIC CHEMOTHERAPY.** Cytotoxic chemotherapy has been considered as an adjuvant treatment in certain circumstances when the risk of distant recurrence exceeds 20%. These circumstances include (1) any stage II tumor, (2) clear cell or papillary serous histology, (3) absence of hormone receptors, (4) preoperative finding of elevated CA-125, and (5) selected stage I disease with deep myometrial invasion. A study from the M. D. Anderson Cancer Center in patients with some of these adverse prognostic factors reported a favorable experience after adjuvant cisplatin, doxorubicin, and cyclophosphamide therapy.<sup>161,162</sup> Confirmation from randomized studies is lacking, however.

Because the only randomized study of adjuvant chemotherapy yielded negative results (GOG 34, a study comparing adjuvant doxorubicin to no further therapy after surgery and radiation for stage I and occult stage II high-risk endometrial cancer),<sup>49</sup> the GOG has subsequently launched studies to evaluate other adjunct modalities. In July 1995, GOG 99, which randomized all cell types (except papillary serous and clear cell) of surgical stage I or occult stage II endometrial cancers to either no additional treatment or pelvic radiotherapy, was closed to accrual. In a simultaneous trial, GOG 94 treated all papillary serous and clear cell tumors, regardless of stage, with whole abdominal radiation. Patients with other cell types and optimally debulked clinical stage III or IV were also eligible for this study.

New clinical trials have been proposed to compare combination chemotherapy (doxorubicin and cisplatin) and pelvic radiation in women with stage IB, IC, IIA, and IIB endometrial cancers. It is hoped that better patient selection, higher dose intensity, use of a more active drug regimen, and avoidance of the toxicities seen in GOG 34 from doxorubicin after pelvic radiation will allow systemic therapy to demonstrate a benefit, even though this combination regimen does not enhance survival in patients with advanced disease.<sup>163</sup> A resurgence of interest in consolidation therapy with simultaneous irradiation and chemotherapy is likely as paclitaxel and cisplatin are more tolerable in such situations than doxorubicin. In addition, drug combinations have been proposed before local irradiation in high-risk patients (those with papillary serous/clear cell histology, pathologic stage III and IVA disease, and earlier stages beyond IA if they have at least any two of the following unfavorable risk factors: grade 3 disease, more than one-third myometrial invasion, cervical stromal invasion, and vascular space involvement).

## TREATMENT OF RECURRENT DISEASE

### *Treatment Failure*

Treatment failure in low-risk patients is exceedingly rare. In our series investigating surveillance strategies, we had only one failure in this group.<sup>164</sup> Tumor recurrence is most common in women with advanced-stage disease or those with high-risk features in their primary tumor. Late recurrence is uncommon, and virtually all failures are clinically evident within 3 years of original diagnosis.<sup>164,165</sup> and <sup>166</sup>

One-half of patients whose tumors recur are symptomatic. A targeted examination and diagnostic evaluation should readily lead to the correct diagnosis. The remaining group with treatment failure have their recurrence detected during routine surveillance. Although the Pap smear and chest radiograph may detect an asymptomatic recurrence, this clinical scenario is rare. Most recurrences are detected by physical examination. Serum CA-125 levels may be useful in monitoring patients for the development of recurrent disease, especially those who have papillary serous carcinomas or intraperitoneal disease.<sup>42,167</sup> Follow-up intervals of 6 to 12 months coupled with prompt evaluation of symptomatic patients seems to be an appropriate approach to surveillance. Routine use of diagnostic studies beyond cytology and the selective use of CA-125 is probably not cost effective.

The patterns of recurrence depend on initial disease distribution. Patients with advanced primary disease tend to have abdominal or systemic failure. Approximately one-third of recurrences seen in women whose primary tumors were confined to the uterus are limited to the pelvis; the remaining two-thirds have some component of distant failure.<sup>3</sup> It is important to identify those cases with isolated pelvic recurrence because some can be salvaged by radiotherapy or ultraradical surgery.<sup>168,169</sup> Conversely, treatment of systemic recurrence is largely palliative.

### *Systemic Agents*

## HORMONE THERAPY.

*Overview of Clinical Studies.* Progestogens have been used in the management of recurrent endometrial cancer after the original report by Kelly and Baker in 1961<sup>153</sup> used the parenterally administered hydroxyprogesterone caproate.<sup>153,170,171</sup> and <sup>172</sup> Beneficial results from these trials were mostly confined to a subset of patients with well-differentiated tumor, metastases to the lung, and a long disease-free interval between diagnosis of the primary tumor and the development of metastases. Subsequent trials, using MPA or megestrol acetate, explored the use of high-dose progestogen therapy on better-selected patients through the study of hormone receptor content of tumors and limiting therapy to receptor-positive cases, paralleling breast cancer strategies.<sup>172,173</sup> Overall, fewer than 30% of patients (even with the best selection) show objective responses, and the survival of patients with metastatic disease is disappointingly short, except for a rare, extremely hormone-responsive patient. Earlier series reporting very long median survival rates reflect carefully selected patients or loose criteria of response.<sup>153,170</sup>

No dose-response effect for progestogens has been proven.<sup>174</sup> Although some responders have very long survival rates, the median duration of response in most studies does not exceed 10 months. The results of treatment with tamoxifen are generally inferior to those obtained with progestogens.<sup>175</sup> It remains to be seen whether tamoxifen in sequential combination with progestogens (to modulate receptors) will have an advantage over progestogen therapy alone.

Other hormonal manipulations are increasingly under study. These include not only combinations of tamoxifen and MPA, but also other selective estrogen receptor modulators such as raloxifene, luteinizing hormone–releasing hormone (LHRH) agonists and antagonists, aromatase inhibitors, and miscellaneous other drugs ( [Table 36.3-8](#) ).<sup>176,177,178,179</sup> and <sup>180</sup> It is likely that the same subset of patients responds to these hormonally directed therapies, and no obvious advantage of one agent over another has emerged to date. Moreover, results from small studies may be discordant, reflecting the importance of patient selection in maximizing the probability of response.

**TABLE 36.3-8.** Selected Series of Hormonally Based Therapy in Women with Advanced Endometrial Cancer

**Biologic and Pharmacologic Considerations.** The presence of estrogen and progesterone receptors in tumors has been shown to correlate with well-differentiated cancers and with response to progestogens.<sup>181,182,183</sup> and <sup>184</sup> Sequentially alternating tamoxifen and MPA or megestrol acetate regimens are based on the concept of up-regulation of progesterone receptors by the antiestrogen.<sup>179</sup> Other laboratory studies indicate the presence of specific binding sites for LHRH and for androgen receptors.<sup>185</sup> Supplementing clinical observations with molecular correlates of response may bring out some differences that are currently not apparent and also possibly lead to crossover hormonal therapies, a concept that has been useful in breast cancer treatment. The rational selection of specific hormonal manipulations from laboratory findings may become more feasible with the wider applicability of molecular immunohistochemical probes.

#### CYTOTOXIC CHEMOTHERAPY.

**Overview of Clinical Trials.** Most women with recurrent or stage IV endometrial cancers, except for those with well-differentiated and receptor-positive metastases, must be assessed for treatment with cytotoxic chemotherapy. Doxorubicin and its analogue epirubicin have shown reproducible antitumor activity in phase II and III trials.<sup>186,187</sup> These phase III studies have indicated that the addition of cyclophosphamide to doxorubicin improves neither response nor survival rates and suggest that the incorporation of progestogens does not improve results.<sup>187,188</sup> and <sup>189</sup> (Table 36.3-9). A number of other drugs studied by the GOG and others also have shown little efficacy but often have been used in combinations. On the other hand, cisplatin and carboplatin both show consistent antitumor activity,<sup>187,191,192,193,194,195,196</sup> and <sup>197</sup> and a phase III study combining cisplatin with doxorubicin showed superior progression-free survival over doxorubicin alone.<sup>190</sup> However, the overall median survival rate for patients receiving doxorubicin plus cisplatin was not improved. Other agents with single-agent activity include paclitaxel,<sup>198,199</sup> ifosfamide,<sup>200</sup> and oral etoposide.<sup>201,202</sup> Paclitaxel (250 mg/m<sup>2</sup>) given on a 24-hour infusion schedule and requiring cytokine support with filgrastim showed remarkable activity,<sup>198</sup> with four complete responses and six partial responses among 28 patients. A 24-hour infusion of 150 mg/m<sup>2</sup> is being tested in phase III studies in combination with doxorubicin. Shorter infusions of paclitaxel have activity with less myelosuppression<sup>199</sup> and are often used in combination with carboplatin<sup>203</sup> or in three-drug combinations.<sup>204</sup> Regimens of platinum and taxanes also have activity against papillary serous cancers<sup>205</sup> and are, therefore, replacing doxorubicin-containing regimens in this condition.<sup>167</sup> On the other hand, the addition of intraperitoneal cisplatin to doxorubicin plus cyclophosphamide did not have an encouraging outcome.<sup>206</sup> In ongoing pilot studies with radiation, platinum and particularly cisplatin are favored.<sup>207</sup>

**TABLE 36.3-9.** Cytotoxic Drug Trials Showing Activity in Women with Endometrial Carcinoma

Carboplatin is the preferred drug when added to paclitaxel because of its lower incidence of severe neurotoxicity relative to cisplatin.

**Biologic and Pharmacologic Considerations.** Laboratory and clinical studies should better define the role of systemic chemotherapy in relation to various known biologic factors in an analogous way to how pathologic features and hormone receptors have assisted in refining hormonal therapies. Endometrial cancers commonly express P-glycoprotein (Pgp). Studying the mechanisms of drug resistance mediated by multidrug resistance gene 1 (MDR1)-mediated Pgp may assist in identifying doxorubicin- and paclitaxel-resistant tumors.<sup>208</sup> Moreover, mutations in p53 occur somewhat concordantly with the expression of Pgp and may help to define a more resistant subpopulation. A relationship between progesterone and the expression of Pgp also has been postulated<sup>209</sup>; prior progestogen therapy might lead to changes in Pgp expression. The epidermal growth factor receptor and HER-2/neu are also likely to be important in determining chemosensitivity and outcome, as well as therapeutic targets.<sup>210,211</sup> Studies are beginning to focus on special subtypes, such as papillary serous and clear cell carcinomas, that not only have a propensity to metastasize early but may also have altered drug sensitivities. Several investigators have known that p53 mutations are more frequent in these cell types and are indicative of poor prognosis. Microsatellite instability, persistence of bcl-2/191, and high proliferation indices may also be of prognostic significance.

#### Radiotherapy

Vaginal recurrences of endometrial carcinomas can often be successfully treated with radiation therapy if there is no evidence of extrapelvic disease. For patients whose initial treatment was hysterectomy alone, vaginal recurrence is usually treated with a combination of external-beam irradiation and intracavitary or interstitial brachytherapy, depending on the extent and distribution of disease. Technical considerations are similar to those for primary vaginal carcinoma.

With this treatment, reported 5-year survival rates for patients who have isolated recurrences in the vaginal apex are usually 40% to 60%.<sup>212,213,214,215,216,217</sup> and <sup>218</sup> Outcome is correlated with the recurrent tumor's grade, size, and extent and the time to recurrence.<sup>212,214,215</sup> and <sup>216</sup> Sears et al.<sup>216</sup> reported 5-year survival rates of 74% and 30% for patients with tumors measuring 2 cm or less, or more than 2 cm, respectively, which suggests that early detection and treatment may be important. These authors also reported significantly better survival rates for patients who had a portion of their treatment given with brachytherapy. Distal vaginal recurrences are less common but may also be cured with irradiation if there is no other evidence of recurrent cancer.<sup>212,213,216,219,220</sup> If possible, the inguinal nodes should be treated when the distal vagina is involved.

The prognosis is much poorer for patients who have recurrent tumor on the pelvic wall.<sup>213,214,216</sup> However, there are anecdotal reports of prolonged disease-free survival after locoregional treatment.<sup>213,216</sup> Recurrence isolated to inguinal nodes should be treated aggressively because cures have been reported after treatment with irradiation.<sup>221</sup>

#### Surgery

Surgery plays a limited role in the management of recurrent endometrial cancer. Although cytoreduction is probably valuable for women with advanced primary cancers, secondary cytoreduction after failure of primary therapy has no real role because of the lack of effective regional or systemic therapy. Two legitimate

indications for surgical management are attempted curative resection of central pelvic recurrence by exenteration and palliative treatment in selected clinical situations.

Historically, ultraradical resection of recurrent endometrial cancer has not been recommended because of the perception that systemic spread was too common. However, reviews that have examined carefully evaluated patients have identified a subset of women whose recurrence is limited to the pelvis. <sup>222</sup> Cure rates of 40% to 50% have been obtained after resection by pelvic exenteration. These values are comparable to those reported for the treatment of central recurrence in patients with cervix cancer. <sup>223,224</sup> Consequently, patients who have recurrent disease that is clinically limited to the central pelvis and have not been successful with radiotherapy should be considered candidates for curative resection. A diligent search for subclinical metastatic disease should be carried out before exploration and at the time of operation.

Palliative surgery is largely limited to patients with intraabdominal recurrences causing bowel obstruction or pain. Candidates for palliative operations must have realistic expectations as to the goals of surgery, and the planned procedure should have a reasonable chance of achieving the desired goal. The patient's life expectancy and clinical status should be adequate for the proposed procedure and the anticipated recovery. The operation performed should be the minimum procedure with the lowest risk capable of correcting the problem. Heroic operations attempted in patients with no chance for long-term survival are pointless.

## OUTCOME AND SURVIVAL

Long-term survival of patients with endometrial cancer is clearly related to their surgical stage and substage. Representative 5-year survival rates by stage are 90% for stage I, 60% for stage II, 40% for stage III, and 5% for stage IV. Because the vast majority of patients have stage I disease and because there is a wide variation in survival based on risk profile within this stage, most research into postoperative adjuvant therapy is aimed at subsets of stage I patients. It is anticipated that the routine use of surgical staging will result in a more homogeneous subgrouping of similar risk patients and allow a more reliable prediction of survival potential. Selected patients with advanced disease that can be encompassed by surgical resection with or without adjunctive irradiation can be cured. However, few patients meet such criteria. Although patients with disseminated disease frequently respond to cytotoxic therapy, such responses tend to be short and provide a limited improvement in progression-free survival. As was suggested earlier, posttreatment surveillance for recurrence should be used to identify candidates for clinical trials of new agents or therapeutic approaches.

## UTERINE SARCOMAS

### TUMOR TYPES

Tumors with a malignant mesenchymal component account for approximately 10% of uterine fundal neoplasms. Pure uterine sarcomas of the homologous type arise from native elements, as is seen in endometrial stromal sarcoma, leiomyosarcoma, and sarcomas of nonspecific supporting tissues (fibrous tissue, vessels, lymphatics). Heterologous sarcomas may contain elements with nonnative differentiation, such as skeletal muscle, bone, and cartilage. <sup>225</sup> The malignant mixed Müllerian tumor (MMT) is a mixture of carcinoma and sarcoma. Although any combination is possible, serous carcinoma admixed with endometrial stromal sarcoma is the most common histologic type. The adenosarcoma is a rare mixed tumor in which a benign epithelial component is mixed with a sarcomatous element.

### CLINICAL PRESENTATION

Uterine sarcomas exhibit the typical gross features of similar tumors at other sites—firm, fleshy growth with areas of hemorrhage and necrosis. The initial growth phase of most sarcomas is within the fundal portion of the uterus. If the tumor involves the endometrial cavity, postmenopausal or abnormal vaginal bleeding is common. Tumors that have a polypoid growth configuration may prolapse through the cervix to present as an upper vaginal mass. This presentation is most often seen with MMTs.

Extensive local growth is another common clinical presentation. Once the tumor has penetrated the uterine serosa, it can rapidly attach to adjacent pelvic structures or loops of bowel positioned in the pelvis ( [Fig. 36.3-6](#)). This locally advanced pelvic tumor presentation is typical of leiomyosarcoma. Patients with locally advanced cancers have symptoms related to an expanding pelvic mass (fullness, pressure, pain, urinary frequency) or to entrapment and destruction of adjacent organs (hematuria, tenesmus, rectal bleeding, bowel obstruction, fistula).

**FIGURE 36.3-6.** Uterine sarcomas tend to present as large, fleshy central pelvic tumors. This leiomyosarcoma has replaced most of the uterine fundus and penetrated the serosa to engulf the adnexa and directly contact intraperitoneal structures.

As is seen for epithelial tumors of the uterus, distant spread from uterine sarcomas may occur by a variety of mechanisms. Intraabdominal and retroperitoneal nodal metastases are frequently associated with the MMT. <sup>226</sup> This is not surprising because the epithelial component is usually papillary serous carcinoma and predominates within metastatic sites. Consequently, patients with advanced MMT follow a clinical pattern similar to that of women with epithelial ovarian cancer. All uterine sarcomas have a propensity for hematogenous dissemination. Pulmonary metastases are most frequently observed. Other sites include liver, bone, and brain. Women with distant spread at the time of diagnosis have symptoms and examination findings based on the location of their disease.

### EVALUATION

Uterine sarcoma should be suspected in any postmenopausal women with an enlarging central pelvic mass. If the tumor projects into the uterine cavity or has partially prolapsed through the cervix, an endometrial or direct biopsy should provide a tissue diagnosis. Evaluation by an experienced pathologist is critical because uterine sarcomas are rare and the biopsy material is often fragmented or necrotic. Tumors originating within the uterine wall require exploratory laparotomy and hysterectomy to establish a diagnosis. Because primary therapy usually includes hysterectomy, the preoperative evaluation should focus on a search for disease at common metastatic sites and assessment of operative risk.

When the diagnosis of sarcoma is known or suspected, the pretreatment evaluation should include a careful history and physical examination, chest radiograph, and laboratory studies. The CA-125 level may be elevated in some cases, particularly in MMT tumors with peritoneal spread. Other markers have not been consistently useful. Computed tomography of the abdomen and pelvis may be helpful in identifying occult extrauterine disease. Cystoscopy, proctosigmoidoscopy, and barium enema should be performed in patients with advanced pelvic disease. Brain, bone, or liver imaging should be considered in patients with abnormal physical or laboratory findings.

### TREATMENT

#### **Surgery**

Patients in whom the diagnosis of uterine sarcoma is not anticipated often undergo hysterectomy for a presumed diagnosis of uterine leiomyoma or “central” pelvic mass. Although most of these cases are not surgically staged, many are apparently stage I tumors. When the diagnosis of sarcoma is established and hysterectomy is technically feasible, surgical resection of the primary tumor should be attempted. Such surgery may be curative for tumors confined to the uterus. Because of the overall poor prognosis associated with uterine sarcomas, we proceed with extended surgical staging similar to that used for patients with endometrial adenocarcinoma when disease is clinically limited to the uterus. Although a survival benefit to surgical staging has not been demonstrated, knowledge of the true extent of disease is helpful in selecting therapy options.

In more extensive disease cases, resection or debulking of the central tumor can provide important palliation of bleeding and pain. Tumor reduction may enhance the ability of postoperative adjunctive therapy to extend survival, but this concept is not as well established as in epithelial ovarian tumors. The aggressiveness of the surgical approach must include a balance between the desire to remove as much tumor as possible and the risks of additional operative procedures. Patients with widespread or bulky unresectable disease should not be subjected to high-risk operations under the guise of cytoreduction.

Occasionally, surgical intervention is indicated in women with advanced or recurrent disease, but such situations are clinically uncommon. Some women have obtained long-term survival and apparent cure after resection of an isolated pulmonary metastasis.<sup>167,227,228</sup> Exploration to palliate bowel obstruction or fistula is appropriate in selected refractory disease patients who have a good performance status and reasonable projected survival time. Potentially morbid palliative operations in women with terminal disease should be avoided whenever possible.

### Radiotherapy

**MIXED MÜLLERIAN TUMOR.** The role of radiation therapy in the management of carcinosarcoma is controversial. Patients are frequently treated with postoperative pelvic radiotherapy, but irradiation has never been proven to influence survival. Retrospective comparisons of treatments are invariably biased by physicians' tendencies to select treatment on the basis of known prognostic indicators. No randomized study has directly compared patients with similar prognostic features who were treated with or without radiotherapy.

Most retrospective reviews of patients with carcinosarcoma have demonstrated a lower rate of pelvic tumor recurrence in patients who received postoperative pelvic irradiation.<sup>229,230,231,232,233,234,235,236,237,238</sup> and <sup>239</sup> In most cases, this has not resulted in a demonstrable improvement in the survival rate. However, few studies have evaluated risk factors that could have influenced treatment selection. Potential bias and the small number of patients in most studies have made it impossible to determine the efficacy of treatment.

The GOG retrospectively evaluated its experience in two studies.<sup>233,240</sup> Hornback et al.<sup>233</sup> reviewed the influence of pelvic radiotherapy in a study originally designed to evaluate the role of doxorubicin. In this study, radiotherapy was given at the discretion of the investigator. In 109 patients with stage I or II disease (95 of whom had carcinosarcoma), the pelvis was the first site of recurrence in five of 49 patients (10%) who had radiation therapy versus 14 of 60 patients (23%) treated with surgery alone. However, irradiated patients had a higher rate of distant metastasis, and no significant difference in the 2-year survival rate was reported. In a more recent review of another GOG study, the pelvis was reported to be the first site of recurrence in 17% and 24% of patients with carcinosarcoma treated with or without postoperative irradiation, respectively. The overall relapse rates were not significantly different. As with other reviews, because the tumor stage, grade, and depth of invasion and rates of lymph node involvement were not compared for patients receiving different treatments, the efficacy of radiotherapy cannot be determined from these studies.

**LEIOMYOSARCOMA AND ENDOMETRIAL STROMAL SARCOMA.** Few studies have separately reported control rates for patients treated with radiotherapy for leiomyosarcoma, and the numbers of patients are too small to evaluate efficacy.<sup>233,236,240</sup> Patients with close surgical margins may benefit from postoperative irradiation. Because lymph node metastasis from leiomyosarcoma is uncommon, treatment of the operative bed (usually the lower pelvis) may be sufficient in most cases.

Several authors reporting small series of patients with endometrial stromal tumors have commented on the role of radiotherapy, either suggesting that it is effective<sup>241,242</sup> and <sup>243</sup> or ineffective.<sup>244</sup> Berchuck et al.<sup>242</sup> reported dramatic responses in two of three patients who had measurable tumor. One patient remained free of disease for more than 10 years after treatment. However, reports of radiotherapy for these tumors are little more than anecdotal, and further study is needed to define the role of radiotherapy adequately.

### Chemotherapy and Hormonal Therapy

Differences in the management of metastatic uterine leiomyosarcomas and MMTs with respect to systemic chemotherapy have been established, and separate trials are conducted for these two entities (Table 36.3-10 and Table 36.3-11). Endometrial stromal sarcomas are less common and usually not included in clinical trials. Because antitumor activity of chemotherapy regimens has been documented in advanced stages, several trials are ongoing or planned in earlier stages of disease. Evidence to support the use of chemotherapy as an adjuvant to surgery is not yet forthcoming. One randomized study of the addition of doxorubicin after surgery in stage I and II uterine sarcomas yielded no advantage for the adjuvant chemotherapy group.<sup>245</sup>

TABLE 36.3-11. Selected Cytotoxic Drug Trials in Uterine Mixed Mesodermal Tumors

In mixed mesodermal tumors of stage I, II, and III, a GOG trial begun in 1993 is comparing whole abdominal radiation to chemotherapy with cisplatin and ifosfamide.<sup>179</sup> These trials require several years to complete, a difficulty compounded by the evolving nature of the adjuvant treatments that are applied.

**LEIOMYOSARCOMA.** Doxorubicin was shown to be an effective drug against leiomyosarcomas arising in the uterus.<sup>246</sup> Drug combinations were claimed to improve results in both childhood and adult sarcomas of extrauterine origin, but the addition of dacarbazine to doxorubicin did not improve the survival of patients with metastatic uterine sarcomas beyond that obtained with doxorubicin alone.<sup>246</sup> Response rates were, however, significantly better in the doxorubicin plus dacarbazine arm. A subsequent randomized study also performed by the GOG failed to show that the addition of cyclophosphamide in modest doses was advantageous over doxorubicin by itself.<sup>247</sup> The alkylating agent ifosfamide has modest activity<sup>248</sup> but does not add substantially to the therapeutic efficacy of doxorubicin.<sup>249,250</sup> Other drugs, such as cisplatin,<sup>251,252</sup> etoposide,<sup>253,254</sup> and paclitaxel,<sup>179,255</sup> also have been evaluated and have modest to minimal activity. A combination of hydroxyurea, etoposide, and dacarbazine had antitumor activity without major toxicities.<sup>256</sup>

**MIXED MÜLLERIAN TUMOR.** Ifosfamide<sup>257</sup> and cisplatin<sup>254</sup> have greater antitumor activity against uterine MMT than does doxorubicin. Accordingly, the two drugs in combination have been explored in all stages and also compared with ifosfamide alone<sup>258</sup> in advanced, persistent, or recurrent disease. The results indicate an advantage for the combination in terms of responses and progression-free survival, but nearly equivalent median survival at a cost of increasing toxicity. The combination is being administered to completely resected stage I and II MMTs of the uterus (GOG 117), but the assessment will require a comparison to historical controls. Taxanes, such as paclitaxel, have been evaluated,<sup>179</sup> and this agent has already formed part of an active combination with the pegylated liposomal doxorubicin, Doxil.<sup>259</sup> Experience with a number of other platinum-based combinations has been reported in very small series. These should be regarded as leads for future trials rather than a reliable indicator of activity.<sup>260</sup>

**ENDOMETRIAL STROMAL SARCOMA.** The systemic treatment of endometrial stromal sarcoma is guided by reports from individual institutions<sup>242,244,261,262</sup> and case reports.<sup>263,264</sup> The tumor's relative rarity does not support the conduct of clinical trials. Because of the presence of hormonal receptors in low-grade (fewer than ten mitoses per high-power field) tumors, hormonal therapy has been advocated.<sup>261,265</sup> However, high-grade tumors are treated with chemotherapy.<sup>263,265</sup> Investigation of biologic and pharmacologic issues may point the way for hypothesis-driven drug trials.

**BIOLOGIC AND PHARMACOLOGIC CONSIDERATIONS.** The growth of benign leiomyomas is under both estrogenic and progestogenic control.<sup>266,267</sup> Accordingly, the study of receptors and hormone-action inhibitors for antitumor activity may be relevant to the management of malignant smooth muscle tumors.<sup>268</sup> Receptors also have been studied in endometrial stromal sarcomas<sup>269,270</sup> and justify exploration of inhibition or depletion of hormonal mediators in the management of these tumors. Overexpression in MDR2 and mutations in p53 have been noted in some uterine sarcomas, but not in leiomyomas.<sup>271</sup> For the development of cytotoxic therapy, the role of MDR1-mediated Pgp expression in determining resistance to doxorubicin has been investigated in a cell line from a leiomyosarcoma of the uterus and its doxorubicin-resistant derivative.<sup>271</sup> Drugs that are substrates for Pgp may restore sensitivity to doxorubicin in this resistant variant. Trials of such resistance-reversing agents, including the cyclosporin analogue PSC-833, may lead to a reassessment of the potential for drugs such as doxorubicin, taxanes, and vinca alkaloids in the treatment of these traditionally refractory tumors.<sup>272</sup>

## OUTCOME AND SURVIVAL

Stage is the most significant predictor of outcome for women with uterine sarcomas. Patients whose tumors are confined to the uterus have a survival rate of 60% to 70% after surgical resection. Major sites of failure include the pelvis, upper abdomen, and lung. Few well-conducted prospective adjuvant therapy trials have been accomplished, so a precise role for either adjuvant irradiation or chemotherapy remains undefined. As has been noted for endometrial carcinoma, adjuvant pelvic irradiation may reduce the rate of pelvic failure without improving survival if more patients succumb to distant failure. Pelvic irradiation and local tumor control may be an important issue in tumors with extension to the cervix. However, so few patients are placed in this category that meaningful treatment data are not available.

Very few patients with tumor spread outside of the uterus can be curatively treated. Some women with small-volume regional disease have obtained long-term survival after external-beam irradiation. However, most patients with advanced or recurrent disease ultimately experience disease progression and die. These women are excellent candidates for new therapeutic trials.

#### INTRODUCTION

Gestational trophoblastic disease encompasses a spectrum of interrelated conditions spanning proliferative changes resulting from an abnormal fertilization to highly malignant lesions such as choriocarcinoma. Four distinct clinicopathologic entities have been described: molar pregnancy (including complete and partial hydatidiform moles), invasive mole (chorioadenoma destruens), placental-site trophoblastic tumors, and choriocarcinoma. Although these constitute fewer than 1% of gynecologic malignancies, they are highly important to recognize because of their life-threatening potential and their high curability if treated early and by experienced centers.

#### EPIDEMIOLOGY

Gestational trophoblastic disease most commonly follows molar pregnancy but may also occur after normal or ectopic pregnancies and spontaneous or therapeutic abortions. Its incidence varies widely among various populations, with figures as high as 1 in 120 pregnancies in some areas of Asia and South America, compared to 1 in 1200 in the United States.<sup>1</sup> The risk is fivefold greater in women older than 40 years<sup>2</sup> and is also increased in those younger than 20 years.<sup>2</sup> Prior molar pregnancies, lower socioeconomic status, and blood group A women married to group O men are at higher risk.<sup>1,2</sup> and<sup>3</sup> Parity, ethnicity, nutritional factors, and cigarette smoking have been examined as risk factors, but no clear association has been found. However, oral contraceptives and the number of sexual partners before the index pregnancy appear to double the risk of gestational trophoblastic tumors.<sup>4</sup>

#### PATHOLOGY AND BIOLOGY

Hydatidiform moles (complete and partial) are characterized by clusters of hydropic villi, and trophoblastic hyperplasia with atypia. Partial moles show a variable amount of focal trophoblastic hyperplasia and have identifiable fetal or embryonic tissues. Invasive moles (chorioadenoma destruens) have findings similar to complete moles but display a greater tendency to invade surrounding tissues. The rare placental-site trophoblastic tumors<sup>5</sup>—initially named *trophoblastic pseudotumors*—are derived from intermediate trophoblast cells [which secrete placental lactogen in greater amounts than human chorionic gonadotropin (HCG)], and they present clinically as nodules in the endometrium and myometrium after removal of a mole. Microscopically, these tumors show no chorionic villi and are characterized by a proliferation of cells with oval nuclei and abundant eosinophilic cytoplasm. They usually arise after nonmolar abortion or a term pregnancy, but occasionally after hydatidiform mole and, in one case, after a metastatic gestational trophoblastic neoplasia.<sup>6</sup> Choriocarcinomas consist of invasive and anaplastic trophoblastic tissue made up of cytotrophoblastic and syncytiotrophoblastic elements, obligatory secretion of HCG, and rich vascularity. Commonly accompanying the trophoblastic neoplasia are one or more theca lutein ovarian cysts that are a result of HCG stimulation. Rarely, the malignancy can coexist with an intact pregnancy.<sup>7</sup> Treatment has evolved based on prognostic-factor risk classification and staging and not on pathologic features.

Cytogenetics has provided clues as to the origin of hydatidiform moles: Most complete moles have a 46XX karyotype, with the minority being 46XY. All X chromosomes are from paternal origin. These are believed to arise from fertilization of an empty ovum by a haploid sperm that then undergoes duplication. Maternal mitochondrial DNA has been identified.<sup>8</sup> On the other hand, partial moles contain both maternal and parental chromosomes, are triploid, and their sex chromosomes are typically XXY. Presumably, as a result of fertilization of a normal ovum by two sperms, if the extra haploid set is of parental origin, a partial mole arises. If the extra haploid set is of maternal origin, then a trisomic fetus develops.<sup>9,10</sup>

The molecular biology of trophoblastic malignant transformation has been explored; insulin-like growth factor from parental chromosomes, and growth factors released through immunologic mechanisms have been studied.<sup>11,12</sup> Overexpression of the epidermal growth factor receptor has been described.<sup>13</sup> The epidermal growth factor is capable of modulating the expression of placental lactogen in a rat choriocarcinoma line.<sup>14</sup> Mutations in p53 have not been found.<sup>15</sup>

#### CLINICAL DIAGNOSIS AND HUMAN CHORIONIC GONADOTROPIN

A molar pregnancy is suspected with first-trimester bleeding, a uterus larger than expected for gestational age, and absence of fetal heart sounds and fetal parts in association with a markedly elevated HCG level. Iron-deficiency anemia is common at diagnosis because of recurrent bleeding. Other signs include hyperemesis, the passage of "prune juice-like" clots and even actual grape-like villi, toxemia during the first or second trimester, presence of ovarian enlargement with theca lutein cysts, and hyperthyroidism. Invasive moles may cause rupture of the uterus. Rupture of an ovarian cyst and metastatic disease may rarely be the presentation of an otherwise unrecognized or silent gestational trophoblastic disease. In fewer than 1% of molar pregnancies, a normal fetal (twin) pregnancy may coexist. Radiologic procedures, particularly ultrasonography, are used to suggest the diagnosis. HCG determinations are of central importance in the diagnosis, treatment, follow-up, and likely pathogenesis of gestational trophoblastic disease.

HCG consists of a and b chains, and its primary function is the maintenance of the corpus luteum during pregnancy. The a chain is cross-reactive with luteinizing hormone and with thyrotropin (previously thyroid-stimulating hormone). The b-2 subunit (b-HCG) is unique to HCG and has been used for the radioimmunoassay of HCG in the presence of luteinizing hormone.<sup>16</sup> Normally, HCG peaks at 10 to 12 weeks of gestation, and actual levels and serial changes in b-HCG are essential to diagnose and track the outcome of trophoblastic disease. After evacuation of a molar pregnancy, b-HCG titers usually disappear in 8 to 10 weeks.<sup>17</sup> Persistence may indicate local and, less often, metastatic disease: From the New England Trophoblastic Disease Center experience, 15% of women with a complete mole and 5.5% of women with partial moles developed nonmetastatic trophoblastic disease.<sup>18</sup> A b-HCG level of 100,000 mIU/mL or more, a uterine size greater than expected from gestational age, and the presence of theca lutein ovarian cysts larger than 6 cm in diameter identify women at high risk for persistent gestational trophoblastic disease after evacuation of a complete mole. For these women, the risk of subsequent nonmetastatic manifestations is 31%, and 8.8% develop metastases, contrasting with 3.5% and 0.6%, respectively, for women without these risk factors. Such a risk may be reduced by chemoprophylaxis with short courses of methotrexate and dactinomycin.<sup>19</sup> Although such use of preventive chemotherapy is controversial, serial b-HCG measurements are essential in both high- and low-risk groups. Weekly HCG measurements until three nondetectable determinations, followed by monthly tests for 6 months, are advised. In addition, effective contraception during the entire period of follow-up is essential to avoid confusing the clinical picture.

Other tumor marker measurements may assist in the management of gestational trophoblastic disease: The placental-site trophoblastic tumor produces low levels of HCG but may be identified by measurement of placental lactogen.<sup>20</sup> The serum CA-125 has been found useful as a predictor of persistence of molar disease.<sup>21</sup> Finally, the ratio of serum to cerebrospinal fluid b-HCG has been used to identify brain metastases if such a ratio is less than 60:1.<sup>22</sup>

#### CHORIOCARCINOMA

#### CLINICAL FEATURES AND STAGING

Metastatic disease occurs in 4% of patients after local management of hydatidiform moles and very rarely after term pregnancies (1 in 40,000) or abortions. Rapid growth and a high propensity for hemorrhage make this tumor a medical emergency. Metastases are found in lung (80%), vagina (30%), pelvis (20%), brain (10%), and liver (10%). Other rare sites are the spleen, kidneys, and gastrointestinal tract.<sup>18</sup> The lungs are often involved with multiple lesions, and at times this involvement is massive at presentation, leading to respiratory insufficiency.<sup>23</sup> On the other hand, early detection in the asymptomatic state may take place through computed tomography in cases with persistent moles. The central nervous system is seldom involved in the absence of pulmonary metastases.

Anatomic staging of choriocarcinoma (I, confined to corpus; II, metastases to pelvis and vagina; III, pulmonary metastases with or without uterine, pelvic, or vaginal involvement; and IV, other metastases, such as brain, liver, kidneys, or gastrointestinal tract) is seldom used. Therapeutic planning relies on the scoring system based on prognostic factors that was developed at the Charing Cross Hospital by Bagshawe<sup>24</sup> and later adopted by other groups, including the World Health Organization (Table 36.4-1). The importance of this scoring system lies in the identification of a high-risk choriocarcinoma that requires more intensive use of drug combinations to achieve cures and prevent emergence of resistance.

Factor	Score			
	0	1	2	3
Age	<35	35-44	45-54	≥55
Anterior pregnancy	Yes	No	Yes	No
Interval from previous abortion	<1	1-4	5-12	>12
Serum human chorionic gonadotropin	<100 IU/L	100-1000 IU/L	1000-10000 IU/L	>10000 IU/L
ABO group	O or A	B or AB		
Largest tumor	<5 cm	5-10 cm	>10 cm	
Metastatic sites	Lung	Spleen, kidney	Gastrointestinal tract, liver	Brain
Number of metastases	0	1-3	4-8	>8
Prior chemotherapy	No	Yes	Yes	Yes

TABLE 36.4-1. Prognostic Scoring System for Gestational Trophoblastic Disease

The total score for a patient is obtained by adding the individual scores for each prognostic factor, with a score of 4 being considered low risk, a score of 5 to 7 as intermediate risk, and a score of greater than 7 as high risk.

## TREATMENT

Chemotherapy is highly effective for all forms of gestational trophoblastic disease. The curative effects of methotrexate in a disease that had previously resulted in the death of 60% of patients with disease confined to the uterus and 90% of patients with metastatic disease heralded the era of modern chemotherapy.<sup>25</sup> The current challenges are to provide the proper follow-up after evacuation of hydatidiform moles, to balance drug administration with surgical interventions when more invasive trophoblastic disease is present, and finally to tailor the type of chemotherapy to the risk group of gestational trophoblastic disease that has been identified. The scoring system in Table 36.4-1 assists in reaching decisions, but the expertise of a multidisciplinary team cannot be overemphasized. In particular, hysterectomy and single-agent chemotherapy must be considered in stage I disease depending on the patient's desire for future fertility. In this circumstance, chemotherapy reduces dissemination during surgery and treats any occult metastases not previously detected.

The therapeutic regimens for low-risk disease based on the scoring that has been developed have sought to maximize efficacy while minimizing toxicity. As shown in Table 36.4-2, these regimens have consisted of methotrexate by itself or with leucovorin rescue or dactinomycin. Monitoring with b-HCG to document a prompt 1 log or greater reduction in the titer in 18 days, along with continued monthly monitoring of negative values for 1 year, is standard practice. In small series, most patients failing to achieve a satisfactory response to methotrexate were adequately treated with dactinomycin<sup>26</sup> or etoposide.<sup>27</sup> Myeloid leukemia and secondary cancers are a concern with etoposide,<sup>28</sup> which is not encouraging for its use in low-risk patients. Therefore, current Gynecologic Oncology Group studies for low-risk disease are comparing methotrexate with dactinomycin and also assessing dactinomycin in patients not responding to methotrexate.

<b>LOW RISK (SINGLE AGENTS)</b>
Methotrexate: 30-50 mg/m <sup>2</sup> IM weekly; 0.4 mg/kg IM or IV daily × 5 d (repeat in 2 wk); or 1 mg/kg IM or IV on days 1, 5, 9, and 7 (repeat in 2 wk) plus folic acid (leucovorin), 0.1 mg/kg or IV on days 2, 4, 6, and 8
Dactinomycin: 1.25 mg/m <sup>2</sup> IV (repeat in 2 wk); or 10 µg/kg (up to 0.5 mg) IV daily × 5 d (repeat in 2 wk)
<b>INTERMEDIATE OR HIGH RISK (DRUG COMBINATIONS)</b>
EMA-CO consists of alternating cycles of EMA (days 1 and 2) and CO (day 3)
Day 1 EMA: etoposide, 100 mg/m <sup>2</sup> IV; and dactinomycin, 0.5 mg IV; and methotrexate, 100 mg IV push followed by 200 mg/m <sup>2</sup> 12-h IV
Day 2 EMA: etoposide, 100 mg/m <sup>2</sup> IV; dactinomycin, 0.5 mg IV; and folic acid, 15 mg IV or PO every 12 h × 4, 24 h after onset of methotrexate toxicity
Day 3 CO: vincristine, 1 mg/m <sup>2</sup> IV; and cyclophosphamide, 600 mg/m <sup>2</sup> IV
<b>SALVAGE REGIMENS</b>
FEBA: cisplatin, etoposide, bleomycin, doxorubicin <sup>29</sup>
VIP: vincristine, ifosfamide, and etoposide (toxic as per green cell regimen)
Single agents: oxaliplatin and vinorelbine analog, topoisomerase I inhibitors, ifosfamide, gemtuzumab <sup>30</sup>
<sup>29</sup> Requires normal renal and bone marrow function and no stomatitis.

TABLE 36.4-2. Drug Regimens for Gestational Trophoblastic Disease

In intermediate- and high-risk patients, combination chemotherapy is the treatment of choice, and the serum EMA-CO (etoposide, dactinomycin, and folic acid; vincristine and cyclophosphamide) combination (see Table 36.4-2) is most commonly used. This combination was introduced after recognition of the activity of etoposide, even after failure of other drug regimens, including those for low risk plus cyclophosphamide, vincristine, doxorubicin, hydroxyurea, and 5-fluorouracil.<sup>24</sup> The Gynecologic Oncology Group has used a combination of methotrexate, dactinomycin, and chlorambucil (MAC) with excellent results in intermediate risk patients.<sup>25</sup> Familiarity with one regimen ensures greater safety and proper application.

Results with EMA-CO are excellent in intermediate risk and most high-risk disease patients.<sup>24</sup> However, approximately 20% of patients, predominantly high-risk or intermediate risk who are methotrexate resistant,<sup>30</sup> do not show a complete response. Some of these patients may be salvaged, or could be treated when methotrexate resistance is identified, with regimens containing cisplatin. Deaths from choriocarcinoma usually result either from very late presentations leading to complications such as respiratory failure or central nervous system hemorrhage, or from the development of drug resistance if the tumor burden is excessive at the outset or if treatment has not been sufficiently aggressive. In any event, as for germ cell tumors and other gynecologic cancer, resistance to cisplatin determines an unfavorable outcome. Experimental strategies to overcome such resistance include dose intensification, analog development, and use of new drugs such as taxanes and topoisomerase I inhibitors, although experience is limited.<sup>29</sup> In addition, radiation and surgical resection of metastases may play a role. Specifically, radiation given concomitantly with chemotherapy has been advocated from the outset in patients who have brain metastases to decrease the risk of hemorrhage. A dose of 3000 cGy given over 10 fractions has been found satisfactory.<sup>31</sup>

#### OVARIAN CANCER

On the basis of distinct clinical and pathologic features, ovarian carcinomas can be separated into three major entities: epithelial carcinomas, germ cell tumors, and stromal carcinomas. The vast majority of ovarian carcinomas are epithelial in origin, accounting for more than 90% of the estimated 25,200 new cases of ovarian cancer diagnosed in 1999 in the United States.<sup>1</sup> Fallopian tube carcinomas and extraovarian peritoneal carcinomas are much less common, but because of marked similarities to ovarian epithelial carcinomas in their biology and clinical presentation, these tumors also are considered in this chapter. Approximately 14,500 women died in the United States of ovarian cancer in 1999, making this tumor the leading cause of death from a gynecologic cancer.<sup>1</sup> Overall, ovarian cancer accounts for 4% of all cancer diagnoses and 5% of all cancer deaths. The lifetime risk of further development of ovarian cancer is approximately 1.5%, and 1 woman in 100 will die of the disease.<sup>2</sup>

The vast majority of epithelial ovarian carcinomas are diagnosed in postmenopausal women, and the median age at diagnosis is 63 years. The age-specific incidence increases from 15 to 16 per 100,000 in the 40 to 44 age group to a peak rate of 57 per 100,000 in the 70 to 74 age group.<sup>3</sup> Since the late 1970s, there has been little change in incidence or mortality rates.<sup>4</sup> However, a statistically significant increase in 5-year survival rates has been seen—36% in 1970 versus 50% in 1994.<sup>1</sup> This improvement in survival is likely the result of more effective platinum-based chemotherapy and improvements in surgery and supportive care. African American women in the United States have a lower incidence (10.3 per 100,000 women) compared with white women,<sup>5</sup> and the stage-specific 5-year survival rates for white and African American women are similar: localized disease, 96% versus 91%; regional, 80% versus 78%; and advanced disease, 28% versus 24%, respectively.<sup>1</sup>

The biology and carcinogenesis of ovarian cancer is detailed elsewhere in this text (see [Chapter 36.1](#)). Hormonal, environmental, and genetic factors all have been identified as playing an important role in the development of ovarian cancer.

A family history is the single most important risk factor for the development of ovarian cancer. However, the vast majority of ovarian cancers are sporadic in nature. Fewer than 10% of cases can be defined as hereditary ovarian cancer (at least two first-degree relatives with ovarian cancer) in which predisposition for the disease follows a classic pattern of autosomal dominant transmission with a variable degree of penetrance. Two distinct clinical syndromes associated with hereditary ovarian cancer have been identified in which there is a germline inheritance of a mutant gene that is transmitted in an autosomal dominant manner and leads to increased susceptibility to ovarian cancer. The hereditary breast-ovarian cancer syndrome (HBOC) is the most common of these and accounts for 85% to 90% of all hereditary ovarian cancer cases currently identified.<sup>5</sup> The majority of these tumors are associated with mutations of the BRCA1 locus, in which more than 100 mutations have been thus far identified. A second breast-ovarian cancer susceptibility gene, BRCA2, has been localized to chromosome 13q12.<sup>6</sup> BRCA2 shares structural and functional similarities with BRCA1 and also appears to be involved in cell progression and cell differentiation.

Initial family pedigree studies revealed multiple cases of ovarian cancer without any increase in breast cancer, and this finding led to the possibility of a site-specific form of ovarian cancer.<sup>7</sup> However, linkage studies have failed to identify additional loci other than BRCA1, which suggests site-specific manifestation is not a distinct hereditary syndrome but rather represents a variant of HBOC in which early-onset breast cancer is infrequent.<sup>5</sup> It also has been demonstrated that hereditary ovarian cancer is a component of the hereditary nonpolyposis colorectal cancer syndrome (HNPCC).<sup>8</sup> HNPCC is an autosomal dominant genetic syndrome that is also known as *Lynch syndrome II*.<sup>9</sup>

Ovarian cancer associated with germline mutations of BRCA1 appears to present with distinct clinical and pathologic features compared with sporadic ovarian cancer.<sup>10</sup> The vast majority of BRCA1-associated cancers are serous adenocarcinomas, with an average age at diagnosis of 48 years. BRCA1-associated cancer may have a more favorable course than sporadic ovarian cancer. In a study by Rubin et al.<sup>10</sup> they reported a median survival of 77 months in 43 patients with advanced BRCA1-associated disease compared with 29 months for matched controls. These results have been confirmed in some, but not all, retrospective studies. A large prospective study is currently in progress by the Gynecologic Oncology Group (GOG) to compare the clinical course of sporadic ovarian cancer with that associated with BRCA1 and BRCA2 mutations.

Close surveillance and screening with transvaginal sonography is frequently used in women at high risk for hereditary ovarian cancer, although there is no evidence yet that such an approach decreases mortality.<sup>11</sup> The National Institutes of Health Consensus Development Panel has recommended that prophylactic oophorectomy be strongly considered in women with hereditary ovarian cancer at age 35 years or after childbearing is completed. However, an increased risk remains for peritoneal carcinomatosis in women with hereditary ovarian cancer, which persists after prophylactic oophorectomy. Oral contraceptives, however, may reduce the risk of ovarian cancer in women with mutations in the BRCA1 or BRCA2 gene. Narod et al.<sup>12</sup> demonstrated that use of oral contraceptives for 6 or more years is associated with a 60% reduction in risk in a study of 207 women with hereditary ovarian cancer with 161 of their sisters as controls. These data strongly suggest that oral contraceptive use should be considered in the prevention of cancer in women with BRCA1 or BRCA2 mutations. In addition, it is essential that patient education and counseling by trained geneticists be part of any risk-assessment program.

#### PATHOGENESIS

The common epithelial tumors account for 60% of all ovarian neoplasms and for 80% to 90% of ovarian malignancies. The remaining tumors arise from germ or stromal cells. The epithelial tumors arise from the surface epithelium, or serosa, of the ovary. During embryogenesis, the lining of the celomic cavity consists of mesothelial cells of mesodermal origin, and the gonadal ridge is covered by serosal epithelium. Müllerian ducts, which give rise to the fallopian tubes, uterus, and

vagina, are the result of invagination of the mesothelial lining. When the epithelium becomes malignant, it can express a variety of Müllerian-type differentiations. Serous carcinomas can resemble the fallopian tube, mucinous tumors the endocervix, endometrioid carcinomas the endometrium, and clear cell tumors can resemble endometrial glands occurring in pregnancy. It is thought that germ cell tumors originate in a primitive streak and can migrate to the gonads. The mesenchyma gives rise to the ovarian stroma, and stromal tumors arise from this cell type.

The most common form of dissemination of epithelial tumors throughout the peritoneal cavity is by exfoliation of malignant cells through the surface of the ovarian capsule. The circulation of the peritoneal fluid to the undersurface of the right hemidiaphragm facilitates the widespread dissemination of malignant tumor cells. All intraperitoneal surfaces are at risk. In addition, the omentum is a frequent site of tumor growth. Tumor spread also occurs via the lymphatics from the ovary. A primary source of drainage follows the ovarian blood supply in the infundibulopelvic ligament to lymph nodes around the aorta and vena cava to the level of the renal vessels. There is also lymphatic drainage through the broad ligament and parametrial channels; consequently, pelvic sidewall lymphatics, including the external iliac, obturator, and hypergastric chains, are also frequent sites of lymphatic metastases from ovarian primary tumors. More rarely, spread may occur along the course of the round ligament, resulting in involvement of inguinal lymph nodes. Spread to lymph node is common, and approximately 10% of patients with ovarian cancer that appears to be localized to the ovaries have metastases to paraaortic lymph nodes. Retroperitoneal lymph node involvement is found in the majority of cases of advanced ovarian cancer when the disease has spread throughout the peritoneal cavity.

The dissemination of ovarian cancer can be clinically occult. As is described later in the section [Staging](#), surgical staging requires meticulous histologic examination of visually normal tissues throughout the peritoneal cavity because microscopic disease frequently is detected in the undersurfaces of the diaphragm and other peritoneal sites. Hematogenous metastases to extraabdominal sites can occur but is uncommon. There can be direct extension of the tumor from the ovary to involve the peritoneal surfaces of the bladder, rectosigmoid, and pelvic peritoneum.

## HISTOLOGIC CLASSIFICATION OF EPITHELIAL TUMORS

[Table 36.5-1](#) details the classification of common epithelial tumors that has been developed by the World Health Organization and the International Federation of Gynecology and Obstetrics.<sup>13</sup> The nomenclature for these tumors reflects the cell type, location of the tumor, and degree of malignancy, ranging from benign epithelial tumors to tumors of low malignant potential to invasive carcinomas. Tumors of low malignant potential (“borderline malignancy”) have an excellent prognosis compared with invasive carcinomas, and their clinical behavior and management is described later in the section [Borderline Tumors](#). Tumors of low malignant potential are characterized by epithelial papillae with atypical cell clusters, cellular stratification, nuclear atypia, and increased mitotic activity. The differentiation between these tumors and carcinomas is primarily made on the architectural basis of invasion. Frankly malignant tumors are characterized by an infiltrative destructive growth pattern, with malignant cells growing in a disorganized pattern and dissection into stromal planes.

**TABLE 36.5-1.** World Health Organization Classification of Malignant Ovarian Tumors

The invasive epithelial carcinomas are characterized by histologic type and grade (the degree of cellular differentiation). The histologic type has limited prognostic significance independent of clinical stage. Histologic grade is an important independent prognostic factor in patients with early-stage epithelial tumors. Grading systems have been based on cytologic detail or a pattern grading classification based on the degree to which a tumor forms papillary structures or glands versus solid tumor. The relative prognostic value of histologic subtype and grade compared with other surgical and biologic factors is discussed in the section [Prognostic Factors](#).

## DIAGNOSIS AND SYMPTOMS

Epithelial cancers of the ovary have been described as a silent killer because the overwhelming majority of patients present with disease that has spread outside of the ovary and indeed outside of the pelvis at the time of initial presentation. Approximately 70% of patients with epithelial cancers of the ovary present with stage III or IV disease, whereas 70% of patients with germ cell ovarian malignancies present with stage I disease.<sup>14</sup> Unlike epithelial cancers, ovarian germ cell malignancies tend to stretch and twist the infundibulopelvic ligament, causing severe pain while the disease is still confined to the ovary. Functioning ovarian tumors of the sex cord–stromal type may present with symptoms suggestive of excessive endogenous estrogen or androgen production. Granulosa cell tumors occurring in premenarchal women present with precocious puberty. Women in the reproductive years with granulosa cell tumors present with amenorrhea, and postmenopausal women may present with postmenopausal bleeding. Sertoli-Leydig cell tumors may present with symptoms of virilization.

Abdominal discomfort and bloating are the most common symptoms experienced by women with epithelial ovarian cancers, followed by vaginal bleeding, gastrointestinal symptoms, and urinary tract symptoms. Patients presenting with nonspecific lower abdominal discomfort and bloating require a prompt and careful pelvic examination. Not performing routine rectovaginal pelvic examinations may result in women with relatively early-stage ovarian cancer having a delay in diagnosis. Papanicolaou smear screening is inadequate for identifying ovarian cancer, although 1% to 2% of women seen at the Yale–New Haven Medical Center with ovarian cancer have an abnormality on their Papanicolaou smear suggesting the presence of an adenocarcinoma not of cervical origin.

Barber and Graber<sup>15</sup> have recommended that a palpable ovary in a postmenopausal woman is an indication for surgery. This report in 1971 predated the modern era of ultrasound technology. The identification of an adnexal mass on routine pelvic examination is now an indication for diagnostic ultrasound evaluation. Advances in endovaginal ultrasound and color Doppler flow techniques have resulted in identifying characteristics of pelvic masses that either make them highly suggestive to be benign or highly suggestive for malignancy ([Fig. 36.5-1](#)). Morphology indices have been developed to indicate the likelihood of pelvic masses being malignant. Kurjak et al.<sup>16</sup> has reported that particular color Doppler flow patterns and resistive indices are characteristic of malignant pelvic masses. Taylor and Schwartz<sup>17</sup> have presented data suggesting that resistive indices and pulsatility indices are not always effective in distinguishing benign masses from pelvic masses. As a general rule, an adnexal mass suspicious for malignancy by ultrasound morphology criteria is probably the best technique available short of biopsying the mass to identify which masses are most likely malignant.

**FIGURE 36.5-1.** Endovaginal ultrasound with color Doppler flow studies demonstrating an epithelial ovarian cancer. (Courtesy of Dr. Kenneth J. W. Taylor.)

The most common complaints associated with ovarian malignancies in the pediatric population are pain, abdominal swelling, and pelvic mass. Ovarian masses in premenarchal women require prompt evaluation and an exploratory laparotomy, because functional cysts do not occur in this group. Most premenarchal women with adnexal masses have benign disease.

Small ovarian cysts are often identified with use of ultrasound examinations of postmenopausal ovaries. Approximately 8% to 9% of postmenopausal women who do not have clinically palpable ovaries are found by ultrasound examination to have ovarian cysts between 1.5 to 3.0 cm in size.<sup>18</sup> These cysts do not need to be removed if they appear to be unilocular and are associated with a normal level of CA-125 and normal color Doppler flow studies. Postmenopausal women with complex pelvic masses, simple cysts in association with elevated serum CA-125 levels, or simple cysts in association with abnormal color Doppler flow studies should undergo prompt surgery.

Enlarged ovaries in reproductive-age women are relatively common and frequently are due to either functioning ovarian cysts, such as endometriomas and corpus luteum cysts, or to benign ovarian cysts. Women found to have such cysts are evaluated with serum CA-125 levels. CA-125 levels are often elevated in such patients and can be misleading if one uses the standard cutoff of 35 U/mL to distinguish benign cysts from malignancy in menstruating women. Studies suggest that a CA-125 cutoff from 65 to 200 U/mL is necessary to distinguish benign cysts from malignant cysts in premenopausal women.<sup>19</sup>

Cysts that appear by ultrasound criteria to be functional in nature may be followed through several menstrual cycles. Often they disappear over this short observation interval. Functional cysts may also disappear when oral contraceptives are used. Neoplastic cysts do not disappear under the influence of oral contraceptives. Rising values of serial CA-125 assays obtained during the observation period are an indication that a malignancy may be present. In turn, CA-125 values that are stable or declining generally reflect the presence of a functional cyst. CA-125 assays should always be obtained when a woman is not actively menstruating, because menses have been associated with marked elevation of serum CA-125.

Computed tomographic (CT) scans are useful in preoperatively evaluating the extent of disease when a pelvic mass is present. CT scans are most useful when combined with oral and intravenous contrast. They allow assessment of retroperitoneal lymph nodes in the paraaortic area and the identification of intraperitoneal and mesenteric implants.

Diagnostic laparoscopy is now being used for evaluation of unexplained pelvic pain and small adnexal masses. The difficulty with the laparoscopic approach to the evaluation of pelvic masses is rupturing a malignant tumor. In general, if a stage IA ovarian tumor can be removed intact, there is little evidence that additional therapy has a major impact on survival. Survival in this situation is extremely good. However, once an ovarian malignancy has been ruptured, patients are treated with either radiation therapy or cytotoxic chemotherapy.<sup>20</sup> Both treatment modalities carry with them physical as well as psychological trauma. Although there is no solid evidence that rupture of an early-stage ovarian malignancy decreases survival, avoidance of rupture of an ovarian neoplasm should be the routine method of approaching ovarian masses suspicious for malignancy.

Another technique for the diagnosis of ovarian cancer is peritoneal cytology. Aspiration of obvious ascites for cytologic assessment is routinely performed to identify malignant cells. If no ascites is present, saline may be instilled percutaneously or through the vaginal apex to flush the abdominal cavity and pelvis. The fluid is then withdrawn and sent for cytologic assessment. This diagnostic technique is quite uncomfortable for the patient and has been associated with poor patient acceptance and high false-positive results. Culdocentesis is not routinely used in the United States for the evaluation of a woman with possible ovarian cancer.

Serum CA-125 is the gold standard for tumor markers in the evaluation of pelvic masses, particularly epithelial ovarian cancers. Serum  $\alpha$ -fetoprotein (AFP) and human chorionic gonadotropin (HCG) have been helpful in recognizing preoperatively the presence of an endodermal sinus tumor, embryonal carcinoma, choriocarcinoma, or mixed germ cell tumor.<sup>14</sup> However, most young women with these diseases are not recognized preoperatively to have a malignancy. Levels of AFP and HCG are best applied in serially monitoring the effectiveness of therapy. Failure to identify preoperatively elevations of these markers does not preclude one from using them postoperatively in determining efficacy and duration of treatment for these diseases.<sup>14</sup>

In summary, a woman suspected of having ovarian cancer requires a preoperative workup that should include a CT scan to evaluate the extent of disease in both the pelvis and the upper abdomen and to rule out occult alternative primary sites for the origin of the disease, such as the pancreas. A serum CA-125 measurement is useful because 80% of women with advanced ovarian cancer have elevations of CA-125. The marker may be used as a secondary support for ovarian cancer being present preoperatively, and it may be used postoperatively to confirm the effectiveness of therapy. Radiologic studies of the upper intestinal tract as well as the lower tract are not routinely recommended unless the patient is having symptoms related to the intestinal tract. A barium enema or Hypaque enema can be very helpful in determining whether there is compromise of the sigmoid colon lumen in women with obstructive symptoms.

Patients with a preoperative evaluation consistent with the diagnosis of ovarian cancer would do best if referred to a gynecologic oncologist. Survival data suggests that those patients operated on by gynecologic oncologists for early-stage and late-stage disease do better in terms of progression-free and overall survival, at least in part because of more aggressive cytoreductive surgery performed by gynecologic oncologists and more appropriate surgical staging of the patient before initiating treatment.

## STAGING

Ovarian cancer is a surgically staged disease. Thus, it is important for physicians to be thoroughly familiar with the International Federation of Gynecologists and Obstetricians (FIGO) staging system for primary carcinomas of the ovary<sup>21</sup> (Table 36.5-2). As described earlier in the section [Pathogenesis](#), ovarian cancer spreads by direct extension to neighboring organs by exfoliating cells into the peritoneal cavity that can implant on parietal and visceral peritoneum throughout the peritoneal cavity. It also disseminates by lymphatic spread, particularly to the pelvic sidewall lymph nodes (external iliac and obturator chains) and along the gonadal vessels to the upper common iliac and paraaortic lymph node chains (Fig. 36.5-2). Surgical staging procedures must evaluate sites to which ovarian cancer is likely to spread.

**FIGURE 36.5-2.** Ovarian cancer spread pattern. (From Young RC, Perez CA, Hoskins WV. Cancer of the ovary. In: DeVita VT Jr, Hellman S, Rosenberg SA, eds. *Cancer: principles and practice of oncology*, 4th ed. Philadelphia: JB Lippincott Co, 1993:1226, with permission.)

Stage	Description
I	Stage I: Limited to the ovary
IA	Stage IA: Limited to the ovary, capsule intact
IB	Stage IB: Limited to the ovary, capsule ruptured
IC	Stage IC: Limited to the ovary, capsule ruptured, with capsular rupture
II	Stage II: Limited to the ovaries
IIA	Stage IIA: Limited to the ovaries, capsule intact
IIB	Stage IIB: Limited to the ovaries, capsule ruptured
IIIC	Stage IIIC: Limited to the ovaries, capsule ruptured, with capsular rupture
III	Stage III: Limited to the ovaries and peritoneum
IIIA	Stage IIIA: Limited to the ovaries and peritoneum, capsule intact
IIIB	Stage IIIB: Limited to the ovaries and peritoneum, capsule ruptured
IIIC	Stage IIIC: Limited to the ovaries and peritoneum, capsule ruptured, with capsular rupture
IV	Stage IV: Distant metastasis

**TABLE 36.5-2.** International Federation of Gynecologists and Obstetricians Stage Grouping for Primary Carcinoma of the Ovary (1998)

Complete surgical staging is a necessity to properly evaluate the patient and to determine whether additional therapy should be recommended. Proper surgical staging requires that a vertical incision be used that extends from the pelvis into the upper abdomen. Subumbilical incisions do not allow the surgeon to perform complete surgical staging. On entering the peritoneal cavity, any fluid present should be aspirated and sent for cytologic studies. Peritoneal fluid, even if limited to the pelvis, is more likely to yield malignant cells than are cytologic washings.<sup>22</sup> If no fluid is present, however, one should routinely irrigate the pelvis and paracolic spaces with normal saline. The fluid is then aspirated and sent to the cytology lab for evaluation. Careful inspection of the abdominal cavity should then be performed. Adhesions should be lysed to restore normal anatomy. Samples of the adhesions should be sent for microscopic evaluation.

If intraperitoneal carcinomatosis is not present, it is most appropriate to first resect the ovarian tumor and then to proceed with surgical staging. For women who are operated on for a tumor seemingly limited to one ovary, if preservation of fertility is an issue, the grossly normal opposite ovary should be biopsied or any implants on the ovarian surface should be excised. Preservation of fertility should be considered in any women of reproductive age with either a borderline malignant tumor of the ovary or an invasive epithelial cancer grossly confined to one ovary. A frozen section assessment of any abnormality involving the contralateral ovary helps guide the surgeon in determining whether to remove that ovary. Samples of pelvic peritoneum from the area of the ipsilateral infundibulopelvic and round ligaments, the cul-de-sac of Douglas, and urinary bladder are obtained. Pelvic retroperitoneal lymph nodes are removed in all patients with unilateral tumors. Patients in whom bilateral disease is suspected undergo bilateral pelvic lymph node sampling. Any enlarged pelvic retroperitoneal lymph nodes are removed, regardless of their locations. Lymphadenectomy is an important part of staging ovarian cancers, particularly when the disease is grossly limited to one ovary. In this situation, up to 20% of women have been found to have paraaortic lymph node metastases.<sup>23</sup>

The vertical incision is then extended to assess disease in the upper abdomen. If gross disease is not present in the omentum, an intracolic omentectomy is sufficient for diagnostic purposes. When disease is present in the omentum, the omentum should be excised from the greater curvature of the stomach ( Fig. 36.5-3). The upper abdominal evaluation continues with a careful inspection of the right hemidiaphragm, liver serosa, and parenchyma. If no disease is visually present, a 1 cm X 2 cm piece of peritoneum is excised off of the suprahepatic diaphragm, care being given not to remove underlying musculature and create a pneumothorax. The spleen is then carefully inspected, as is the left diaphragm. The paracolic spaces are then evaluated, and large strips of peritoneum (3 cm X 5 cm) are removed from the left and right paracolic spaces if no obvious disease is present. The large bowel is then carefully inspected. The small intestine is evaluated, and any implants present on bowel or its mesentery are removed. The colon, either the ascending or the descending colon, is then mobilized to expose the paraaortic area. If the peritoneal cavity has been freed of bulky tumor such that the maximum residual tumor is less than 1 cm in stage III patients, retroperitoneal lymph nodes are removed by taking the fat pad from the upper half of the common iliac artery up to the level of the renal vessels. However, if bulky residual disease (greater than 1 cm) is left in the upper abdomen, there is no role for paraaortic lymphadenectomy.<sup>24</sup> An international prospective randomized trial is now being conducted to determine the role of systematic pelvic and paraaortic lymphadenectomy for advanced ovarian cancer in women with 1 cm or smaller intraperitoneal residual tumor.<sup>25</sup> In postmenopausal women or women in whom fertility is no longer desired, one should routinely perform a bilateral salpingo-oophorectomy and total abdominal hysterectomy. The hysterectomy is performed because the serosal surface of the uterus is a large peritoneal surface for implantation of malignant cells. In addition, field effects may be present whereby the epithelium of the fallopian tubes or uterus are involved with premalignant or malignant processes. The latter changes cannot be grossly recognized at the time of surgery.

**FIGURE 36.5-3.** Excising omentum off stomach. A, artery. (From Young RC, Perez CA, Hoskins WV. Cancer of the ovary. In: DeVita VT Jr, Hellman S, Rosenberg SA, eds. *Cancer: principles and practice of oncology*, 4th ed. Philadelphia: JB Lippincott Co, 1993:1226, with permission.)

**POSTSURGICAL STAGING**

Understaging occurs rather frequently at the time of the initial surgery for ovarian malignancies, especially when the preoperative diagnosis is that of a benign process. This leads to use of inappropriate incisions that does not allow complete surgical staging when the diagnosis of a malignancy is recognized intraoperatively. At other times, it is due to a lack of familiarity with commonly accepted surgical staging procedures.

The issue of the inadequately staged early-stage patient with ovarian cancer is a difficult one. The simplest solution for such patients is to subject them to a properly performed staging laparotomy performed by a gynecologic oncologist. However, if this is not possible or practical, an alternative is to obtain a CT scan and a CA-125. If the CT scan and CA-125 are normal and the tumor was one of low malignant potential, no further therapy is recommended at the Yale–New Haven Medical Center. If the tumor is an invasive epithelial malignancy, we would consider giving single-agent chemotherapy, such as carboplatin, to such a patient. However, no prospective randomized series of patients have been reported using this approach. If the CT scan is positive, a surgical procedure to remove gross disease should be performed.

Postoperative reevaluation by laparotomy or laparoscopy has been advocated by some authors.<sup>26</sup> Earlier laparoscopic surgical staging papers revealed that as much as 30% to 40% of patients originally thought to have FIGO stage I or II disease actually had disease in the upper abdomen.<sup>26</sup> Complications as a result of earlier laparoscopic procedures had been relatively limited and included pneumothorax, bleeding requiring transfusions, wound infections, and hypotension.<sup>26</sup> More recently, more thorough laparoscopic techniques have been described that allow for paraaortic lymph node dissections and omentectomies.<sup>27</sup> As the degree of the aggressiveness of laparoscopic surgical procedures advances, the complications become more significant.

**SCREENING**

Successful screening for ovarian cancer, by definition, would decrease mortality and morbidity from the disease. With currently available tests, routine screening for ovarian cancer cannot be recommended. Successful screening for any malignancy requires detection either at a time when the disease is in its early stages or in a precancerous stage without invasive features. Although the patterns of spread of ovarian cancer have been well defined, the precise natural history is poorly

understood. It has not been established that untreated stage I routinely progresses to more advanced stages. Even if an orderly progression from stage I to stage IV takes place, the time frame for such a progression remains to be established. The entire peritoneum is at risk because peritoneal carcinomatosis may develop after an oophorectomy. Furthermore, the syndrome of extraovarian peritoneal carcinomatosis is characterized by widespread intraperitoneal epithelial carcinoma in the presence of histologically normal ovaries. In addition, there is no direct evidence for a premalignant lesion in ovarian cancer. As noted, no experimental data suggest that an ovarian cyst can progress to a borderline tumor that can, in turn, lead to an invasive carcinoma.

The primary reason that screening is not recommended, however, is because the currently available screening techniques (ovarian palpation, transvaginal ultrasound, and serum CA-125 determinations) are not sufficiently accurate for general screening. These tests have been limited by their sensitivity and specificity. Because a laparotomy is required to diagnose ovarian cancer, the positive predictive value (PPV) for screening is the primary consideration due to the cost, morbidity, and even mortality associated with unnecessary laparotomies for a false-positive screening test.<sup>28</sup> The PPV is defined as the ratio of a true-positive test (laparotomy) to true-positive plus false-positives. Most investigators think that the PPV of a laparotomy should be at least 10%.<sup>29</sup>

Whereas pelvic examinations continue to be routinely recommended for women, ovarian palpation has not been established as a useful screening procedure. Most screening studies have used either serum tumor markers or ultrasonography or both. Although serum CA-125 levels correlate with progression or regression of established disease<sup>29</sup> and are also useful in the preoperative evaluation of a pelvic mass, the test does not have sufficient specificity to be used as a routine screen for ovarian cancer.<sup>28</sup> Besides ovarian cancer, many other conditions can be associated with an elevated CA-125 level, including cirrhosis, peritonitis, pancreatitis, endometriosis, uterine leiomyomata, benign ovarian cysts, and pelvic inflammatory disease.

In a Swedish study,<sup>30</sup> CA-125 levels were measured annually in 550 women older than 40 years. In women with levels greater than 30 U/mL, sequential CA-125 levels were obtained every 3 months, along with pelvic examinations and transabdominal ultrasounds performed every 6 months. In this study, 175 women were found to have elevated CA-125 levels, and six ovarian cancers were detected.

Transvaginal ultrasonography is a more specific alternative to both transabdominal ultrasonography<sup>31</sup> and CA-125 screening. In studies from the University of Kentucky of more than 3000 asymptomatic postmenopausal women, the PPV was less than 10%.<sup>32</sup> In an effort to improve the unacceptably high rate of false-positive results with transvaginal ultrasonography, color Doppler imaging also has been studied in an effort to identify areas of vascularization that are associated with malignancy.<sup>33</sup> However, the addition of color Doppler imaging has not yet been established to improve the overall efficacy of ultrasonographic screening.

Several large screening trials have used a sequential combination of serum CA-125 and ultrasonography. In an English study, 22,000 volunteers without a family history of ovarian cancer underwent screening with serum CA-125 that was followed by abdominal ultrasonography for elevations of greater than 30 U/mL.<sup>34</sup> Women underwent a laparotomy for any detectable ovarian abnormality. In this study, 11 women had ovarian cancer, seven with stage III or IV disease. The PPV was less than 10% for early-stage disease. [Table 36.5-3](#) summarizes the results of uncontrolled trials of ovarian cancer screening in more than 36,000 women.<sup>35</sup> A total of 41 cases of ovarian cancer were identified, but only 12 were in women with stage I disease. In the 29 women who were diagnosed with advanced-stage ovarian cancer, it is unlikely that survival would have been significantly improved by an earlier diagnosis because the disease had already spread throughout the peritoneal cavity. Screening may ultimately be more effective in women with a positive family history of ovarian cancer.<sup>36</sup> At this point, however, no evidence shows that even screening such a high-risk population has an impact on morbidity and mortality.

Country	Reference	Participants	Ovarian Cancer Diagnosed	
			Stage I	Total
Sweden	30	5550	2	6

United Kingdom	34	21,959	3	11
United States	32	3220	2	3
<b>Total</b>		<b>36,208</b>	<b>12</b>	<b>29</b>

(From ref. 99, with permission.)

**TABLE 36.5-3.** Uncontrolled Trials of Ovarian Cancer Screening

Several large ovarian cancer screening trials are currently in progress. The National Cancer Institute's Prostate, Lung, Colon, Ovarian Cancer (PLCO) trial compares screening with an annual CA-125 measurement, transvaginal ultrasound, and pelvic examination to usual medical care in 76,000 women aged 60 through 74.<sup>37</sup> The participants in the study will be followed for 10 years. A European multicentric study headquartered at St. Bartholomew's Hospital in London will evaluate 120,000 postmenopausal women randomized to receive no screening or screening with transvaginal ultrasound followed by color flow Doppler examinations in women with abnormal transvaginal ultrasounds. In addition, serial CA-125 levels will be used to determine which participants should go on to the next stage of screening. Studies are also in progress to identify more sensitive tumor markers. Macrophage colony-stimulating factor (M-CSF) has been detected in epithelial ovarian tumors and in 70% of the serum or ascites of patients with diagnosed carcinomas.<sup>38</sup> Serum M-CSF levels, together with CA-125 levels, may be more predictive than CA-125 levels alone. Similarly, OVX-1 is a newly developed antibody that may also complement CA-125.<sup>39</sup> The combination of these two antibodies has been more accurate in predicting the presence of residual disease at second-look surgical procedures. Furthermore, a panel of CA-125, M-CSF, and OVX-1 was shown to identify early-stage ovarian cancer with extremely high sensitivity and moderate specificity in preliminary studies.<sup>40</sup> The levels of these tumor markers and their rate of change over time are being prospectively analyzed to help identify an individual's risk of ovarian cancer. Lysophosphatidic acid, which had previously been shown to be elevated in malignant ascites, may also have utility as a predictive biomarker for ovarian cancer, because an elevated level was found in nine of ten patients with early-stage disease.<sup>41</sup> Additional studies of sensitivity and specificity are in progress.

Inasmuch as screening has not been effective in diagnosing early-stage ovarian cancers, prophylactic oophorectomies have been advocated by some for women in high-risk groups. However, women still are at risk for peritoneal carcinomatosis even after normal ovaries have been removed. A multicenter prospective evaluation of the role of prophylactic oophorectomy in high-risk individuals is in progress. Preliminary results support a protective effect of an oophorectomy, although peritoneal carcinomatosis occurs at a higher rate in this group of women than in the general population.<sup>42</sup> Karlan et al.<sup>43</sup> have reported on the findings of peritoneal serous papillary carcinoma in women at high risk by family history for ovarian cancer. These investigators performed BRCA1 and BRCA2 gene mutation studies on four patients who developed serous carcinomas of the peritoneum and found that three of the four had BRCA1 mutations. None of the patients with peritoneal serous papillary carcinomas was recognized before intraabdominal carcinomatosis was evident.<sup>43</sup>

## PROGNOSTIC FACTORS

At the conclusion of a comprehensive laparotomy, the clinical findings and the histology are used to select postoperative therapy. In addition, new prognostic factors are being evaluated that may be used to identify groups of patients in whom more specific biologic treatments or more aggressive therapy is indicated.

Clinicopathologic findings determined to be clinically useful include the following:

- FIGO stage
- Histologic subtype
- Histologic grade
- Factors associated with tumor dissemination
- Malignant ascites
- Malignant peritoneal washings
- Tumor excrescences on ovarian surface
- Ruptured capsule

- Dense ovarian adhesions
- Volume of residual disease after cytoreductive surgery

The tumor stage remains the most important prognostic variable. Few trials provide an accurate assessment regarding the long-term survival of patients with early-stage ovarian cancer because earlier studies often included inadequately staged patients. Stage I patients with well- or moderately well-differentiated tumors have a greater than 90% 5-year survival rate.<sup>20</sup> Patients with stage I disease with poor prognostic features are often included in treatment protocols for patients with stage II disease. This group of patients has been termed *early-stage disease with unfavorable characteristics*. However, limited information is available regarding the actual survival impact of some of the factors used to characterize patients as having an unfavorable prognosis. Rupture of the capsule increases the stage to IC. In a Swedish series, however, no adverse effect on survival could be established for early-stage patients in whom the capsule was ruptured during surgery.<sup>44</sup> Furthermore, in contrast to the established adverse effect of malignant ascites, there is limited information regarding the prognostic significance of positive peritoneal cytology. Recently, tumor adherence in the presence of dense adhesions has also been considered an adverse prognostic factor, and such patients should be considered as having stage II disease even in the absence of pathologic confirmation.<sup>45</sup> Tumor size, bilaterality, and cytologically negative ascites have no prognostic significance. The most reliable long-term survival data on accurately staged early-stage ovarian cancer patients is derived from studies of the GOG. In these studies, unfavorable prognosis early-stage ovarian cancer patients have a five-year survival rate of approximately 80%.<sup>20</sup>

Patients with stage III disease have a 5-year survival rate of approximately 15% to 20% that is dependent in large part on the volume of disease present in the upper abdomen. Patients with stage IV disease have less than a 5% 5-year survival.

Volume of residual disease after cytoreductive surgery for patients with advanced ovarian cancer has a significant impact on survival. After the administration of postoperative cisplatin-based combination chemotherapy, 5-year survival rates for patients with optimal stage III disease (defined as no residual nodule greater than 1 cm in diameter) is approximately 35%.<sup>46</sup>

The true prognostic impact of histologic subtype and grade in patients with epithelial ovarian cancer remains to be determined. In patients with early-stage ovarian cancer, grade is an accepted determinant of risk and used to assign postoperative therapy as discussed earlier in the section [Management of Early-Stage Disease](#). Studies have also identified an adverse prognostic effect of clear cell histology in early-stage ovarian cancer.<sup>20,47</sup> In advanced-stage patients, mucinous histology and clear cell histology also have been shown to have an adverse prognostic significance.<sup>47</sup> In a GOG analysis, no negative second-look laparotomies in patients with mucinous or clear cell tumors were performed. Some studies also have demonstrated that histologic grade has an impact on survival in patients with advanced-stage disease.

Serum CA-125 levels frequently reflect the volume of disease and, as such, in multivariate analysis, preoperative levels have not exerted an independent prognostic effect on survival.<sup>48</sup> However, postoperative CA-125 levels were shown to be an independent prognostic variable.<sup>49</sup> Most studies also have demonstrated that serum CA-125 levels after three cycles of chemotherapy are accurate predictors for the probability of a patient achieving a complete remission.<sup>49</sup> However, the CA-125 level after three cycles of chemotherapy cannot be used as a guide for treatment decisions because of the lack of predictive power.

The prognostic significance of age on survival of patients with ovarian cancer has been recognized.<sup>50</sup> Median survival is at least 2 years longer in women younger than age 65 compared with those older than 65.

The prognostic significance of DNA ploidy and S-phase fraction have been examined in ovarian cancer.<sup>51</sup> Investigators in Europe have now included aneuploidy in their selection of high-risk early-stage ovarian cancer patients for adjuvant therapy.<sup>51</sup> Controversy remains, however, as to the nature of the relationship between histologic grade and degree of aneuploidy. In the GOG, aneuploidy has not been included as a criteria for risk in early-stage disease.

A series of new molecular factors have been proposed to have prognostic significance in ovarian cancer ( [Table 36.5-4](#)).<sup>52,53</sup> and <sup>54</sup> These factors include markers of proliferation, drug resistance, serum cytokine levels, growth factor receptors or signal transduction pathways, genes associated with metastases, and oncogene expression. Most of these factors have been identified in retrospective studies without multivariate analysis or confirmation in larger studies. These factors were developed from experimental studies in the biology of ovarian cancer (described in [Chapter 36.1](#)). Currently, none of these markers is routinely used to select therapy for patients with ovarian cancer.

Morphometry
DNA ploidy and S-phase fraction
Drug resistance markers
P-glycoprotein immunoreactivity
Glutathione S-transferase p1
c-mycBcl-2
Multidrug resistance protein (MDR)
Nucleotide excision DNA repair genes ERCC1 and XPC
BAX
Osteopontin
Mutant p53 expression
ARF1
Markers of proliferation
Ki67
Proliferating cell nuclear antigen
Markers of tumor spread
Metastasis-related genes (msi25-44)
Cathopin D
Urokinase-type plasminogen activator
Colony-stimulating factor 1
CD44 molecules
Cytokine levels and other active proteins
Hes-check protein
Interleukin-6
Platelet-derived growth factor

**TABLE 36.5-4.** Experimental Prognostic Factors in Ovarian Cancer

## MANAGEMENT OF EARLY-STAGE DISEASE

A subset of patients with early-stage ovarian cancer definitely has been shown not to require any additional postoperative therapy after a comprehensive staging laparotomy. Patients with stage IA or IB disease with well- or moderately well-differentiated tumors have a 5-year survival rate of more than 90% without any adjuvant treatment.<sup>20</sup> Patients with favorable prognosis early-stage ovarian cancer (stage IA and IB with grade 1 and 2 tumors) were randomized in an earlier GOG study to receive no treatment or oral intermittent melphalan (0.2 mg/kg daily for 5 days) with repeat cycles every 4 to 6 weeks for a total of 12 courses or 18 months of therapy. With a median follow-up of more than 6 years, only six deaths have been reported in 81 patients: four in the observation group and two in patients who received melphalan. Disease-free survival and overall survival is shown in [Figure 36.5-4](#). Patients with favorable prognosis early-stage ovarian cancer can be spared the acute and chronic toxicities of chemotherapy, including myeloproliferative disorders such as leukemia.

**FIGURE 36.5-4.** Disease-free (A) and overall (B) survival of patients with early-stage ovarian cancer. The top two curves represent patients with favorable prognoses randomized to observation or melphalan. The lower two curves represent patients with unfavorable prognoses randomized to either phosphorus 32 or melphalan. (From ref. 20, with permission.)

The optimum treatment of early-stage ovarian cancer patients with unfavorable prognosis remains an area of controversy. Opinions differ as to not only what modality of treatment should be used (external-beam radiotherapy, intraperitoneal radioisotopes, or chemotherapy) but also with regard to the role of immediate therapy or to delay of treatment until disease progression. Furthermore, as noted, consensus has not been established as to the prognostic significance of some clinicopathologic features, such as positive peritoneal cytologies and a surgically ruptured capsule with contamination of the pelvis with cyst fluid. Clinicopathologic factors currently used by the GOG to define unfavorable prognosis early-stage disease include FIGO stage II and IC, clear cell histology, and grade 3 tumors.

### External-Beam Radiotherapy

Although cisplatin- or paclitaxel-containing chemotherapy has become the standard initial treatment for patients with unfavorable prognosis early-stage ovarian cancer in all but a few centers, a number of studies have demonstrated that carefully applied whole abdominal radiotherapy is also a highly effective treatment for some patients.

Early nonrandomized studies suggested that pelvic disease control and survival were improved when patients with early-stage ovarian carcinoma were treated with postoperative pelvic radiation. In particular, patients with stage II disease had consistently better survival rates if the pelvis was treated ( [Table 36.5-5](#)).<sup>55,56,57,58,59,60,61</sup> and <sup>62</sup> However, these studies also demonstrated the importance of the coelomic pattern of metastatic spread, which limited the benefit of pelvic irradiation.

Reference	Treatment	
	Surgery Alone (%)	Surgery and Radiation (%)
Kent and McKay <sup>58</sup>	9/32 (28)	19/36 (53)
Van Orden <sup>62</sup>	2/8 (25)	8/22 (36)

**TABLE 36.5-5.** Results of Early Series Comparing Postoperative Pelvic or Lower Abdominal Radiation versus Surgery Alone for Stage II Carcinoma of the Ovary

On the basis of these findings and encouraging responses of ovarian carcinoma to alkylating agents, investigators at the M. D. Anderson Cancer Center conducted a prospective trial that compared pelvic and whole abdominal irradiation with pelvic irradiation and single-agent chemotherapy (melphalan).<sup>63</sup> Patients who had stage I to III ovarian carcinomas with less than 2 cm of residual disease after surgery were included. Abdominal treatment was delivered with cobalt (<sup>60</sup>Co) using the moving strip technique. Each strip was treated with 26 to 28 Gy in 8 to 12 fractions with partial shielding of the liver and kidneys. The authors reported that survival rates were similar for patients treated in the two arms, but the rate of serious bowel complications was higher for patients who received whole abdominal irradiation. It was concluded that chemotherapy was a superior treatment, and subsequent clinical trials at the M. D. Anderson Cancer Center and throughout the United States focused on the search for more effective chemotherapy.

Four years later, Dembo and associates<sup>64</sup> published the results of a similar prospective randomized study conducted at the Princess Margaret Hospital in Toronto. Patients with stage IB or II ovarian cancer were randomized to one of three treatment arms: pelvic irradiation, pelvic plus whole abdominal irradiation, or pelvic irradiation plus single-agent chemotherapy. Patients with “asymptomatic” stage III disease were randomized only between the last two arms. Although the treatment arms were similar to those of the M. D. Anderson trial, the details of the treatments differed significantly from that study. Patients on the chemotherapy arm received chlorambucil, an alkylating agent that has since been demonstrated to yield poorer response rates than melphalan. The total dose of abdominal strip irradiation (22.5 Gy) and the daily fraction size (2.25 Gy) were less than those used in the M. D. Anderson trial, but the liver was not shielded and particular care was taken to include the domes of the diaphragm in the treatment fields.

Of 190 patients entered on the study, 132 had a hysterectomy and bilateral salpingo-oophorectomy performed at their initial laparotomy. Of these 132 (who were considered to have minimal residual disease), the 50 who received whole abdominal irradiation had significantly better rates of survival and abdominal disease control than did patients who received pelvic irradiation with chlorambucil ( [Table 36.5-6](#)). Although the study has been criticized for using inconsistent surgical staging methods, it undoubtedly demonstrates the efficacy of abdominopelvic irradiation for at least some subsets of patients with minimal residual disease. Subsequent analysis of patients treated at Princess Margaret Hospital demonstrated that patients who had grade 1; stage I or II, grade 2; or stage I or II, grade 3 disease and no gross residual tumor after surgery were most likely to have a prolonged disease-free interval after abdominopelvic irradiation ( [Table 36.5-7](#)).<sup>55,66</sup>

Treatment	Number of Patients (%)			4-Y Survival Rate
	Total	Pelvis	Abdomen	
Pelvic RT <sup>a</sup>	31	8 (27)	8 (27)	50%
Pelvic RT plus chlorambucil	51	10 (20)	13 (25) <sup>b</sup>	55% <sup>c</sup>
Pelvic plus whole abdominal RT	50	11 (22)	0 (0)	81% <sup>d</sup>

RT, radiation therapy.

**TABLE 36.5-6.** Survival Rates and Relapse Sites for 116 Patients with Stage IB, II, and Asymptomatic III Ovarian Cancer Who Had a Total Hysterectomy and Bilateral Salpingo-Oophorectomy Completed at Initial Operation<sup>a</sup>

Stage	Gross Residual Disease	Proportion with Disease Recurrence		
		Grade 1	Grade 2	Grade 3
I	No	—	.21 (33)	.30 (27)
II	No/uncertain	.09 (32)	.29 (35)	.47 (36)
II	Yes	.17 (12)	.38 (16)	.86 (14)
III	No/uncertain	.20 (10)	.57 (18)	.67 (15)
III	Yes	.40 (15)	.79 (24)	.84 (38)

Numbers in parentheses are the number of patients treated in each group.  
 (From ref. 67, with permission.)

**TABLE 36.5-7.** Proportion of 325 Patients in Whom Disease Recurred after Treatment with Abdominopelvic Irradiation between 1971 and 1981

Differences in the chemotherapy and radiotherapy techniques described above may explain the apparently contradictory results of the two trials. An imbalance in the proportion of stage IA patients may have favored the chemotherapy arm in the M. D. Anderson trial, but subset analysis by stage also failed to suggest an advantage with whole abdominal irradiation.<sup>65</sup> The high total dose and fraction size per strip used at M. D. Anderson may explain the high rate of severe enteric complications compared with the 3% to 4% rate reported at Princess Margaret Hospital.<sup>67</sup>

A number of other reports document that patients with postoperative residual disease have been cured with abdominopelvic irradiation alone; relapse-free survival rates of 40% to 60% at 10 to 15 years have been reported for patients with residual gross disease measuring less than 2 cm (Table 36.5-8).<sup>68,69,70,71,72,73</sup> and 74 Collectively, these studies demonstrate the efficacy of abdominopelvic irradiation and its superiority over pelvic radiotherapy alone. They also indicate that irradiation alone is insufficient treatment for most patients with gross residual disease, particularly when the residuum is extrapelvic.

Study Center	Size of Residuum		End Point
	<2 cm	>2 cm	
Princess Margaret Hospital <sup>66</sup>	38 (91)	6 (91)	10y relapse-free rate
Stanford <sup>72</sup>	50 (42)	14 (54)	15y failure-free rate
Salt Lake City <sup>68</sup>	62 (12)	0 (10)	10y relapse-free survival
Walter Reed Hospital <sup>71</sup>	42 (24)	10 (20)	10y survival rate
Yale <sup>73</sup>	41 (27)	—	5y surviving fraction

Numbers in parentheses are the number of patients treated in each group.

**TABLE 36.5-8.** Evidence for Cure of Ovarian Cancer by Abdominopelvic Radiotherapy: Long-Term Outcome in Patients with Stage II and III Disease and Macroscopic Residuum

Randomized data comparing abdominopelvic irradiation with modern cisplatin- or paclitaxel-based chemotherapy have been difficult to obtain. Although retrospective studies do not demonstrate a clear advantage of one treatment over the other for patients with minimal residual disease, physician biases are strong and several multiinstitutional trials addressing this question have been closed prematurely because of inadequate patient accrual. In 1993, Redman and coworkers<sup>75</sup> published the results of a randomized trial comparing abdominopelvic irradiation with single-agent cisplatin in 40 patients with microscopic residual disease, stages IC to III. The 5-year survival rates were 58% and 62% in the two arms, respectively, but the power of the study was weak because of the small number of patients. In 1994, Chiara and colleagues<sup>76</sup> reported results of a second study comparing whole abdominal radiotherapy with cisplatin and cyclophosphamide in 70 patients with high-risk stage I or II disease. This study was compromised by poor accrual and protocol violations; 8 (24%) of the 34 patients assigned to receive radiotherapy were treated with chemotherapy. Projected 5-year survival rates for those treated with radiation (25 patients) or chemotherapy (44 patients) were 53% and 71%, respectively ( $F = .16$ ).

However, these studies still leave us with an incomplete understanding of the role of radiotherapy in initial management of ovarian cancer. Although pelvic irradiation was routinely added to early treatments with single alkylating agents, it generally has been abandoned since platinum-containing regimens became standard. Early studies of pelvic radiation therapy alone and the success of whole abdominal plus pelvic irradiation in selected patients indicate that radiation is an active agent and suggest that pelvic irradiation may be a useful addition to chemotherapy for selected patients who have a high risk of pelvic recurrence. However, no study has ever been done to determine whether pelvic irradiation could improve the control rates achieved with modern chemotherapy.

### Whole Abdominal Radiotherapy Technique

The <sup>60</sup>Co moving strip technique was developed at the M. D. Anderson Cancer Center in the 1960s to improve the acute tolerance of patients to large whole abdominal fields of radiation. The abdomen was divided into horizontal strips of 2.5 cm each; two to four contiguous strips were treated each day, moving down gradually until the whole abdomen had received the prescribed dose of irradiation. Subsequent studies suggested that large stationary megavoltage fields could be tolerated, and they were technically less difficult to deliver.<sup>58</sup> Dembo and coworkers<sup>77</sup> subsequently reported a randomized comparison of open field whole abdominal irradiation (22 Gy in 22 fractions) with the moving strip technique (22.5 Gy in ten fractions per strip), demonstrating lower complication rates and comparable tumor control with the simpler open field technique.

The high rate of subdiaphragmatic recurrences observed after treatment with early “whole abdominal” fields that did not completely cover the diaphragms illustrate the critical importance of covering the entire peritoneal cavity. More recently, in a review of a prospective multiinstitutional trial, Klaassen and colleagues<sup>78</sup> reported a significantly poorer survival rate for patients whose whole abdominal radiation fields were found to deviate seriously from protocol specifications.

Patients should always be simulated under fluoroscopy, and fields should provide a 1-cm margin on the maximum cephalad excursion of the diaphragmatic domes under quiet respiration. It is often necessary to flash the lateral abdominal wall and to include the entire bony pelvis in whole abdominal fields to avoid excluding peritoneal surfaces. In obese patients with poor abdominal tone, the fields may need to extend laterally beyond the bony pelvis. This is particularly true when the patient is treated in the prone position. The thickness of the abdominal wall should be considered in choosing the energy of the radiation beam. When fields are designed using CT scans of the whole abdomen, coverage of peritoneal surfaces can be assured. The total dose of whole abdominal irradiation varies between 22 and 30 Gy depending on the fractionation scheme, use of concurrent chemotherapy, and patient tolerance. Posterior kidney blocks are placed to limit the renal dose to 15 to 18 Gy, and a portion of the liver may be shielded during part of the treatment, limiting the dose to 22 to 25 Gy. The true pelvis is usually treated to a higher dose of 45 to 50 Gy, either after whole abdominal irradiation or concurrently as a “field within a field” (not to exceed a total daily dose to the pelvis of 180 cGy). Martinez and coworkers<sup>73</sup> have suggested boosting the dose to the paraaortic nodes and medial diaphragms with a T-shaped field in selected patients. Chemotherapy that is given before or after irradiation can influence normal tissue tolerance and should be considered in estimations of organ tolerance.

### Intraperitoneal Radioisotopes

The characteristic transcolonic pattern of dissemination of ovarian cancer first led clinicians to treat patients with intraperitoneal isotopes in the 1950s, and this treatment is still used by some practitioners for a selected group of patients with minimal disease. The isotope that is usually used is chromic phosphate (<sup>32</sup>P). <sup>32</sup>P decays with a half-life of 14.3 days, emitting  $\beta$ -particles with a mean energy of 0.69 MeV. Because the average penetration of these particles in soft tissue is less than 1 to 2 mm, treatment with chromic phosphate is inappropriate for patients who have macroscopic residual disease. Because the goal is to distribute the isotope evenly over peritoneal surfaces, patients with intraabdominal adhesions that inhibit the flow of the isotope-containing fluid are poor candidates for this treatment.

Intraabdominal distribution is usually evaluated before treatment by scanning the patient after an intraabdominal injection of technetium 99m sulfur colloid. If a good distribution is confirmed, the patient is treated with 10 to 20 mCi of chromic phosphate diluted in saline and then is positioned to optimize distribution. It is estimated that this dose delivers 20 to 40 Gy of radiation to the peritoneal surface. However, nonuniform distribution can produce variations in the dose of tenfold or more.

A GOG study, published in 1990, randomized 141 patients with poorly differentiated stage IA to B, stage IC, or completely resected stage II disease to receive either melphalan (0.2 mg/kg/d for 5 days, repeated every 4 to 6 weeks for 12 cycles) or intraperitoneal <sup>32</sup>P (15 mCi at the time of surgery).<sup>20</sup> The 5-year survival rates of 81% and 78% for patients treated with melphalan or <sup>32</sup>P, respectively, were not significantly different. Toxic effects were acceptable for most patients on both arms. However, four (6%) patients treated with <sup>32</sup>P required an operation for small bowel obstruction, and two (3%) patients treated with melphalan developed leukemia. The authors concluded that intraabdominal <sup>32</sup>P was the preferred treatment for these patients because of its limited toxicity and no known risk for causing leukemia.

Three randomized studies have compared <sup>32</sup>P with cisplatin-containing chemotherapy<sup>79,80</sup> and 81; none demonstrated a significant difference in survival between the two treatments. Vergote and colleagues<sup>80</sup> randomized 347 patients who had no gross residual disease after laparotomy to receive intraperitoneal <sup>32</sup>P (7 to 10 mCi) or

cisplatin (six courses of 50 mg/m<sup>2</sup> each). The estimated 5-year survival rates were 83% and 81%, respectively ( $P = .6$ ). Although the dose of <sup>32</sup>P was relatively low, 12 (9%) of 136 patients who had this treatment experienced small bowel obstructions compared with 2% of patients treated with cisplatin. For this reason, the authors recommended cisplatin as standard treatment.

In a GOG study, Young and colleagues<sup>81</sup> compared intraabdominal <sup>32</sup>P with combination chemotherapy (cisplatin and cyclophosphamide) for patients with high-risk early-stage disease. The 5-year survival rates were 76% and 84%, respectively ( $P = .08$ ). One toxic death was reported in each treatment arm, but these authors also concluded that the greater risk of bowel complications with <sup>32</sup>P outweighed the hematologic complications of chemotherapy; on this basis, the authors recommended chemotherapy as the preferred treatment.

The most common complication of <sup>32</sup>P administration is transient abdominal pain in 15% to 20% of patients. Chemical or infectious peritonitis is a rare complication that occurs in 2% to 3% of patients. The most serious late complication of treatment is small bowel obstruction, which has been reported in 5% to 10% of patients treated with <sup>32</sup>P alone. This risk increases to an unacceptable rate of 20% to 30% when intraperitoneal <sup>32</sup>P is combined with external-beam radiotherapy, an approach that is no longer recommended.

These clinical trials, however, did not establish whether any form of adjuvant therapy was, in fact, superior to no immediate treatment for patients with early-stage ovarian cancer with unfavorable prognostic features. The Italian Inter-regional Cooperative Group of Gynecologic Oncology has conducted a randomized trial with a no-treatment arm in patients with stage I or IB, grade 2 or 3 tumors who are randomized to receive cisplatin (50 mg/m<sup>2</sup> for six cycles) or to observation.<sup>82</sup> With a median observation time of 76 months, overall survival rates between the two treatment arms is similar (88% with cisplatin vs. 82% in the control group), although there is a marked improvement in disease-free survival for patients treated with cisplatin (83% vs. 65%). The absence of a larger difference in overall survival reflects the ability of cisplatin-based chemotherapy to salvage patients at the time of recurrence. Two additional trials, in which there is a no-treatment arm, are also in progress in Europe for early-stage ovarian cancer patients (Table 36.5-9). The Scandinavian randomized trial is similar in design to that of the Italian study. In an English trial, however, the randomization is between observation and treatment with single-agent carboplatin. Unlike the Scandinavian study, the English trial has no requirement for extensive surgical staging.

Randomization	Result
GOG trial	
GOG protocol 17	Paclitaxel (75 mg/m <sup>2</sup> in a 24-hour infusion) plus carboplatin (area under the curve [AUC] of 7.5) three versus six cycles
GOG protocol 15	Three cycles of paclitaxel (75 mg/m <sup>2</sup> in a 24-hour infusion) plus carboplatin (AUC = 6) followed by randomization to observation or 24 weekly administrations of paclitaxel (80 mg/m <sup>2</sup> )
ECOC trial	Carboplatin (AUC = 6) versus observation
Scandinavian trial	Carboplatin (AUC = 6) versus observation

AUC, area under the curve; GOG, Gynecologic Oncology Group; ECOC, International Collaborative Ovarian Neoplasm trial.

**TABLE 36.5-9.** Clinical Trials in Early-Stage Ovarian Cancer

The current GOG trial for patients with early-stage ovarian cancer with unfavorable prognosis compares three cycles against six cycles of a treatment with paclitaxel and carboplatin (see Table 36.5-9). The details of this combination are discussed later in the section [Paclitaxel Combination Therapy](#).

It is apparent that the optimum postoperative treatment for patients with early-stage ovarian cancer with unfavorable prognostic features remains to be established. Pending the results of the ongoing clinical trials, treatment options include chemotherapy with cisplatin or carboplatin, total abdominal and pelvic irradiation, and paclitaxel-based chemotherapy. In addition, a no-treatment option can be considered, although this choice has been shown to be associated with a decrease in disease-free survival. Second-look operations after completion of adjuvant therapy are not routinely recommended.

## TREATMENT OF ADVANCED-STAGE OVARIAN CANCER

The generally accepted treatment for patients with either stage III or IV (advanced stage) ovarian cancer has been similar—cytoreductive surgery, when feasible, followed by chemotherapy.

### Cytoreduction

Aggressive surgery to remove virtually all gross tumor (i.e., cytoreductive surgery or tumor debulking surgery) has become an integral part of initial surgery for management of ovarian cancer. The theoretical benefits of cytoreductive surgery are to remove large necrotic tumors with poor blood supplies and to remove large tumors that are in a slower growth phase, leaving behind tumors that are more sensitive to the effects of chemotherapy. Theoretically, all patients with stage III and IV disease are candidates for cytoreductive surgery. Stage IV patients, based on the presence of parenchymal liver disease, enlarged retrocrural lymph nodes, supraclavicular lymph nodes, mediastinal metastases, and parenchymal lung metastases may not be candidates for optimal cytoreductive surgery. In addition, we have found that women who have disease on CT scan that involves the porta hepatis or is associated with suprarenal lymphadenopathy or omental metastases that extend into the hilum of the spleen frequently have such advanced disease at the time of the cytoreductive surgery that the likelihood of optimal cytoreduction being accomplished is virtually nil. Women with stage IV disease based only on the presence of malignant pleural effusion have been able to undergo optimal cytoreductive surgery. Its impact on their survival has been questioned.<sup>83</sup> Studies have suggested that an optimal surgical cytoreductive effort should be performed in women with stage IV disease, even when parenchymal liver disease is recognized preoperatively.<sup>84,85</sup> If patients can be optimally cytoreduced to less than 1 to 2 cm maximum diameter of residual tumor, their median survival has varied from 25 to 40 months, whereas those women who were suboptimally cytoreduced had median survival rates of 10 to 18 months. Interestingly, the stage IV patients optimally cytoreduced in three of the four series had a superior survival to optimally cytoreduced patients with stage III ovarian cancer treated in prospective randomized trials by the GOG.<sup>46</sup>

Successful surgical management of stage III or IV ovarian cancer requires meticulous attention to surgical techniques to avoid complications and a thorough knowledge of abdominal and pelvic anatomy to allow the successful accomplishment of cytoreductive surgery. In general, it is wisest to start with an incision in the lower abdomen to free the pelvis of cancer, then work up into the upper abdomen to attempt to clear it of cancer, then complete the procedure with paraaortic and pericaval retroperitoneal lymph node sampling or resection if optimal cytoreduction has been accomplished within the peritoneal cavity. The goal of optimal cytoreductive surgery is complete removal of all palpable or visible tumor. A minimal goal of cytoreductive surgery is to reduce the residual tumor to less than 1 cm and preferably less than 0.5 cm in maximum diameter.

On entering the abdominal cavity, normal anatomy is restored by lysing adhesions and freeing organs from adherent tumor. Frequently the pelvis is completely filled with tumor. By identifying the round ligaments and suture ligating and dividing them, the pelvic retroperitoneum can be entered and the external iliac arteries and veins, the hypogastric arteries, and the ureters can be rapidly identified. Accomplishing this allows ligation of the infundibulopelvic ligaments with the ovarian vessels; resection of peritoneum, along with the attached vessels down to the tumor mass; and dissection of the ovarian mass off of, or with, the underlying peritoneum to elevate the mass from the pelvic sidewall. By dividing the utero-ovarian ligaments and fallopian tubes, one can then remove the mass. At times, it may be necessary to resect small bowel or sigmoid colon in continuity with the ovarian mass. An end-to-end or side-to-side anastomosis restores bowel continuity. Less frequently a colostomy is necessary. Once each of the ovaries has been removed, a hysterectomy is performed. At times, ovarian cancers infiltrate into the uterus and it is necessary to take the uterus out *en bloc* with the ovarian tumor. Implants in the cul-de-sac may be resected using retroperitoneal dissection. Sigmoid colon implants usually involve epiploic appendices, which can be resected without performing a sigmoid colon resection. Retroperitoneal lymph nodes are routinely removed from the external iliac artery and vein, hypogastric arteries, and the obturator fossa. An appendectomy is routinely performed.

Having resected the pelvic disease, a complete omentectomy is performed and large masses implanting on peritoneal surfaces, including the diaphragm, are removed. Once the abdomen has been cleared of disease, or the maximum residual disease is less than 1 cm, the fat pad overlying and surrounding the aorta and vena cava is removed, as are lymph nodes involved with metastatic disease in this area. In general, if large residual tumor volume is left within the peritoneal cavity,

there is not much benefit in resecting retroperitoneal disease. However, when intraperitoneal disease has been optimally cytoreduced to less than 1-cm maximal residual tumor volume, retroperitoneal lymphadenectomies are appropriate.

### Impact of Primary Cytoreductive Surgery

The clinical rationale for cytoreductive surgery has been ascribed to Griffiths,<sup>86</sup> who demonstrated in 1974 that survival was directly effected by the initial degree of cytoreductive surgery for women with advanced-stage ovarian cancer. In a retrospective review, patients with no residual disease had a mean survival of 39 months compared with 29 months for residual disease of less than 0.5 cm, 18 months for residual disease of 0.6 to 1.5 cm, and 11 months for those who were not cytoreduced below 1.5 cm. None of the latter patients survived beyond 26 months. Women who underwent optimal cytoreductive surgery had similar survival rates to women who had minimal-size abdominal metastases at the initial surgery. Subsequent to that report, numerous series have confirmed that aggressive cytoreductive surgery to 2 cm of residual tumor or less significantly enhances survival for patients. Most patients participated in trials in which multidrug chemotherapy was used, usually involving cisplatin-based chemotherapy. A review of nine reports, in which primary cytoreductive surgery resulted in disease of less than 2 cm or greater than 2 cm, demonstrated a mean survival in the optimally cytoreduced group of 29.4 months compared with 13.4 months in the group in whom cytoreductive surgery was suboptimal.<sup>86,87,88,89,90,91,92,93</sup> and <sup>94</sup> (Table 36.5-10).

Author/Year	Chemotherapy	Residual Disease	Survival (months)

TABLE 36.5-10. Effect of Residual Disease at the Conclusion of Primary Cytoreductive Surgery on Survival

Two metaanalyses gave conflicting views on the survival impact of cytoreductive surgery.<sup>95,96</sup> Hunter et al.<sup>95</sup> reviewed a total of 58 separate studies containing 6962 patients to determine whether maximum cytoreduction surgery benefits the survival of women with advanced ovarian cancer. These authors looked at the median survival times of groups of women with advanced ovarian cancer and used multiple linear regression techniques to analyze the effects on median survival. The variables studied were the proportion of each cohort undergoing maximum cytoreductive surgery, the use of cisplatin chemotherapy, the dose intensity of the chemotherapy, the proportion of each cohort with stage IV disease, and the year of publication of the study. The use of cisplatin chemotherapy resulted in an increased survival time of 53% [95% confidence intervals (CI), 35% to 73%]. For each 0.2 unit increase in dose intensity, the increase in median survival time was 11.1% (95% CI, 6% to 17%,  $P = .001$ ). Stage IV disease had a negative impact on survival. For each 10% increase in the number of stage IV patients in the study, a negative survival increase of 2.6% (95% CI, -0.1% to -5.4%) was found. For each 10% increase in the percentage of women who underwent maximum cytoreductive surgery, the increase in survival was only 4.1% (95% CI, -0.6% to 9.1%,  $P = .089$ ) (Fig. 36.5-5). This study concluded that cytoreductive surgery has only a small effect on the survival of women with advanced ovarian cancer and that the type of treatment used (i.e., cisplatin) was far more important.

FIGURE 36.5-5. Graph of log median survival time (MST; in months) versus percent maximum cytoreductive surgery (MCS) for 76 cohorts for which dose intensity could be calculated after adjustments for effects of dose intensity, percent stage IV, and platinum chemotherapy. (From ref. 95, with permission.)

Allen et al.<sup>96</sup> performed metaanalyses on 12 reports of women with stage III ovarian cancer in which they could determine that patients either had no residual disease, residual disease less than or equal to 2 cm, or residual disease greater than 2 cm, and on four reports of stage IV ovarian cancer for which similar analyses were possible. The results of these metaanalyses were consistent with survival benefits accruing to patients with no residual disease and residual disease less than or equal to 2 cm after surgery for stage III and IV disease when compared with patients with residual tumor masses greater than 2 cm. These authors, however, indicated that the survival benefit for women with small residual tumor probably reflects more the biology of the tumor and suggests that less-invasive tumors may be more chemotherapy-sensitive than those tumors in which optimum cytoreductive surgery was not possible. To date, no prospective randomized trials have been performed assessing the value of cytoreductive surgery in advanced ovarian cancer.

Three GOG studies give important insight into the impact of cytoreductive surgery in advanced ovarian cancer. The first demonstrated that removing all gross tumor defines true optimal cytoreductive surgery. Women treated with cisplatin-based chemotherapy who had no gross disease left had a progression-free interval of 42 months compared with 20 months for those with residual disease of less than 1 cm.<sup>97</sup> The second study revealed that women who had 1 to 2 cm residual tumor had a significant survival improvement compared with those who had more than 2 cm of residual tumor.<sup>98</sup> This third study refuted early data suggesting that women undergoing optimal cytoreductive surgery have similar survival as those patients initially found at surgery to have low-volume disease.<sup>46</sup> The latter study reported on 348 women with 1 cm or less residual tumor, 200 of whom initially had abdominal disease of 1 cm or less. When implants were present on parietal or visceral peritoneum, even when optimally cytoreduced, survival rates significantly decreased. Indeed, the best survival for stage III patients observed were those whose initial macroscopic tumor was less than 1 cm in the omentum and associated with either no disease or microscopic disease in other abdominal sites ( $P = .0001$ ). Those with the poorest survival had tumors initially greater than 1 cm involving omentum and had gross disease in other abdominal sites (Fig. 36.5-6). This study refutes early data suggesting that women undergoing optimal cytoreductive surgery have the same survival as those patients initially found at surgery to have low-volume disease. The study demonstrates that biologic factors responsible for bulk disease may be as important as technical ability to resect the disease.

**FIGURE 36.5-6.** Survival time by initial maximum omental (Omen.) and abdominal (Abdom.) tumor diameter. Micro, microscopic. (From ref. 46, with permission.)

Aggressive cytoreductive surgery incurs complications. Chen and Bochner<sup>99</sup> reported on 60 patients who underwent optimal cytoreductive surgery. These patients had a 5% operative morbidity. Blythe and Wahl<sup>100</sup> have looked at quality of life in optimal residual disease (less than 2 cm in diameter) and suboptimal residual disease (more than 2 cm in diameter) and found that 75% of the optimal group were judged to have good or good-to-fair quality of life, but only 18% of the suboptimal group achieved this quality of life. It has been argued that perhaps those women who are able to be optimally cytoreduced have biologically less virulent disease than those patients in whom optimal cytoreductive surgery cannot be achieved. This question has yet to be answered as there are no data from prospective randomized trials available.

CT scans have been used to identify the extent of ovarian cancer metastases and, in particular, to identify disease in the upper abdomen that may result in technical difficulties leading to significant residual tumor at the completion of attempted cytoreductive surgery. These sites include parenchymal liver disease, confluent sheets of tumor on the diaphragm and serosa of the liver, porta hepatis infiltration, omental replacement with metastatic tumor that extends into the hilum of the spleen, and suprarenal lymph node metastases. Although it is possible to resect some of these sites, CT scan findings in general reflect less than the actual findings at the time of surgery, but CT scan findings frequently indicate which patients have disease present that can be routinely surgically cytoreduced to optimal levels. We have used this information at the Yale–New Haven Medical Center to avoid initially performing possible suboptimal cytoreductive surgery in such patients and have offered those patients neoadjuvant chemotherapy.<sup>101,102</sup> Fifty-nine consecutive women with advanced malignancies compatible with ovarian cancer based on a physical examination, CT scans, and cytologic or histologic specimens underwent neoadjuvant chemotherapy with platinum-based combination regimens at the Yale–New Haven Medical Center.<sup>103</sup> Forty-one subsequently underwent cytoreductive surgery. Their overall progression-free survival rates were compared with those of 206 consecutive women with stage III and IV epithelial ovarian cancers treated with conventional cytoreductive surgery followed by the same platinum-based combination chemotherapy.<sup>103</sup> No statistical difference was observed in the overall survival or in progression-free survival between the group treated with neoadjuvant chemotherapy and the conventionally treated patients, despite the neoadjuvant patients being statistically older than the conventionally treated ones and having a statistically poorer performance status than the conventionally treated group. Women undergoing cytoreductive surgery after neoadjuvant chemotherapy had a statistically improved overall survival ( $P < .0001$ ) compared with those who received neoadjuvant chemotherapy but did not undergo surgery. Surwit et al.<sup>104</sup> used neoadjuvant chemotherapy in 29 women with advanced ovarian cancer. The latter authors followed log decreases in serum CA-125 levels and compared those decreases in CA-125 levels to survival. A two-log decrease in CA-125 before surgery resulted in a median survival of 37 months, whereas patients with less than 1 log response in CA-125 had a survival of 18 months. The hospital stays, operative time, and blood loss at the time of surgery were substantially reduced in women who received neoadjuvant chemotherapy compared with studies published in the literature.<sup>104</sup> In addition, complications such as pneumonia, febrile episodes, and wound infections also appeared to be substantially reduced in Surwit's series. These results were consistent with the Yale–New Haven series as well.

The initial experience with neoadjuvant chemotherapy in the management of women with advanced disease who do not appear to be surgically resectable or have evidence for stage IV disease suggests that neoadjuvant chemotherapy with cisplatin-based treatment may be as effective as the conventional approach of chemotherapy after suboptimal cytoreductive surgery.<sup>101,102</sup> Paclitaxel-based neoadjuvant chemotherapy is now being used at the Yale–New Haven Medical Center. Potential advantages of neoadjuvant chemotherapy appear to be a much more rapid improvement in quality of life, a less expensive treatment program for patients and, when surgery is ultimately performed, an easier operation requiring shorter hospitalization. Prospective randomized trials incorporating neoadjuvant chemotherapy in the management of advanced-stage ovarian cancer are definitely needed.

### Chemotherapy

Chemotherapeutic agents from a wide variety of different classes have been shown to produce responses in patients with ovarian cancer. Numerous combination chemotherapy regimens have been studied, and comparisons have been made of individual drugs with combinations. Since the mid-1990s, a new chemotherapeutic combination consisting of the combination of paclitaxel and a platinum compound has been accepted as the standard of care in the United States.

**PLATINUM COMPOUNDS.** Before demonstration of the marked activity of paclitaxel in ovarian cancer, platinum compounds were considered to be the most active agents in this disease. Several clinical trials compared platinum-containing combinations to non-platinum-containing regimens. The largest trial was performed by the GOG<sup>105</sup> in which 120 patients received cyclophosphamide plus Adriamycin and were compared with 107 patients who were treated with cyclophosphamide, Adriamycin, and cisplatin (CAP). The CAP regimen was deemed superior based on a higher overall response rate (51% vs. 26%), longer progression-free duration (13.1 months vs. 7.7 months), and an improvement in overall survival rate (15.7 months vs. 9.7 months). A metaanalysis of 45 clinical trials in ovarian cancer confirmed the survival benefit of immediate cisplatin-based treatment compared with treatment with a non-platinum-containing regimen.<sup>106</sup> The metaanalysis also demonstrated a modest survival advantage for platinum combinations when compared with treatment with single-agent cisplatin.

The development of carboplatin as a less toxic analogue led to several prospective randomized trials comparing single-agent carboplatin to cisplatin in previously untreated patients with advanced disease. The longest study currently has a minimum follow-up of 8 years, and no statistically significant differences in survival have been found—5-year survival rates of 15% and 19% for cisplatin and carboplatin, respectively.<sup>107</sup> Similarly, an updated metaanalysis that included all clinical trials comparing single-agent carboplatin with single-agent cisplatin also has failed to detect any significant differences in progression-free interval or in overall survival for these drugs.<sup>108</sup> In addition, combination chemotherapy regimens containing carboplatin have been compared with cisplatin-containing regimens.<sup>109,110</sup> In North America, carboplatin plus cyclophosphamide was compared with cisplatin plus cyclophosphamide by the Southwest Oncology Group<sup>109</sup> and by the National Cancer Institute of Canada.<sup>110</sup> No survival differences were reported in these trials. However, some investigators have suggested that in certain subsets of patients, the cisplatin treatment may be superior. A European trial compared CHAP-5 (cyclophosphamide, hexamethylmelamine, Adriamycin, and cisplatin) with CHAC, in which carboplatin replaced cisplatin.<sup>111</sup> Complete remission rate for the cisplatin regimen was 32% compared with 27% for the CHAC combination. A trend toward improvement in the survival rate was seen for patients with less than 1 cm of disease who were randomized to the cisplatin regimen. In patients with bulky disease, no survival differences were found.

In these studies, platinum-based regimens were routinely administered for six cycles. Prospective randomized trials have compared five cycles with ten cycles<sup>112</sup> or six with 12,<sup>113</sup> and no statistically significant differences have been reported in survival for patients treated with the greater number of cycles. However, numerous questions remain regarding the role of dose and dose intensity of these agents in the overall treatment of patients with ovarian cancer. Cisplatin dose intensity (expressed as mg/m<sup>2</sup>/wk) was studied retrospectively in 33 published trials in ovarian cancer.<sup>114</sup> This retrospective analysis provided evidence for the importance of dose with regard to response and survival. Doses of cisplatin beyond 100 mg/m<sup>2</sup> have been associated with unacceptable toxicity, primarily neurotoxicity. Several prospective clinical trials have compared differences in cisplatin dose intensity (Table 36.5-11). In the GOG trial, 485 patients with bulky stage III or IV disease were randomized to receive either eight cycles of cisplatin (50 mg/m<sup>2</sup>) plus cyclophosphamide (500 mg/m<sup>2</sup>) every 3 weeks, or four cycles of cisplatin (100 mg/m<sup>2</sup>) plus cyclophosphamide (1000 mg/m<sup>2</sup>) every 3 weeks.<sup>116</sup> This study demonstrated that a regimen could be administered at double the dose intensity of cisplatin with increased grade 3 and 4 myelotoxicity. However, no significant difference was noted in overall response rate or survival for patients who received the high-dose regimens. Two similar studies from Italy also were not able to demonstrate any improvement for patients who received double-dose intensity of cisplatin.<sup>117,118</sup> In contrast, the study from the West Scotland's Clinical Trial Group compared two different cisplatin plus cyclophosphamide regimens and initially reported an improvement in survival for patients receiving the higher-dose intensity.<sup>214</sup> In this trial, patients with stage IC to IV disease were randomized to treatment with either 50 mg/m<sup>2</sup> (low dose) or 100 mg/m<sup>2</sup> (high dose) cisplatin, with all patients receiving 750 mg of cyclophosphamide. With the longer follow-up, the differences in survival appear to be decreasing.<sup>120</sup> There currently is no evidence that a dose of cisplatin greater than 75 mg/m<sup>2</sup>/cycle should be routinely used in combination chemotherapy

for patients with advanced ovarian cancer.

Country	Adjuvant	Randomization	Number of Patients	Result	Comment
United Kingdom	111	Cisplatin, 50 mg/m <sup>2</sup> versus 80 mg/m <sup>2</sup>	61	Increased survival for high dose	Toxicity not reported
United States	114	100 mg/m <sup>2</sup> cisplatin plus 1000 mg/m <sup>2</sup> cyclophosphamide versus 50 mg/m <sup>2</sup> cisplatin plus 1000 mg/m <sup>2</sup> cyclophosphamide	65	No difference in survival	Due to toxicity of cisplatin doubled
Italy	117	75 mg/m <sup>2</sup> cisplatin versus 100 mg/m <sup>2</sup> cisplatin	20	No difference in survival	Due to toxicity of cisplatin doubled
Italy	118	100 mg/m <sup>2</sup> cisplatin plus cyclophosphamide 1000 mg/m <sup>2</sup> versus 50 mg/m <sup>2</sup> cisplatin plus cyclophosphamide 1000 mg/m <sup>2</sup>	16	No difference in response or survival	Therapeutic dose increase continuation leading to more toxicity but no survival benefit
Sweden	119,120	100 mg/m <sup>2</sup> cisplatin plus 700 mg/m <sup>2</sup> cyclophosphamide versus 50 mg/m <sup>2</sup> cisplatin plus 700 mg/m <sup>2</sup> cyclophosphamide	30	Improved survival in high-dose arm	Survival difference is decreasing with longer follow-up

**TABLE 36.5-11.** Randomized Trials of Cisplatin Dose Intensity

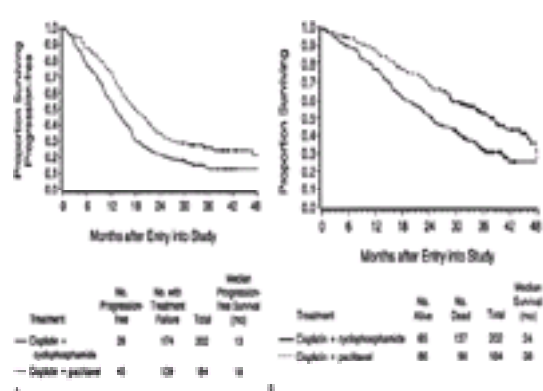

In contrast to cisplatin, carboplatin is rapidly excreted in the kidney. The area under the concentration-time curve is dependent on glomerular filtration rate (GFR). Retrospective studies have identified a correlation between response and toxicity and area under the curve (AUC), with a plateau reached for response at an AUC of 6 to 7.<sup>121</sup> Formulas have been developed to individualize dose based on AUC and patients' renal function. In Calvert's formula, the dose (mg) = AUC × [GFR + 25].<sup>122</sup> In these studies, GFR was estimated by <sup>51</sup>CrEDTA clearance. Creatinine clearance, however, can be used to approximate GFR and can be measured or estimated with age and serum creatinine. Prospective randomized trials have been performed in which patients with advanced ovarian cancer have been randomized to different AUCs covering a twofold difference in dose intensity. In a study from the Danish Ovarian Cancer Study Group, there was no increased efficacy for patients randomized to receive an AUC of 4 versus 8.<sup>123</sup> All patients in this trial also received cyclophosphamide. In the trial from the United Kingdom,<sup>125</sup> patients received carboplatin dosed to an AUC of 6 or 12. Greater grade 4 toxicity in patients scheduled to receive an AUC of 12 subsequently was found, which led to substantial dose reduction.

Several randomized trials also have explored cisplatin plus cyclophosphamide versus doxorubicin-containing combinations. In the GOG trial,<sup>125</sup> 349 patients with advanced disease were randomized to receive either cisplatin plus cyclophosphamide or a PAC combination (cisplatin, doxorubicin, and cyclophosphamide). No significant differences were reported with regard to complete remission rates (30% vs. 33%), progression-free interval (median, 22.7 months vs. 24.6 months), or overall survival rate (median, 31.2 vs. 38.9 months). In contrast, a large Italian trial has reported a significantly higher, surgically confirmed, complete remission rate (62% vs. 40%) and a 10-month increase in median survival for patients treated with PAC compared with cyclophosphamide and cisplatin (CP).<sup>126</sup> Two separate metaanalyses pooling the data from these clinical trials has identified a survival benefit between 5% and 7% from years 2 to 6 for patients with the doxorubicin regimens.<sup>127,128</sup> Direct comparison of these regimens, however, has been somewhat limited by differences in toxicity and dose intensity. Only the GOG study was performed with regimens that produced comparable hematologic toxicity. Although the metaanalysis suggested that the addition of doxorubicin slightly prolonged survival, a large prospective comparison [International Collaborative Ovarian Neoplasms (ICON) trial II] of single-agent carboplatin (AUC = 5) versus the PAC regimen did not demonstrate any differences in either progression-free survival or overall survival rates.<sup>129</sup>

Before the demonstration of the role of paclitaxel in the initial chemotherapy of patients with advanced ovarian cancer, standard chemotherapy regimens in the United States consisted primarily of either cisplatin (75 mg/m<sup>2</sup>) or carboplatin (dosed to an AUC of 6 to 7, or approximately 350 mg/m<sup>2</sup>) together with cyclophosphamide (at a dose of 600 to 750 mg/m<sup>2</sup>). In contrast, many clinicians in Europe continue to use the PAC regimen or single-agent carboplatin.

**PACLITAXEL COMBINATION CHEMOTHERAPY.** Taxanes are a new class of cytotoxic agents with a unique mechanism of action. Paclitaxel and docetaxel both have been demonstrated to have activity in platinum-resistant patients.<sup>130,131</sup> The taxanes exert their cytotoxicity primarily by their effect on microtubules. Taxanes bind to microtubules and shift their equilibrium toward microtubular assembly, leading to a cell-cycle arrest in G<sub>2</sub>/M. Premedication with steroids, cimetidine, and diphenhydramine has essentially eliminated the hypersensitivity reactions that limited early phase I trials. Of particular importance in the phase II trials, which demonstrate an overall response rate of 30% to 40%, was the observation that paclitaxel was active in patients who had disease progression while receiving cisplatin or had a duration of remission of less than 6 months. In the GOG trial of 43 patients, 27 were defined as platinum-resistant.<sup>130</sup> The overall response rate in this subset of patients was 33%, compared with the overall response rate of 37%. Toxicities of paclitaxel include alopecia, myalgia, and myelosuppression (primarily neutropenia with little effect on platelets). The activity of paclitaxel was confirmed in other phase II trials.<sup>132</sup>

Based on these results, a series of prospective randomized trials have compared platinum and paclitaxel versus regimens without paclitaxel (Table 36.5-12). The GOG study<sup>133</sup> randomized almost 400 patients with suboptimal stage III and IV disease to paclitaxel plus cisplatin or to cyclophosphamide plus cisplatin. The paclitaxel regimen was superior with regard to response rate, complete remission, second-look rate, progression-free survival, and overall survival (Fig. 36.5-7). In this group of patients with poor prognosis and advanced disease, a 14-month improvement in median survival (24 months vs. 38 months) is seen in patients treated with the paclitaxel combination. The results of this study were confirmed by a European/Canadian trial that had a similar randomization.<sup>134</sup> In this trial, however, paclitaxel was administered at 175 mg/m<sup>2</sup> in a 3-hour infusion instead of the 24-hour infusion used in the GOG trial. Furthermore, in the latter trial, in contrast to GOG 111, patients initially randomized to the nonpaclitaxel combination were frequently crossed over at the time of disease progression if they were initially randomized to cisplatin plus cyclophosphamide. Nevertheless, the results of this trial also showed a 10-month improvement in overall survival for patients treated initially with paclitaxel plus cisplatin.<sup>134</sup> The subsequent trial by the GOG in the same group of patients was a three-arm study in which patients were randomized to receive single-agent cisplatin (100 mg/m<sup>2</sup>), single-agent paclitaxel (200 mg/m<sup>2</sup>), or the combination of cisplatin plus paclitaxel as described earlier in this section.<sup>135</sup> In this protocol (GOG 132), most patients randomized to single-agent treatment actually received both drugs in sequence, as patients were routinely crossed to the other arm before clinical progression was noted through either persistent disease radiographically or findings of residual disease at second-look laparotomy. Although no difference was found in median survival between any treatment approach and GOG 132, six cycles of combination chemotherapy were judged to be the preferable regimen because of decreased toxicity.

**FIGURE 36.5-7.** Disease-free (A) and overall (B) survival of patients with suboptimal stage III and IV ovarian cancer randomized to treatment with cisplatin plus cyclophosphamide (solid line) or cisplatin plus paclitaxel (dotted line). (From ref. 133, with permission.)

**TABLE 36.5-12.** Randomized Trials of Paclitaxel plus Platinum in Advanced Ovarian Cancer

The preliminary results of the European trial (ICON III) comparing carboplatin plus paclitaxel versus single-agent carboplatin or combination chemotherapy versus a PAC regimen also have been reported.<sup>136</sup> Mature survival data and subset analysis are awaited. Although the initial results did not demonstrate any significant difference in survival rate, the current recommendation that initial chemotherapy consist of paclitaxel plus a platinum compound was not altered by the results of this trial.

Although a series of prospective randomized trials and two metaanalyses demonstrated equivalent activity of carboplatin versus cisplatin, concern still remained that carboplatin was the inferior platinum compound in patients with optimal stage III disease. Consequently, three prospective randomized trials have been performed throughout the world comparing cisplatin plus paclitaxel versus carboplatin plus paclitaxel (Table 36.5-13).<sup>137,138</sup> and <sup>139</sup> Bookman et al.<sup>140</sup> initially reported that these two drugs could be combined at full therapeutic doses if carboplatin was dosed according to AUC considerations and if paclitaxel was administered at 175 mg/m<sup>2</sup> in a 3-hour infusion. The selection of a 3-hour paclitaxel infusion was based on a prior European/Canadian trial<sup>132</sup> in which patients with previously treated advanced ovarian cancer were randomized in a two-by-two bifactor design to receive paclitaxel by 24- or 3-hour infusion and one of two different doses of paclitaxel (175 mg/m<sup>2</sup> or 135 mg/m<sup>2</sup>). A 3-hour infusion at 175 mg/m<sup>2</sup> was the preferred paclitaxel dose schedule for patients with ovarian cancer because of decreased neutropenia and a trend toward increased efficacy at the higher dose. The GOG pilot study demonstrated the safety and efficacy of paclitaxel (175 mg/m<sup>2</sup>) in a 3-hour infusion together with carboplatin (dosed to an AUC of 7.5).<sup>140</sup> The overall response rate to this combination was 75%, with 67% of 24 patients with measurable disease achieving a clinical complete remission. The median dose of carboplatin was 470 mg/m<sup>2</sup> when using the Calvert formula to select an AUC of 7.5 (Fig. 36.5-8). This dose of carboplatin, even when combined with paclitaxel at 175 mg/m<sup>2</sup>, was higher than that usually used in combinations when the drug is empirically dosed based on body surface area (300 to 350 mg/m<sup>2</sup>).

**FIGURE 36.5-8.** Comparison of carboplatin dosage by area under the curve (AUC) and body surface in ovarian cancer patients receiving combination chemotherapy with paclitaxel and carboplatin. Most patients received an AUC of 7.5, which corresponds to a mean dose (based on body surface area) of 471 mg/m<sup>2</sup>. (From ref. 140, with permission.)

**TABLE 36.5-13.** Randomized Trials of Carboplatin plus Paclitaxel versus Cisplatin plus Paclitaxel

All three randomized trials comparing cisplatin plus paclitaxel versus carboplatin with paclitaxel have been presented in preliminary form and all have come to the same conclusion. GOG 151<sup>137</sup> was the largest of these trials and was different from the European studies in that only patients with optimal stage III disease were eligible. More than 800 patients were randomized to cisplatin (75 mg/m<sup>2</sup>) plus paclitaxel (135 mg/m<sup>2</sup> at 24-hour infusion) versus carboplatin (AUC = 7.5) plus paclitaxel (175 mg/m<sup>2</sup> in a 3-hour infusion). Patients were well balanced for prognostic factors. No difference was found in median times to progression between these two regimens, and the hazard ratio was 0.90 (95% CI, 0.76 to 1.11), which essentially excludes the possibility that carboplatin plus paclitaxel is inferior to cisplatin plus paclitaxel. In addition, increased metabolic and gastrointestinal toxicity was associated with the cisplatin regimen. Survival comparisons between the two treatment arms await further penetration of the data. The Arbeitsgemeinschaft Gynaekologische Onkologie trial<sup>138</sup> incorporated the quality-of-life instrument in its comparison of cisplatin plus paclitaxel versus carboplatin plus paclitaxel and demonstrated the superiority of the carboplatin combination. Based on these clinical trials, carboplatin plus paclitaxel is now generally accepted to be the preferred platinum regimen for treatment of patients with advanced ovarian cancer.

Numerous issues still remain regarding the optimal use of paclitaxel with carboplatin in patients with ovarian cancer. The importance of dose and schedule of paclitaxel has not been established. Phase II trials of high-dose paclitaxel (250 mg/m<sup>2</sup>) had reported a response rate of 48%,<sup>141</sup> which was higher than other phase II trials using lower doses. The GOG has completed a randomized trial of two different doses of paclitaxel. This trial showed that high-dose paclitaxel (250 mg/m<sup>2</sup>) had only a modest effect in patients with recurrent ovarian cancer.<sup>142</sup> The overall response rate was 36% versus 27.5% for a 175 mg/m<sup>2</sup> dose. Survival was similar—12.5 months versus 11.9 months. However, even with granulocyte colony-stimulating factor (G-CSF) support, substantially greater toxicity was seen with the higher dose schedule. Additional studies are currently in progress in Europe in previously untreated patients with advanced ovarian cancer who are randomized to receive two different doses of paclitaxel, with all patients receiving the same carboplatin dose. No survival data are yet available from these trials. The optimal number of cycles of paclitaxel plus carboplatin to be used as initial therapy for patients also remains to be determined. No evidence suggests that increasing the number of cycles of cisplatin plus cyclophosphamide improves outcome. Prospective randomized trials are, however, in progress in which patients who achieve a clinical complete remission with paclitaxel plus carboplatin are randomized to maintenance paclitaxel therapy for 3 to 12 months. Until the completion of these trials, standard chemotherapy for patients with advanced ovarian cancer consists of six cycles of paclitaxel (175 mg/m<sup>2</sup> in a 3-hour infusion) plus carboplatin dosed to an AUC of 5.0

to 7.5.

### **Management after Induction Chemotherapy**

The majority of previously untreated patients achieve a clinical complete remission after induction chemotherapy. Clinical complete remission is defined as no evidence of disease on physical examination or by radiographic studies, together with a normal CA-125. However, between 50% and 75% of advanced-disease patients ultimately relapse from a clinical remission. Even patients who are surgically confirmed to be in a complete remission (negative second look) still remain at high risk with a relapse rate of 30% to 50% after platinum-based chemotherapy.

**SECOND-LOOK SURGERY.** Second-look surgery is a carefully planned systematic surgical approach to evaluating patients who have completed a program of chemotherapy and who, by clinical examination and by diagnostic imaging studies, are free of evidence of persistent cancer. The purpose of the second-look operation is to completely explore the abdominal cavity, sample any abnormalities found, and biopsy peritoneal surfaces where microscopic ovarian cancer is likely to be found. If disease is present, additional therapy should be routinely recommended.

Second-look operations were originally introduced by Wangenstein et al.<sup>143</sup> for evaluating patients with colon cancer. It was then applied in a series of studies to ovarian cancer management. The surgery is performed through a vertical incision that allows access to the peritoneal cavity from the pelvis to the diaphragm. On entering the abdominal cavity, washings of the paracolic and pelvic spaces are performed. Adhesions are lysed and sent for histologic assessment. Sampling then begins in the pelvis with removal of large strips of peritoneum (2 cm × 3 cm) from the pelvic side walls in the areas of the round ligaments and the infundibulopelvic ligaments, from the bladder flap peritoneum, and from the cul-de-sac peritoneum. Epiploic appendices of the sigmoid colon are removed. The retroperitoneal spaces are examined, and any residual lymph node or fatty tissues surrounding the external iliac artery, vein, or hypogastric artery are removed.

Remnants of omentum are then removed, as are large strips (3 cm × 5 cm) of peritoneum in the right and left pericolic spaces. The diaphragm is carefully inspected; any abnormalities are removed. If no abnormalities are present, a strip of peritoneum overlying the inferior surface of the diaphragm also is removed. The bowel is carefully inspected. Any nodules on the bowel surfaces are removed. Any mesenteric implants are removed. The retroperitoneal space is then explored by mobilizing the bowel. The paraaortic and vena cava areas are explored, and nodularities and fat pads are removed. The anterior abdominal wall peritoneum is also sampled. At the completion of the procedure, somewhere between 20 and 40 biopsies of peritoneum and fat pads, including the retroperitoneal lymph node-bearing areas, should have been obtained. The thoroughness of the second-look operation is determined less by the number of samples obtained and more by the size of the sheets of peritoneum that are stripped off. The larger the volume of tissue available for the pathologist to inspect, the greater the chances are that occult disease will be identified.

The most important factors determining whether a second-look operation is negative are cancer stage at the initial operation and the volume of residual disease at that operation.<sup>144,145</sup> Patients with stage I disease have a very high incidence of negative second-look operations, whereas those with advanced disease have a significantly lower incidence of negative second-look surgeries. Patients with no residual disease after primary cytoreductive surgery have a 77% incidence of negative second-look operations. Those with less than 2 cm of residual disease have an approximately 45% incidence of negative second-look surgeries, and those with disease greater than 2 cm have no more than a 25% incidence.<sup>145</sup> The timing of second-look surgery has changed over the years. With the introduction of cisplatin and doxorubicin chemotherapy in the 1970s, prolonged chemotherapy was no longer indicated. As noted, randomized clinical trials did not demonstrate any improvement after six cycles of platinum-based treatment. Second-look operations only are routinely recommended for women participating in clinical trials.

Second-look operations are not without complications. A report by Rubin and Lewis<sup>145</sup> analyzing 682 second-look surgeries suggested that the overall rate of morbidity was approximately 19%. A typical problem associated with this operation is infections in the surgical incision, the urinary tract, and the lungs. Some reports also have indicated the presence of bleeding and the need for blood transfusions. Experience at the Yale–New Haven Medical Center would suggest that incidence of recurrent ovarian cancer after a negative second-look operation was in the 15% to 20% range; however, others have reported recurrence rates as high as 50% within 1 year.

The greatest value of second-look surgery is assessing patients on clinical protocols in which an answer to a question regarding therapeutic efficacy is being asked or for patients who are willing to go on to second-line therapy in a research format when the status of their cancer is important to answer clinical research questions.

Advances in laparoscopic surgery have led to recommendations for laparoscopy as an alternative to laparotomy.<sup>27,146</sup> Laparoscopic surgery can be useful if the patient is found to have disseminated miliary-type cancer and can avoid a laparotomy. However, if the patient has focal disease, it may be missed at second-look laparoscopy because of technical reasons, or it may not be resectable through a laparoscope and a second-look laparotomy must be performed. Gynecologic oncologists skilled with advanced laparoscopic techniques are now providing data suggesting that, in their hands, laparoscopic second-look operations are comparable to laparotomies.

Patients at highest risk for recurrent disease after achieving a complete remission are those who had large-volume disease before initiation of chemotherapy and those with more poorly differentiated tumors.<sup>147</sup> The overall survival rate for patients with recurrent ovarian cancer is poor, and it depends on a multiplicity of factors, the most important being the length of the initial disease-free interval. However, the vast majority of patients with recurrent ovarian cancer ultimately succumb to their disease. Consequently, numerous clinical strategies are being studied in an effort to prevent or delay recurrences in patients who achieve a clinical complete remission.

**RADIOTHERAPY AFTER OR COMBINED WITH CHEMOTHERAPY.** Numerous small phase I and II studies have used whole abdominal irradiation as salvage treatment for patients with minimal residual disease after chemotherapy. Some authors have reported 3-year progression-free survival rates as high as 25% to 35% and occasional 10- to 15-year disease-free survivors among patients treated with abdominal irradiation after an incomplete response to chemotherapy.<sup>148,149,150 and 151</sup> However, others have reported high complication rates and have been discouraged by the short duration of most remissions, particularly for patients with high-grade disease or macroscopic residual tumor.<sup>152,153</sup> Reported 5-year survival rates for patients treated with abdominal irradiation after a negative second-look laparotomy have been approximately 60% to 70%, but are not clearly different from reported survival rates with platinum-based chemotherapy alone.

Two randomized trials have compared whole abdominal irradiation with additional consolidative chemotherapy for patients with minimal disease after surgical cytoreduction and platinum-containing chemotherapy. Bruzzone and associates<sup>154</sup> randomized patients who had minimal or no residual disease after chemotherapy [doxorubicin, cyclophosphamide (Cytoxan), and cisplatin or carboplatin] to receive whole abdominal irradiation or three more cycles of chemotherapy. The study was closed after accruing only 41 patients because disease progression had been observed in 55% of patients treated with radiation versus 29% of those treated with additional chemotherapy ( $P = .08$ ). The authors recommended treatment with chemotherapy, but the small number of patients and short median follow-up weaken the conclusions of their study. In a second study by Lambert and coworkers,<sup>155</sup> 254 patients with stage IIB to IV disease received five monthly courses of carboplatin and second-look laparotomy. The 117 patients who had residual disease of 2 cm or less after secondary cytoreduction were then randomized to receive either five additional courses of carboplatin or whole abdominal irradiation (24 Gy in 5 weeks). The authors reported no statistical difference in survival or disease-free survival rates between the two treatment arms.

Although a small proportion of patients treated with whole abdominal irradiation for microscopic residual disease after chemotherapy enjoy long disease-free intervals, the control rates appear to be much poorer than those reported for patients treated with initial radiation for a similar volume of residual disease. A number of factors may contribute to these disappointing results. Patients who have not responded completely to chemotherapy may have disease that is inherently more aggressive than that of patients chosen for primary treatment with whole abdominal irradiation. Radiotherapy is often compromised because of poor hematologic tolerance after aggressive chemotherapy, which further decreases the probability of the tumor being sterilized. It also has been suggested that cytoreductive treatments (surgery, irradiation, or chemotherapy) may stimulate the proliferation of clonogenic tumor cells. Consequently, to overcome rapid repopulation, higher doses of radiation may be required to sterilize tumor cells that remain after a course of chemotherapy.

Hoskins and colleagues<sup>156</sup> have reported encouraging results for a regimen that integrated whole abdominal irradiation in the initial treatment of patients with minimal residual disease after cytoreduction. In their study, radiation was given after the first three of six cycles of cisplatin and cyclophosphamide. Comparison with the results of similar patients treated during a later time with six cycles of chemotherapy alone favored the alternating regimen, particularly for patients with stage I disease ( $P = .04$ ).

Clinical trials of other modalities focused on preventing or delaying recurrence after initial chemotherapy are in progress: consolidation with high-dose chemotherapy,

whole abdominal irradiation, intraperitoneal  $^{32}\text{P}$ , intraperitoneal chemotherapy with cisplatin, intraperitoneal immunotherapy, and additional cycles of systemic chemotherapy and hormonal therapy with agents such as tamoxifen. Randomized trials addressing these modalities have been limited by slow accrual, and currently there is no evidence that consolidation treatment is able to improve survival after six cycles of initial treatment with paclitaxel plus a platinum compound.

## TREATMENT OF RECURRENT OVARIAN CANCER

The selection of treatment modalities and drug regimens for patients with recurrent ovarian cancer is based on the initial chemotherapy regimen used and on the nature of the initial response to treatment. Patients with recurrent ovarian cancer can be broadly divided into two subsets with a markedly different prognosis. Patients whose disease recurs with a disease-free interval of less than 6 months have a worse prognosis that approaches that of patients who progress while receiving their initial chemotherapeutic regimen. In contrast, patients who have a disease-free interval of more than 6 months or 1 year have a markedly improved prognosis, primarily because of the increased efficacy of salvage chemotherapy. In patients with a long disease-free interval, secondary cytoreductive surgery can be considered in select subsets of patients.

### Secondary Cytoreductive Surgery

Primary cytoreductive surgery has well-documented benefits in the management of women with advanced ovarian cancer. The possibility that secondary cytoreductive surgery (i.e., surgery performed to remove known persistent or recurrent disease after initiating chemotherapy) may be beneficial to patients has been suggested by numerous authors.<sup>144</sup> Berek et al.<sup>157</sup> reported that secondary cytoreductive surgery could be performed on 12 of 32 patients (38%), and their tumors were reduced to less than 1.5 cm of residual disease. The median survival for that group was 20 months, compared with 5 months for the 20 patients whose disease could not be optimally cytoreduced. The patients most likely to undergo optimal cytoreductive surgery were those who previously had optimal primary cytoreduction, less than 1000 mL of ascites, and a tumor size of less than 5 cm at the second operation. The interval from the primary to secondary surgery should be longer than 12 months. Factors that did not have an impact on secondary cytoreductive surgery included patient age, tumor grade, type of chemotherapy, and the presence or absence of bowel obstruction. Subsequently, Segna et al.<sup>158</sup> reported their experience with secondary cytoreductive surgery. They too were able to show that if optimal secondary cytoreductive surgery could be performed, patients lived longer before succumbing to ovarian cancer. Factors that influenced successful efforts in cytoreductive surgery were a time interval of more than 1 year between the original operation and the secondary cytoreductive surgery and having optimal cytoreductive surgery performed at the initial operation. It is the current recommendation at the Yale–New Haven Medical Center that women who would be suitable for secondary cytoreductive surgery at the time of recurrence are those who have had more than a 1-year time interval between the initial operation and the diagnosis of recurrence. These women preferably had optimal cytoreductive surgery performed at the initial operation. However, if a review of the operative report suggests that an aggressive attempt at optimal cytoreductive surgery was not performed, this would make them suitable for secondary cytoreductive surgery.

Neijt et al.<sup>159</sup> compared the survival of women who underwent optimal cytoreductive surgery with the survival of women who were unsuccessfully optimally cytoreduced but in whom, generally after three cycles of cisplatin-based chemotherapy, a secondary cytoreductive surgery was attempted. Those patients who underwent optimal secondary cytoreductive surgery had a statistically improved survival rate compared with those who were unable to undergo optimal secondary cytoreductive surgery. However, those patients who were optimally secondarily cytoreduced did not have a survival rate comparable to those patients who had optimal cytoreduction performed at the initial operation ( Fig. 36.5-9).

**FIGURE 36.5-9.** Survival after cytoreductive surgery leading to tumor residuals of 1 cm or smaller at the staging laparotomy (staging) or during chemotherapy (intervention cytoreductive surgery). (From ref. 159, with permission.)

van der Burg et al.<sup>160</sup> reported on the European Organization for Research and Treatment of Cancers (EORTC) experience with debulking surgery after induction chemotherapy for advanced ovarian cancer. Three hundred nineteen of 425 patients with advanced epithelial ovarian cancer who had more than 1 cm in diameter of residual tumor after primary surgery received three cycles of cyclophosphamide and cisplatin and were randomized to undergo secondary cytoreductive surgery or no surgery. Both groups received additional chemotherapy. The progression-free and overall survival rates were both significantly longer in the group that underwent surgery ( $P = .01$ ) ( Fig. 36.5-10). The difference in survival was 6 months. At 2 years after initial diagnosis, 56% of the group that underwent surgery were alive, as opposed to 46% of the group that did not. In an update, the 5-year survival rate was 23% for the surgery group and 12% for the nonsurgery group.<sup>161</sup> A multivariate analysis determined that debulking surgery was an independent prognostic factor ( $P = .012$ ) for survival. After adjusting for all other prognostic factors, the risk of dying was reduced by 33% (95% CI, 10% to 50%;  $P = .008$ ). This study statistically confirmed improved survival with optimal secondary cytoreductive surgery. However, secondary cytoreductive surgery does not make up for inadequate cytoreductive surgery performed at the initial operation.

**FIGURE 36.5-10.** Survival of patients with advanced epithelial ovarian cancer who did not have debulking surgery and patients who had such surgery, according to whether the lesions were less than 1 cm in diameter before cytoreduction, less than 1 cm after cytoreduction (optimal), or more than 1 cm after cytoreduction (suboptimal). (From ref. 160, with permission.)

Palliative surgery may be necessary in women with advanced ovarian cancer. This surgery may involve a colostomy for relief of a large bowel obstruction, lyses of adhesions, and surgical management of small bowel obstruction. Small bowel obstruction is a common complication as ovarian cancer advances and becomes refractory to chemotherapy. In considering surgery to relieve small bowel obstruction, the time from the original diagnosis and treatment of the ovarian cancer to the time of the obstruction is important, as is the adequacy of the initial cytoreductive surgery. Women who present with small bowel obstruction during the initial course of chemotherapy and who have not undergone optimal cytoreductive surgery generally have biologically aggressive tumors for which the role for surgery of the small bowel is minimal. A palliative gastrostomy tube may be most appropriate in this situation. In turn, women who have had prolonged periods during which they were free of disease, usually lasting more than 1 year from the original diagnosis, do benefit from small bowel surgery to relieve obstruction. However, a pseudo-small bowel obstruction pattern can be seen in women with advanced ovarian cancer with intraabdominal carcinomatosis, which occurs when ovarian cancer cells infiltrate the

myenteric plexus of the small bowel. Surgery generally plays no role in management of these patients. Medical treatment with metoclopramide, which stimulates motility of the upper gastrointestinal tract without stimulating gastric, biliary, or pancreatic secretions, may at times be helpful. Large bowel obstruction, particularly sigmoid colon obstruction, is relieved by performing colostomies and can allow the patient to have significant prolongation of life and improved quality of life if the disease is confined to the pelvis.

### **Chemotherapy for Recurrent Disease**

Patients with ovarian cancer who had a response to chemotherapy and then relapsed after a disease-free interval of more than 6 months are considered drug sensitive. These patients are routinely retreated with single-agent carboplatin or paclitaxel. The likelihood of achieving a secondary response to either of these agents is based on the length of the disease-free interval.<sup>162</sup> Single-agent carboplatin has a more favorable toxicity profile than cisplatin and remains the preferable platinum compound for treatment of recurrent disease. Some studies have suggested that the weekly administration of paclitaxel may be superior to the use of the traditional 3-week schedule in patients with recurrent ovarian cancer,<sup>163</sup> although prospective randomized trials comparing these two different schedules are currently in progress. In addition to the "platinum-free" interval, the probability of response to second-line chemotherapy is related to additional clinical factors. Eisenhauer et al.<sup>164</sup> identified three factors in a multivariate analysis of 704 patients who received prior treatment with platinum-based chemotherapy as independent predictors of response: serous histology, number of disease sites, and tumor size.<sup>164</sup> Time from last treatment, when evaluated as a continuous variable, was not found to be an independent prognostic factor and was highly correlated with tumor size.

Retreatment with combination chemotherapy also has been used in patients with recurrent ovarian cancer. Rose et al.<sup>165</sup> reported that second-line therapy with paclitaxel plus carboplatin produced a 70% clinical complete remission rate, with an additional 20% of patients achieving a partial response in patients who had previously demonstrated sensitivity to this combination when used as initial treatment. The majority of patients developed recurrence with a median interval of 9 months. Although the response rate with combination chemotherapy appears to be higher than reported for single agents, this study does not establish a clinical necessity for using combination chemotherapy in drug-sensitive ovarian cancer patients at the time of recurrence. It is possible that the same long-term survival rates could have been achieved by use of these drugs in sequence. For most patients, the appropriate choice of second-line treatment consists of single-agent chemotherapy with combinations reserved primarily for patients who have a prolonged disease-free interval.

For patients who did not respond to platinum- or paclitaxel-based retreatment or who developed resistance to these drugs when used as second-line agents, numerous other agents have been shown to have activity. However, response rates are significantly lower in patients who have platinum- or paclitaxel-resistant ovarian cancer, and these patients should be encouraged to enter experimental clinical trials. Drugs that have been shown to be active in patients with platinum- and paclitaxel-resistant ovarian cancer include topotecan,<sup>166,167</sup> oral etoposide,<sup>168</sup> gemcitabine,<sup>169</sup> liposomal doxorubicin,<sup>170</sup> and vinorelbine.<sup>171</sup>

Topotecan, a second-generation semisynthetic camptothecin analogue, has been extensively evaluated in patients with recurrent ovarian cancer. In a phase III randomized comparison with paclitaxel, similar response rates were reported in patients who had received initial therapy with an alkylating agent and platinum.<sup>172</sup> Bookman et al.<sup>167</sup> reported on 139 patients with recurrent ovarian cancer in whom 81% had resistant disease. The overall response rate was 13.7%, with a 12.4% response rate in platinum-resistant patients. Median survival was 47 weeks. Grade 4 neutropenia was the primary toxicity that occurred in 82% of the patients.

The GOG performed a phase II trial of oral etoposide in both platinum-sensitive and platinum-resistant patients.<sup>168</sup> Among 41 platinum-resistant patients, a 27% response rate, including a 7% clinical response rate, was noted. Median survival time in the platinum-resistant patients was 10.8 months. Grade 3 or 4 hematologic toxicity was common. Gemcitabine, a novel pyrimidine analogue with activity against other solid tumors, including lung cancer and pancreatic cancer, was shown in phase II studies also to have significant activity in patients resistant to platinum or to the combination of platinum and paclitaxel.<sup>169</sup> Similarly, with liposomal doxorubicin, a response rate of 26% was observed in platinum-resistant patients with a median progression-free survival rate of 5.7 months. Grade 3 and 4 nonhematologic skin and mucosal toxicities were common.

In addition to these newer drugs, older agents, such as hexamethylmelamine and ifosfamide, also have activity in platinum-resistant patients, although it appears that in patients with resistance to both platinum and paclitaxel, the response rates are low (approximately 10%).

Hormonal therapy has long been used in the treatment of patients with refractory ovarian cancer.<sup>173,174</sup> The overall response rate of progestational agents and antiestrogens has been approximately 10% to 15%. A large GOG study, however, reported an 18% response rate for tamoxifen administered at a dose of 20 mg orally twice per day, including a 10% clinical complete remission rate.<sup>173</sup> The majority of patients achieving a response in this study had elevated levels of estrogen receptor. Hormonal therapy continues to be a viable therapeutic option for patients who cannot tolerate or who have been unsuccessful with numerous cytotoxic regimens. Tamoxifen also has been recommended as the initial salvage therapy for patients who have a rising CA-125 level as the only manifestation of their disease.<sup>174,175</sup> Although a rising CA-125 level in a patient in a clinical complete remission is highly predictive of a symptomatic recurrence (median time to physical or radiographic evidence of recurrent disease is 4 to 6 months), there is no evidence that immediate treatment with salvage chemotherapy is more effective than reserving such treatment for when other manifestations of recurrent disease appear. A trial is ongoing in the United Kingdom in which patients with elevated markers are randomized to immediate systemic therapy or to treatment at the time of symptomatic progression.

### **Palliative Radiotherapy**

Radiation therapy can play an important role in palliation of patients with incurable ovarian cancer. Symptoms from a growing pelvic mass frequently dominate the final months of life for patients with terminal ovarian cancer, causing pain, bleeding, and rectal narrowing. Palliative pelvic radiotherapy can provide rapid relief and, in some cases, may prevent or delay the need for diverting colostomy.

Palliative treatment courses are designed to be convenient and to achieve rapid symptom relief. At the M. D. Anderson Cancer Center, palliation of pelvic disease has been achieved using two single-fraction treatments of 10 Gy each to the true pelvis delivered 1 month apart.<sup>176</sup> Treatment is delivered using 18 to 25 MeV photons. In a report of 42 patients who had advanced ovarian cancer and were treated with this approach, Adelson and coworkers<sup>176</sup> reported that tumors in 19% of patients partially or completely responded to irradiation after one fraction and 75% responded after two fractions. Toxicity was minimal if treatment was limited to two fractions (20 Gy). However, they reported major hemorrhagic complications in four of eight patients who survived more than 6 months after three fractions. Spanos and colleagues<sup>177</sup> reported a high rate of gastrointestinal complications (49% at 1 year) in patients who were treated with three fractions of 10 Gy each and misonidazole for a variety of advanced pelvic malignancies.

The Radiation Therapy Oncology Group investigated the efficacy of a multiple daily fraction split-course regimen (14.8 Gy delivered at 3.7 Gy per fraction in 2 days) in patients with advanced pelvic malignancies.<sup>178</sup> Treatment was repeated every 2 to 4 weeks for a total dose of up to 44.4 Gy. A complete or partial tumor response was reported in 34% of patients (42% of those completing three courses), and toxic effects were acceptable. The interval between fractions had no significant influence on the response rate.

Other authors have reported relief of pelvic pain, bleeding, large bowel obstruction, pulmonary compromise, bone pain, and other symptoms of metastatic disease with radiotherapy using a variety of fractionation schemes.<sup>179</sup> Patients with isolated cerebral metastases should be treated with combined surgical resection, postoperative whole brain irradiation, and chemotherapy, if possible.<sup>180</sup> With this treatment, some patients survive for more than 3 years. Survival after treatment with radiation alone is usually less than 6 months.

### **Intraperitoneal Chemotherapy**

Clinical trials evaluating direct intraperitoneal installation of antineoplastic agents were based on the biology of ovarian cancer and on pharmacologic modeling studies.<sup>181</sup> Physiologic and anatomic characteristics of the peritoneal cavity and the chemical properties of antineoplastic drugs suggested that the intraperitoneal administration of anticancer agents in a large volume would lead to a pharmacologic advantage compared with intravenous therapy. A series of phase I studies demonstrated that large-volume intermittent dialysis was feasible via a semipermanent Tenckhoff catheter (Table 36.5-14). These studies demonstrated that, despite a significant number (20% to 30%) of instances in which uniform distribution of drugs containing dialysate could not be achieved because of adhesions, overall intraperitoneal therapy was technically feasible and associated with a marked pharmacologic advantage defined as the ratio of antineoplastic agent in the dialysate compared with blood levels. The development of implantable peritoneal access devices (Port-A-Cath) facilitated patient acceptance and decreased the complication rate. Most recently, paclitaxel has been evaluated via the intraperitoneal route.<sup>181</sup> Intraperitoneal administration led to a marked pharmacologic advantage, and 61% of

patients who had microscopic disease before intraperitoneal paclitaxel achieved a response to therapy.

Agent	Peak Peritoneal Cavity to Plasma Concentration Ratio
Doxorubicin	474
Mitomycin	620
Cisplatin	20
Carboplatin	18
Minomycin	71
5-Fluorouracil	298
Methotrexate	92
Paclitaxel	1000

(From ref. 181, with permission.)

**TABLE 36.5-14.** Pharmacokinetic Advantage Associated with Intraperitoneal Administration of Selected Cytotoxic Agents

Phase II trials demonstrated that cisplatin had the highest activity when administered via the intraperitoneal route to patients with recurrent ovarian cancer. Intraperitoneal chemotherapy had no advantage in patients with bulky disease. However, in patients with small-volume residual ovarian cancer, responses were observed (40%) in those patients who had prior response to intravenous cisplatin.<sup>182</sup> Because this is the same group of patients who also had the greatest benefit from retreatment with systemic cisplatin,<sup>183</sup> the possibility remained that the primary benefit of intraperitoneal therapy in these trials was due to systemic absorption and delivery to the tumor via the microcirculation.

More recently, intraperitoneal chemotherapy has been compared with intravenous therapy in randomized trials. A large prospective randomized study of intraperitoneal cisplatin (100 mg/m<sup>2</sup>) combined with intravenous cyclophosphamide (600 mg/m<sup>2</sup>) compared with intravenous cisplatin (100 mg/m<sup>2</sup>) and intravenous cyclophosphamide in patients with optimal advanced ovarian cancer was initiated in the late 1980s<sup>184</sup> (Table 36.5-15). Patients eligible for this intergroup study all had residual tumor masses of less than 2 cm at the completion of cytoreductive surgery. The intraperitoneal arm was considered to be superior based on pathologically confirmed complete remission (40% vs. 31%, *P* = .10) and patient survival (median survival, 49 months vs. 41 months) and a decrease in the death-hazard ratio to 0.76 for the patients treated with intraperitoneal therapy. In addition, clinical hearing loss and neutropenia were more frequent and more severe in patients receiving intravenous cisplatin. During the long duration of this study, standard intravenous chemotherapy for ovarian cancer has changed from cisplatin plus cyclophosphamide to carboplatin plus paclitaxel. Consequently, it remains to be determined whether intraperitoneal cisplatin produces a similar advantage when combined with intravenous paclitaxel. A prospective randomized trial comparing intravenous cisplatin and paclitaxel to an experimental arm consisting of two cycles of carboplatin dosed to an AUC of 9 followed by six cycles of intraperitoneal cisplatin and intravenous paclitaxel has been completed.<sup>185</sup> Recurrence-free survival was increased in the experimental arm by 5.1 months, although there is no statistically significant difference in overall survival. The experimental arm had significantly increased toxicity. Based on these results and the activity of intraperitoneal paclitaxel, the GOG is conducting another randomized trial in which patients with optimal stage III disease are comparing standard intravenous paclitaxel plus cisplatin to an experimental regimen of intravenous paclitaxel on day 1, intraperitoneal cisplatin on day 2, and intraperitoneal paclitaxel on day 8.

	Intraperitoneal Cisplatin (100 mg/m <sup>2</sup> ) plus Cyclophosphamide (600 mg/m <sup>2</sup> )	Intravenous Cisplatin (100 mg/m <sup>2</sup> ) plus Cyclophosphamide (600 mg/m <sup>2</sup> )
Stage III with less than 2 cm residual disease	53 patients	51 patients
Response rate (complete remission)	42/54 (77%)	32/54 (59%)
Median survival	49 mo	41 mo
Improvement versus intravenous drug combination	31	—
Toxicity	—	Hearing loss, neutropenia

(From ref. 184, with permission.)

**TABLE 36.5-15.** Intraperitoneal Cisplatin in Previously Untreated Ovarian Cancer

A separate phase III trial of intraperitoneal chemotherapy is in progress in Europe. Patients with a surgically confirmed complete remission to standard induction chemotherapy are randomized to receive six cycles of intraperitoneal cisplatin as a consolidation regimen compared with observation. No results are available from this trial.

## EXPERIMENTAL THERAPY

### High-Dose Chemotherapy with Hematologic Support

Standard-dose chemotherapy produces response rates in more than 70% of patients with advanced ovarian cancer. However, most patients develop disease recurrence, at which point salvage therapy has limited curative potential. Because of the high response rate to standard-dose chemotherapy and because of retrospective studies identifying a relationship between dose intensity and response, numerous clinical studies have evaluated high-dose chemotherapy with hematologic support. However, no established role has yet been determined for high-dose chemotherapy with hematologic support in the routine treatment of patients with advanced ovarian cancer.

The initial trials used autologous bone marrow rescue in heavily treated patients who were treated with single agents followed by transplantation. Subsequently, combinations of high-dose alkylating agents and platinum compounds were evaluated. Shpall et al.<sup>186</sup> summarized the results of phase I and phase II trials in ovarian cancer patients. The overall response rate is approximately 70% to 80%; however, the median duration of response is less than 10 months.

More recently, Stiff et al.<sup>187</sup> reported on the results with high-dose chemotherapy with hematologic support in 100 patients with recurrent or persistent ovarian cancer. They performed a univariate and multivariate analysis to identify factors associated with prolonged survival after high-dose chemotherapy. Cisplatin sensitivity and bulk of disease were identified as the best predictors for progression-free survival. Median progression-free and overall survival rates for 20 patients with platinum-sensitive disease with less than 1 cm of volume were 19 and 30 months, respectively. In the absence of a prospective randomized trial, there is no evidence that this approach produces superior results in patients with platinum-sensitive small-volume disease compared with what could be achieved with traditional second-line chemotherapy.

In this and other studies, it is apparent that the most favorable group of patients in whom additional trials with high-dose chemotherapy are indicated consists of patients who have both chemotherapy-sensitive tumors as well as a low tumor burden. Preclinical and clinical studies also suggest that multiple applications of high-dose chemotherapy may be superior to single courses. The combination of peripheral stem cell transfusions with hematopoietic growth factors has permitted the evaluation of multiple courses of high-dose therapy in patients with ovarian cancer. Investigators at the Memorial Sloan-Kettering Cancer Center<sup>188</sup> performed phase I and II studies of dose escalation of paclitaxel with high-dose cyclophosphamide and peripheral blood stem cell transfusions in chemotherapy-naïve patients with advanced ovarian cancer. Induction therapy consisted of two cycles of cyclophosphamide (3 g/m<sup>2</sup>) plus escalating doses of paclitaxel (from 150 to 350 mg/m<sup>2</sup>) followed by G-CSF and leukopheresis to harvest peripheral stem cells. Patients then received four courses of rapidly cycled carboplatin and cyclophosphamide (1500 mg/m<sup>2</sup> per course) with hematopoietic rescue. Multiple cycles of high-dose chemotherapy could be safely administered with hematopoietic support. The overall

response rate was 100%, with 34% of the patients achieving a surgically confirmed complete response. A similar trial was reported by Schilder et al.<sup>189</sup> in previously untreated patients using a regimen that included high-dose carboplatin, paclitaxel, and topotecan. In high-risk patients with bulky disease, a 67% clinical complete response rate was reported.

Based on these results, the GOG is conducting a pilot study of multiple cycles of high-dose chemotherapy followed by peripheral stem cell transfusion in patients with small-volume disease. If it can be demonstrated that such an approach is feasible in a multicenter study, then a larger prospective randomized comparison against standard doses of chemotherapy in previously untreated patients will be performed. In addition, clinical trials are planned in evaluating the role of multiple cycles of high-dose chemotherapy as a consolidation treatment in patients who achieve an initial response to induction chemotherapy. There is no evidence from clinical trials that high-dose chemotherapy has significant curative potential in patients who have either bulky residual disease or drug-resistant tumors. At present, high-dose chemotherapy with hematologic support should be considered an experimental procedure, and patients should be entered on clinical trials evaluating safety and efficacy.

### **New Drug Combinations**

The standard chemotherapy for ovarian cancer now consists of paclitaxel plus a platinum compound. Although the majority of patients achieve a response to therapy, time to progression is 22 months for patients with optimal stage III disease and 18 months for patients with suboptimal stage III and stage IV disease. As noted earlier in the section [Chemotherapy for Recurrent Disease](#), a series of new agents have been shown to have activity in ovarian cancer, including topotecan, gemcitabine, oral etoposide, and encapsulated doxorubicin. New combinations based on the activity of paclitaxel and platinum are currently being evaluated.

Hansen et al.<sup>190</sup> reported on a phase II trial of gemcitabine in combination with paclitaxel and carboplatin. This combination resulted in a response rate of 100%, with the majority of patients having suboptimal disease. Herben et al.<sup>191</sup> reported that the three-drug combination of paclitaxel, cisplatin, and topotecan also produced a high response rate (60% clinical complete response and 27% partial response) in previously untreated patients, but was associated with significant neutropenia that required large dose reductions in all three agents and G-CSF support. With the large number of active compounds available for recurrent disease, numerous new potential combinations and sequences are under consideration. Currently, preclinical models have not been shown to be predictive in identifying the clinical activity of new combinations. Empirical phase I and phase II trials are in progress and will be followed by prospective randomized comparisons of three-drug combinations and sequential therapy to determine if there is any clinical benefit in the combination of paclitaxel and carboplatin compared with standard treatment.

### **Reversal of Drug Resistance**

The molecular mechanisms associated with drug resistance, the primary factor that limits the curative potential of any salvage therapy in patients with ovarian cancer, are being extensively studied. Resistance to alkylating agents and platinum compounds has been shown to be multifactorial, and specific biochemical resistance pathways include (1) decreases in drug accumulation; (2) increased inactivation in the cytosol via detoxification enzymes, such as glutathione S-transferase, or by direct binding to nonprotein thiols such as glutathione; and (3) increased activity of DNA repair enzymes that remove lethal DNA adducts. For the taxanes, at least two mechanisms of acquired resistance have been identified in cells made resistant by prolonged exposure *in vitro*. In paclitaxel-resistant cells, increased expression of the membrane P glycoprotein efflux pump is seen, which leads to partial cross-resistance to bulky natural products, including vinca alkaloids and anthracyclines. In addition, paclitaxel-resistant cells have structure alterations in a and b tubulin protein subunits, which form an integral part of microtubules.

The inhibitor of g-glutamylcysteine synthetase, buthionine sulfoximine, has entered phase II trials based on a phase I trial that demonstrated the agent could be safely administered while producing an 80% reduction in growth-stimulating hormone levels in circulating lymphocytes in the majority of drug-resistant patients.<sup>192</sup> Furthermore, growth-stimulating hormone depletion in tumor cells was also documented in this study. In the phase II trial, drug-resistant patients are receiving the combination of buthionine sulfoximine plus melphalan.

Additional clinical trials aimed at reversing drug resistance to platinum compounds are focused on DNA repair pathways. In platinum-resistant tumors, increased expression of nucleotide excision repair enzymes has been demonstrated, in particular XPA and ERCC1.<sup>193</sup> Previous studies had demonstrated that platinum sensitivity could be restored by inhibition of DNA polymerase  $\alpha$  with aphidicolin.<sup>194</sup> Clinical evaluation of aphidicolin has been limited by drug availability. Current clinical trials are using inhibitors of ribonucleotide reductase (e.g., gemcitabine and hydroxyurea) in combination with cisplatin.

Combinations of cyclosporin and cisplatin have also been studied in platinum-resistant patients.<sup>195</sup> Cyclosporin and nonnephrotoxic and nonimmunosuppressive analogues, such as PSC 833, have the potential to reverse platinum resistance by down-regulation of oncogenes involved in signal transduction, which are elevated in platinum-resistant tumors.<sup>193</sup> These drugs are also potent inhibitors of the multidrug resistance (MDR)-1 efflux pump, although this pathway is not involved in platinum resistance. A GOG trial<sup>195</sup> reported a 25% response rate in platinum-resistant patients treated with cyclosporin and cisplatin. Larger trials with the less toxic PSC 833 are in progress.

Platinum resistance also has been linked to increased expression of c-erbB-2. Antibodies to c-erbB-2 in combination with cisplatin have shown synergistic cell kill *in vitro*.<sup>196</sup> Clinical evaluation of such a combination is in progress.

Numerous clinical trials have explored the potential to reverse the multidrug resistance phenotype in ovarian cancer. Three distinct patterns of this phenotype have been identified: (1) the classic MDR-1 (P glycoprotein) mechanism associated with natural products, such as the vinca alkaloids and doxorubicin; (2) altered topoisomerase (atypical MDR) phenotype, primarily associated with drugs involving inhibition of topoisomerase II, such as etoposide; and (3) multidrug resistance-associated protein (MRP). The clinical importance of each of these mechanisms of drug resistance in ovarian cancer has not been established. Tumors from doxorubicin-treated patients (approximately 30% to 50%) have higher levels of immunostaining of P glycoprotein than do tumors from untreated patients (approximately 10% to 15%), suggesting that MDR expression is at least associated with resistance to natural products.<sup>197</sup> However, because doxorubicin has not been routinely used as part of induction regimens, clinical trials of MDR inhibition in ovarian cancer have had decreased interest. The identification of the prominent role of paclitaxel in ovarian cancer has led to new interest in modulation of natural product resistance. It is clear, however, that paclitaxel resistance is multifactorial and includes alteration in molecular species and levels of tubulin, which may be more important than MDR.

Clinical studies have identified the association of MRP expression and drug resistance.<sup>198</sup> The frequency of MRP expression in ovarian cancer remains to be determined. One study suggests that an associated drug-resistant protein (Lrp) may have prognostic significance in ovarian cancer.<sup>199</sup>

### **Immunotherapy and Gene Therapy in Ovarian Cancer**

Genetic alterations in oncogene and suppressor gene function and the immunobiology of ovarian cancer are reviewed elsewhere in this text. Abnormalities in suppressor gene function, particularly TP53, are common in ovarian cancer. Cisplatin sensitivity is associated with TP53 function, with loss of function usually resulting in resistance.<sup>193</sup> Loss of TP53 function may inhibit the drug-induced pathways of apoptosis. In experimental models of gene therapy, sensitivity to cisplatin can be restored in resistant cell lines by reintroduction of p53 into tumor cells.<sup>200</sup>

An additional potential gene therapy in ovarian cancer relates to molecular chemotherapy in which a gene product can selectively sensitize tumor cells to an agent not ordinarily toxic. Adenoviral-mediated delivery of herpes simplex virus thymidine kinase has been shown to selectively sensitize human ovarian cancer cells to ganciclovir, and clinical evaluation is planned for this combination.

The immunotherapy of ovarian cancer has evolved from the administration of nonspecific immunostimulants, such as *Corynebacterium parvum* to more specific therapies targeting antigens and surface receptors present on tumor cells. Interleukin-2 (IL-2) has been studied extensively in ovarian cancer patients, either as a single agent administered intraperitoneally or as part of adoptive immunotherapy together with lymphokine activated killer cells. In initial studies with IL-2 and lymphokine activated killer cells, peritoneal toxicity was unacceptable.<sup>201</sup> Subsequent trials with lower doses of IL-2 produced acceptable toxicity, and the preliminary report described apparent durable responses in selected patients with recurrent ovarian cancer treated with intraperitoneal IL-2.<sup>202</sup>

Antibody conjugates (either with antineoplastic drug, biologic toxin, or radioisotopes) also have been evaluated in early trials in ovarian cancer patients. On the basis of prolonged survival observed in a pilot study in patients with small-volume residual disease treated with iodine 131-labeled monoclonal antibody directed against an ovarian cancer phosphatase,<sup>203</sup> a larger confirmatory trial of this conjugate is planned in Europe.

## BORDERLINE TUMORS

Epithelial tumors of low malignant potential (borderline malignant potential tumors), are unusual in that they have the capacity to metastasize yet the required treatment seems to be limited to surgery for the overwhelming majority of patients. The different pathologic and biologic natures of these tumors were not recognized by FIGO until 1971 and the World Health Organization in 1973.<sup>204</sup> Borderline malignant potential tumors are distinguished from benign mucinous and serous tumors by the presence of epithelial budding, multilayering of the epithelium, increased mitotic activity, and nuclear atypia. However, they are also associated with absence of stromal invasion. These tumors can be quite large in size, with the serous tumors having mean diameters varying between 7 and 12 cm and bilaterality ranging from 33% to 75%.<sup>205</sup> Mucinous tumors of borderline malignant potential tend to be larger, with a mean diameter of 17 to 20 cm, and can be associated with pseudomyxoma peritonei. One must always be certain to rule out the possibility of a synchronous appendiceal primary tumor when dealing with the latter entity.

Borderline malignant potential tumors represent approximately 4% to 14% of all ovarian malignancies. The mean age of women developing tumors of low malignant potential is 40 years, approximately 20 years earlier than the mean age for women with epithelial cancers of the ovary. Ovarian tumors of low malignant potential have been associated with infertility and ovulation induction.<sup>206</sup>

Ovarian tumors of low malignant potential are staged in the same manner as epithelial cancers (see [Table 36.5-1](#)). However, their survival rate, stage for stage, is far superior. Kurman and Trimble<sup>207</sup> reported that the survival for 538 women with tumors of low malignant potential who had stage I disease was 99% with a mean follow-up of 7 years. The survival for 415 women with stage II and III disease was 92% with a mean follow-up of 7 years. The causes of death in this review were radiation-associated complications in three patients, chemotherapy-associated complications in nine, and bowel obstruction in eight. Eight women died from invasive carcinoma, and 18 died of disease without any additional information. Noteworthy was the fact that more patients died of treatment-related complications than died of bowel obstruction from progressive disease.

Management of patients with low malignant potential tumors of the ovary is similar to that of the surgical management of invasive cancer. However, preservation of fertility should be routinely performed in young women. Tazelaar et al.<sup>208</sup> found no evidence of microscopic disease in grossly normal ovaries that were bivalved in 61 patients with stage I low malignant potential tumors of the ovary. Women with advanced disease or who have completed childbearing should undergo total abdominal hysterectomy and bilateral salpingo-oophorectomy with complete cancer staging. If intraabdominal disease is present, aggressive cytoreductive surgery should be performed.

The evidence is scant to suggest that treatment beyond that of the initial surgery has any beneficial role. This is true for stage II and III disease as well as for stage I disease. Appropriate adjuvant therapy has yet to be identified in the management of women with tumors of low malignant potential. Trope et al.<sup>209</sup> studied adjuvant therapy in 253 women with stage I and II ovarian tumors of low malignant potential in four randomized trials at the Norwegian Radium Hospital between 1970 and 1984. Adjuvant treatment consisted of (1) external radiation and intraperitoneal radioactive gold, or external radiation alone; (2) intraperitoneal radioactive gold or phosphorus followed by no further treatment or thiotepa; (3) thiotepa versus no further treatment; and (4) cisplatin versus intraperitoneal phosphorus. No differences in the two arms in any of the four randomized studies could be identified. It was recommended that adjuvant radiation and chemotherapy were not indicated in patients with stage I or II ovarian tumors of low malignant potential. A series of 94 patients reported by Chambers et al.<sup>210</sup> from Yale–New Haven Medical Center did not reveal any significant impact on adjuvant therapy for women with ovarian tumors of low malignant potential. Barnhill et al.<sup>211</sup> reported on 146 women with stage I serous tumors of low malignant potential. No adjuvant therapy was offered, and with a median follow-up of 42.4 months (range 1.6 to 108.0), no patient has developed a recurrence.

Attempts to identify women who might be at increased risk for recurrence based on flow cytometry studies have not demonstrated consistent results.<sup>212,213</sup> Evidence has yet to be presented confirming that routinely treating patients whose tumors are aneuploid provides survival benefit. Surgery should be the main treatment approach for this disease. Chemotherapy should be reserved for progressive disease that does not respond to surgical management.

## SEX CORD–STROMAL TUMORS

Ovarian sex cord–stromal tumors represent approximately 5% of all ovarian cancers. In general, they tend to present with stage I disease and frequently are associated with hormonal effects, such as precocious puberty, amenorrhea, postmenopausal bleeding, or virilizing symptoms. Granulosa cell tumors are the most common of the sex cord–stromal tumors and may be associated with endometrial hyperplasia and endometrial carcinoma. One cannot always tell the steroid production of the malignancies based on histologic appearance. For example, granulosa cell tumors have been reported to be associated with virilization. Sertoli-Leydig cell tumors have been associated with endometrial cancer.<sup>214</sup> Pascale et al.<sup>215</sup> have demonstrated that, in virilized women, the findings of increased serum testosterone with normal gonadotropin levels and gonadotropin-releasing hormone agonist suppression of gonadotropins leading to normalization of testosterone levels suggest that various ovarian androgen-secreting tumors are not autonomous but apparently depend on gonadotropin stimulation.

Willemsen et al.<sup>216</sup> reported on 12 patients who developed granulosa cell tumors. All patients in the series underwent ovarian hyperstimulation for the treatment of infertility. All patients received clomiphene citrate and gonadotropins or both. Willemsen et al.<sup>216</sup> postulated that granulosa cell tumors may already be present in the ovaries and are simply waiting for a hormone trigger or that the increased follicle-stimulating hormone concentrations used in ovulation induction are oncogenic to granulosa cells.<sup>216</sup> However, it is also possible that the discovery of granulosa cells during ovarian stimulation is coincidental.

Surgical staging of sex cord–stromal tumors is the same as that for epithelial ovarian cancers (see [Table 36.5-1](#)). Surgical management of sex cord–stromal tumors is based on the stage of the tumor as well as the age of the patient. In general, premenarchal women or patients presenting in the reproductive years tend to have stage I disease in most series. A unilateral salpingo-oophorectomy is all that is routinely necessary for the management of this disease. The role for adjuvant therapy in younger women has not been demonstrated. However, in women who have completed childbearing, surgery should be more aggressive, including a bilateral salpingo-oophorectomy and total abdominal hysterectomy along with standard surgical staging. Women older than age 40 at diagnosis are more likely to experience a recurrence of granulosa cell tumors, and it is for that reason that adjuvant therapy is recommended by some<sup>214</sup> in the older age population, although definitive evidence for its efficacy in preventing or delaying recurrences is lacking.

Patients with advanced-stage disease (i.e., stage II to IV) may benefit from additional therapy. Cisplatin-based combination chemotherapy has been the most frequently used treatment. However, few series have been reported, and they involve small numbers of women with granulosa cell tumors. Colombo et al.<sup>217</sup> demonstrated that primary treatment of six women with advanced granulosa cell tumor was effective using cisplatin, vinblastine, and bleomycin (the PVB regimen). However, their experience with the PVB regimen in five patients with recurrent disease was complicated by significant toxicity, leading to two deaths.<sup>217</sup> Pectasides et al.<sup>218</sup> reported on ten patients with advanced or recurrent granulosa cell tumor treated with cisplatin, Adriamycin, and cyclophosphamide (CAP). Five complete and one partial response was obtained. One of the pathologically complete respondents, however, relapsed 48 months after the onset of chemotherapy. Homesley et al.<sup>219</sup> reported a collaborative group experience using bleomycin, etoposide, and cisplatin combination chemotherapy in the treatment of women with sex cord–stromal tumors. Forty-eight of the 57 tumors were granulosa cell tumors. For the series as a whole, 35 patients (61.4%) receiving this combination chemotherapy regimen had complete responses. Eighteen of the 35 underwent second-look surgery. Fourteen of the 18 patients had pathologically negative second-look results, four patients had a partial response, 14 patients had stable disease, and two patients had progression of disease among the 55 patients evaluable for response. Sixteen patients received the chemotherapy after primary surgery, nine of whom had received the chemotherapy because of positive peritoneal cytology and seven for the treatment of gross residual disease. Eleven of 16 primary treatment patients (68.8%) are free of progressive disease, whereas 21 of 41 (51.2%) were free of disease when they were treated only after recurrent disease was noted.

The overall survival in two large series of granulosa cell tumors was 85% and 90%, with one series reporting 100% survival for stage I disease and the other reporting 94% survival for stage I disease at 5 years.

The current recommendations at Yale–New Haven Medical Center for women with early-stage granulosa cell tumors are surgery only for those younger than 40 and surgery followed by etoposide and carboplatin chemotherapy for women older than 40 who have stage I disease. For women older than 40 or for any woman with advanced-stage or recurrent disease, we recommend doxorubicin, cisplatin, and etoposide. Serum inhibin levels may be useful in monitoring for relapse.<sup>220</sup> However, there is at least anecdotal experience that it may be elevated for unexplained reasons. Another tumor marker, Müllerian inhibiting substance (MIS), is usually undetectable in females before puberty.<sup>221</sup> Gustafson et al.<sup>221</sup> reported that elevated MIS levels dramatically declined in two girls with granulosa cell tumors after surgery. MIS may be an effective marker for granulosa cell tumors and Sertoli-Leydig cell tumors. Lane et al.<sup>222</sup> have demonstrated preoperative elevations of MIS in six of eight subjects (75%) with juvenile granulosa cell tumors and seven of nine (78%) with adult granulosa cell tumors. None of 21 women with normal or

nondetectable MIS levels developed recurrent granulosa cell tumors, but incompletely resected or recurrent disease was associated with elevated MIS levels in 6 of 15 patients.

Roush et al.<sup>223</sup> performed flow cytometric DNA ploidy and S-phase fraction analysis on 18 women with granulosa cell tumors of the ovary. Eleven of the tumors were diploid and 7 were aneuploid. Only one of ten (10%) with euploid tumors died of disease, whereas four out of five (80%) with aneuploid tumors died of the disease. This observation did not reach statistical correlation. Perhaps in the future flow cytometric studies may be useful in identifying which group of patients might benefit from adjuvant therapy as opposed to observation.

Sertoli-Leydig cell tumors occur much less often than granulosa cell tumors yet are the second most common sex cord–stromal tumor. Their management is the same as that of granulosa cell tumors in terms of staging, surgical management, and adjuvant chemotherapy. Rare forms of sex cord–stromal tumors include sex cord tumors with annular tubules associated with the Peutz-Jeghers syndrome that are usually confined to the ovaries and can be treated with surgery alone. Thecomas rarely are malignant. Malignant thecomas would be treated in the same manner as granulosa cell tumors.

Recurrent sex cord–stromal tumors are treated with surgical resection followed by adjuvant therapy. If the recurrence is isolated and could be encompassed in a radiation field, older literature suggests that radiation therapy may be of value if the malignancy is a granulosa cell tumor. The natural history of granulosa cell tumors is to be slow growing. Although late recurrences occur, it is difficult to know for certain whether it is the resection of the recurrent cancer or resection followed by the radiation therapy that has had an impact on prolonging patient survival. Patients with extensive recurrences should be treated with cisplatin-based combination chemotherapy.

## EXTRAOVARIAN PERITONEAL CARCINOMA

The diagnosis and management of women who present with intraperitoneal carcinomatosis can represent a diagnostic and therapeutic problem. In some patients, the primary site is unknown, and peritoneal carcinomatosis can present as part of the syndrome of adenocarcinomas of unknown primary site. Adenocarcinomas of unknown primary site who present with peritoneal carcinomatosis can respond to chemotherapy with platinum-based regimens. In a series of 18 women treated with a platinum-based regimen, median survival was 23 months, and five patients had complete remissions and long-term survival.<sup>224</sup> The histologic classification and nomenclature of peritoneal carcinomatosis has been unclear and has included terms such as *mesothelioma*, *peritoneal papillary serous carcinoma*, *extraovarian serous carcinoma*, and *paraovarian cystadenocarcinoma*. Although embryologically the germinal epithelium of the ovary and the mesothelium of the peritoneal cavity are derived from the same celomic epithelium, a subset of peritoneal tumors can be morphologically identified that have a more favorable clinical behavior in response to therapy compared with peritoneal mesotheliomas.<sup>225</sup> It has been proposed that the former disease process be termed *peritoneal adenocarcinoma (serous) of Müllerian type*.<sup>225</sup> The serous type of peritoneal carcinomatosis is the most common. However, other histologic types of peritoneal carcinomatosis resulting from the common ancestry of celomic epithelium are possible, including mucinous, endometrioid, clear cell, and mixed peritoneal adenocarcinoma of Müllerian type. Using the proposed terminology, when an uncommon subtype other than serous is present, it can be encompassed in the description. Malignant mesotheliomas have a different histologic pattern and, in most cases, can be separated from the Müllerian-type peritoneal adenocarcinomas. Peritoneal mesotheliomas are more aggressive tumors, with a survival rate of usually less than 1 year. Furthermore, in women they are relatively less common than peritoneal adenocarcinomas of Müllerian type.

Most patients with extraovarian peritoneal carcinomatosis have signs and symptoms similar to those women who present with advanced-stage ovarian cancer. At surgery, these women frequently have ascites with diffuse peritoneal carcinomatosis. Attempts at cytoreductive surgery usually are made, although no evidence supports survival benefit in those women with peritoneal carcinomatosis who undergo optimum cytoreductive surgery. This may be due to the fact that although no tumor nodule larger than 1.5 cm is left behind, these women have innumerable such nodules throughout the peritoneal cavity and their actual tumor burden after cytoreductive surgery remains substantial. It appears that approximately 50% of patients with peritoneal carcinomatosis can be successfully surgically cytoreduced. Survival for patients with Müllerian peritoneal adenocarcinoma is similar to that reported for advanced ovarian cancer. In a large study from the University of California, Los Angeles, the median survival of patients who received chemotherapy after primary cytoreductive surgery was 28.4 months.<sup>225</sup> Patients who received cisplatin-based chemotherapy had a substantially longer survival rate (57% living longer than 23 months) than patients who were not treated with cisplatin-based regimens. Based on the pattern of metastases and chemosensitivity to platinum-based chemotherapy, it seems prudent that current therapy for this group of patients should include cytoreductive surgery followed by chemotherapy with paclitaxel plus a platinum compound.

## GERM CELL TUMORS OF THE OVARY

Germ cell tumors of the ovary are much less common than epithelial ovarian neoplasms. However, because they are highly curable and because they affect primarily young women of childbearing potential, appropriate management by specialists is exceedingly important. Germ cell tumors account for 2% to 3% of all ovarian cancers in Western countries. They almost always occur in younger women, and their peak incidence is in the early 20s. An increased incidence of germ cell tumors is found in Asian and black societies, and these tumors represent as many as 15% of all ovarian cancers in these populations.

### PATHOLOGY

[Table 36.5-1](#) provides the World Health Organization classification for germ cell tumors of the ovary. Serum tumor markers for HCG and AFP are useful in the diagnosis and management of these tumors. They are often divided clinically into dysgerminoma and nondysgerminoma germ cell tumors.

### DIAGNOSIS

Abdominal pain, pelvic fullness, and urinary symptoms are common in patients with germ cell tumors of the ovary. In a minority of patients (approximately 10%), abdominal pain can be severe, usually the result of hemorrhage, rupture, or torsion of the tumor. Abdominal distention can also be a symptom and often is associated with ascites.

Patients frequently have a palpable adnexal mass that should be ultrasonographically evaluated. Surgical exploration is usually required in masses of 8 cm or larger. Serum levels of HCG and AFP are useful in the diagnosis of some germ cell tumors.

### PATTERNS OF METASTASIS

In contrast to epithelial tumors, approximately 60% to 70% of germ cell tumors are stage I at diagnosis.<sup>226</sup> Stage II and IV are relatively uncommon, and stage III accounts for approximately 25% to 30% of tumors. Primary germ cell tumors can be very large and often are greater than 20 mL in size. With the notable exception of dysgerminoma, bilateral ovarian involvement is not common. Multiple peritoneal surfaces are often involved in addition to frequent lymph node involvement. These tumors also appear to have a greater tendency for hematogenous metastases compared with epithelial tumors, and liver and lung involvement can be observed. Ascites is infrequent (approximately 20% of cases).

### SURGICAL MANAGEMENT

The importance of initial surgical approach for the treatment of germ cell tumors of the ovary cannot be overemphasized.<sup>226</sup> Most patients can have fertility preserved, and the type of operative procedure is dictated by operative findings. In most cases, the contralateral ovary and the uterus can be preserved. Even in those situations of dysgerminoma in which the incidence of bilaterality is more common, bilateral oophorectomy is not routinely necessary because postoperative chemotherapy is curative and fertility can be preserved. In cases in which the contralateral ovary is grossly abnormal, cystectomy or biopsy can be performed and bilateral salpingo-oophorectomy performed in the case of a dysgenetic gonad.

The principles with regard to surgical staging of germ cell tumors are similar to those described for epithelial tumors. After a large transverse incision, the entire peritoneal cavity should be carefully inspected. In the absence of ascites, peritoneal washings should be obtained and all fluids should be histologically examined. If disease is grossly confined to the pelvis, random biopsies should be performed analogous to surgical staging of early-stage epithelial ovarian carcinomas. Particular emphasis should be paid to paraaortic and pelvic lymph nodes because these are more commonly involved than in epithelial tumors. Although sampling of suspicious nodes is indicated for staging, no evidence suggests that lymphadenectomy is beneficial. Cytoreductive surgery is recommended as for epithelial tumors of the ovary. However, it must be emphasized that, even in the presence of widespread metastatic disease, because of the efficacy of chemotherapy, the contralateral ovary can

frequently be preserved.

There is no role for routine second-look operations in patients with a germ cell tumor who are clinically free of disease after chemotherapy. In particular, if the primary tumor was completely resected and did not contain teratoma, second-look procedures after chemotherapy are of no established benefit <sup>227</sup> (Table 36.5-16). In some patients with a teratomatous tumor, however, a second-look procedure may be beneficial. Such patients may have residual mature teratoma, particularly if the initial resection was incomplete and postchemotherapy removal of benign teratomas is beneficial. Unresected teratomas in males with testicular cancer have been known to progress and lead to significant morbidity unless completely resected. Although experience with germ cell tumors of the ovary is not as extensive, the presumption remains that teratomas can lead to life-threatening complications and should be removed after initial chemotherapy.

### MANAGEMENT OF DYSGERMINOMAS

Dysgerminomas are the most common malignant germ cell tumors of the ovary and often have been considered the female equivalent of a seminoma. In contrast to nondysgerminomatous tumors, dysgerminomas are more frequently stage I, involve both ovaries, spread to retroperitoneal lymph nodes, and are markedly sensitive to radiotherapy. Because these tumors are also exquisitely sensitive to cisplatin-based chemotherapy, the role of curative radiation therapy has decreased. Furthermore, current chemotherapy usually does not result in ovarian ablation.

The vast majority of patients with dysgerminoma are diagnosed with early-stage disease. Because preservation of fertility is an important issue for most of these women, all carefully staged patients with stage IA disease can be observed without compromising cure because only 15% to 25% of patients recur and they can be successfully salvaged. <sup>227,228</sup> Until the demonstration that metastatic dysgerminoma could be cured with cisplatin-based chemotherapy, most patients with stage I disease and all patients with higher stages were treated with radiotherapy. Virtually all early-stage patients were cured of their disease. Even in patients with stage III disease treated with radiation therapy, the 5-year survival rate was 80% to 90%, although recurrence-free survival was substantially lower.

The GOG evaluation of platinum-based chemotherapy in dysgerminomas has followed reports on the efficacy of different regimens in testicular cancer. <sup>228</sup> In the early 1980s, ovarian germ cell tumors were treated with the PVB regimen. <sup>229</sup> Subsequently, based on studies in testicular cancer that demonstrated increased efficacy and less toxicity for the bleomycin, etoposide, and cisplatin (BEP) regimen, this regimen has been used in patients with metastatic germ cell tumors, including dysgerminoma (see Table 36.5-16). With a median follow-up of more than 2 years, 17 of 18 patients with advanced-stage dysgerminoma treated with one of these platinum-based regimens are disease free. <sup>228</sup> Based on these results in advanced disease, the current approach within the GOG is to examine the role of carboplatin (400 mg/m<sup>2</sup>) and etoposide (120 mg/m<sup>2</sup> on days 1 to 3) in completely resected stage IB to III patients with dysgerminoma.

Initial Therapy	Second-Look Result		
	Negative	Mature Teratoma	Immature Teratoma
Complete resection of tumor at initial therapy	38	5	2
Incomplete resection of tumor at initial therapy			
No teratoma in primary tumor (48 patients)	45	—	—
Teratoma in primary tumor (24 patients)	4	16	4

TABLE 36.5-16. Second-Look Laparotomy in Germ Cell Tumors of the Ovary

### NONDYSGERMINOMATOUS GERM CELL TUMORS

The vast majority of nondysgerminomatous germ cell tumors of the ovary are treated with surgery followed by combination chemotherapy.

The immature teratomas are the second most common germ cell malignancy, accounting for 10% to 20% of all ovarian tumors seen in women younger than 20 years. The tumors rarely occur in postmenopausal women and most commonly occur between the ages of 10 and 20 years. These tumors contain elements resembling embryologically derived tissues and can occur in combination with other germ cell tumors (mixed germ cells). Occasionally, they are the source of excessive steroids, and patients can present with sexual pseudoprecocity. Tumor markers for AFP and HCG are negative unless a mixed germ cell tumor is present.

The most important prognostic feature, and that which is used to dictate therapy, is the grade of the lesion. In stage IA, grade 1 lesions, 5-year survival rates are greater than 90%, and no evidence suggests that chemotherapy improves outcome. However, this is the only subset of patients with immature teratomas in whom chemotherapy should not be used. Even patients with stage IA, grade 2 and 3 disease have such a high relapse rate that postoperative chemotherapy is indicated. <sup>226,227,228</sup> and <sup>229</sup>

In patients whose tumors are confined to the ovary, unilateral oophorectomy or salpingo-oophorectomy should be performed. As noted, contralateral tumor involvement is rare in germ cell tumors other than dysgerminoma. The most frequent sites of dissemination are the peritoneum and retroperitoneal lymph nodes. Widespread dissemination to lungs, liver, or brain are uncommon. Before the development of effective chemotherapy, prognosis for patients with advanced-stage germ cell tumor was poor. The same combination that was found to be curative in disseminated testicular cancer quickly replaced nonplatinum regimens such as vincristine, dactinomycin, and cyclophosphamide. The PVB regimen produced a survival rate of 71% in a heterogeneous group of germ cell patients. <sup>229</sup> The current chemotherapy regimen of choice for patients with nondysgerminomatous germ cell tumors is the BEP regimen (Table 36.5-17). In the GOG trial, 89 of 93 stage I, stage II, and stage III patients with completely resected tumor are disease free after three courses of this regimen. <sup>229</sup>

Cisplatin	20 mg/m <sup>2</sup> /d × 5 d
Etoposide (VP-16)	100 mg/m <sup>2</sup> /d × 5 d
Bleomycin	20 U/m <sup>2</sup> /wk

Cycles are administered every 21 days.

TABLE 36.5-17. Bleomycin, Etoposide, and Cisplatin Regimen in Germ Cell Tumors

Although no prospective comparison has been performed between PVB and BEP in patients with advanced-stage germ cell tumor of the ovary, the latter regimen is preferred because of the results of the randomized trial in patients with advanced testicular cancer in which the superiority of BEP was established. <sup>230</sup> In that trial, PVB produced a 70% 4-year survival rate in patients with metastatic, far-advanced testicular tumors, which was inferior to results obtained with BEP. Furthermore, the BEP regimen was less toxic than PVB because of elimination of vinblastine-related neuromuscular toxicities.

Endodermal sinus (yolk sac) tumors are derived from the primitive yolk sac and are the third most frequent germ cell tumor of the ovary. These tumors secrete AFP, which can be used as a marker for response and recurrence. Similar to other germ cell tumors, a unilateral oophorectomy can be performed because the tumors are rarely, if ever, bilateral. Most patients have early-stage disease, but all patients, regardless of stage and extent of initial surgery, are treated with platinum-based chemotherapy.<sup>231</sup> No evidence supports a correlation between extent of initial surgery and survival. Before the development of effective chemotherapy, 2-year survival was only 20%. However, with platinum-based chemotherapy, the complete response rate is approximately 60%.

Embryonal carcinoma and nongestational choriocarcinoma of the ovary are both extremely rare. Embryonal carcinomas can secrete both AFP and HCG, whereas pure choriocarcinomas secrete only HCG. Due to the rarity of these tumors, long-term results with chemotherapy have not been specifically described. However, the recommended treatment approach consists of unilateral oophorectomy or salpingo-oophorectomy followed by combination chemotherapy with the BEP regimen.<sup>231</sup> Similarly, mixed germ cell tumors of the ovary that contain two or more elements should also be treated with surgery followed by combination chemotherapy. Prognosis in mixed germ cell tumors is related to the relative amount of the most aggressive malignant component. The most frequent combination consists of elements of endodermal sinus tumor and dysgerminoma. Mixed germ cell tumors may secrete any combination of markers, depending on the histologic components of the tumor.

## FALLOPIAN TUBE CANCER

Primary malignant neoplasms of the fallopian tube are exceedingly rare, and only a few hundred new cases are diagnosed annually in the United States, making it the least common site of origin for a malignant neoplasm of the female genital tract. Most fallopian tube carcinomas present as papillary serous adenocarcinomas. Intraperitoneal dissemination of fallopian tube carcinomas is similar to that observed with epithelial ovarian cancer. However, there appears to be a higher propensity to spread outside the peritoneal cavity. Survival has been shown to be dependent on the depth of invasion of the tumor in the fallopian tube.<sup>232</sup> For intermucosal lesions, 5-year survival is 91%, compared with 53% for tumors with mucosal wall invasion, and less than 25% in those situations in which the tumor has penetrated the tubal serosa. In addition to the depth of invasion, histologic differentiation and lymphatic capillary space involvement also have been shown to be of prognostic significance.<sup>233</sup> In cases of metastatic disease, the distinction between metastatic ovarian carcinoma can be difficult. Criteria frequently used to confirm the diagnosis of a primary fallopian tube carcinoma include tumor in the fallopian tube and rising from the endosalpinx, histologic pattern reproducing the epithelium of the mucosa with a papillary pattern, evidence for transition between benign and malignant tubal epithelium in the wall, and less tumor in the ovaries than in the tubes. In difficult cases, tumors are at times referred to as *tubo-ovarian carcinoma*. A minority of fallopian tube carcinomas are bilateral at the time of diagnosis. In contrast to patients with ovarian cancer, the majority of patients with tubal carcinoma are diagnosed with disease confined to the tubes and pelvic structures.

Patients with fallopian tube carcinomas appear to have a shorter history of symptoms compared with those with epithelial ovarian carcinomas.<sup>233</sup> The most common symptom is postmenopausal vaginal bleeding. Abdominal pain and leukorrhea are also common. Tubal distention produces more intense pain than is usually reported by patients with ovarian cancer, and these symptoms may account for the fact that more patients present with earlier stage carcinoma than patients with epithelial ovarian cancer in whom the absence of specific symptoms may account for more disseminated disease.

The surgical management of patients with fallopian tube carcinoma is identical to those with epithelial ovarian cancer.<sup>233</sup> Survival is improved in that group of patients in whom cytoreductive surgery is successful. Similarly, postoperative chemotherapy for fallopian tube carcinoma is analogous to that for patients with epithelial ovarian cancer. Currently, no data have been reported on the role of paclitaxel in this tumor. However, based on similar responses to cisplatin-based chemotherapy, it appears that the combination of paclitaxel plus a platinum compound should be considered the current chemotherapy regimen of choice for fallopian tube carcinoma.

## GENETICS

### FAMILIAL DISEASE

The purpose of this chapter is to provide an introduction to the cellular, genetic, biochemical, and molecular bases of breast cancer. Although the roles of steroid hormones have occupied breast cancer researchers since the 1950s, the roles of growth factors did not begin to emerge until the 1980s. The 1980s also saw the discovery of many of the oncogenes and suppressor genes driving progression of the disease and highlighted their connections to growth factor and steroid regulatory pathways. The 1990s witnessed the discovery of genes causing the familial forms of breast cancer. The final decade of the twentieth century also ushered in major advances in our understanding of the cell cycle, DNA repair, and cell death (apoptosis) and their regulation.

Much excitement has been generated over the successes in identifying the inherited defects in somatic genes responsible for hereditary and familial breast cancers (Table 37.1-1). Although hereditary breast cancers occurring in defined syndromes are characterized by a very high penetrance of multiple types of cancer, breast cancer families may also display a lower penetrance and not be so clearly associated with elevated risk for multiple other types of cancer. The incidence of the former category is estimated at 1% of breast cancer cases, whereas the latter make up approximately 5% to 10% of cases.<sup>1</sup> Most researchers in the field of hereditary genetics of breast cancer have focused on genes that conformed to the two-hit hypothesis, which states that a point mutation might be inherited in one allele of a candidate gene at a putative susceptibility locus and that loss of heterozygosity (LOH) or another genetic alteration might occur in the other allele of that locus later in life, leading to cancer.

ESTABLISHED FAMILIAL BREAST CANCER (ALL TUMOR SUPPRESSORS)			
Gene	Chromosomal Location	Class	Disease
TP53 (p53)	17p13 (recessed, LOH)	Oncogene (antibond)	Li-Fraumeni syndrome of multiple secondary cancers
PTEN	10q25 (recessed, LOH)	Oncogene (antibond)	Cowden's syndrome of multiple secondary cancers
BRCA 1	17q21 (recessed, LOH)	Suppressor gene (antibond)	Familial female breast and ovarian cancers
BRCA 2	13q14 (recessed, LOH)	Suppressor gene (antibond)	Familial female and male breast cancers

ESTABLISHED BREAST CANCER PROGRESSION GENES			
Gene	Chromosomal Location	Class	Function
ERBB2	17q12	Oncogene (antibond)	Growth factor receptor
ERBB3	4q12	Oncogene (antibond)	Growth factor receptor
ERBB4	12q13	Oncogene (antibond)	Growth factor receptor
RET	10q11	Oncogene (antibond)	Cellular G <sub>1</sub> regulator
RET2	10q11	Oncogene (antibond)	Cellular G <sub>1</sub> regulator
RET3	10q11	Oncogene (antibond)	Cellular G <sub>1</sub> regulator
RET4	10q11	Oncogene (antibond)	Cellular G <sub>1</sub> regulator
RET5	10q11	Oncogene (antibond)	Cellular G <sub>1</sub> regulator
RET6	10q11	Oncogene (antibond)	Cellular G <sub>1</sub> regulator
RET7	10q11	Oncogene (antibond)	Cellular G <sub>1</sub> regulator
RET8	10q11	Oncogene (antibond)	Cellular G <sub>1</sub> regulator
RET9	10q11	Oncogene (antibond)	Cellular G <sub>1</sub> regulator
RET10	10q11	Oncogene (antibond)	Cellular G <sub>1</sub> regulator
RET11	10q11	Oncogene (antibond)	Cellular G <sub>1</sub> regulator

TABLE 37.1-1. Major Genetic Defects in Breast Cancer

The first triumph in the identification of genes leading to the multicancer syndromes that include breast cancer was the demonstration that the *TP53* gene (on chromosome 17p13) is responsible for the Li-Fraumeni syndrome of hereditary breast cancers, sarcomas, and other tumor types.<sup>1,2 and 3</sup> As is discussed later in the section [The Cell Cycle and Cell Death](#), mutations in this gene had been previously described in the context of progression of sporadic cancers of the breast and other organs. More recently, mutations in the *PTEN* (or *MMAC1*) gene (on chromosome 10q22-23) have been described in Cowden's syndrome of hereditary breast cancers and multicutaneous lesions.<sup>4</sup> This gene also is discussed later in the context of growth factor signal transduction, but it may not be commonly mutated in sporadic breast cancers. Other studies have implicated mutations of the *STK11/LKB1* gene (on chromosome 19) in the Peutz-Jeghers syndrome of hamartomatous polyps, breast cancers, gastrointestinal cancers, and reproductive cancers,<sup>5</sup> and the *MLH1* and *MLH2* genes in the Muir-Torre syndrome of gastrointestinal and genitourinary tumors and breast cancer.<sup>6</sup> Finally, although initially proposed to do so, mutations in the *ataxia telangiectasia* gene do not appear to contribute to the risk of developing breast cancer.<sup>7</sup>

Two important genes that confer risk for the more pervasive, familial forms breast cancer have been identified. Carriers of these mutant genes may display a wide range of levels of increased risk of cancer, and the genes are quite prevalent in certain populations. King and coworkers<sup>8</sup> first localized *BRCA-1* (for breast cancer and ovarian cancer-1) to chromosome 17q21. The gene was subsequently cloned and found to be novel, containing an amino terminal, a zinc- and DNA-binding "ring finger" motif, a carboxyl terminal BRCT (BRCA carboxy terminal) domain, and a nuclear localization sequence as recognizable motifs.<sup>9</sup> Interestingly, mutations in this gene are particularly prevalent in breast cancer of Ashkenazi Jewish women; however, some of these women belong to families nearly devoid of multiple afflicted members.<sup>1</sup> The detection of *BRCA-1* mutations in women with no familial association of the disease also has been reported in other studies comparing different carrier populations, emphasizing the variable penetrance of inherited risk conferred by this gene. Mutations in the *BRCA-1* gene have been verified in familial breast and ovarian cancer patients, but surprisingly, mutations have not been detected in sporadic breast cancers. Thus, *BRCA-1* does not appear to be a classic tumor suppressor gene of relevance to both tumor onset and progression. However, studies have observed that the *BRCA-1* protein may have an aberrant, cytoplasmic localization in breast cancer cell lines from sporadic tumors, suggesting that a nonclassic mode of functional inactivation could be at work in this tumor type.<sup>10</sup> Other studies have suggested that decreased expression of the BRCA-1 protein also occurs during the progression of sporadic breast cancers.<sup>11</sup> Consistent with these findings are observations that antisense oligonucleotides directed against the *BRCA-1* messenger RNA (mRNA) enhance the proliferation of breast tumor cells and mammary epithelial cells in culture *in vitro*. Correspondingly, other studies have demonstrated that retroviral transfer of the nonmutated *BRCA-1* gene selectively inhibits growth of breast cancer cells *in vitro* and *in vivo* in nude mice.<sup>12</sup>

A separate body of work has identified a separate locus, termed *BRCA-2* (on chromosome 13q13), which is associated with familial cancers of the female and male breast and, to a lesser extent, of the ovaries. This gene also has been cloned; it shares homology with *BRCA-1*<sup>13</sup> and its encoded protein is now thought to function biochemically in a fashion very similar to BRCA-1. However, although *BRCA-2* confers risk of female breast cancer, its effects on risk of ovarian cancer appear smaller than the risk conferred by *BRCA-1*. In addition, mutations of *BRCA-2* confer risk of male breast cancer and (to a more limited extent) several other cancers, such as prostate cancer, pancreatic cancer, non-Hodgkin's lymphoma, basal cell carcinoma, bladder carcinoma, and fallopian tube tumors. Breast cancers of *BRCA* carriers are, overall, of similar prognostic significance when matched for other characteristics to the sporadic cases of breast cancer in noncarriers, although they also

show more often a high nuclear grade and p53 mutations.<sup>1</sup>

As already noted, the structure and function of the two BRCA proteins appear to be similar. Each appears to serve as an important regulator of cell-cycle “checkpoint control” mechanisms, involving cell-cycle arrest, cell death (apoptosis), and DNA repair. BRCA-1 appears to directly interact with the p53 protein (leading to induction of a cell-cycle inhibitor, p21), the RNA polymerase holoenzyme, the transcription factor CREB, and two novel proteins termed BAP1 and BARD1. Both BRCA-1 and BRCA-2 are also found in complexes with Rad51, a protein important for the cellular response to DNA damage.<sup>1</sup> In addition, BRCA-1 is phosphorylated by the ATM (ataxia telangiectasia mutated) kinase in response to DNA damage.<sup>14</sup> Thus, the roles of both BRCA proteins are now emerging as central gatekeepers of genomic stability.<sup>1</sup> In studies of mice bearing a conditional knockout of the *BRCA-1* gene, its further functions have emerged: mammary ductal morphogenesis and checkpoint control in the G<sub>2</sub>/M phase of the cell cycle.<sup>15,16</sup> Finally, and perhaps most interesting of all, the normal BRCA-1 protein appears to function to suppress the signaling of mammary epithelial cells by the estrogen receptor.<sup>17</sup> This observation may place the BRCA proteins at center stage in control of the sex steroid–regulated pathways, long suspected to induce breast cancer.<sup>18</sup>

## CYTOGENETIC STUDIES

Breast cancers, like other forms of malignancy, are thought to progress by accumulation of a series of genetic and resulting phenotypic changes in the pathways regulating cellular proliferation, differentiation, death (apoptosis or necrosis), DNA repair, tissue compartmentalization, and responses to therapy. Although several specific genetic alterations (discussed later in [Oncogenes and Suppressor Genes of Breast Cancer Progression](#)) have been identified with high frequency and proven relevance in breast cancer, certainly many more important genetic changes remain to be fully elucidated. Using classic cytogenetic methodologies and studies of LOH, genetic regions identified as frequently rearranged, amplified, deleted, or otherwise altered have been commonly detected on chromosomes 1, 3, 6, 7, 8, 9, 11, 13, 15, 16, 17, 18, and 20. More recently, the powerful techniques of comparative genomic hybridization and chromosome painting followed by spectral karyotyping have allowed implication of additional chromosome regions, including areas of 10, 12, and 22.<sup>19,20</sup> Although they have only begun to be used in this type of study, the techniques of comparative genomic hybridization and spectral karyotyping allow rapid analysis of subtle genomic imbalances and chromosomal rearrangements. Using these techniques, the benign lesions termed *fibroadenomas* are observed to be largely devoid of genetic imbalances (although they do contain some chromosomal defects), whereas aneuploid breast tumors contain far more chromosomal aberrations than diploid breast tumors.<sup>20</sup> Considering genetic changes on a broad scale, it appears that breast cancer (in contrast to certain other common epithelial tumors, such as colon cancer) is primarily characterized by chromosomal instability, as opposed to point mutagenesis. These chromosomal changes may arise from defects in the centrosomes and in the associated spindle apparatus of mammary epithelial cells. However, the exact pathogenesis of these defects remains obscure.<sup>21,22</sup>

## ONCOGENES AND SUPPRESSOR GENES OF BREAST CANCER PROGRESSION

The most common genetic abnormalities in the progression both of sporadic and familial breast cancers (as in many other types of solid tumors) appear to be losses of heterozygosity at multiple loci (see [Table 37.1-1](#)). As noted earlier, an LOH event uncovers the functional consequences of a mutation in an allele of a tumor suppressor gene by removal of the dominant, normal allele. At the present time, in addition to the *TP53* gene and the two *BRCA* loci noted earlier, LOH on 13q, 9p, and 16q are known to involve specifically the tumor suppressor genes *RB-1* (retinoblastoma-1), *CDKN2* (encoding the p16 protein), and *CDH1* (encoding the E-cadherin protein), respectively. *RB-1* and *CDKN2* regulate the cell cycle, whereas *CDH1* primarily regulates differentiation and tissue compartmentalization. Other suspected tumor suppressor genes involved in the progression of breast cancer have been proposed to reside on 6q, 7q, 11p, 11q, 15q, 17q, 20, and 22. It is notable that two types of DNA alteration can lead to suppressor gene inactivation on one allele, before LOH of the other allele. For example, although point mutation may be more common for *TP53* and *Rb*, gene methylation may be more common for *CDKN2* and *CDH1*.<sup>23</sup> In some cases, genomic areas containing tumor suppressor genes also are susceptible to complete loss or deletion of both alleles. Certain tumor suppressor gene candidates, such as the gene encoding the p27 cell-cycle regulatory protein,<sup>24</sup> exhibit the characteristic of haploid insufficiency, whereby (in contrast to *TP53*, *BRCA-1*, *BRCA-2*, *PTEN*, *CDKN2*, and *CDH1*) a single normal copy of the gene is not fully suppressive of cancer. For this type of suppressor gene, mutation deletion and LOH are not common.<sup>24</sup>

The second most common type of cytogenetic alteration in breast cancer appears to be gene amplification. The initial step in gene amplification is thought to be the formation of extrachromosomal, self-replicating units termed *double-minute chromosomes*. These genetic elements then later become permanently incorporated into chromosomal regions and are termed *homogeneous-staining regions*. An amplified genetic unit (amplicon) is initially much larger than the actual size of the principal gene of biologic importance to tumorigenesis. Thus, silent or irrelevant genes may be detected coamplified with one or more expressed genes on an amplicon. The principal, best-established amplified and functional genes for tumorigenesis (also called *dominant oncogenes*) detected to date in breast cancer are the growth factor receptor *c-ERBB<sub>2</sub>*, the nuclear transcription factor *c-MYC*, and the cell-cycle kinase regulator *CCND1*. A significant amount of work remains to be done to identify other potentially important oncogenes in breast cancer. For example, DNA gains are common on 6q, 8p, 8q, 11q, 12q, 13q, and 20q. In each of these cases, however, the specific genes involved in driving the chromosome amplification process are still under active investigation.<sup>25,26</sup>

## STEROID AND GROWTH FACTOR PATHWAYS OF CELLULAR REGULATION

### STEROID RECEPTORS

The estrogen and progesterone receptors are dimeric, gene-regulatory proteins. Estrogen and progesterone are well-established endocrine steroid regulators that modulate multiple aspects of mammary gland pathology. These two hormones work together to direct mammary epithelial growth, differentiation, and survival.<sup>18,26,27</sup> Although both steroids are commonly thought to be of primary importance for tumors arising in the reproductively competent years between puberty and menopause, local aromatization of adrenal androgens provides additional estrogens in the postmenopausal years. Both estrogen and progesterone act through their nuclear receptors (ER and PR, respectively) to modulate transcription of target genes.<sup>28</sup> Genes encoding the receptors for each class of steroids are members of a single large superfamily of transcription-modulating factors. ERs may exist in either homodimeric or heterodimeric species, composed of a and b receptors. In contrast, the PR is always a heterodimeric protein. Research on each system has defined additional, alternately spliced and mutated receptor forms. The biologic roles of these additional variant receptor subunits is under current investigation. Each steroid receptor dimer is also associated with other proteins, including heat-shock proteins, to allow ligand-binding association with its cognate, palindromic DNA elements. Other studies also have defined coactivational and corepressive proteins (CBP/p300, SRC-1, TIF2, AIB-1, N-CoR, SMRT, NSD1), which also interact with steroid receptors and function to modulate histone acetylation and deacetylation, a critical process thought to allow full access of the DNA to steroid receptors. DNA interaction of steroid receptors occurs through zinc finger structures of the receptors and promotes formation of a stable initiation complex to facilitate the transcription of responsive genes. Of considerable interest is the observation that the cell-cycle regulator cyclin D1 (product of the *CCND1* gene) also interacts with the ER to promote its transcriptional activity.<sup>26,27</sup> Superimposed on this complexity, each receptor is able to adopt multiple conformations, depending on the characteristics of interaction of the steroid (or nonsteroid ligand) with the receptor binding pocket. For example, the estrogen receptor can adopt at least three distinct conformations, depending on the antiestrogen bound.<sup>28</sup> Other studies suggest that the signal transduction pathways induced by growth factors and hormones may directly or indirectly regulate steroid receptor function. For example, cyclic adenosine monophosphate (cAMP), epidermal growth factor (EGF), heregulin (an EGF family member), and insulin-like growth factor (IGF)-1 appear to be able to modulate the activity of the estrogen receptor through phosphorylation; receptor phosphorylation modulates as well the steroid specificity of receptors for transactivation of steroid responsive genes.<sup>26,29,30</sup> The steroids are also well known for their ability to modulate directly the expression of cell-cycle regulatory genes known as *nuclear protooncogenes*, such as *c-MYC*, and the EGF receptor (EGFR)/HER-2 growth factor–receptor pathways.<sup>31,32</sup> The nuclear protooncoproteins and other cell-cycle regulatory proteins, such as cyclin D1, represent points of regulatory convergence of both steroid and growth factor pathways in cells. These findings describe a complex role for growth factors in the expression of progressively more malignant phenotypes and in escape from normal hormonal control.

Because the growth of breast cancer is often regulated by the female sex steroids, determinations of the cellular concentrations of ER and PR in the tumor are currently used to predict which patients have a good prognosis and which may also benefit from antihormonal therapy. Although these assays were originally designed as radioligand techniques, they are more commonly performed today using radioimmunoassay and immunohistochemical technologies. Although extremely useful, it has been repeatedly noted that these assays do not provide perfect prognostic tools for the disease. Although more than 60% of human breast cancers are ER-positive, no more than two-thirds of these ER-positive tumors respond to endocrine therapy.<sup>26,33,34,35</sup> and <sup>36</sup> In addition, 5% to 10% of the patients designated as ER-negative appear initially to respond to endocrine therapy.<sup>26,37</sup> To improve the value of determinations of the ER for tumor prognosis, the presence of the estrogen-regulated PR protein is now routinely performed. In many breast tumor cell lines and in normal ER-containing tissues, such as the endometrium and brain, PR expression also has been shown to be positively regulated by estrogen.<sup>26,38</sup> It is still not known whether ER regulates PR in normal human mammary epitheliums in precisely the same subpopulation of ductal and lobular luminal cells, although this supposition is considered to be likely. It is of interest that the ER and PR appear to be strongly up-regulated in ductal carcinoma *in situ* and in hormone-dependent breast cancer, relative to normal mammary epithelium. Whereas the ER- and PR-positive epithelial cell populations are distinct from the majority of proliferative cells in the normal gland, in cancer these cells grow rapidly. It is of interest that in

histologically normal breast tissue adjacent to cancer, the epithelium also displays an aberrant, proliferative response to estrogen.<sup>39,40</sup> As already noted, other studies have made a connection between the ER and the tumor suppressor BRCA-1; expression of the normal form of BRCA-1 suppresses the transactivational activity of the ER.<sup>17</sup>

It is not clear what relationship exists between ER-positive and ER-negative forms of the disease. Several ER-negative breast cancer cell lines do not transcribe the ER mRNA because of an extensive methylation of the 5' promoter of the gene.<sup>41</sup> Treatment of ER-negative breast cancer cells *in vitro* with azacytidine, an inhibitor of gene methylation, resulted in expression of a functional ER.<sup>42</sup> However, the generality of this mechanism to clinical breast cancer is not yet certain. Central questions in breast cancer research focus on mechanisms of desensitization of the disease to antihormonal therapy and design of strategies to maintain antihormonal responses in patients. Studies have suggested that tamoxifen resistance of breast cancer may be associated with cellular hypersensitization to the weakly estrogenic effects of the drug, perhaps due to expression of receptor-associated regulatory proteins, receptor mutation, or selection for variant receptor isoforms.<sup>26,43,44</sup> and <sup>45</sup> Several variant receptor isoforms are under investigation with respect to the latter possibility. An exon 5–deleted ER variant lacks the hormone binding domain, displaying constitutively active, hormone-independent, transactivational characteristics. This receptor isoform is elevated in tamoxifen-relapsing breast cancer. Expression of an exon 4–deleted ER variant correlates with low histologic grade and high PR. Expression of other deletions in exons 2 and 4 or 3 to 7 are associated with high grade and high ER content.<sup>26</sup>

Although measurement of PR improves the predictability of hormone dependency of a tumor, this relationship remains imperfect. Retrospective clinical studies have demonstrated that, among ER-positive tumors, only 70% of those that are also PR-positive, and 25% to 30% of PR-negative tumors, respond to hormone therapy. The reasons for these discrepancies are unclear but may include laboratory error, differential metabolism of tamoxifen, the ability of a mutated ER or PR to regulate gene expression in the absence of ligand, the ability of defective or phosphorylated ER or PR to bind ligand but not regulate gene expression, or the ability of either defective or phosphorylated receptors to induce constitutive synthesis of otherwise regulated proteins.<sup>26</sup> Clearly, a challenge for the future is the development of routine, potentially more informative assays of ER and PR functionally. Another major hope is that study of other genetic changes in breast cancer, including those in growth factors, their receptors, and their signaling, will also improve our ability to predict functionality of the steroid receptor pathways relative to therapeutic outcomes.

The ER cannot be clearly classified either as an oncoprotein or tumor suppressor protein. Although it is thought to mediate the onset and progression of the disease, unexpected results were obtained when the ER was expressed endogenously in ER-positive breast cancer lines and compared to its heterotypic expression in formerly ER-negative lines. In striking contrast to its normal function in ER-positive cell lines, ER expressed in ER-negative cell lines functions to suppress cell growth, in spite of its normal action to regulate expression of certain hormonally responsive genes.<sup>46,47</sup> Thus, the multiple differences between ER-positive and ER-negative breast cancer appear to include incompatible growth regulatory mechanisms. We also do not understand the molecular basis for a lack of expression of PR in certain ER-positive breast cancers. A cell hybridization study with an antiestrogen resistant, ER-positive, but PR-negative subclone of MCF-7 has shown that loss of PR expression is a recessive phenotype in this system.<sup>48</sup> Finally, it should be noted that pathways of estrogen metabolism may be modulated in the pathophysiology of the disease. For example, the enzyme aromatase, which is responsible for conversion of adrenal androgens to estrogen in the postmenopausal breast and in other tissues, has been suggested as a potential, oncoprotein-like molecule in breast cancer.<sup>49</sup>

Increased expression and altered isozyme patterns of the family of cellular enzymes termed *protein kinase C* (PKC) also have been implicated during malignant progression of breast cancer.<sup>50</sup> This enzyme family can act to down-modulate ER mRNA, to activate ER function, to independently induce some estrogen-responsive genes with *AP-1* sites in their promoters, and to allow expression of more invasive cellular characteristics.<sup>51</sup> The PKC family contains at least nine cytoplasmic-nuclear enzymes, each of which possesses serine-threonine specificity for phosphate in addition to other cellular proteins<sup>52</sup>; different isoforms serve different cellular functions. The activity of PKC is known to be regulated by hormones and growth factors during normal lactational differentiation and to contribute to the regulation of casein expression.<sup>52</sup> PKC activity has been suggested to be elevated in ER-negative and drug-resistant breast cancer relative to ER-positive breast cancer. Treatment of ER-positive breast cancer with an activator of PKC, such as the phorbol ester 12-O-tetradecanoyl phorbol-13-acetate, leads to rapid down-regulation of ER, destabilization of its mRNA, and phosphorylation of the ER protein, coincident with modulation of its function.<sup>53,54,55</sup> and <sup>56</sup> Phosphorylation of ER and PR (induced by estrogen itself) by growth factor pathways (such as IGF-1), heregulin, cAMP, dopamine agonists, and other hormones may also constitutively activate the steroid receptors.<sup>57,58,59</sup> and <sup>60</sup> Other current studies have suggested that receptors for other steroids (potential cancer prevention agents, retinoids, vitamin D) may modulate ER/PR function by modulating their chromatin interactions.<sup>61,62</sup>

## GROWTH FACTOR PATHWAYS IN THE NORMAL AND MALIGNANT GLAND

The natural secretory products of the mammary epithelial cell, colostrum and milk, are abundant sources of growth factors.<sup>63</sup> Growth factors in the normal gland probably serve multiple purposes in the development of the newborn, in mammary growth, and in mammary carcinogenesis. A large body of literature has shown that estrogen, antiestrogens, progestins, and anti-progestins strongly regulate certain growth factors and receptors of the EGF and transforming growth factor- $\beta$  (TGF- $\beta$ ) families, as well as growth factors, receptors, and secreted binding proteins of the IGF family (Table 37.1-2).<sup>64,65</sup> EGF, apparently the most abundant milk-derived growth factor, is an important regulator both of the proliferation and the differentiation of the mouse mammary gland *in vivo* and of mouse mammary explants *in vitro*.<sup>66,67</sup> It also has been observed that circulating mouse salivary gland–derived EGF may potentiate spontaneous mammary tumor formation in the mouse model and promote the growth of the tumors once they are formed.<sup>66,68</sup> EGF, or other members of this growth factor family, are also required supplements for the clonal anchorage-dependent growth, *in vitro*, of normal human mammary epithelial cells.<sup>69</sup> In contrast, human breast cancer cells in culture are largely independent of this exogenous requirement. However, most breast cancer cell lines retain EGFRs and appear to be stimulated in their growth by their own autocrine or paracrine production of this family of factors.<sup>33,65</sup>

<b>EGF FAMILY</b>
Growth factors: EGF, TGF- $\alpha$ , amphiregulin
Receptors: EGFR, c-erbB <sub>2</sub>
<b>IGF FAMILY</b>
Growth factors: IGF-2
Receptors: IGF-1R, IGF-2R, insulin receptor
Binding proteins: BP-2, BP-3, BP-4, BP-5
<b>TGF-<math>\beta</math> FAMILY</b>
Growth factors: TGF- $\beta_1$ , TGF- $\beta_2$ , TGF- $\beta_3$
<b>PDGF FAMILY</b>
Growth factors: PDGF-1, PDGF-2
BP, binding protein; EGF(R), epidermal growth factor (receptor); IGF, insulin-like growth factor; PDGF, platelet-derived growth factor; TGF, transforming growth factor.

TABLE 37.1-2. Sex Hormone Regulation of Growth Factor Systems in Breast Cancer

Direct modulation of signal transduction pathways of EGF and its family members, as well as their indirect regulation by other unrelated growth factors are proving to be critical during mammary development. The EGF family consists of, at present, four receptors and more than six growth factors in mammals, and an additional half-dozen growth factors encoded only by certain mammalian viruses. TGF- $\alpha$  and amphiregulin, close structural and functional homologs of EGF, can produce qualitatively the same proliferative effects as EGF in mouse mammary explants and in cultured human and mouse mammary epithelial cell lines.<sup>65,67</sup> Each of these factors is also produced in proliferative, early ductal development; amphiregulin is also produced in the lobuloalveolar development of pregnancy.<sup>70</sup> However, the detailed localization patterns and functions of each family member differ.<sup>71,72</sup> For example, an immunohistochemical study in the mouse gland has revealed that expression of TGF- $\alpha$  is highest in the basal epithelial, proliferative end-bud cap cells, whereas expression of EGF is in scattered ductal luminal secretory cells.<sup>73</sup> Hepatocyte growth factor, a non-EGF family factor, also appears to be involved in ductal morphogenesis.<sup>74</sup> The EGF-related neuregulin subfamily of isoforms (including heregulin) is expressed primarily in the mammary stroma and appears to modulate the lobuloalveolar development of pregnancy.<sup>75</sup> TGF- $\alpha$ , a heparin-binding family member termed *amphiregulin*, and their common receptor, the EGFR, are all detected *in vitro* in proliferating human mammary epithelial cells in culture. TGF- $\alpha$  mRNA levels are relatively low in explanted, primary cultures of resting epithelial organoids<sup>76,77</sup>; the entire system appears tightly coupled to proliferation in the normal gland. TGF- $\alpha$  and amphiregulin are known to act as autocrine autostimulatory growth factors in normal and immortalized human mammary epithelial cells in mass culture; an anti-EGFR antibody or heparin, respectively, reversibly inhibited proliferation.<sup>77,78</sup> and <sup>79</sup> Although the majority of work on the biology

of the EGF family has focused on regulation of proliferation, it is now clear that many other aspects of mammary biology may be under its control, such as cell differentiation and survival. The complex heterodimerization pattern of the EGFR family may play a role in governing the multiple responses of this system. <sup>80,81</sup>

Since the early work of DeLarco, Todaro, Sporn, and others, overexpression of EGF family members has been thought to contribute to progression of multiple types of cancer. Specifically, in early studies, the level of secretion of TGF- $\alpha$  in breast cancer, fibroblasts, and other cell types was correlated with expression of oncogenes. In breast cancer, a direct correlation among TGF- $\alpha$  production, expression of the *c-ras*<sup>H</sup> oncogene, and malignant transformation was demonstrated *in vitro*.<sup>82,83,84,85,86,87,88</sup> and <sup>89</sup> Subsequent work in human breast cancer and in benign proliferative breast disease has also established that TGF- $\alpha$  overexpression is very common.<sup>84,85</sup>

The development of transgenic technology has allowed additional correlation of expression of TGF- $\alpha$ , amphiregulin, and cripto-1 (another EGF family member, but with an unrelated receptor type) with mammary tumors induced by a wide range of oncogenes.<sup>86</sup> This technology also has allowed study of the effect of overexpression of TGF- $\alpha$  under the control of mammary-selective mouse mammary tumor virus (MMTV) or metallothionine promoters in the mammary glands of mice. The multiple conclusions of these studies implicate TGF- $\alpha$ -induced proliferation, TGF- $\alpha$ -blocked differentiation, and TGF- $\alpha$ -suppressed, postlactational glandular regression in mammary hyperplasia and tumorigenesis.<sup>87,88,89,90,91</sup> and <sup>92</sup> More recently, transgenic expression of the EGF subfamily known as *neuregulins* also has been shown to lead to mammary tumorigenesis.

Although observations of overexpression of EGF family growth factors have led to significant biologic insights into breast cancer, the greatest clinical impact has come from study of EGF family receptors. Gene amplification and resultant overexpression of EGFR-related *c-erbB*<sub>2</sub> (HER-2/neu) protein is found in approximately 25% of human breast cancer cases<sup>93</sup> (see [Table 37.1-1](#)). In addition, expression of the EGFR occurs in 40% of breast tumors, but in the absence of gene amplification. Expression of each protein signifies poor prognosis for the patient.<sup>94</sup> Current studies are addressing the frequency and relevance of expression of the additional, EGFR-related *c-erbB*<sub>3</sub> and *c-erbB*<sub>4</sub> receptors in breast cancer. Transgenic mouse studies also have been successfully used to confirm the oncogenic potential of the *c-erbB*<sub>2</sub> oncoprotein. Interestingly, activation mutations in the extracellular domain of the *c-erbB*<sub>2</sub> oncoprotein were commonly detected in transgenic mouse mammary carcinomas, but this type of mutation has not been described in human breast cancer.<sup>95</sup> Stimulation of cells through the EGFR family may also sensitize cells to other carcinogenic insults. For example, expression of a TGF- $\alpha$  transgene accelerates the progression of carcinogen-initiated mouse mammary tumors.<sup>96</sup> In summary, the etiologic evidence is compelling for EGF family growth factors and their receptors in mammary tumorigenesis after combining data from human pathologic studies and from transgenic mouse models.

In human breast cancer cell lines *in vitro*, autocrine growth dependence of cells on the TGF- $\alpha$ /EGFR system also has been documented in one ER-negative breast cancer cell line—the MDA-MB-468. It is clear in this line that a rare gene amplification of the EGFR sensitizes the cells to autocrine function of TGF- $\alpha$ . This line, thus representative only of a small percentage of breast cancers, expresses more than 10<sup>6</sup> EGFRs (per cell). TGF- $\alpha$  and amphiregulin are also induced by estrogen in hormone-dependent MCF-7 breast cancer cells. Antisense TGF- $\alpha$  complementary DNA, anti-TGF- $\alpha$  antibodies, and anti-*c-erbB*<sub>2</sub> ribozymes partially block estrogen-induced growth *in vitro*,<sup>97,98,99,100,101</sup> and <sup>102</sup> strongly suggesting a hormone-inducible type of autocrine system. The potential clinical relevance of this type of system is significant. Possible autocrine functions of other EGF family members in breast cancer have not yet been fully evaluated, although high expression of neuregulins has been reported in some cell lines *in vitro*. A number of studies have more closely addressed the functions of the neuregulin subfamily in their interactions with the EGFR-related *c-erbB*<sub>3</sub> and *c-erbB*<sub>4</sub> proteins in breast cancer. The neuregulins appear to act *in vitro* with biphasic effects: Low levels are proliferative, whereas higher levels may inhibit epithelial proliferation. The neuregulins also appear to promote differentiation and induce casein synthesis in the developing gland and in breast cancer cells.<sup>75,103,104</sup> To summarize available data, autocrine function of the EGFR ligand system may be most critical in normal gland growth and early stages of breast tumorigenesis, as contrasted with later stages of the disease. Paracrine, tumor-host interactive functions of this family of factors (discussed later in [Process of Malignant Progression](#)) may then begin to dominate its functions as the disease progresses. Strategies using toxic, genetically engineered EGFR ligand bacterial toxin fusion proteins (termed *oncotoxins*) or humanized, anti-*c-erbB*<sub>2</sub> or anti-EGFR antibodies, either alone or coupled with toxins or other therapeutic drugs (*immunotoxins*), could possibly find future therapeutic utility, because a large portion of hormone-independent breast cancers express significant levels of these receptors.<sup>83,93,105,106</sup>

A second growth factor family of potential importance in cancer is the fibroblast growth factor (FGF) family.<sup>107</sup> Members of this family also have been implicated in mammary gland growth and malignant transformation. These growth factors bind to heparin, require a heparin cofactor for proper presentation to and interaction with receptors, and accumulate in the extracellular matrix after their release from cells. Some FGF isoforms do not possess a signal sequence of secretion, but all forms appear to be released by cells by one or more mechanisms. Although FGF-1 and FGF-4 are expressed during the ductal growth phase of the mouse mammary gland in luminal ductal epithelial cells, expression of FGF-2 and FGF-7 are primarily stromal. FGF-1, FGF-2, and FGF-7 have been detected in mammary preneoplasias, tumors, and cell lines, but not in levels significantly higher than normal. FGF-3 (also known in the mouse as *int-2*) is a well-known oncogenic growth factor activated in the mouse mammary gland by MMTV insertional mutagenesis. FGF-4 also has been associated with metastasis of certain mouse mammary tumors.<sup>108</sup> However, although amplification of the genes encoding FGF-3 and FGF-4 have been observed in human breast cancer, these two genes are seldom expressed at the protein level. This finding appears to be the result of their co-amplification with other more important genes located nearby on the chromosomes (genes encoding *c-erbB*<sub>2</sub> and cyclin D1, respectively). In the human mammary gland, FGF-1 and FGF-2 have been localized both to myoepithelial and to epithelial cells. Although studies *in vitro* have implicated FGF-2 as an autocrine growth factor in immortalized human mammary epithelial cells,<sup>109</sup> expression of FGF-2 in clinical human breast cancer is correlated with a good prognosis. Although FGF-1 also has been detected in human breast cancer, it is localized primarily to macrophages<sup>110</sup>; its biologic role is not fully known, but it could potentially contribute to inflammation and angiogenesis. FGF receptors (FGFR) 1–4 each have been localized (and the gene encoding FGFR1 occasionally amplified) in human breast cancer.<sup>111,112</sup> and <sup>113</sup> Receptor heterodimerization is likely to represent a locus of control for FGFR function. Several of the FGF family members have been shown to promote tumor growth and dissemination of metastasis in xenograft models of human breast cancer, at least partially through effects on the tumor vasculature. However, the complete relevance of these observations to the pathophysiology of human breast cancer is still under investigation.<sup>114</sup>

TGF- $\beta$ , a family of at least three growth factors distinct from FGF and EGF families, is also present in the normal and malignant mammary epithelium and in human milk.<sup>115,116</sup> Receptors for TGF- $\beta$ s comprise a family of heterodimeric serine-threonine kinases.<sup>117</sup> TGF- $\beta$ s are profoundly negative in their proliferative effects on ductal epithelial proliferation in mouse mammary glands *in vivo*<sup>27</sup> and on most other epithelial cell types. Expression of TGF- $\beta$  family members is suppressed by estrogen and progesterone.<sup>27,65</sup> All three TGF- $\beta$  isoforms are detected at the mRNA level in the developing mouse mammary epithelium. All isoforms of TGF- $\beta$ , once produced, are retained in the stromal matrix surrounding the mammary ducts, but TGF- $\beta$  is absent from the matrix of growing end buds and lateral branches.<sup>118</sup> Glandular production of TGF- $\beta$  decreases, along with its stromal accumulation around alveoli during midpregnancy and lactation; TGF- $\beta$  is suppressive of lactation.<sup>119,120</sup> and <sup>121</sup> However, TGF- $\beta$  is again elevated as postlactational glandular regression occurs.<sup>122</sup> The role of TGF- $\beta$  also has been examined by using a transgenic mouse approach. Targeted expression of TGF- $\beta$  in the pregnant mammary epithelium with an MMTV promoter leads to inhibition of both alveolar development and lactation.<sup>120</sup> All three TGF- $\beta$  isoforms have been detected in the human gland, with a similar distribution to that observed in the mouse. Paradoxically, TGF- $\beta$  production increases with malignant progression in breast cancer. Its accumulation may have significance for development of the characteristic fibrous desmoplastic stroma of breast cancer,<sup>123</sup> tumor angiogenesis, and immune suppression.<sup>124</sup> Thus, although serving a growth-inhibitory role in the normal gland, progression to cancer may be associated with desensitization of this pathway. Overproduction of TGF- $\beta$  may thus contribute to aberrant tumor-host interactions in breast cancer.<sup>118,125,126</sup> It is of interest, at least in some cell lines *in vitro*, that TGF- $\beta$  may even stimulate tumor cell invasion.<sup>127</sup> An active area of current investigation involves study of inactivating mutations in the TGF- $\beta$  receptor. To date, however, loss of TGF- $\beta$  receptor by mutation or by loss of expression has been observed in colon cancer and retinoblastoma, respectively.<sup>128</sup>

A complex regulatory system is also emerging from studies of the insulin-like growth factors. Whereas the IGF-1 receptor (IGF-1R) is a heterodimeric tyrosine kinase, closely related to the insulin receptor, the IGF-2R is an unrelated binding protein also capable of interacting with TGF- $\beta$  and with cathepsin D. IGF-2 production, as well as cellular responsiveness to IGFs, is stimulated by estrogen and inhibited by antiestrogens in some hormone-dependent breast cancer cell lines. IGF-2 is thought to be a potential autocrine growth factor in breast cancer; in contrast, IGF-1 is synthesized in the tumor stroma and is considered to have important paracrine growth and survival-stimulatory actions in the disease. Transgenic mouse models have demonstrated that mammary expression of IGF-1 causes ductal hypertrophy and suppression of postlactational involution and that IGF-2 expression can lead to mammary cancer. The cellular responsiveness to IGFs appears to be modulated by estrogens and antiestrogens as a result of regulation of both receptors (type 1 being induced and type 2 repressed); IGF-binding proteins 2, 4, and 5 (each of which are estrogen-induced); IGF-binding protein 3 (which is estrogen inhibited), and the signal transduction docking phosphoprotein insulin receptor substrate 1 (IRS-1) (which is estrogen-induced). The biologic functions of the IGF binding proteins (BP) are not fully understood, although BP-1 appears inhibitory of the actions of IGF-1, even with *in vivo* models. Although BP-3 may contribute to poor prognosis of breast cancer, BP-4 and IGF-1R correlates with good prognosis. IGF-2R is under active investigation as a tumor suppressor gene in cancers of the breast and other tissues. Its gene is subject to frequent LOH and, possibly, mutations in

breast cancer.<sup>129,130,131 and 132</sup>

It should be noted that, at present, several dozen other growth factors have been identified in breast cancer, but their consideration is beyond the scope of this chapter; this information is reviewed elsewhere.<sup>133</sup> To summarize some of these data, prolactin<sup>134</sup> and mammary-derived growth factor-1 might be autocrine positive factors in breast cancer, and mammary-derived growth inhibitor and mammostatin may serve negative growth functions.<sup>133</sup> In addition, hepatocyte growth factor/scatter factor is a stromal-derived paracrine-acting stimulator both of epithelial growth and of tumor angiogenesis. Finally, vascular endothelial growth factor, pleiotropin, and platelet-derived growth factor may serve as angiogenic, vascularization-inducing factors in breast cancer.<sup>65,133</sup> Other growth factors under hormonal regulation in breast cancer probably remain undiscovered; future investigations should evaluate this possibility. Many studies have also established that steroid regulation of growth factors is important in the uterus and, possibly, the prostate gland, as well as in the breast.<sup>133</sup>

## SIGNAL TRANSDUCTION AND NUCLEAR ONCOGENES

Unifying, mechanistic links between the proliferative actions of growth- and survival-modulatory steroids, growth factors, and integrins in diverse tissues are represented by the multiple classes of nuclear protooncogenes and other transcription factors (see [Table 37.1-1](#)).<sup>65,135</sup> These transcription-regulating proteins mediate convergent pathways of regulatory stimuli directly through steroid action, through growth factor-induced mitogen-activated protein (MAP) kinases, through other cytoplasmic tyrosine kinases (Fak, Src) or phospholipase C-PKC, through cytokine-induced JAK-STAT pathways, through TGF- $\beta$ -family-induced SMAD molecules, and through integrin-induced Fak/Src pathways. The MAP kinase pathways are central pathways for the proliferative and survival stimuli exerted through the EGFR, the c-erbB<sub>2</sub> receptor, and the insulin receptor type 1 families. Receptors trigger this pathway through autophosphorylation and subsequent binding to src homology 2/3 (SH2/SH3) or phosphotyrosine-binding (PTB) domains of signal transduction adaptor proteins. After mitogenic growth factor treatment of many types of cells, including normal and malignant breast epithelial cells, and a cascade of protein phosphorylations, c-Myc, AP-1-acting (c-fos, c-Jun, and Jun B), c-Myb, and Ets protooncogenes and ATF, EIK, SRF, and NF $\kappa$ B transcription factors are commonly observed to be induced. The protein products of at least three nuclear protooncogenes, c-MYC, c-FOS, and c-JUN, are also induced by both estrogen and progesterone in breast cancer. Progestins additionally induce c-JUNB.<sup>133,135</sup> Not surprisingly, tamoxifen down-modulates c-MYC expression during treatment-induced regression of patient tumors.<sup>136</sup> c-MYC, c-FOS, and c-JUN induction also have been shown to occur in human mammary epithelial cells *in vitro* and in the rat uterus in response to estrogen treatment *in vivo*.<sup>137,138 and 139</sup> Cyclin D1 also appears to be a central nuclear protooncogene-like molecule further downstream of AP-1 and other mitogenic transcriptional controls. Not only does it regulate the G<sub>1</sub> phase of the cell cycle, but similar to the AIB-1 (amplified in breast cancer) protein, it also appears to directly modulate in a positive way the transactivational ability of the estrogen receptor.<sup>140,141</sup>

c-Fos and c-Jun proteins contain specific domains that allow them to form a heterodimeric complex that can interact with the gene promoter consensus sequence termed AP-1. In an analogous manner, the c-Myc protein, of central importance to estrogenic stimulation of breast cancer cells, dimerizes with another protein termed Max (or Myn in the mouse) to modulate genes through a different consensus sequence, termed an E-box (and possibly other sequences). The cellular supply of Max that is available for productive dimerization with c-Myc depends on its interaction with its other family members, termed Maa and Mxi1. The interaction of Max with either of these proteins serves to reduce its availability for interactions with Myc and may exert negative transactivational through E-box sites. Myc-Max dimers are known to induce proliferation, apoptosis, and chromosomal instability, depending on the cellular context and degree of expression. Myc-Max interaction with the TATA binding protein represents one transactivational mechanism to stimulate basal transcription. A second specific transactivational mechanism involves E-box promoter genes such as those encoding the CAD (carbamoyl phosphate synthetase-aspartate transcarbamoylase-dihydro orotase), DHFR (dihydrofolate reductase), and ODC (ornithine decarboxylase) enzymes.<sup>142</sup> However, multiple c-Myc-regulated genes do not appear to possess E-boxes, and E-box-interactive sequences do not appear to be required for c-Myc effects on proliferation and apoptosis.<sup>143</sup>

Several other c-Myc-interactive proteins exist in addition to the TATA binding protein and Max; they include TRRAP, BIN1, DAM, p107, YY1, MIZ1, and TFII-1. Thus, multiple other potential mechanisms may exist for transactivational and transcriptional suppressive effects of c-Myc.<sup>142</sup> Estrogen and progesterone induce c-Myc; the latter appears to primarily modulate the mammary epithelial cell cycle both by inducing the synthesis of cyclin E and the CDC25A phosphatase and by triggering the degradation of p27 (kip1), resulting in an active CDK2. Activation of CDK2 results in inhibitory phosphorylation of Rb and promotes cell-cycle progression through G<sub>1</sub>/S. Additional primary effects of c-Myc appear to be induction of cyclin A to activate CDK2 and induction of the E<sub>2</sub>F<sub>1</sub> transcription factor to promote cell-cycle progression through S.<sup>142,144,145</sup>

Although much is known about the cellular and molecular biology of c-Myc, it is clearly an understudied oncoprotein in breast cancer. It appears to be central to the disease in two respects. First, antisense oligonucleotides directed against the c-Myc mRNA have been used to block estrogen-induced proliferation in breast cancer cells.<sup>146</sup> Second, amplification of the c-MYC gene is now known to be one of the most common genetic alterations in breast cancer; approximately one-fifth of breast cancers contain this genetic change. A putative (but currently unidentified) suppressor gene on chromosome 1p32-pter is proposed to control c-MYC amplification in breast cancer.<sup>144,147</sup> Despite its apparent importance, study of c-MYC gene expression in breast cancer has been slow because of difficulties in measuring its encoded protein in tumor biopsies. Specifically, the protein has a very short half-life,<sup>148</sup> and there have been a lack of suitable monoclonal antibodies capable of staining paraffin sections. A few studies focusing on gene amplification have shown that c-MYC is associated with poor prognosis, high S phase, and postmenopausal disease, although the latter has not been confirmed.<sup>144,147</sup> Based on several investigations in various epithelial malignancies, including those of the ovary and liver, c-MYC amplification is thought to cooperate with TGF- $\alpha$  with EGFR overexpression and with downstream signaling pathways. Thus, dual stimulation of the EGFR pathway and c-Myc may serve a general cooperative function in epithelial transformation.<sup>149,150 and 151</sup>

The c-Myc protein may, therefore, act in multiple systems to regulate gene expression, promote cell proliferation, inhibit differentiation, modulate cell adhesion, and effect immune recognition. Central to these effects is its role to specifically regulate initiation of DNA replication. Overall, gene regulatory activities of the protein also encompass both activation and suppression of gene expression; modulation of the cell cycle; activation of apoptosis (programmed cell death); and modulation of DNA metabolism, DNA dynamics, energy metabolism, and macromolecular synthesis. It is also known that the c-Myc protooncogene product can immortalize cells. Of current interest, the role of c-Myc to induce apoptosis depends on p19<sup>ARF</sup>-mediated activation of the p53 tumor suppressor gene, at least in fibroblasts. However, this mechanism has not yet been demonstrated in mammary cancer.<sup>142,148</sup> A variety of other malignancy-associated biologic consequences of c-MYC amplification also have been described. Very pertinent to the process of malignant progression, some reports have suggested that expression of the c-MYC gene may allow amplification of other genes, (e.g., ODC and DHFR)<sup>142</sup>, alter cellular resistance to cis-platinum and other DNA strand scission-inducing drugs,<sup>152</sup> and act to suppress differentiation in association with the decrease of collagen gene transcription.<sup>153</sup> The c-Myc protein may also inhibit transcription of the rat *neu* oncogene (c-ERBB2 homologue).<sup>154</sup> However, the importance of this interaction for human breast cancer is not yet known. Nevertheless, c-MYC amplification appears not to be closely associated with c-ERBB2 amplification in primary breast cancer. c-Myc may also relate to the aging and senescence process; increased expression of c-Myc in multiple tissue types with aging may reflect cumulative proliferation-associated dysregulation and has been proposed to contribute to aberrant mitogenic responses of the tissue in postmenopausal breast cancer.<sup>155</sup> However, increased expression of the c-Myc partner Mxi1 is also enhanced during aging and may attenuate the effects of c-Myc.<sup>156</sup>

The c-MYC gene and other oncogenes have been introduced into immortalized human or mouse mammary epithelial cells using an amphotropic retroviral vector. These studies have observed that either c-Myc or the simian virus 40T nuclear oncoproteins (but not v-Ras<sup>H</sup> or v-Mos cytoplasmic oncoproteins) allowed the cells to grow in soft agar in response to FGF-1, FGF-2, EGF, or TGF- $\alpha$ .<sup>157</sup> Because mammary fibroblasts produce EGF- and FGF-related growth factors<sup>158</sup> and because their conditioned media could support transforming growth of nuclear oncogene-transfected mammary epithelial cells, these observations have supported a role *in vivo* for stromal-epithelial interactions. Such a synergistic interaction has been observed *in vitro* in TGF- $\alpha$ /c-Myc bitransgenic mice. Co-overexpression of these two gene products allows rapid (10 weeks) onset of highly proliferative mammary tumors, independent of sex hormones in either gender.<sup>150,151</sup> Thus, an amplified c-MYC gene may function in breast cancer to allow growth factors or hormones to act to drive aberrant, transformed growth.<sup>145</sup>

## THE CELL CYCLE AND CELL DEATH

### TUMOR SUPPRESSOR GENES

Seminal studies by Broca in the nineteenth century<sup>159</sup> established that breast cancer can have a familial pattern of onset in 5% to 10% of cases. In addition, it has been observed that families with a very high incidence of the disease sometimes display a high incidence of additional cancer(s), such as ovarian cancer. A hypothesis has been proposed that such families inherit a defective or lost allele encoding a tumor suppressor gene. This hypothesis was based largely on work by Knudson, who suggested that the inactivation of two alleles of a gene was required in the disease known as retinoblastoma,<sup>160</sup> and Harris, who demonstrated that

certain chromosomes could suppress malignancy *in vitro* in cell hybrid studies.<sup>161</sup> This concept has led to the discovery of several tumor suppressor genes in breast cancer, some regulating the cell cycle and cell death, and others regulating different aspects of the progression of the disease.

The first tumor suppressor gene shown to confer risk of an inherited breast cancer syndrome was termed *TP53*, and more recently, the *PTEN* gene was implicated in this respect. Also, the two *BRCA* genes (see [Table 37.1-1](#)) are responsible for a larger group of patients with an inherited pattern of breast cancer (*BRCA-2*) and breast plus ovarian cancers (*BRCA-1*). It is now widely accepted that *BRCA-1*, *BRCA-2*, and *PTEN* all function as tumor suppressor genes. However, in contrast to *TP53*, their mutations are uncommon in sporadic breast cancers. Conversely, three other well-established tumor suppressor genes, *CDKN2* (p16), *RB-1*, and *CDH1* (E-cadherin), are commonly altered (mutation, methylation, LOH, and deletion) in sporadic breast cancer but do not appear to be involved in conferring familial risk of the disease (see [Table 37.1-1](#)).

During the malignant progression of breast cancer to its fully metastatic state, mutation, inactivation, loss, or down-regulated expression of tumor suppressing genes commonly occurs. Estimated incidences of these processes for the relevant, known suppressor genes are as follows: *TP53*, 30% to 40%; *RB-1*, 15% to 20%; *CDKN2*, 20% to 30%; and *CDH1*, 20% to 30%.<sup>135</sup> Tumor suppressor genes appear to function in four major ways: as antiproliferative or antisurvival factors, as DNA-repair inducers, and as differentiation-promoting agents. *BRCA-1* and *BRCA-2* serve roles to direct repair of damaged DNA. The ATM protein (described earlier as a suspected tumor suppressor) detects the damage and transmits the signal to the *BRCA* proteins, while multiple other proteins, such as Rad51 and p53, serve roles downstream of the *BRCA*s.<sup>162,163</sup> E-cadherin, a suppressor that works through an unrelated pathway, serves to strengthen homotypic interactions of mammary epithelial cells and maintain their differentiated status; in addition, it promotes sequestration of b-catenin (a proliferation-promoting protein that regulates the T-cell factor (TCF) class of transcription factors).<sup>164</sup> p53, by inducing the p21 protein (Waf-1/CIP-1), also inhibits proliferation, whereas the p16 protein also serves to inhibit the cell cycle; both p53 and p16 suppressor proteins ultimately promote phosphorylation and inactivation of Rb to block G<sub>1</sub> and G<sub>1</sub>/S transit of the cell cycle.<sup>165,166</sup> Although Rb is thought to be a central tumor suppressor protein in breast cancer, it appears to be understudied at present, particularly with respect to its mutation status. *PTEN* serves to suppress cell survival and proliferation by dephosphorylating phosphoinositides to prevent their activation of the three AKT signal transduction kinases.<sup>167,168</sup> and <sup>169</sup> Beyond the scope of this chapter is the consideration of literally dozens of additional candidate tumor suppressor genes that also function on these cellular pathways (see also the section [Process of Malignant Progression](#)).<sup>135</sup>

Study of the *TP53* gene has provided remarkable insights into multiple areas of cancer biology. *TP53* is a tumor suppressor gene, but when mutated in one of several sensitive regions, its conformation changes, its stability increases, and its regulatory properties are radically altered. Mutation can confer a loss of tumor suppressor activity and gain of tumor promotion function.<sup>170</sup> The nonmutated p53 gene product is an oligomeric DNA binding protein that functions to trigger cellular responses to DNA damage; it has been termed the “guardian of the genome.” p53 functions both by protein-protein interactions and by regulation of transcription. The p53 protein appears to function in the context of DNA damage as a G<sub>1</sub>/S and G<sub>2</sub>/M checkpoint controller to slow cell growth and induce DNA repair; cell death is triggered in a process termed *apoptosis* if damage is too severe for repair. It is of particular importance for the progression of many cancers, including breast cancer, that mutation of p53 is associated with enhanced genetic instability.<sup>171</sup> Certain viral proteins, although they are probably not relevant to breast cancer, are known to inactivate p53 as a critical event in viral carcinogenesis.<sup>170</sup>

It is not yet fully clear what molecular events induce (through protein stabilization) the p53 protein. However, it is well known that UV irradiation and double-strand DNA breaks are strong inducers of p53 stabilization through the DNA-dependent protein kinase and the ATM gene product. ATM is a signal transduction protein with high homology to phosphatidylinositol-3 kinase.<sup>172</sup> Of uncertain molecular bases are observations that inhibitors of PKC inhibitors, serine-threonine phosphatases, and cAMP can prevent p53-mediated responses. On a molecular level, p53 induces growth arrest in multiple points of the cell cycle through induction of p21, a multipotent inhibitor of cyclin-dependent kinases (CDKs), which blocks cell-cycle progression (discussed later in [Cyclins, Cyclin-Dependent Kinases, and Inhibitors](#)); p21 also blocks a catalytic inhibitor of a DNA replication termed *proliferating cell nuclear antigen* (PCNA). A very important, specific consequence of p21 induction is the inhibition of cyclin E-CDK2-catalyzed phosphorylation of the Rb protein. Hypophosphorylation of Rb allows its function as an additional cell-cycle inhibitor. p53 is also thought to directly modulate transcription of Rb and to directly bind a partner of Rb (termed *p107*) at the protein level.<sup>173</sup> Additionally, p53 induces transcription of genes encoding cyclin G, ERCC (excision repair cross-complementing), and Gadd 45 (growth arrest DNA damage protein), all proteins thought to be involved in DNA repair. A third general process triggered by p53 is apoptotic death. This process is quite distinct from necrotic death in that it requires ATP, the cell condenses the chromatin of its nucleus, the nucleus undergoes fragmentation, and the cell maintains an intact plasma membrane until the final stage, at which point terminal cells are consumed by macrophages.<sup>170,173</sup> Negative regulators of p53 are thought to include its phosphorylation by several kinases, its nuclear exclusion by unknown mechanisms, and its complexation with a protein called *MDM-2* (murine double-minute gene-2), itself a p53-inducible protein and an oncogene (at least in some cancers other than breast cancer).<sup>173</sup>

The most extreme result of p53 induction is apoptosis. A protein whose transcription is directly inhibited on this pathway is Bcl-2<sup>174</sup> ([Table 37.1-3](#)). Bcl-2 is an apoptosis-preventing protein, commonly expressed in breast cancer in p53-mutated cells.<sup>175</sup> Bcl-2 is localized in the mitochondria, nuclear membrane, and endoplasmic reticulum. It functions, along with a homologue termed *BclxL*, to suppress the function of Bax, a death-inducing protein; many Bcl family members act to form mitochondrial pores of differential ionic permeability. Several other stimulatory and inhibitory family members exist, including Bclx<sub>S</sub>, a promoter of apoptotic death. This entire system functions to regulate death by regulating a series of regulatory cysteine proteases within the cell. The apoptotic system is thought to be triggered by hypoxia or by a shift in the redox potential of the cell; Bcl-2 and Bclx<sub>L</sub> protect against death (induced by proapoptotic Bax) by modulating mitochondrial permeability and regulating mitochondrial release of cytochrome C.<sup>170,171</sup> In addition, two family members of p53, called *p73* and *p63*, are under current study for their p53-like properties.<sup>176,177</sup>

**TABLE 37.1-3.** Cell Death (Apoptosis) Regulatory Factors in Breast Cancer

Although quite complex, the balance of life/apoptosis is critically regulated in cancer progression and response to therapy (see [Table 37.1-3](#)). Estrogen, progesterone, TGF- $\alpha$ , EGF, and insulin all appear to suppress apoptosis and promote survival of breast cancer model systems. Antiestrogens, antiprogesterins, TGF- $\beta$ , and the overexpressed c-Myc oncoprotein can induce apoptosis unless countered with a survival-promoting, environmental influence. Current research is focused on how these factors regulate the apoptotic pathway(s).<sup>178,179</sup> The system has clear implications for response of breast cancer to radiation, antihormonal and biologic therapies, chemotherapy, and even gene therapy. For example, it has been suggested that estrogen promotes chemotherapy resistance of breast cancer by induction of Bcl-2,<sup>180</sup> that p53 mutation results in resistance to chemotherapy,<sup>181</sup> and that experimental gene therapy with *bclx* can differentially kill tumor cells and sensitize them to chemotherapy but spare bone marrow cells.<sup>182,183</sup> Gene therapy addressing the *p53* gene directly has also been proposed.<sup>170</sup>

The *RB-1* gene product also has tumor suppressor functions and is a nuclear protein. When mutated in one of several critical regions, the function of the gene product is inactivated. The Rb protein is also functionally inactivated by phosphorylation; this phosphorylation is catalyzed by one or more cyclin-dependent protein kinases. It is of interest that a large number of cellular growth regulatory proteins, such as members of the c-Myc, CDK, and E<sub>2</sub>F-1 families, bind the Rb protein or its family members. Rb appears to function to restrict cellular entry into the S phase of the cell cycle ([Table 37.1-4](#)). Hypophosphorylated Rb binds E<sub>2</sub>F-1 and DF-1 family members to restrict access of these transcription factors to the chromatin. The result is a blockade of transcription from genes involved in G<sub>1</sub>/S progression and S phase in the cell cycle.<sup>165,184</sup>

Phase	Cdk/Regulator	G <sub>1</sub> /S		G <sub>2</sub> /M	
		CDK	Cycle	Inhibitor	Regulator
G <sub>1</sub>	Integrin, progesterone, growth factors, c-Myc, p53	CDK2, CDK4	34,36,38	p15, p16, p18, p19, p21, p27, p29	CDK4, CDK6
G <sub>1</sub> /S	c-Myc, c-Myc, estradiol, estrone, estradiol, estrone	CDK2	1	p15, p16, p18, p19, p21, p27, p29	CDK2
S	-	CDK2	1	p15, p16, p18, p19, p21, p27, p29	-
G <sub>2</sub> /M	p53, MDM2	CDK1	1,3	p15, p16, p18, p19, p21, p27, p29	CDK1

CDK, cell division cycle; Cdk, cyclin-dependent kinase; 34, 36, 38, DNA binding partner of p15, MDM2, mouse double-strand break protein 2, retinoblastoma protein.  
 The gene encoding the inhibitor also encodes, in an alternate reading frame, p19<sup>INK4</sup> an inhibitor of CDK2, the protein that inhibits the function of p15.

**TABLE 37.1-4.** The Cell Cycle

### CYCLINS, CYCLIN-DEPENDENT KINASES, AND INHIBITORS

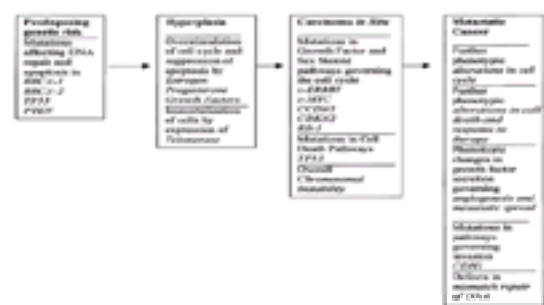

Growth factors and inhibitors, as well as oncogenes and tumor suppressors, function to a large extent in the G<sub>1</sub> phase of the cell cycle. The cell cycle (see [Table 37.1-4](#)) is directly controlled by an ordered series of CDKs, their positive regulatory subunits (cyclins), and their inhibitors. Early G<sub>1</sub> is driven by the three cyclin D family members bound to CDK4 and CDK6. In the next portion of the cycle, the G<sub>1</sub>/S transition is driven by cyclin E–CDK2. The S phase is driven by cyclin A–CDK2, and then the G<sub>2</sub>/M transition is driven by cyclin B/A–CDC2 (CDK1).

As important regulators of the epithelial cell cycle in breast cancer, tyrosine kinase receptor-acting growth factors and sex steroids induce both c-Myc and cyclin D1. c-Myc itself appears to suppress D1 in cycling cells, induce cyclin E (and possibly CDC25A), and trigger the proteasome-mediated destruction of the CDK1 p27 (kip1) and activation of CDK2. Cyclin D1–CDK4 is inhibited by the CDK1 called p15 (INK4), by the tumor suppressive CDK1 p16 (MTS1 or INK4b), and by p18 and p19, more recently defined CDK1s of the same family. Cyclin D–CDK4 and cyclin E–CDK2 are also each inhibited by the CDK1 termed p21 (Waf-1/CIP-1), which is induced by p53; by p27 (kip1); and by p57 (kip2), which may be involved in cellular senescence. It has been shown that synthesis of CDK4 is inhibited by TGF- $\beta$ ; overexpression of CDK4 leads to TGF- $\beta$  resistance. p27 is also of note because it is induced by growth-inhibitory TGF- $\beta$ . Rb is phosphorylated and inactivated both by the cyclin D–CDK4 and by the cyclin E–CDK2 kinases. Many the effects of multiple regulators of G<sub>1</sub> and G<sub>1</sub>/S are thus integrated by their collective effects on phosphorylation of Rb. c-Myc also disregulates S phase by inducing cyclin (to activate CDK1) and E<sub>2</sub>F-1. P53 also functions later in the cycle; its mutation not only abrogates the G<sub>1</sub>/S checkpoint, but also a post-M spindle assembly checkpoint. [135,185,186](#)

As should now be evident, a major body of work has begun to implicate cyclins as likely oncogenes and CDK inhibitors as likely tumor suppressors (see [Table 37.1-1](#)). These studies have shown that the genes encoding cyclin D1 and cyclin E are commonly amplified and deregulated, respectively, in breast cancer. The amplification of the cyclin D1 (*CCND1*) gene occurs in approximately 30% of breast cancer cases; its prognostic significance is under current investigation. [187,188](#) It is of note that the genes for both cyclin D1 and cyclin E can function as mammary cancer-inducing oncogenes when driven by the MMTV promoter in the transgenic mouse. [189](#) Deletion of the gene-encoding cyclin D1 (*ccnd1*) in a mouse model results in failure of lobuloalveolar development of the mammary gland. [190](#) More recent studies, initially in cancer cell lines, have also implicated the cyclin inhibitor p16 [MTS-1(multiple tumor suppressor-1)] and p27 (kip-1) as major tumor suppressors; the *CDKN2* gene (encoding p16) is commonly inactivated by gene methylation, [191](#) whereas the gene encoding p27 is commonly down-regulated. Finally, the *RB-1* gene is commonly mutated, deleted, and down-regulated in breast cancer. The result of all of these common aberrations seems to be similar—defective G<sub>1</sub>/S transitions in the mammary epithelial cell cycle. [192](#)

### PROCESS OF MALIGNANT PROGRESSION

Evidence is rapidly accumulating that the development of cancer is a process that not only involves dysregulation of proliferative factors and activation of oncogenes but also dysregulation of inhibitory factors and loss of suppressor gene function ( [Fig. 37.1-1](#)). Studies in breast cancer have served to underscore the role of germline deletion or mutation of suppressor genes in the familial forms of the disease, and somatic gene amplifications, mutations, deletions, and rearrangements during malignant progression of the disease. Malignant progression of breast cancer involves a progressive deterioration of the normal mechanisms of cell-cycle progression. DNA repair, apoptotic controls, and tissue compartmentalization break down (through angiogenesis and tumor invasion) until the highly abnormal state of metastatic disease is reached. Early aberrations in proliferation probably only slightly perturb the pathways activated by systemic hormones (estrogen and progesterone) and local growth factors (such as TGF- $\alpha$ ). The actual mechanisms for these early hyperactive proliferative controls to induce benign breast disease or premalignant atypical ductal or lobular carcinoma are not at all clear at the present time. Some studies have shown that genetic damage is minimal in these early lesions, although this area of study is only in its earliest stages. [193](#)

**FIGURE 37.1-1.** Summary of the genetic and phenotypic alteration of mammary epithelial cells associated with the onset and progression of breast cancer.

An interesting, current area of research into mechanisms of onset of breast cancer involves the DNA replication–associated enzyme telomerase. High levels of expression of this enzyme have been shown to lead to cell immortalization, a widely hypothesized early step in human tumorigenesis. One study has implicated the catalytic subunit of this enzyme (hTERT) plus two oncogenes—simian virus 40T (a viral oncogene that inactivates both p53 and Rb) and the mutant form of the signal transduction protein c-RasH—in converting human embryonic kidney cells to cancer. [194](#) Telomerase overexpression has been detected in the earliest stages of breast cancer; it is known to be induced both by estrogen and by c-Myc. Thus, telomerase dysregulation may serve a subtle, early function in breast tumorigenesis—replicative immortality. [195,196,197](#) and [198](#)

The next steps in tumorigenesis almost entirely involve spontaneous gene amplification, LOH, and mutations, which arise because of overactive cell cycles or defective cell death that are largely due to abnormal cell-cycle checkpoint controls. Once these types of genetic alterations begin to occur, a cascade of further genetic changes occurs, resulting from overall genomic and chromosomal instability. Familial disease may bypass one or more steps in this cascade. The mechanisms for genetic instability and accumulation of further mutations in other cancers, such as colon cancer, have been proposed to initially depend on overexpression of a mutator gene termed *MSH2*. [199](#) To date, however, these mechanisms have not been fully evaluated for breast cancer, and mismatch repair defects appear to be associated primarily with later stages of progression and metastasis of breast cancer. In contrast to colon cancer, centrosomal defects appear to predominate in early breast cancer, potentially causing the chromosomal type of instability. [200](#)

Almost certainly, the most important consequences of these molecular changes initially relate to limited effectiveness of antihormonal therapy, chemotherapy, and

radiation therapy. The mechanisms of failure of antihormonal therapy in hormone receptor–positive disease may potentially relate to sensitization of the tumor to very low levels of sex hormones and to the partially estrogenic properties of the clinically utilized hormonal antagonists, such as tamoxifen. Chemotherapy resistance in breast cancer is also not fully understood, but probably involves altered cell death responses and altered metabolism of the drugs. <sup>200,201</sup> Resistance to radiation is also not fully understood, but probably involves defects in the ATM pathway (including BRCA proteins and p53), leading to DNA damage–induced death. <sup>172</sup> Full consideration of mechanisms of resistance to each of these therapeutic modalities is beyond the scope of this chapter; however, the answers probably lie in the events made possible by genetic instability, aberrant proliferation, and defective death mechanisms. During treatment-associated malignant progression, as additional amplifications, LOHs, and mutations occur, the cancer cells with the greatest capacity for growth, invasion, or survival undergo positive selection. Other cells may be more susceptible to necrotic or apoptotic death. <sup>202,203</sup> Some studies have detected genetic changes in histologically normal tissue surrounding breast tumors, consistent with this clonal evolution hypothesis. <sup>204,205</sup>

The oncogenes, suppressor genes, growth factors, and sex hormones discussed in this chapter may also interact in critical patterns during treatment-associated disease progression. For example, certain common patterns of cytogenetic alterations exist in breast tumors, possibly the signature of distinct pathways of progression. <sup>206</sup> Many studies have now used cell lines *in vitro* and in the transgenic mouse in an attempt to sort out the biologic roles of likely tumor etiologic factors and their interactions. <sup>207</sup> From these studies, it appears that certain acquired genetic changes may interact unfavorably with residual growth regulatory pathways operant in the normal tissue. One example already discussed is the unfavorable interaction between cyclin D1 and the estrogen receptor. <sup>140</sup> Several other examples may include the interaction of amplified *c-ERBB2* or *c-MYC* genes in the presence of an autocrine- or paracrine-activated EGFR system. <sup>207,208</sup> *c-ERBB2* amplification in association with downstream overexpression of the signal transduction *c-RASH* gene is also an unfavorable interaction. <sup>208,209</sup> The tyrosine kinase signal transduction pathways (such as c-Ras<sup>H</sup>) that govern proliferation, survival, or both, also clearly interact with c-Myc in cellular models *in vitro* and in transgenic mouse models of mammary cancer. <sup>151,207,209,210</sup> and <sup>211</sup> Another type of synergistic interaction may result from c-Myc expression in association with overexpression of apoptosis-suppressing Bcl-2. A final example is that of p53. Mutated p53 may interact unfavorably with c-erbB<sub>2</sub> by blocking apoptotic pathways. <sup>207,212</sup>

Study of the interactions of growth regulatory pathways with mutations in genes involved in signal transduction cell-cycle and cell-death pathways is thus in its infancy. A major approach for the future understanding of this phenomenon will involve increased use of the transgenic and gene knockout mouse models, with the eventual hope of establishing the biochemical and cellular bases of various patterns of malignant progressions. Future studies aimed at detailed characterization of the interaction of ER, PR, growth factors, protooncogenes, and suppressor genes with various therapeutic approaches in these animal models are thus likely to shed much light on their interactive roles in the onset and progression of breast cancer. At present, however, few studies *in vivo* have focused on combinations of genetic alterations thought to be important in human disease or on the use of transgenic models for studies of treatment-induced resistance and disease progression to metastasis.

The ultimate event that leads to mortality from breast cancer is metastasis. Two separate but apparently interactive cellular processes seem to occur to allow metastasis of the disease: tumor angiogenesis and loss of proper tissue compartmentalization (invasion). It is not yet fully established whether genetic or phenotypic changes underlie these alterations. However, several molecular determinants have been proposed to relate to each process. Loss of cell-cell attachment, altered cell substratum attachment, and altered cytoskeletal organization play a role in regulating cellular invasion. In addition, cell locomotion, proteolysis, and the ability to survive and proliferate at distant sites also must contribute. <sup>213,214</sup> and <sup>215</sup> Although acquisition of this group of characteristics is responsible for a cancer to locally invade host tissue, the ability of a tumor to distribute itself to distant sites also requires the development of a tumor vasculature—the complex process of angiogenesis. <sup>216,217</sup> Some studies have shown that metastatic alterations may have at least some genetic basis <sup>218</sup> and that distant metastases are more likely to exhibit dominance of a malignant clone than primary tumors. <sup>219</sup> Because of space limitations, we cannot discuss the processes of angiogenesis and metastasis further here; the reader is directed to the more general chapter covering some of these processes earlier in this volume ( [Chapter 9](#) ).

## IMPLICATIONS OF MOLECULAR BIOLOGY FOR TUMOR PREVENTION, EARLY DETECTION, PROGNOSIS, AND RESPONSE TO THERAPY

A major hope in the study of genetic changes in breast cancer is that they lead to development of new prevention and early detection strategies, therapies, and prognostic tools. In the area of prevention, there is much current work to establish more rapid, accurate, and cost-effective assays of *BRCA-1* and *BRCA-2* mutations to better identify women with a familial propensity for breast cancer. In addition, the gene(s) responsible for a significant number of breast cancer families remain to be identified, and the bases (genetic and/or environmental) for the variable penetrance of the *BRCA* genes remain to be determined. Women at high risk will undoubtedly be the population of emphasis for future prevention trials. Although the benefits of prophylactic mastectomy and oophorectomy are now established, tamoxifen is also known to be an effective prevention strategy. A major, current trial is comparing tamoxifen to raloxifene (an antiestrogen thought to produce fewer endometrial cancers and to provide other benefits). However, new pharmacologic or dietary strategies are needed, particularly to prevent ER-negative breast cancer. <sup>220,221</sup> and <sup>222</sup>

In the area of early detection, we now know that overproduction of growth factors such as TGF- $\alpha$  and hepatocyte growth factor are very common, but they have not yet been shown to distinguish benign proliferative disease from malignant disease. <sup>223,224</sup> and <sup>225</sup> However, exciting results have been reported in the area of chromosomal instability. It is possible that detection of telomerase expression or the ability to detect subtle genetic alterations will provide useful new approaches for marking the onset of cancer. Development of new nipple aspirate methodologies and blood and urinary assays for growth factors, growth factor receptors, autoantibodies to oncoproteins, and tumor DNA are also currently under way. <sup>226,227,228</sup> and <sup>229</sup>

In the area of prognosis and response to therapy, much hope has been vested in development of more accurate and rapid methods for immunohistochemical and fluorescent *in situ* methodologies for characterization of oncogenes, suppressor genes, and related proteins. <sup>230</sup> Serum and plasma assays for growth factors are also of interest, in addition to more classical tumor markers of CA15.3 and CEA (carcinoembryonic antigen) for determining prognosis and response to therapy. Sensitive assays to detect tumor-derived cells and DNA in the blood are also under development. Obviously, detection of ER and PR in tumors has led the way for integration of molecular markers into clinical decisions regarding prognosis and response to therapy. Pure antiestrogens and aromatase inhibitors are now in clinical trials for ER-positive, relapsing tumors. More recently, detection of the c-erbB<sub>2</sub> oncoprotein has also proven its value for characterization of poor-prognosis tumors, as well as for those that are likely to have a poor response to adjuvant hormonal therapy and chemotherapy. Although technically more difficult to measure, EGFR is of interest for future study of tumors likely to have a poor prognosis and poor response to hormonal therapy. Because of common expression or overexpression of these two receptors in breast cancer, they are now targets of new experimental therapies that use antibodies to their extracellular domains and couple or gene-fuse these antibodies to toxic moieties. <sup>231,232</sup> and <sup>233</sup>

A large group of studies have confirmed that 20% to 30% of breast tumors contain an amplification of the *c-ERBB2* gene and overexpress the encoded receptor protein. *c-ERBB2* is also overexpressed in a very high portion of ductal carcinoma *in situ*. <sup>234,235</sup> Expression of the c-erbB<sub>2</sub> protein is associated with an elevated mitotic rate; it correlates with poor clinical response to certain chemotherapeutic and antihormonal drugs (5-fluorouracil, methotrexate, Cytoxan, and tamoxifen-containing regimens) and insensitivity to tamoxifen *in vitro*. <sup>235,236</sup> c-erbB<sub>2</sub> expression is also associated with poor prognosis in patients who do not receive treatment with chemotherapeutic or antihormonal drugs. <sup>237,238,239,240</sup> and <sup>241</sup> Although one might postulate that *c-ERBB2* gene amplification directly modulates metastatic capacity based on data with tumor models, its association with poor prognosis would appear to relate to other features of tumor biology still to be fully elucidated.

The c-erbB<sub>2</sub> protein also holds significant interest for breast tumor immunology. Certain antibodies to the extracellular domain of the c-erbB<sub>2</sub> protein seem to sensitize cells to killing by *cis*-platinum, carboplatinum, and doxorubicin *in vivo*. It is thought that the mechanism of this effect is interference with DNA repair mechanisms. <sup>242,243</sup> The shed extracellular domain of c-erbB<sub>2</sub> protein may represent a useful, antigenic blood-borne marker of breast cancer burden, <sup>244</sup> and the c-erbB<sub>2</sub> protein itself may be a new target of immunotherapy of cancer, <sup>243,245,246</sup> as with EGFR. <sup>247</sup> Specifically, a humanized, anti-c-erbB<sub>2</sub> antibody termed *herceptin* is showing promise in clinical trials. <sup>243</sup> More recent results also suggest the possibility of active immunotherapy targeting the c-erbB<sub>2</sub> protein; a lymphoplasmacytic infiltrate in breast cancer was shown to indicate good prognosis for an erbB<sub>2</sub>-positive subset of patients. This study noted production of growth-inhibitory antibodies by peripheral lymphocytes from these patients. <sup>243,248</sup>

Although many studies have demonstrated the prognostic significance of c-erbB<sub>2</sub> expression for lymph node–positive patients, the role of the oncoprotein in the malignant process is not clear. For example, many established human breast cancer cell lines overexpressing c-erbB<sub>2</sub> are frequently of poor tumorigenicity in the nude mouse. This fact could theoretically be due to a lack of coexpression of a heterodimeric receptor partner or a ligand, or to coinduction of a suppressive phosphatase. <sup>249</sup> Overexpression of c-erbB<sub>2</sub> in immortalized breast epithelial and breast cancer cell lines has suggested that it is only weakly transforming *in vitro*, and

it has not significantly induced or enhanced a tumorigenic phenotype *in vivo* in several studies.<sup>250</sup> However, in the transgenic mouse, c-erbB<sub>2</sub> expression results in long-latency, metastatic breast tumors.<sup>251</sup> Association of the c-erbB<sub>2</sub> protein with, and activation of, the c-Src oncoprotein in this model are thought to be critical in the tumorigenic pathway. Because the c-erbB<sub>2</sub> protein can heterodimerize with other receptor family members, co-overexpression of all family members and cross-dimerization must eventually be taken into account in prognostic and therapeutic studies. Of interest in this respect are studies identifying a constitutively active, variant form of EGFR in human cancers.<sup>252</sup>

As we have emphasized, nuclear protooncogenes are common mechanistic links between the actions of growth-promoting steroids and growth factors in diverse tissues. Although amplification of the c-*MYC* nuclear protooncogene is one of the most common genetic alterations in breast cancer (approximately 20% of breast cancers contain this amplicon), it must be the target of much future investigation because of its central role in a diversity of cellular processes.<sup>147,253,254,255,256 and 257</sup> Study of c-*MYC* gene expression in breast cancer has been hampered by immunologic and stability difficulties in measuring the protein in tumor biopsies, but new fluorescence *in situ* and polymerase chain reaction methodologies are likely to improve c-Myc studies in human breast cancer. The c-Myc protein has a very short half-life, and only now are high-quality monoclonal antibodies capable of staining paraffin sections becoming available. In spite of these difficulties, several studies have shown that amplification of the c-*MYC* gene is clearly associated with poor prognosis.<sup>147,256,257</sup> In addition, in *in vivo* and *in vitro* models, EGF family growth factors have been shown to dramatically interact with the c-Myc oncogene product in tumorigenesis. These studies provide food for thought in development of future clinical studies, such as those targeting the EGFR or c-erbB<sub>2</sub> together with c-Myc.<sup>258</sup>

There also is significant hope that studies of c-Myc will aid in the prediction of tumor response to therapy. Expression of Myc may also alter cellular resistance to *cis*-platinum and other DNA strand scission-inducing drugs,<sup>259</sup> and it may suppress differentiation in association with decreased collagen gene transcription.<sup>260</sup> c-*MYC* amplification is clearly not associated with c-*ERBB2* amplification in primary breast cancer<sup>261</sup>; rather, it identifies a subset of biologically different, poor-prognosis tumors. These studies also suggest that tumors containing either of these two important amplicons may be of such different biologic significance that the amplicons are mutually incompatible.<sup>262,263 and 264</sup>

Another major effort in better understanding breast tumor prognosis and response to therapy surrounds the genes involved in controlling cell death and DNA repair. Specifically, the *TP53* gene, whose protein product has the potential to mediate apoptotic death induced by virtually all forms of adjuvant therapy, is easily measured by immunohistochemical methodology. A major caveat is that pathologists cannot be certain that the accumulation of p53 protein they measure is due to mutation rather than to induction from a proapoptotic stimulus. Much effort will go into improvements in p53 methodology. Data, so far, clearly indicate that *TP53* overexpression confers poor prognosis and likelihood of a poor response to endocrine therapy and chemotherapy,<sup>265,266</sup> but much additional study needs to apply high-throughput mutation analysis to routine assay. *TP53* also is widely discussed as a potential gene for gene therapy trials of cancer. Three regulators downstream of p53 are also promising. First, loss of Rb detected by immunohistochemistry appears to indicate poor prognosis,<sup>267</sup> as does expression of bcl-2 and down-regulation of Bax.<sup>268,269,270 and 271</sup> However, more studies must be carried out on *RB-1* mutation analyses and detection of other Bcl family members. Finally, a new area of study is the identification of poor-prognosis and response-to-therapy genes by use of high throughput complementary DNA chip assay analyses. Such studies have the potential to improve tumor diagnosis and prognosis.<sup>272,273</sup>

Studies of metastasis have suggested that quantification of tumor angiogenesis and deposition of the extracellular matrix protein (termed *tenascin*) may be of value in evaluating this critical transition of the disease. To supplement the traditional lymph node biopsy measurements, promising new drugs are in clinical trial for blockade of angiogenesis.<sup>274</sup> Metastasis itself seems to depend on the elaboration of proteases (such as urokinase/plasminogen activator and matrix metalloproteases), the most promising of which for prognostic significance is the cognate inhibitor urokinase PAI-1 (plasminogen activator inhibitor-1). New drugs, such as marimastat, are currently in clinical trials studying blockade of proteases. This will be a very active area of future drug development.<sup>275,276</sup> Finally, the adhesive changes that metastatic cells undergo are of major interest. Loss of expression of E-cadherin (and acquisition of a mesenchymal phenotype marked by the intermediate filament vimentin), loss of α<sub>2</sub>β<sub>1</sub> integrin, overexpression of a 67-kD laminin binding protein, and overexpression of a variant form of the hyaluronic acid receptor (CD44) are all of poor prognosis or correlated with poor tumor grade in early clinical studies.<sup>277,278,279,280,281,282 and 283</sup> Much larger studies are needed to fully evaluate the clinical significance of these metastasis-associated cellular changes.

In summary, although a very large number of genetic and phenotypic alterations have been suggested in breast cancer, only a handful have been fully identified and brought to clinical study. It is quite encouraging that study of each of these genes and phenotypic changes has provided its own unique perspective to the biology of the disease. The challenge for the future, however, is to take advantage of this knowledge to improve detection of familial risk; develop prevention strategies; improve early detection, clinical diagnosis, and prediction of therapeutic outcome; develop therapies; and rapidly apply more novel biologic therapeutics.<sup>284</sup> It is our prediction that future discovery in breast cancer will focus on the molecular bases of processes involved in treatment failure—invasion, angiogenesis, metastasis, and resistance to therapy. Central to these hopes are the development of new technologies for high throughput analyses of pathologic material (such as laser capture microdissection techniques, fluorescence *in situ* hybridization, and other molecular cytogenetic methods), complementary DNA chip array assay methods, SAGE (serial analysis of gene expression), and other cutting-edge RNA and protein analysis techniques. It is essential that new technologies be brought to improve tumor diagnosis and prediction of response to existing therapies. These approaches should also result in discovery of new targets for more biologic-based therapies and prevention strategies for breast cancer. Prospects for clinical translation of basic molecular biologic results appear to be bright.

## INTRODUCTION

Breast cancer has a major impact on the health of women. Approximately 183,000 women are diagnosed with invasive breast cancer each year and nearly 41,000 women die of the disease.<sup>1</sup> In American women, breast cancer is the most frequently diagnosed cancer and the second leading cause of cancer death.<sup>1</sup> In women aged 40 to 55, breast cancer is the leading cause of all mortality. There has been a slight decline in breast cancer mortality overall,<sup>1</sup> which can be attributed both to the success of early detection programs and to advances in treatment, particularly developments in systemic therapy. Data from the Surveillance, Epidemiology, and End Results (SEER) program indicate that white women in the United States have a 13.1% lifetime risk of developing breast cancer, whereas African American women have a 9.6% lifetime incidence.<sup>2</sup> The lifetime risk of dying from breast cancer is 3.4% for both African American and white women in the United States.

For several decades there had been a dramatic increase in the incidence of invasive breast cancer. While the incidence of invasive breast cancer has leveled off,<sup>1</sup> the number of *in situ* cancers, particularly ductal carcinoma *in situ* (DCIS), has been on the rise. SEER data indicate that there was a 130% increase in *in situ* cancers in whites and a 190% increase in African Americans from 1983 to 1996.<sup>2</sup> It is estimated that *in situ* carcinoma was diagnosed in almost 40,000 women in the United

States in 1999.<sup>1</sup> The increase in *in situ* cancers, particularly DCIS, is largely a result of the increasing use of screening mammography.

In this chapter, we describe the salient features of breast cancer, stressing practical information of importance to clinicians and findings that are new since the last edition of this text. The increasing incidence of *in situ* cancer and the more complex management issues surrounding DCIS are reflected in an expanded section dealing with these issues. For more details about breast cancer, the interested reader is referred to a related textbook in this series devoted exclusively to diseases of the breast.<sup>3</sup>

## RISK FACTORS FOR BREAST CANCER

Multiple factors are associated with an increased risk of developing breast cancer, including increasing age, family history, exposure to female reproductive hormones (both endogenous and exogenous), dietary factors, benign breast disease, and environmental factors. The majority of these factors convey a small to moderate increase in risk for any individual woman. It has been estimated that approximately 50% of women who develop breast cancer have no identifiable risk factor beyond increasing age and female gender.<sup>4</sup> Since breast cancer is such an overwhelmingly female disease, gender is often not even considered among the risk factors. The importance of age is sometimes overlooked as well. Many women, particularly young women, overestimate their risk of developing breast cancer.<sup>5</sup> As can be seen in [Table 37.2-1](#), age plays a major role in breast cancer risk.<sup>2</sup> In women under 30, breast cancer is extremely uncommon. From 1992 to 1996, the incidence of breast cancer in women aged 35 to 39 was 59 per 100,000; however, in women 55 to 59, the incidence was 296 per 100,000. The annual incidence continues to rise, albeit more gradually, as a woman enters her 60s and 70s.

Age and Race	Breast Cancer Incidence (per 100,000)		
	All Races	White	Black
15-19	0.0	0.0	0.0
20-24	0.0	0.0	0.0
25-29	0.0	0.0	0.0
30-34	0.0	0.0	0.0
35-39	59.0	65.0	50.0
40-44	100.0	110.0	80.0
45-49	150.0	160.0	120.0
50-54	210.0	220.0	170.0
55-59	296.0	300.0	230.0
60-64	350.0	350.0	280.0
65-69	400.0	400.0	320.0
70-74	450.0	450.0	380.0
75-79	500.0	500.0	450.0
80-84	550.0	550.0	500.0
85-89	600.0	600.0	550.0
90-94	650.0	650.0	600.0
95-99	700.0	700.0	650.0

**TABLE 37.2-1.** Surveillance, Epidemiology, and End Results Incidence and Mortality Age-Specific Rates by Race from 1992 to 1996<sup>a</sup>

## FAMILIAL FACTORS

A family history of breast cancer has long been recognized as a risk factor for the disease. The majority of women diagnosed with breast cancer do not have a family member with the disease, and only 5% to 10% have a true hereditary predisposition to breast cancer.<sup>6</sup> Many women with a positive family history overestimate their risk of developing breast cancer,<sup>7</sup> and women considering genetic testing have been shown to overestimate their chance of having a mutation.<sup>8</sup> Overall, the risk of developing breast cancer is increased 1.5- to 3.0-fold if a woman has a mother or sister with breast cancer.<sup>9,10</sup> Family history, however, is a heterogeneous risk factor with different implications depending on the number of relatives with breast cancer, the exact relationship, the age at diagnosis, and the number of unaffected relatives. For example, there may be minimal elevation in breast cancer risk for a woman whose mother was diagnosed with breast cancer at an advanced age and who has no other family history of the disease. In contrast, a woman who has multiple family members diagnosed with early-onset breast cancer is at a much higher risk of developing the disease.<sup>11</sup> Even in the absence of a known inherited predisposition, women with a family history of breast cancer face some level of increased risk, likely from some combination of shared environmental exposures, unexplained genetic factors, or both. For women with a limited family history, assessment tools such as the Gail model may be helpful in providing a quantitative estimate of breast cancer risk.<sup>12</sup> Of note, the Gail model was used in the National Surgical Adjuvant Breast Project (NSABP) breast cancer prevention study with tamoxifen.

## INHERITED PREDISPOSITION TO BREAST CANCER

The identification of the two tumor suppressor genes BRCA1<sup>13</sup> and BRCA2<sup>14</sup> has provided new insights into the understanding of breast cancer genetics. When a woman has a mutation in either of these genes, she faces a markedly increased lifetime risk of developing breast cancer.<sup>15,16</sup> and <sup>17</sup> The possibility of a mutation in either BRCA1 or BRCA2 should be considered when breast cancer is diagnosed at a young age (i.e., less than 45 to 55), when multiple relatives are affected, when there is a history of other cancers in the family (particularly ovarian cancer), or any combination of these factors. Although an increased risk of ovarian cancer is seen in families with both BRCA1 and BRCA2 mutations, the presence of ovarian cancer in a family member of a woman with breast cancer is more consistent with a mutation in BRCA1.<sup>15</sup> Both BRCA1 and BRCA2 are inherited in an autosomal dominant manner and can be passed to offspring through either maternal or paternal lineage. A number of models have been developed to help clinicians estimate the chance of identifying a gene mutation.<sup>18,19</sup>

In 1990, chromosome 17q21 was identified as the likely location for a breast cancer susceptibility gene.<sup>20</sup> The BRCA1 gene was ultimately cloned in 1994.<sup>13</sup> Mutations in BRCA1 are associated with a 50% to 85% risk of developing breast cancer during a woman's lifetime, with a particularly striking predisposition to early-onset breast cancer.<sup>21,22</sup> The risk of ovarian cancer is elevated, though not to the same extent as breast cancer. Nevertheless, the presence of both early-onset breast cancer and ovarian cancer in either a single individual or within a family is highly suggestive of a BRCA1 mutation. Men with BRCA1 mutations do not appear to be at increased risk of breast cancer, but are probably at increased risk of prostate cancer and possibly of colon cancer.<sup>23</sup> The BRCA1 gene is large, with 24 coding regions and 1863 amino acids; hundreds of mutations have been described throughout the gene. As a result, screening for a mutation in BRCA1 is costly and time consuming. Polymorphisms in the gene are not uncommon and probably do not convey an elevated cancer risk.

BRCA2 is located on chromosome 13 and is an even larger gene than BRCA1.<sup>14</sup> Women with BRCA2 mutations are thought to be at a similar risk of developing breast cancer as those with BRCA1 mutations.<sup>16,24</sup> There is an increased risk of ovarian cancer in women with BRCA2 mutations, although to a lesser degree than with BRCA1. Men with BRCA2 mutations develop breast cancer with a lifetime incidence that is estimated to be 6%.<sup>25</sup> In addition, there are a variety of other cancers that appear to be associated with BRCA2; however, studies to date remain limited.

In the general population, it is estimated that between 1 in 500 and 1 in 800 individuals carry a BRCA1 mutation. BRCA2 mutations are even less common.<sup>26</sup> In contrast, mutations in either BRCA1 or BRCA2 occur in approximately 1 in 40 individuals of Ashkenazi Jewish background.<sup>22</sup> Within this population, three founder mutations (185delAG and 5382 insC in BRCA1 and 6174delT in BRCA2) appear to have been passed on for generations. Because of the higher gene frequency in individuals of Ashkenazi descent, the chance of finding a mutation in an Ashkenazi Jewish woman with a personal history, family history, or both of breast cancer, ovarian cancer, or both is much higher than in a non-Ashkenazi. Because of the high frequency of the founder mutations in this group of individuals, genetic testing can begin with an assessment for the presence of the three mutations. In Ashkenazi Jewish women diagnosed with breast cancer at age 40 or earlier, it has been estimated that 20% or more have a mutation.<sup>27</sup>

Genetic testing should be preceded by a careful evaluation of an individual's personal cancer history and family history. The implications of genetic testing for both the individual and the extended family are considerable, and these issues should be addressed in genetic counseling session(s) before any testing. A more extensive discussion of this issue is found elsewhere in this text.

There are many unanswered questions about both BRCA1 and BRCA2. Since the genes are large and mutations can be highly variable in location, an important issue is whether all mutations convey the same level of risk. It is unknown to what extent breast cancer risk is modified by other genes, hormonal factors, or environmental exposures. For example, preliminary reports have suggested that early pregnancy is not protective,<sup>28</sup> although oophorectomy appears to lower breast cancer risk.<sup>29</sup> For women with mutations who have not developed breast cancer, a variety of strategies have been considered to lower risk and are described later, in [Breast Cancer](#)

## Prevention.

Women with BRCA1-associated breast cancers are thought to have a high proportion of high-grade, hormone receptor–negative cancers, although it is not clear that their overall outcome is different from that of women with sporadic breast cancer.<sup>30,31</sup> and<sup>32</sup> The tumors in women with BRCA2 mutations do not appear to have distinctive features and bear a closer resemblance to sporadic breast cancer.<sup>32</sup> At this time, it is not known whether a woman's genetic status should influence management decisions when breast cancer is diagnosed. Women with mutations have a higher risk of developing contralateral cancers, but their clinical course has otherwise not been shown to be different from other women with breast cancer.<sup>31</sup> For this reason, there are insufficient data to indicate that either local or systemic management of the patient with a mutation should differ from what is the standard of care based on stage, tumor grade, receptor status, and general health status.

Breast cancer is also observed as part of other familial syndromes, including Li-Fraumeni syndrome,<sup>33</sup> Cowden syndrome,<sup>34</sup> Muir syndrome,<sup>35</sup> and ataxia-telangiectasia.<sup>36</sup>

## HORMONAL FACTORS

The development of breast cancer in many women appears to be related to female reproductive hormones. Epidemiologic studies have consistently identified a number of breast cancer risk factors, each of which is associated with increased exposure to endogenous estrogens. Early age at menarche, nulliparity or late age at first full-term pregnancy, and late age at menopause increase the risk of developing breast cancer.<sup>12,37</sup> In postmenopausal women, obesity<sup>38</sup> and postmenopausal hormone therapy,<sup>39</sup> both of which are positively correlated with plasma estrogen levels and plasma estradiol levels,<sup>40,41</sup> are associated with increased breast cancer risk. Furthermore, *in utero* exposure to high concentrations of estrogen may also increase breast cancer risk.<sup>42,43</sup>

The age-specific incidence of breast cancer increases steeply with age until menopause. After menopause, although the incidence continues to increase, the rate of increase decreases to approximately one-sixth of that seen in the premenopausal period. This dramatic slowing of the rate of increase in the age-specific incidence curve suggests that ovarian activity plays a major role in the etiology of breast cancer. The relative risk of developing breast cancer for a woman with natural menopause before age 45 is one-half that of a woman whose menopause occurs after age 55.<sup>44</sup> There is substantial evidence that estrogen deprivation via iatrogenic premature menopause can reduce breast cancer risk. Epidemiologic studies have shown that premenopausal women who undergo oophorectomy without hormone replacement have a markedly reduced risk of breast cancer later in life. Oophorectomy before age 50 decreases breast cancer risk, with an increasing magnitude of risk reduction as the age at oophorectomy decreases.<sup>45</sup> In a small study of women undergoing ovarian ablation as part of adjuvant breast cancer treatment, contralateral breast cancer rates were reduced compared with women not undergoing ovarian ablation.<sup>46</sup> Recent data from women with BRCA1 mutations suggest that early oophorectomy has a substantial protective effect on breast cancer risk in this population as well.<sup>29</sup>

Age at menarche and the establishment of regular ovulatory cycles are strongly linked to breast cancer risk.<sup>47,48</sup> Earlier age at menarche is associated with an increased risk of breast cancer<sup>48</sup>; there appears to be a 20% decrease in breast cancer risk for each year that menarche is delayed.<sup>47</sup> Of note, hormone levels through the reproductive years in women who experience early menarche may be higher than in women who undergo a later menarche.<sup>49</sup> Additionally, late onset of menarche results in a delay in the establishment of regular ovulatory cycles, although there is some controversy over whether this delay confers any additional protective effect.<sup>50,51</sup> From these data regarding menarche and menopause, it seems likely that the total duration of exposure to endogenous estrogen is an important factor in breast cancer risk.

The relationship between pregnancy and breast cancer risk appears more complicated. Age at first full-term pregnancy clearly influences breast cancer risk. Based on epidemiologic studies, women whose first full-term pregnancy occurs after age 30 have a two- to fivefold increase in breast cancer risk in comparison with women who have a first full-term pregnancy before approximately age 18.<sup>52,53</sup> Nulliparous women are at greater risk for the development of breast cancer than parous women, with a relative risk of about 1.4.<sup>52</sup> During pregnancy, mammary cells differentiate into mature breast cells prepared for lactation. After this differentiation, these cells have a longer cell cycle, allowing more time for DNA repair in G<sub>1</sub>.<sup>54</sup> Breast cancer risk increases transiently after a pregnancy.<sup>55</sup> The increased risk, which lasts approximately 10 years, is then associated with a more durable protective effect.<sup>55,56</sup> The reason for the increased risk has been hypothesized to be the increase in proliferation, growth, and maturation of breast cells preparing for lactation, leading to the development of mutations. Alternatively, risk may increase secondary to the effect of high levels of hormones on subclinical cancers.

Studies of lactation on breast cancer risk have had inconsistent results. Studies have suggested that a long duration of lactation reduces breast cancer risk in premenopausal women.<sup>57,58</sup>

The effect of abortion, whether spontaneous or induced, on breast cancer risk is less clear. Several studies have found that termination of a pregnancy not only negates any protective effect, but, in fact, increases breast cancer risk.<sup>59</sup> More recent studies, including a large population-based cohort comprised of 1.5 million Danish women,<sup>60</sup> show no increase in long-term risk after early termination of a pregnancy.<sup>61,62</sup> These apparently contradictory effects of pregnancy on risk have been explained in a variety of ways. As breast tissue undergoes differentiation as a result of hormonal changes of a full-term pregnancy, these fully differentiated cells may be less likely to undergo malignant transformation. In incomplete pregnancy, the breast is exposed only to the high estrogen levels of early pregnancy. These unopposed high levels theoretically could be responsible for an increased risk in women who do not carry the pregnancy to term and thus do not experience the full mammary differentiation in preparation for lactation. Despite these theoretical arguments, at this time there is no *conclusive* evidence that early termination of a pregnancy has any effect on breast cancer risk.

The effects of exogenous hormones, in the form of hormone replacement therapy and oral contraceptives, on breast cancer risk have been studied extensively. Metaanalyses of the effect of hormone replacement therapy demonstrate small, but statistically significant, increases in risk (relative risks, 1.02 to 1.35) for users.<sup>35,63,64</sup> Risk appears to increase with current use and duration of use. This finding is consistent with studies demonstrating that postmenopausal women with higher concentrations of endogenous estrogen levels have a greater risk of developing breast cancer than women with lower estrogen levels.<sup>40,41</sup> More recent studies have found statistically significant increases in risk in women taking both estrogen and progestin compared with those taking estrogen alone for hormone replacement.<sup>65,66</sup> It is of interest that several more recent studies suggest that breast cancer arising in women on hormone replacement therapy may be histologically more favorable.<sup>67,68</sup> Furthermore, the increased risk of breast cancer appears to be reduced after cessation of hormone replacement therapy and may actually disappear after approximately 5 years.<sup>68</sup>

Overall, there is no convincing evidence of a significantly increased risk of breast cancer in women who have used oral contraceptives.<sup>69,70</sup> Some studies suggest that a slightly increased risk of breast cancer is seen in women who are younger than 35 and who use oral contraceptives, possibly related to duration and/or recency of use.<sup>69,71</sup> Studies of subsets of patients, including those with a family history of breast cancer or a history of benign breast disease, have not produced consistent findings.<sup>72</sup>

## LIFESTYLE AND DIETARY FACTORS

A possible relationship between breast cancer and diet has been suggested by the large international variation in breast cancer incidence rates. Studies of immigrant groups suggest that these differences are not due solely to genetic factors.<sup>73,74</sup> Japanese women immigrating to the United States and first-generation American-born Japanese women were found to have an incidence of breast cancer almost equal to that of whites in the same area and considerably higher than that of women in Japan.<sup>74</sup> Because national per capita fat consumption correlates with incidence and mortality from breast cancer, many investigators have sought to determine the relationship between fat intake and breast cancer risk. Kinlen compared breast cancer rates of nuns who ate no or very little meat with single British women who ate regular diets and observed no differences.<sup>75</sup> Breast cancer mortality among Seventh Day Adventists, a group that adheres to a diet low in animal fats, is not significantly lower than expected when compared with the general population.<sup>76</sup> A pooled analysis of seven prospective cohort studies involving 337,819 women demonstrated no difference in breast cancer risk between women in the highest and lowest quintile of fat intake.<sup>77</sup> Furthermore, this study and other more recent studies have also been unable to detect any relation between risk of breast cancer and consumption of specific types of fats.<sup>77,78</sup> and<sup>79</sup> Thus, over the range of fat intake seen in western societies, there is no apparent association between breast cancer risk and fat intake in adults. Any effect of fat intake during childhood or adolescence, however, cannot be ruled out based on available data.

Examination of the relationship between energy balance and breast cancer has been more revealing. Data have been consistent for a positive association between

birth weight and breast cancer.<sup>43,80</sup> Most case-control and cohort studies of attained height, a variable highly correlated with age at menarche, and risk of breast cancer suggest a positive relationship.<sup>81</sup> Although being overweight during early adult life has been associated with a lower incidence of premenopausal breast cancer,<sup>38,82</sup> weight gain after age 18 is associated with a significantly increased risk in postmenopausal breast cancer.<sup>38,83</sup> The protection conferred by increased weight early in life is thought to be secondary to increased irregularity of menstrual cycles in these women, suggesting their exposure to endogenous estrogens is decreased.<sup>84</sup> The increased risk with weight gain in later adult life has been explained by increased estrogen levels in these women secondary to increased production in adipose tissue.<sup>38</sup>

These findings are also consistent with the possible influence of physical activity on breast cancer risk. A premenopausal woman's level of physical activity, even if moderate, can have an effect on the likelihood of ovulatory cycles and, for this reason, may alter breast cancer risk.<sup>85,86</sup> Furthermore, physical activity influences body fat stores, the principal source of estrogen in postmenopausal women.

Multiple studies suggest a positive association between alcohol intake and breast cancer risk. A large metaanalysis demonstrated a relative risk of 1.1 for one drink per day, 1.2 for two drinks per day, and 1.4 for three drinks per day.<sup>87</sup> Additional data from prospective studies confirm this increase in risk.<sup>88</sup> The effect of alcohol intake, which is associated with increased estrogen levels, appears to be mitigated by high folic acid intake.<sup>89</sup>

Many investigators have examined the effects of specific dietary components on breast cancer risk. Despite the lack of evidence that fiber or individual vitamins and minerals confer any significant protective effect, it appears that a diet high in fruits and vegetables may decrease breast cancer risk.<sup>90,91</sup>

## BENIGN BREAST DISEASE

Benign breast lesions are classified as proliferative or nonproliferative. Nonproliferative disease is not associated with an increased risk of breast cancer, whereas proliferative disease without atypia results in a small increase in risk (relative risk, 1.5 to 2.0). Atypical hyperplasia is associated with a greater risk of cancer development (relative risk, 4.0 to 5.0).<sup>92</sup>

Dupont and Page found a marked interaction between atypia and a family history of a first-degree relative with breast cancer.<sup>92</sup> This subgroup of patients had a risk 11-fold that of women with nonproliferative breast disease. The absolute risk of breast cancer development in women with a positive family history and atypical hyperplasia was 20% at 15 years, compared with 8% in women with atypical hyperplasia and a negative family history of breast carcinoma. Proliferative breast disease appears to be more common in women with a significant family history of breast cancer than in controls, further supporting its significance as a risk factor.<sup>94</sup> Of note, however, the majority of breast biopsies done for clinical indications demonstrate nonproliferative disease. In Dupont and Page's study of 10,000 breast biopsies, 69% had nonproliferative changes and only 3.6% demonstrated atypical hyperplasia.<sup>92</sup> No increased risk of breast cancer development has been observed in women with a diagnosis of proliferative disease who have used estrogens after breast biopsies.<sup>93</sup>

## ENVIRONMENTAL FACTORS

Exposure to ionizing radiation, either secondary to nuclear explosion or medical diagnostic and therapeutic procedures, increases breast cancer risk. Because of the long latency period for radiation-induced breast cancers, in addition to the increased sensitivity to mutagenic damage in a developing breast, radiation exposure after age 40 produces a minimal increase in risk, while exposure early in life carries the greatest risk. A markedly increased risk of breast cancer development has been reported in women who received mantle irradiation for the treatment of Hodgkin's disease before age 15.<sup>95</sup> Other environmental factors, including exposure to electromagnetic fields and organochlorine pesticides, have been suggested to increase breast cancer risk, but further data are needed before drawing firm conclusions.

## MANAGEMENT OF THE HIGH-RISK PATIENT

A woman's risk of developing breast cancer is influenced by a range of factors. There is no formal definition of what constitutes *high risk*. Without question, women who carry mutations in either BRCA1 or 2 or who have a family history consistent with genetically transmitted breast cancer are considered to be at higher risk than those in the general population.<sup>6,22</sup> A second and much less common group of high-risk women consists of those individuals who have received mantle irradiation, usually for treatment of Hodgkin's disease.<sup>95,96</sup> Women with lobular carcinoma *in situ* (LCIS) or atypical hyperplasia on breast biopsy are also considered high risk. Although a variety of hormonal factors (e.g., early menarche, late age at first full-term pregnancy) affect breast cancer risk on a population basis, these conditions have a relatively small effect on risk for any individual woman.

In approaching women concerned about breast cancer risk, it is important to recognize that many women overestimate their risk of developing breast cancer.<sup>7,97</sup> In one study, respondents overestimated their probability of dying from breast cancer within 10 years by more than 20-fold.<sup>97</sup> A number of studies have demonstrated that overestimation of risk is associated with psychological morbidity and, in some cases, avoidance of proven screening measures.<sup>98,99</sup> Providing women with an accurate assessment of breast cancer risk may have a number of benefits, including allaying anxiety and facilitating treatment decisions<sup>100</sup> (Table 37.2-2).

---

Enhanced understanding of actual risk
Improved medical decision-making regarding:
Hormone replacement therapy after menopause
Mammography in women aged 40-49
Tamoxifen therapy to lower breast cancer risk
Prophylactic mastectomy
Possible psychological benefit of accurate risk perception

**TABLE 37.2-2.** Potential Benefits of Breast Cancer Risk Assessment

The first step in determining a woman's risk of developing breast cancer is to take a thorough history, evaluating for the presence of known risk factors. Of these, family history, age, and the presence of a premalignant lesion on previous breast biopsy are probably the most significant. Because of the substantially higher risk of identifying a BRCA1 or BRCA2 mutation in women of Ashkenazi Jewish descent, ethnic background should also be established. It can be helpful to provide women who are concerned about their breast cancer risk with a numeric risk estimate. A number of models for risk assessment are available, of which the Gail model<sup>14,101</sup> and a model developed by Claus and colleagues from the Cancer and Steroid Hormone Study<sup>11</sup> are the most frequently used. The Gail model, which calculates a woman's risk of developing breast cancer based on age at menarche, age at first live birth, number of previous breast biopsies, the presence or absence of atypical hyperplasia, and the number of first-degree female relatives with breast cancer, has been used in the NSABP breast cancer prevention trials. Efforts to validate the Gail model in different settings have produced variable results. In the Nurses' Health Study cohort, the Gail model was found to overestimate breast cancer risk,<sup>102</sup> although, in other settings, it has proven to be more accurate.<sup>103</sup> In the NSABP prevention trial, the Gail model performed extremely well, with a ratio of observed to predicted cancers in study participants of 1.03 (95% confidence interval, 0.88 to 1.22).<sup>104</sup> In general, the Gail model is thought to underestimate risk in women with strong family histories, at least in part because it only incorporates a family history in first-degree relatives. The Claus model, on the other hand, takes into account both first- and second-degree relatives, although it does not include other risk factors. Not surprisingly, the numeric assessments produced by different models may produce discordant estimates.<sup>105</sup> The widespread use of the Gail model as part of the NSABP prevention trials has led to its general acceptance in clinical practice. In communicating model-based estimates to high-risk women, the limitations of these models should be emphasized. Clinicians should also be aware that women who are anxious about their breast cancer risk may continue to overestimate their risk of developing the disease even after receiving individualized counseling.<sup>7</sup>

Although there is extensive literature on breast cancer screening in the general population, there are few data available on which to base screening recommendations in women with inherited susceptibility genes or other factors that markedly increase breast cancer risk. For high-risk women over the age of 40, annual mammography is recommended.<sup>106</sup> The area of greatest controversy is in screening women under the age of 40. An expert panel has recommended that women with an inherited susceptibility gene should perform monthly breast self-examinations, undergo a clinical breast examination once or twice a year, and have annual mammograms beginning between the ages of 25 and 35.<sup>107</sup> The role of more frequent mammograms (i.e., twice annually), digital mammography, or magnetic resonance imaging (MRI) is uncertain. Ongoing studies are addressing these issues.

## BREAST CANCER PREVENTION

The identification of risk factors associated with the development of breast cancer has led to an effort to prevent breast cancer in women at increased risk. Numerous strategies have been considered, including risk factor modification, lifestyle alteration, drug therapy, and prophylactic surgery. Only preliminary evidence suggests that behavioral approaches can be used to alter breast cancer risk,<sup>86,108</sup> and, unfortunately, most of the known risk factors for breast cancer are not easily modifiable. Few women would be willing to modify the age at which they have a first pregnancy in an effort to lower breast cancer risk. While early menopause may be associated with lower breast cancer risk, there are adverse psychological and physical consequences of premature menopause. Some investigators have attempted to alter a woman's natural hormonal milieu to lower breast cancer risk, and it is possible that such approaches might have future promise.<sup>109</sup> To date, however, most efforts to lower a woman's risk of developing breast cancer have focused on pharmacologic interventions.

## SELECTIVE ESTROGEN RECEPTOR MODULATORS

Adjuvant trials of tamoxifen have demonstrated clear reductions in the development of contralateral breast cancers in women treated with tamoxifen.<sup>110</sup> These data, as well as preclinical evidence supporting a role for tamoxifen in breast cancer prevention,<sup>111,112</sup> led to the development of the NSABP's Breast Cancer Prevention Trial and to various studies in Europe.

The NSABP trial, known as P-1, randomized over 13,000 patients to either tamoxifen for 5 years or to a placebo.<sup>113</sup> To be eligible, women 35 years of age or older had to have at least a 1.66% chance of developing breast cancer over the ensuing 5 years based on the Gail model. Because of the elevated risk associated with age, any woman over the age of 60 was eligible for the trial. Overall, women randomized to 5 years of tamoxifen experienced a 49% decrease in invasive breast cancer, with similar risk reduction seen in women both younger than 50 and older than 50. The benefits of tamoxifen were seen across all patient subgroups (Table 37.2-3) and were highly statistically significant. Despite the high level of statistical significance, the absolute benefit from tamoxifen is of relatively small magnitude, even if one also considers the cases of DCIS prevented by tamoxifen (69 cases in the placebo arm and 35 in women on tamoxifen). To date, the benefit seen with tamoxifen only applies to the prevention of estrogen receptor (ER)-positive cancers; in P-1, there was no reduction in the risk of ER-negative cancers. While there is reason to believe that the beneficial effects of tamoxifen may extend beyond 5 years,<sup>110</sup> it is unknown to what degree a 5-year course of tamoxifen affects a woman's lifetime risk of developing breast cancer.

	Placebo		Tamoxifen		RR Ratio (95% Confidence Interval)
	% of Cases	Annual Rate per 100 Women	% of Cases	Annual Rate per 100 Women	
All women (n = 13,000)	27	4.76	14	3.41	0.72 (0.54-0.96)
Women younger than 50 (n = 5,277)	10	4.79	5	3.77	0.79 (0.57-1.09)
Women 50 to 59 (n = 4,941)	10	4.28	5	3.31	0.77 (0.54-1.10)
Women 60 or older (n = 2,782)	7	7.73	4	5.33	0.69 (0.47-1.03)
Women with history of lobular carcinoma in situ (n = 125)	10	12.80	1	3.60	0.28 (0.10-0.80)
Women with history of atypical hyperplasia (n = 138)	25	18.11	7	5.07	0.28 (0.10-0.80)

TABLE 37.2-3. Incidence of Invasive Breast Cancer in Women Participating in P-1

The benefits associated with tamoxifen must also be balanced against the potential risks, in terms of both serious toxicities and adverse consequences with respect to quality of life.<sup>113,114</sup> Increases in both endometrial cancer and thromboembolic events were seen in women on tamoxifen, although more commonly in older women (50 and older) than their younger counterparts. Based on these findings, it is thought that tamoxifen may be most beneficial in younger women with an elevated risk of developing breast cancer.<sup>115</sup>

The findings from NSABP P-1 must also be considered in light of two European studies evaluating tamoxifen.<sup>116,117</sup> Both the Royal Marsden Hospital chemoprevention trial and the Italian prevention trial failed to demonstrate a protective effect of tamoxifen. The studies were considerably smaller than P-1 (2494 in the Royal Marsden trial and a total of 5408 in the Italian), and a number of explanations have been offered to explain the negative results. The Royal Marsden trial, for example, may have included a substantial number of women from families with BRCA1 and BRCA2 mutations, and the Italian study results could have been compromised by poor compliance with the study medication. Nevertheless, the European findings provide a sobering counterpoint to the P-1 study. These results, as well as recognition of the limitations of what has been learned from P-1, underscore the need for further research in this area. At present, the need to individualize decision making about tamoxifen in the prevention setting cannot be overemphasized.

Raloxifene, another selective ER modulator, has also been shown to lower the risk of developing invasive breast cancer. In a randomized trial in postmenopausal women with osteoporosis, two doses of raloxifene (60 or 120 mg) were compared with placebo. Treatment with raloxifene not only led to an improvement in bone density and fracture risk, but also appeared to prevent breast cancer.<sup>118,119</sup> Among 5129 women randomized to raloxifene, there were a total of 13 cases of breast cancer, compared with 27 cases among 2576 who were assigned to placebo (relative risk, 0.24; 95% confidence interval, 0.13 to 0.44). Like tamoxifen, raloxifene increased the risk of thromboembolic disease (relative risk, 3.1; 95% confidence interval, 1.5 to 6.2) but did not appear to increase the risk of endometrial cancer. The follow-up of patients on the trial was relatively short (median, 40 months), and women participating in the trial were generally not at increased risk of developing breast cancer (apart from the increased risk associated with increasing age). The NSABP is now conducting a second-generation prevention trial (P-2) in which tamoxifen and raloxifene are being compared directly in postmenopausal women who are at increased risk of developing breast cancer. Until the results of that trial or additional data are available, the routine use of raloxifene to lower a woman's risk of developing breast cancer cannot be recommended.<sup>120,121</sup>

## OTHER PHARMACOLOGIC AGENTS TO LOWER BREAST CANCER RISK

Ongoing trials are evaluating a wide range of other agents to lower a woman's risk of developing breast cancer. A randomized Italian study indicated that fenretinide, a differentiating agent in the retinoid family, lowers the risk of contralateral cancers.<sup>122</sup> Unfortunately, symptomatic nyctalopia is a problem for approximately 10% of patients taking this agent.<sup>123</sup> A U.S. Intergroup trial comparing tamoxifen plus placebo versus tamoxifen plus N-(4-hydroxyphenyl) Retinamide was stopped prematurely, making it unlikely that there will be a definitive answer as to whether N-(4-hydroxyphenyl) Retinamide plays a role in a woman's risk of developing breast cancer. Trials involving other differentiating agents, aromatase inhibitors, and vaccines are ongoing, but it is unlikely that there will be any commercially available agent to lower breast cancer risk in the next several years.

## PROPHYLACTIC MASTECTOMY

For years it has been assumed that prophylactic mastectomy would lower a woman's risk of developing breast cancer. Since a small amount of breast tissue remains following mastectomy, the level of protection was debated. In a retrospective but rigorously conducted analysis at the Mayo Clinic, Hartmann et al. have demonstrated a 90% reduction in breast cancer risk as a result of prophylactic mastectomy.<sup>124</sup> Most women and their physicians consider prophylactic mastectomy to be an extreme procedure<sup>125</sup>; however, for certain high-risk women, such as those with an inherited genetic predisposition, it is currently an option. Modeling studies have

demonstrated that prophylactic mastectomy in women with BRCA1 mutations may result in a modest improvement in survival.<sup>126,127</sup> The decision to proceed with prophylactic surgery should be considered carefully. Unlike many other choices that high-risk women may face, this is one that is irreversible and should not be made without carefully considering all the available options. Women who are considering prophylactic mastectomy with reconstruction should also recognize the potential short- and long-term complications associated with breast reconstruction (see [Breast Reconstruction](#), later in this chapter).

## BIOPSY TECHNIQUES FOR SUSPICIOUS BREAST LESIONS

In this section, the various techniques employed to biopsy suspicious palpable and mammographic breast lesions are described. The major techniques used to diagnose palpable breast masses are fine-needle aspiration (FNA), core-cutting needle biopsy, and excisional biopsy. (Incisional biopsy is occasionally used to diagnose large breast masses, but this technique has largely been replaced by the less invasive aspiration or core biopsy.) The advantages and disadvantages of the three techniques are listed in [Table 37.2-4](#). Both FNA and core biopsy are office procedures. Excisional biopsy, with rare exceptions, is an outpatient procedure that can be done using local anesthesia.

Technique	Advantages	Disadvantages
Fine-needle aspiration cytology	Rapid, painless, inexpensive; no incision before selection of local therapy	Will not distinguish in situ from invasive cancer; no histologic detail; false-negative results and insufficient specimens occur; requires experienced cytopathologist
Core biopsy	Rapid, painless, inexpensive; no incision; can be read by any pathologist	False-negative results and incomplete characterization of the lesion can occur
Excisional biopsy	Complete histology before treatment decision; avoids false-negative results and insufficient samples; may serve as definitive therapy	Expensive, more painful, and can be evident cosmetically; excision or incision to be incorporated into definitive surgery

**TABLE 37.2-4.** Biopsy Techniques for Palpable Masses

The main issue surrounding the use of FNA is the risk of false-negative results. Large series of FNA have demonstrated a sensitivity of 87%, an incidence of insufficient specimens ranging from 4% to 13%, and a false-negative rate of 4.0% to 9.6%.<sup>128,129</sup> and <sup>130</sup> Fibrotic tumors, infiltrating lobular, tubular, and cribriform histologies, and physician inexperience have all been found to be sources of false-negative aspirate results.<sup>128,131,132</sup> False-positive aspirates are extremely uncommon and are reported in fewer than 1% of cases in most large series.<sup>128,129,130,131</sup> and <sup>132</sup> FNA does not, however, reliably distinguish invasive cancer from DCIS, potentially leading to the overtreatment of gross DCIS.

Core-cutting needle biopsy has many of the advantages of FNA, in addition to which it provides histologic details of the lesion. The accuracy of core biopsy is similar to that reported for FNA, with sensitivities of 79% to 94%.<sup>133,134</sup> Shabot et al.<sup>135</sup> prospectively compared the diagnostic accuracy of FNA and core-cutting needle biopsy in 81 women. The accuracy of FNA was 96%, compared with 79% for the core-cutting needle technique. No false-positive results were observed in any of these reports.<sup>133,134</sup> and <sup>135</sup>

Excisional biopsy has been the standard technique used in diagnosing breast masses. This method affords the physician complete evaluation of tumor size and histologic characteristics before selecting definitive local therapy. When an excisional biopsy is performed, an attempt should be made to remove a small margin of grossly normal tissue around the tumor. Kearney and Morrow<sup>136</sup> used such an approach in 239 patients with cancer and obtained negative margins in 95% of cases, thus avoiding the need for a reexcision as part of definitive breast-conserving therapy. Proper specimen handling with inking of the margins facilitates this approach. There is no evidence that a one-step procedure (i.e., biopsy under general anesthesia followed by definitive surgery if positive) is associated with any survival benefit compared with biopsy followed by definitive surgery at a later time.

Until relatively recently, nonpalpable, mammographically detected lesions have been routinely approached by needle-localized excisional biopsy. The most important factor in the success of this approach is how close the localizing needle is placed to the mammographic abnormality. Gallagher et al.<sup>137</sup> reported wire placement to within 2 mm of the target in 96% of cases, allowing excision with a median specimen volume of 6.0 cm, and 96% of the lesions were removed with a single specimen. Specimen radiography is an essential part of the biopsy procedure done for microcalcifications in order to confirm that the calcifications are present in the biopsy specimen. Although nonpalpable masses can frequently be identified grossly at the time of biopsy, specimen radiography is also useful to ensure that the gross lesion corresponds to the mammographic abnormality. Failure to excise the mammographic lesion is reported in fewer than 5% of cases in most modern series.<sup>138,139</sup> and <sup>140</sup> When this occurs, persistence of the lesion on mammogram should be confirmed and repeat biopsy undertaken.

Frozen section is generally reliable in the diagnosis of palpable breast masses, but indications for its use in the evaluation of nonpalpable breast lesions are limited. The abnormalities being sought by needle-localization biopsy are usually small and are often histologically borderline and difficult to diagnose on frozen section. Sacchini et al.<sup>141</sup> noted a discordance rate of 12% between the frozen-section diagnosis and the final histologic diagnosis in a study of 403 nonpalpable lesions. Errors in distinguishing atypical hyperplasia from DCIS accounted for most of the discrepancies. Tinnemans et al.<sup>142</sup> had two false-positive results in a series of 297 nonpalpable lesions diagnosed by frozen section, as well as a 3% incidence of false-negative results. Because needle-localization biopsy is rarely undertaken with a plan to proceed to definitive therapy at the same operation, a careful examination of the entire lesion with paraffin sections is generally the more prudent course.

An alternative approach to the diagnosis of nonpalpable abnormalities is the image-guided breast biopsy, using either stereotactic mammography or ultrasound to guide needle placement. The choice of technique is dependent on the visibility of the lesion. In general, ultrasound guidance is more rapid and does not require breast compression, making it better tolerated. Stereotactic guidance is reserved for lesions not visualized on ultrasound.

A review of seven series comparing stereotactic core biopsies with surgical excision demonstrates sensitivities ranging from 71% to 100% for the core-biopsy technique in a selected group of patients.<sup>143</sup> In a series in which core biopsy was performed using automated 14-gauge biopsy devices, sensitivities of 92% to 100% were reported, and insufficient specimens were rare.<sup>144</sup> Extensive experience has been gained with these techniques, and a number of indications for surgical biopsy after core biopsy have been identified. These include lack of concordance between the radiographic finding and the histologic diagnosis, a diagnosis of radial scar, or atypical hyperplasia.<sup>145</sup> Atypical hyperplasia on a core biopsy is associated with DCIS in 30% to 50% of cases,<sup>145,146,147</sup> and <sup>148</sup> while radial scar may be difficult to distinguish from a well-differentiated carcinoma that has elicited a fibrous reaction.

For mammographic abnormalities that are benign, core biopsy is clearly less traumatic and more cost effective than needle localization and excision. For highly suspicious abnormalities (BI-RADS 5), the benefits are less clear. Two studies have demonstrated that, for experienced surgeons, the likelihood of obtaining negative margins with a single operative procedure for excision of nonpalpable abnormalities is the same whether or not a core-biopsy diagnosis of carcinoma is obtained before surgery.<sup>148,149</sup> However, Morrow et al.<sup>148</sup> prospectively evaluated the number of operations needed to complete local therapy in 409 patients with nonpalpable cancer approached initially with core biopsy or needle localization and excision. Core biopsy reduced the number of operations for all types of lesions except when patients were treated by lumpectomy alone. This suggests that for small calcified lesions with a high likelihood of being pure DCIS, surgical excision may remain the diagnostic procedure of choice.

## DUCTAL CARCINOMA IN SITU

DCIS, also known as *intraductal carcinoma*, is an entity distinct in both its clinical presentation and its biologic potential from LCIS, the other lesion classified as noninvasive carcinoma. The widespread use of screening mammography has resulted in a significant increase in the detection rate of DCIS, and the acceptance of breast-conserving therapy for the treatment of invasive carcinoma has led to changes in the management of women with DCIS. Uncertainty exists as to the proportion of women with mammographically detected DCIS who will develop invasive carcinoma during their lifetimes. This has led to a debate regarding whether all DCIS

should be treated as early-stage carcinoma with either mastectomy or lumpectomy and irradiation, or whether some DCIS can be excised and observed.

An abnormal mammographic report of clustered microcalcifications is currently the most common presentation of DCIS. DCIS can also present as a mass or pathologic nipple discharge, or can be identified as an incidental finding in a breast biopsy. In many reports of mammographically directed biopsies, DCIS accounts for one-half or more of the malignancies identified.<sup>140,150</sup>

The widespread use of screening mammography has resulted in a remarkable increase in the incidence (or detection rate) of DCIS.<sup>151</sup> This increase in the incidence of DCIS has been observed in women both younger than and older than 50 years of age, and in both white and African American women. This dramatic increase in the number of DCIS cases has led some authors to suggest that screening results in the detection of biologically indolent DCIS that is unlikely to become clinically significant during a woman's lifetime. The findings that patients with lesions detected by screening have a higher frequency of grade 3 lesions than patients with lesions not detected by screening<sup>152</sup> and that the risk factors for DCIS and invasive carcinoma are similar<sup>153</sup> argue against this point.

DCIS is characterized pathologically by a proliferation of presumably malignant epithelial cells within the mammary ductal-lobular system, without light microscopic evidence of invasion into the surrounding stroma. However, DCIS encompasses a heterogeneous group of pathologic lesions that differ in their growth pattern and cytologic features. At present, there is no universal agreement as to how best to subclassify these lesions. Proposed classification schemes for DCIS have variously emphasized (1) architectural features or growth pattern of the neoplastic cells within the ductal-lobular system, (2) cytologic features of the neoplastic cells, and (3) cellular necrosis, singly and in combinations. The traditional system for classifying DCIS was based primarily on architectural pattern and recognized five major subtypes: comedo, cribriform, micropapillary, papillary, and solid. DCIS is commonly subdivided into the comedo type and the noncomedo type (which encompasses the other variants). This is based on the observations that the comedo type usually appears more malignant cytologically and is more often associated with invasion<sup>154,155</sup> than are the other DCIS types. Classification systems based primarily on architecture have a number of limitations: (1) many DCIS display a mixture of patterns, (2) the correlation between architecture and nuclear grade is not very high, and (3) interobserver reproducibility in the categorization of DCIS lesions by architectural pattern is poor.<sup>156</sup> Several newer systems classify DCIS lesions primarily on the basis of nuclear grade, necrosis, or both, with architectural pattern given secondary or no consideration.<sup>156,157,158,159</sup> and <sup>160</sup> In 1997, a consensus conference was convened in an attempt to reach agreement on the classification of DCIS.<sup>161</sup> While the panel did not endorse any one system of classification, there was agreement that certain features be routinely documented in pathology reports of DCIS lesions. These include nuclear grade (low, intermediate, or high grade), the presence of necrosis (comedo or punctate), cell polarization, and architectural pattern(s).

A number of biologic markers in DCIS lesions have been evaluated. These studies have generally shown that comedo or high-grade lesions more frequently than noncomedo or low-grade lesions lack estrogen and PR,<sup>162,163</sup> and <sup>164</sup> overexpress the HER-2/*neu* (c-erbB-2) oncogene,<sup>162,163,164,165</sup> and <sup>166</sup> show mutations of the p53 tumor suppressor gene with accumulation of its protein product,<sup>162,163,164,165,166</sup> and <sup>167</sup> and demonstrate angiogenesis in the surrounding stroma.<sup>168,169</sup>

Axillary lymph node involvement in patients with mammographically detected DCIS is a rare event. In one series of 189 patients with DCIS, most of whose tumors were detected by mammography alone, none showed metastases on axillary dissection.<sup>170</sup> A National Cancer Data Base review of 10,946 patients with DCIS who had an axillary dissection between 1985 and 1991 demonstrated that only 406 (3.6%) of this group had axillary metastases.<sup>171</sup>

A frequently encountered issue related to DCIS is the identification of small foci of invasive carcinoma, so-called microinvasion. Unfortunately, this term has not been applied in a consistent, standardized manner, and the histologic diagnosis of microinvasion is not straightforward. In the 1997 edition of the *AJCC Cancer Staging Manual*,<sup>172</sup> microinvasion is defined for the first time as "the extension of cancer cells beyond the basement membrane into the adjacent tissues with no focus more than 0.1 cm in greatest dimension" and are staged as T1mic, a subset of T1 breast cancer. The staging manual further states that "when there are multiple foci of microinvasion, the size of only the largest focus is used to classify the micro-invasion" and that the size of the individual foci should not be added together. Given the problems with both the definition and pathologic diagnosis of microinvasion, the clinical significance of this lesion is controversial. The reported incidence of axillary lymph node involvement in patients given the diagnosis of microinvasion ranges from 0% to 20%.<sup>173,174,175,176,177,178</sup> and <sup>179</sup> The management of this condition is discussed in the next section, [Treatment Options](#).

## TREATMENT OPTIONS

A variety of local treatments, ranging from excision alone to mastectomy, have been proposed for DCIS. Making comparisons among retrospective reports is difficult because of differences in patient populations, lack of standardization of surgical and radiotherapeutic techniques, and changes in treatment practice over time. Mastectomy is a curative treatment for approximately 98% to 99% of patients with DCIS, whether gross or mammographic.<sup>180,181</sup> and <sup>182</sup> Of note, patients with initial biopsies that showed DCIS but who later had invasive carcinoma identified in the mastectomy specimens were excluded from these reports. Recurrences after mastectomy are almost all invasive carcinomas and may present as a chest wall or axillary recurrence or as distant metastases without evidence of local recurrence. Mastectomy is a highly effective treatment for DCIS, but it is a relatively radical approach to a lesion that may not progress to invasive carcinoma during the patient's lifetime. It also seems somewhat paradoxical that a woman with an invasive carcinoma should be able to preserve her breast, whereas the reward for screening and early detection is a mastectomy. The acceptance of breast-conserving therapy for the treatment of invasive carcinoma has led to its use also as a treatment for DCIS.

Treatment of DCIS by mastectomy has not been directly compared with treatment by excision and irradiation, and it is unlikely that such a trial will ever be done. In many cases, the assumption has been made that since these two treatments result in equivalent survival for patients with invasive carcinoma, the same will be true for patients with DCIS. This assumption is flawed, due to the difference in the risk of metastatic disease between patients with invasive carcinoma and those with DCIS. In patients with invasive carcinoma, the risk of metastatic disease is largely present at diagnosis and is not greatly altered by local recurrence in the breast. In patients with DCIS, on the other hand, the risk of metastases at diagnosis is negligible, and an invasive local recurrence carries with it the potential risk of breast cancer mortality. Therefore, the anticipated incidence of invasive recurrence and the results of salvage therapy should determine the suitability of excision and irradiation as a treatment for DCIS. A number of nonrandomized studies are available to address this issue.<sup>183,184,185,186</sup> and <sup>187</sup> Solin and associates<sup>183,184</sup> reported the results of 268 women with 271 breasts with DCIS treated with excision and irradiation at ten institutions in Europe and the United States. At a median follow-up of 10.3 years, the 15-year actuarial rate of local failure was 19%. It is noteworthy that although the local failure rate in this study was relatively high, the 15-year cause-specific survival was 96%. The methods of mammographic and pathologic evaluation and the extent of surgical resection employed in this study would probably not be considered adequate today (e.g., only 15% underwent reexcision, and margin status was unknown in 120 cases; 46%). In spite of these caveats, this study is noteworthy for the large number of patients and relatively long duration of follow-up, and the low cause-specific mortality is reassuring. An examination of the subset of patients with mammographically detected lesions from this series (n = 110) did not reveal a significantly lower rate of local failure than that seen in the group as a whole,<sup>188</sup> a finding also reported by Hiramatsu et al.<sup>185</sup>

Because one-half of the local failures seen after breast-conserving therapy for intraductal carcinoma are invasive carcinoma, the outcome of salvage treatment of these recurrences is important. In a separate report, Solin and coworkers<sup>189</sup> described 42 cases of local failure in 274 cases of DCIS treated with excision plus irradiation. The median follow-up after salvage treatment was 3.7 years. Nineteen of the recurrences (45%) were DCIS, and 14 of these were detected by mammography alone. All of the women with DCIS recurrences remain free of disease after mastectomy, with a median follow-up of 4.7 years. Five patients with invasive recurrence had developed distant metastases, either simultaneously with the recurrence (one patient) or subsequently (four patients). Chest wall recurrences were seen in three patients who had salvage mastectomy for an invasive recurrence, and all of these women developed distant metastases. Of the entire group of 42 women with recurrence, 36 patients (86%) were alive and free of disease, 4 patients (10%) died of disease, 1 patient is alive with disease, and 1 patient died of other causes. Similarly high rates of salvage have been reported in other studies<sup>190</sup>; however, the ultimate breast cancer mortality resulting from breast-conserving therapy cannot yet be assessed given the available follow-up in these studies.

A number of investigators have also examined the use of excision alone as a treatment<sup>190,191,192,193,194</sup> and <sup>195</sup> (Table 37.2-5). Patients treated with this approach are highly selected, usually on the basis of low histologic grade, small lesion size, or both. The percentage of patients with DCIS in the study population meeting these selection criteria is usually not stated, making it unclear how many women with DCIS are candidates for this type of treatment. In general, the results show rates of local recurrence that are higher than that seen with excision combined with irradiation. A 1999 publication by Silverstein et al. suggests that the rate of local recurrence will be low if there is an adequate margin of resection (defined as greater than 10 mm).<sup>194</sup> There are, however, several limitations of the study that are worth noting. First, the group of 93 patients treated by wide excision alone who had margins greater than 10 mm is highly selected. The median size of the lesion was only 9 mm, and only 23% showed comedo necrosis. The patients were cared for by a dedicated team of surgeons, radiologists, and pathologists, and the specimens were routinely handled by total sequential embedding, an ideal technique for assessing margins, but uncommonly used because of its expense. In addition, since these patients were seen more recently in the series compared with the irradiated patients, their follow-up time is shorter, estimated to be approximately 5 years as a median, with many less than 3 years. Therefore, this data set does not allow the conclusion that the full range of DCIS lesions can be managed by wide excision

alone.

Investigator	No. of Patients	Follow-Up (mo)	Recurrences	Percentage Recurrence
Arnesen and Olsen <sup>185</sup>	145	80*	25 (17%)	16
Carpenter et al. <sup>186</sup>	28	30*	5 (18%)	18
Schwartz <sup>187</sup>	191	55*	28 (14%)	15
Sherwin et al. <sup>188</sup>	156	72	38 (24%)	24
Sherwin et al. <sup>189</sup>	93 (margins >1 cm)	?	2 (2%)	—
Hendrickson et al. <sup>190</sup>	33	96	10 (30%)	30
Fisher et al. (B-17) <sup>191</sup>	818	96	109 (13%)	13

**TABLE 37.2-5.** Results of Treatment of Ductal Carcinoma *In Situ* by Excision Alone

To date, there have been two clinical trials with published results in women with DCIS randomized to excision alone or excision plus radiation therapy (RT) [190,196](#) ([Table 37.2-6](#)). Both trials involved patients with DCIS treated with an excision yielding histologically negative surgical margins defined as tumor-filled ducts not touching an inked surface. The NSABP has reported the 8-year results of trial B-17. [190](#) In this study, 818 women were randomized to excision alone or excision plus 5000 cGy of irradiation to the breast. Eighty percent of the women in the study had tumors detected by mammographic screening. At 90 months of follow-up, a persistent reduction was seen with RT. The 8-year incidence of invasive recurrence was significantly reduced from 13.4% to 3.9% by irradiation, and the incidence of recurrent DCIS was also significantly reduced from 13.4% to 8.2%. The European Organization for Research and Treatment of Cancer has reported the 4-year results of trial 10853. [196](#) In this study, 1010 women were randomized to excision alone or excision plus 5000 cGy of irradiation to the breast. Seventy-one percent of the women in the study had tumors detected by mammographic screening. With a median follow-up of 51 months, a 38% reduction in the annual incidence of ipsilateral breast recurrence was observed in the irradiated group. The 4-year incidence of invasive recurrence was significantly reduced from 8% to 4% by irradiation and the incidence of recurrent DCIS was also reduced from 8% to 5%. The overall survival is the same for the two groups, as is the incidence of distant metastases. Of note, the baseline recurrence rate with excision alone was similar in the two trials, but the reduction with RT was somewhat greater in the NSABP trial (59% reduction) compared with the European Organization for Research and Treatment of Cancer trial (38% reduction). In addition, the local benefit of RT for both DCIS trials is lower than that seen for trials of RT for invasive cancers treated by excision.

Trial	No. of Patients	Median Follow-Up (mo)	End Point	Excision (%)	Excision and Radiation Therapy (%)
National Surgical Adjuvant Breast and Bowel Project B-17 <sup>190</sup>	818	96	4-year local recurrence rate	13.4	3.9, P<0.0005
			4-year distant recurrence rate	13.4	12%, P=0.07
			4-year invasive recurrence rate	13.4	3.9%, P<0.0005
European Organization for Research and Treatment of Cancer 10853 <sup>196</sup>	1010	51	4-year local recurrence rate	8	4%, P=0.05
			4-year distant recurrence rate	8	5%, P=0.36
			4-year invasive recurrence rate	8	4%, P=0.04

**TABLE 37.2-6.** Results of Randomized Clinical Trials Testing the Value of Radiation Therapy after Excision

The identification of women at high risk of developing invasive carcinoma after breast-conserving therapy for apparently localized DCIS would be extremely helpful. The NSABP has reported the results of two analyses of the pathologic features of 623 of the 824 patients enrolled in protocol B-17. [197,198](#) In the initial report, moderate or marked comedo necrosis and uncertain or involved margins were associated with an increased risk of local failure. While radiation reduced the risk of failure in all subgroups, the absolute benefit was greatest in those patients at highest risk for recurrence. [197](#) After 8 years, an analysis of nine histologic features, including margins, histologic type, nuclear grade, tumor size, and comedo necrosis, demonstrated that only comedo necrosis significantly predicted for an increased risk of ipsilateral breast recurrence in multivariate analyses. Breast recurrence was much greater in unirradiated patients with moderate or marked comedo necrosis compared with patients with absent or slight comedo necrosis. The addition of RT eliminated most of the risk associated with this factor, with 13% of those with absent or slight comedo necrosis and 14% with moderate or marked comedo necrosis recurring after RT at 8 years. [198](#) Margin involvement was of borderline significance, but only a minority of patients had involved margins.

Several studies have suggested that age may influence the risk of local recurrence after breast-conserving therapy. Solin et al. [184](#) noted a 25% incidence of local failure in patients aged 50 or younger treated with excision and irradiation compared with 2% in patients older than 50, in spite of the fact that nuclear grade, tumor size, and margin status did not differ between groups. The median time to local failure was also shorter in the younger patients (4.9 vs. 8.7 years). Similar findings using a cutoff of 40 years was noted by Van Zee et al. and Fourquet et al. [199,200](#) Other studies have suggested that a family history of breast cancer may affect the risk of local failure after excision and irradiation. [185,186](#)

Attempts have been made to incorporate the size of the lesion, its histologic features, and the extent of the surgical excision into a prognostic index that would direct treatment selection. One such index is the Van Nuys Prognostic Index, which assigns equally weighted scores of 1, 2, or 3 for histologic type, width of the surgical margin, and size of the lesion. [201](#) Lesions with low Van Nuys Prognostic Index scores are said to be suitable for excision alone; those with intermediate scores (5 to 7) require the addition of irradiation; and those with high scores require mastectomy. While such a simplification of the decision-making process is attractive, there are a number of limitations to this index. [202](#) As noted previously, the latest information from this group now suggests that margin width is the key prognostic factor, with lesion size and histologic type much less important. [194](#) Until the Van Nuys Prognostic Index is validated, it should not substitute for an individualized assessment of the risks and benefits of the available treatment options for DCIS.

Tamoxifen has been shown to reduce the risk of both invasive and intraductal carcinoma in women at increased risk for breast cancer development [112](#) and to reduce contralateral breast cancer incidence when used as an adjuvant treatment in women with breast cancer. [203](#) The initial results of NSABP protocol B-24, in which 1804 patients with DCIS treated by lumpectomy and RT were randomized to tamoxifen (20 mg daily) or placebo for 5 years, have been reported with a mean follow-up of 62 months. [204](#) ([Table 37.2-7](#)). Overall, the risk of ipsilateral recurrence of any type (invasive or noninvasive) or of new contralateral breast cancers was reduced from 13.0% to 8.8% at 5 years, a highly significant reduction. These benefits need to be weighed against the potential risks of treatment, which are lowest in patients aged less than 50 [201](#) and those who have had a prior hysterectomy.

	Radiotherapy (RT)			Surgery (S)			Relative Risk	P Value
	No. of Events	Annual	Cumulative	No. of Events	Annual	Cumulative		
		Risk	Risk		Risk	Risk		
Recurrent invasive breast carcinoma	29	0.77	3.6	36	0.42	2.1	0.03	.04
Recurrent noninvasive breast carcinoma	42	1.12	5.2	37	0.36	1.3	0.05	.46
All breast cancer events (ipsilateral and contralateral)	71	1.89	8.8	73	0.78	3.4	0.06	.007

**TABLE 37.2-7.** Results of National Surgical Adjuvant Breast Project Protocol B-24: Addition of Tamoxifen to Lumpectomy and Radiotherapy

The available information on DCIS suggests that, although all patients can be treated with mastectomy, many are candidates for treatment with excision and irradiation, and a smaller group may be appropriately treated with excision alone. When thinking about treatment selection, it is useful to consider (1) the risk for breast cancer recurrence, (2) the risk for an invasive breast cancer, and (3) the risk for dying of breast cancer as well as the patient's perception of the risks and benefits of the treatment options. The available data on breast-conserving treatment (BCT) with irradiation generally show recurrence rates of 10% to 15% at 10 years. Approximately one-half of these recurrences are invasive carcinoma, for a 10-year risk of 5% to 7%. Assuming that the risk of dying of breast cancer is one-third or less the risk of developing an invasive cancer, the risk of breast cancer death with BCT is approximately 2% at 10 years. (If the risk of local recurrence is 5% to 10%, then the breast cancer mortality risk is reduced proportionally.) The risk for death 10 years after a mastectomy for DCIS is 1% to 2%, with nearly all breast cancer mortality seen by that time. In contrast, given the long-term risk of a breast cancer recurrence after BCT, comparisons of breast cancer mortality 30 years after treatment could show greater differences in survival between women having mastectomy and those treated with excision and RT. However, the use of tamoxifen will significantly reduce the risk of invasive recurrence. Whether RT is necessary for all patients with DCIS treated with a breast-sparing approach remains uncertain. Retrospective data indicate that highly selected patients, usually those with small, low-grade (none or slight comedo necrosis) DCIS with widely negative margins, have a low local recurrence rate after excision alone. The effect of tamoxifen on recurrence when RT is not given is uncertain, since this approach has not been directly studied in clinical trials.

While developments in molecular biology may one day allow us to predict more precisely which lesions progress to invasive carcinoma, efforts must now be directed toward minimizing local recurrence in women treated with a breast-conserving approach. The initial step in the evaluation of patients with DCIS is determination of the extent of the lesion. Because most patients with DCIS have nonpalpable mammographic lesions, careful mammographic evaluation before treatment selection is critical. The routine use of magnification views as part of the mammographic evaluation allows the detection of additional calcifications that reduce the discrepancy between the pathologic and the mammographic extent, particularly for well-differentiated DCIS. The goals of surgery are to remove all suspicious microcalcifications and to achieve negative margins of resection. Needle localization should be used to guide the biopsy, and, if the calcifications are extensive, bracketing wires are useful to aid in complete excision. Specimen mammography is essential to confirm the excision of calcifications. In cases in which calcifications are extensive or approach the edge of the surgical specimen (even when the margins are negative), postexcision mammography is useful to confirm the removal of all suspicious calcifications. It is important to recognize that, although DCIS lesions are not clinically detectable, they may be quite large. Morrow et al. found that contraindications to breast preservation were present in 33% of patients with DCIS compared with only 10% of patients with stage I invasive carcinoma.<sup>205</sup> Extensive disease, which could not be encompassed with a cosmetic resection, was the major contraindication to BCT in patients with DCIS.

A detailed pathologic evaluation is also needed and should include orientation and inking of the specimen before sectioning as well as measurement of both specimen and, if present, tumor size. Because accurate measurement of microscopic DCIS is often difficult, reporting the number of blocks in which DCIS is present and the total number of blocks is useful. If DCIS is present on only one slide, then it is useful to note its size. The correlation of microcalcifications with DCIS (i.e., calcifications noted in DCIS, calcifications in adjacent benign breast tissue, or both) and the margin status should be noted. If margins are involved, the extent of involvement should be stated, and when negative, the proximity of the lesion to the margin should be noted.

Clinical trials currently in design or open for accrual in the United States include (1) a randomization following excision to clear margins of 3 mm and tamoxifen to RT or no RT (Radiation Therapy Oncology Group, Intergroup) and (2) trials of wide excision alone (Harvard, Eastern Cooperative Oncology Group).

### MICROINVASIVE CARCINOMA

As previously discussed, microinvasive carcinoma has been a poorly defined pathologic entity. Similar to DCIS, it is being diagnosed more frequently because of the increased use of screening mammography.

The limited available data on patients with microinvasive carcinoma suggest that axillary lymph node metastases are infrequent and the prognosis after surgical treatment is excellent.<sup>173,174,175 and 176,178,179,206,207 and 208</sup> Because of variability in the definition of microinvasion, results from the literature are applicable to an individual patient only if microinvasion is defined in the same way. Since the incidence of axillary node metastases is low, axillary dissection is not routinely indicated. Survival in patients with microinvasive carcinoma seems to be intermediate between that for DCIS and that for small invasive carcinomas. The use of BCT in these patients should follow the same guidelines for careful mammographic and pathologic evaluation with the requirement for negative margins of resection as for patients with an extensive intraductal component–positive invasive carcinoma.

### SUMMARY

DCIS represents a heterogeneous group of lesions of varying malignant potential. Total (simple) mastectomy is associated with a cure rate of 98% to 99% for all types of DCIS. Patients with localized DCIS are candidates for breast-sparing surgery and irradiation. Detailed mammography and careful pathologic evaluation are essential to confirm the localized nature of the lesion and judge the adequacy of resection. The goals of surgery are to remove all suspicious microcalcifications and to achieve negative margins of resection. Excision alone may be an appropriate treatment for selected women with small (less than 1 to 2 cm) low-grade DCIS lesions with clearly negative margins. Axillary dissection is not indicated in DCIS. In women with large high-grade lesions undergoing mastectomy, a low axillary sampling obviates the need for reoperation if invasion is identified. The use of tamoxifen should be considered to reduce the risk of ipsilateral breast tumor recurrence after breast-conserving surgery and to reduce the risk of contralateral breast cancer. A detailed discussion of the risks and benefits of the various options must be undertaken to allow each woman with DCIS to make an informed treatment choice.

### LOBULAR CARCINOMA IN SITU

LCIS is not detectable on macroscopic examination and is always an incidental microscopic finding in breast tissue removed for another reason.<sup>209</sup> Given this, the incidence of LCIS in the general population is unknown. Reviews of large series of benign breast biopsies done for clinical abnormalities have found that only 0.5% to 3.6% are LCIS.<sup>210,211,212 and 213</sup> LCIS is also an uncommon finding in autopsy studies.<sup>214</sup> In all reports, LCIS is noted to be more common in younger women, with the mean age at diagnosis usually reported to be between 44 and 46 years, with 80% to 90% of cases of LCIS occurring in premenopausal women.<sup>210,211,212 and 213</sup> LCIS is reported to occur approximately ten times more frequently in white women than in African American women in the United States.<sup>215</sup> The frequency with which LCIS is diagnosed is increasing, with one series<sup>216</sup> reporting a 15% increase in the number of cases seen from 1973 to 1988. Although some of this increase is due to greater recognition of LCIS as a pathologic entity, the major factor responsible appears to be the increased number of breast biopsies that are performed as a result of screening mammography. A review<sup>217</sup> of 6287 mammographically generated biopsies showed that LCIS was present in 2.3% of total cases, accounting for 9.8% of mammographically detected lesions classified as malignancies. No specific mammographic findings are associated with LCIS. Several studies have examined the distribution of LCIS in an involved breast and the contralateral breast. Multicentric LCIS is identified in 60% to 80% of mastectomy specimens.<sup>218,219 and 220</sup> In addition, LCIS is frequently noted to be bilateral.<sup>211</sup>

In contrast with DCIS, which is heterogeneous in its histologic appearance, the histologic features of LCIS show little variation and are usually easily recognized. LCIS is most often characterized by a solid proliferation of small cells, with small, uniform, round-to-oval nuclei, and variably distinct cell borders. Some cases of LCIS are,

however, characterized by larger cells with larger nuclei that show some degree of pleomorphism. LCIS is typically present in the terminal duct-lobular units and distends and distorts the involved spaces. In some instances, LCIS cells involve extralobular ducts. The growth within these ducts may be either solid or pagetoid (i.e., the LCIS cells are insinuated between the duct basement membrane and the native ductal epithelial cells).

LCIS has a low proliferative rate,<sup>221,222</sup> is typically positive for ER,<sup>221,222</sup> and <sup>223</sup> and rarely, if ever, shows overexpression of HER-2/*neu*<sup>221,222</sup> or accumulation of the p53 protein.<sup>221,222</sup> In addition, LCIS is characterized by loss of expression of the adhesion molecule E-cadherin.<sup>224</sup> While the diagnosis of LCIS is usually straightforward, there is no sharp dividing line between atypical lobular hyperplasia and LCIS. In some patients, LCIS may involve foci of sclerosing adenosis and produce a pattern that mimics invasive carcinoma. Also, the distinction between LCIS and DCIS is sometimes problematic.<sup>225</sup>

The major issue in the management of LCIS is the risk for invasive carcinoma after a diagnosis of LCIS. Six series<sup>210,211,212</sup> and <sup>213,215,225</sup> with long-term follow-up address the malignant potential of LCIS after biopsy alone (Table 37.2-8). With the exception of one study,<sup>225</sup> the studies show that LCIS is associated with an increased risk for the development of breast carcinoma that is approximately seven to ten times that of the index population. In addition, the five studies with long-term follow-up agree that the risk for subsequent cancer development is equal in both breasts. Most carcinomas that develop in women with LCIS are infiltrating ductal, not infiltrating lobular carcinoma.<sup>211,212,227</sup> However, the incidence of infiltrating lobular carcinoma is significantly elevated compared with the 5% to 10% incidence observed among breast cancers in the general population. More recent information about invasive cancer risk associated with a diagnosis of LCIS comes from the NSABP tamoxifen prevention trial.<sup>113</sup> There were 826 women with LCIS in this study, and the average annual rate of invasive carcinoma development among the placebo group was 12.99 per 1000 women. The use of tamoxifen reduced this risk to 5.69, a relative risk of 0.44.

Author	No.	Percentage Invasive Cancer	Follow-Up (y)	Relative Risk
Haagensen et al. <sup>211</sup>	287	18.0	16.3	6.9

<sup>c</sup>Includes ductal carcinoma in situ and invasive carcinoma.

**TABLE 37.2-8.** Follow-Up Studies of Lobular Carcinoma *In Situ*

The observations that most women with LCIS do not develop breast cancer, that the risk for breast cancer is bilateral, and that most tumors are infiltrating ductal carcinomas give credence to the hypothesis that LCIS is a risk factor for cancer development. One management option for the woman with LCIS is careful observation, as would be done for any woman known to be at increased risk for breast cancer development due to a positive family history or prior personal history of breast cancer. The use of tamoxifen in women electing observation only is worthy of consideration. An alternative for women unwilling to accept the risk for breast cancer development (approximately 1% per year) associated with a policy of careful observation is bilateral simple mastectomy, usually with immediate reconstruction. Treatment strategies addressing one breast, such as unilateral simple mastectomy with contralateral biopsy, would seem illogical because the risk of LCIS is bilateral regardless of the findings of the contralateral biopsy. The effectiveness of a program of careful follow-up in detecting potentially curable carcinoma in a population of high-risk women is uncertain. A metaanalysis of 389 reported cases of LCIS followed for a mean of 10.9 years reported a breast cancer mortality of 2.8%, although 16.4% of the group developed carcinoma.<sup>229</sup> In contrast, of 391 women treated initially with mastectomy, breast cancer mortality was 0.9%. However, many of these series antedate the use of modern mammography, and uniform clinical follow-up was not used.

Wide surgical excision and histologically negative margins are not needed when careful follow-up is chosen given that LCIS is known to be a multifocal lesion. Similarly, RT has no role in the management of LCIS. When observation is elected, it is recommended that women with LCIS be examined at 4- to 6-month intervals and obtain annual mammograms. Because the increased risk of breast cancer persists indefinitely, observation must last for the patient's lifetime. The choice between careful observation with or without tamoxifen and bilateral prophylactic mastectomy can only be made by the patient who thoroughly understands the risk she assumes. Surgical treatment of LCIS is not an emergency, and detailed discussions of treatment options are important for patients to overcome the confusion often associated with this diagnosis.

## STAGING OF BREAST CANCER

*Staging* refers to the grouping of patients according to the extent of their disease. It is useful in (1) determining the choice of treatment for individual patients, (2) estimating their prognosis, and (3) comparing the results of different treatment programs. Staging can be based on either clinical or pathologic findings. Currently, staging of cancer is determined by the American Joint Committee on Cancer (AJCC), which is jointly sponsored by the American Cancer Society and the American College of Surgeons. The AJCC system is a clinical and pathologic staging system and is based on the TNM system, in which *T* refers to tumor, *N* to nodes, and *M* to metastasis. The current edition, the fifth, published in 1997<sup>172</sup> is given verbatim below. It provides rules for classification, definition of the anatomy, and stage groupings. Of particular note in the 1997 classification are the new changes: (1) the designation of T1mic for invasive cancers with microinvasion measuring 0.1 cm or less in greatest dimension, and (2) the designation of pN1a for nodal micrometastasis (none larger than 0.2 cm).

The many changes in the AJCC system over time and its complexity have limited its use and usefulness. In addition, the current system does not address present-day issues, such as a patient's suitability for BCT or the risk of distant relapse with and without systemic therapy. In practice, most clinicians simply use the tumor size and the histologic findings of axillary dissection, often grouped for convenience into negative, one to three positive nodes, four to nine positive nodes, and ten or more positive nodes.

## AMERICAN JOINT COMMITTEE ON CANCER RULES FOR CLASSIFICATION

### Clinical Staging

Clinical staging includes physical examination, with careful inspection and palpation of the skin, mammary gland, and lymph nodes (axillary, supraclavicular, and cervical), imaging, and pathologic examination of the breast or other tissues to establish the diagnosis of breast carcinoma. The extent of tissue examined pathologically for clinical staging is less than that required for pathologic staging (see next section, [Pathologic Staging](#)). Appropriate operative findings are elements of clinical staging, including the size of the primary tumor and chest wall invasion, and the presence or absence of regional or distant metastasis.

### Pathologic Staging

Pathologic staging includes all data used for clinical staging, surgical exploration, and resection as well as pathologic examination of the primary carcinoma, including not less than excision of the primary carcinoma with no macroscopic tumor in any margin of resection by pathologic examination. A case can be classified pT for pathologic stage grouping if there is only microscopic, but not macroscopic, involvement at the margin. If there is tumor in the margin of resection by macroscopic examination, it is coded TX because the extent of the primary tumor cannot be assessed. If there is no clinical evidence of axillary metastasis, resection of at least the low axillary lymph nodes (level 1; i.e., those lymph nodes located lateral to the lateral border of the pectoralis minor muscle) should be performed for pathologic (pN) classification. Such a resection ordinarily includes six or more lymph nodes. Metastatic nodules in the fat adjacent to the mammary carcinoma within the breast, without evidence of residual lymph node metastases are classified as regional lymph node metastases (N). Pathologic stage grouping includes any of the following combinations: pT pN pM, or pT pN cM, or cT cN pM.

## ANATOMY

### **Primary Site**

The mammary gland, situated on the anterior chest wall, is composed of glandular tissue within a dense fibroareolar stroma. The glandular tissue consists of approximately 20 lobes, each of which terminates in a separate excretory duct in the nipple.

### **Regional Lymph Nodes**

The breast lymphatics drain by way of three major routes: axillary, transpectoral, and internal mammary. Intramammary lymph nodes are considered with, and coded as, axillary lymph nodes for staging purposes; metastasis to any other lymph node is considered distant (M1), including supraclavicular, cervical, or contralateral internal mammary. The regional lymph nodes are presented here:

1. Axillary (ipsilateral): interpectoral (Rotter's) nodes and lymph nodes along the axillary vein and its tributaries that may be (but are not required to be) divided into the following levels:
  - a. Level I (low axilla): lymph nodes lateral to the lateral border of pectoralis minor muscle
  - b. Level II (midaxilla): lymph nodes between the medial and lateral borders of the pectoralis minor muscle and the interpectoral (Rotter's) lymph nodes
  - c. Level III (apical axilla): lymph nodes medial to the medial margin of the pectoralis minor muscle including those designated as subclavicular, infraclavicular, or apical

Note: Intramammary lymph nodes are coded as axillary lymph nodes.

2. Internal mammary (ipsilateral): lymph nodes in the intercostal spaces along the edge of the sternum in the endothoracic fascia

Any other lymph node metastasis is coded as a distant metastasis (M1), including supraclavicular, cervical, or contralateral internal mammary lymph nodes.

### **Metastatic Sites**

All distant visceral sites are potential sites of metastasis. The four major sites of involvement are bone, lung, brain, and liver, but this widely metastasizing disease has been found in many other sites.

## **TUMOR, NODE, METASTASIS CLASSIFICATION**

### **Primary Tumor**

The clinical measurement used for classifying the primary tumor (T) is the one judged to be most accurate for that particular case (e.g., physical examination or imaging such as a mammogram). The pathologic tumor size for classification (T) is a measurement of *only the invasive component*. For example, if there is a 4.0-cm intraductal component and a 0.3-cm invasive component, the tumor is classified T1a. The size of the primary tumor is measured for T classification before any tissue is removed for special studies, such as for ERs.

### **Microinvasion of Breast Carcinoma**

Microinvasion is the extension of cancer cells beyond the basement membrane into the adjacent tissues with no focus more than 0.1 cm in greatest dimension. When there are multiple foci of microinvasion, the size of only the largest focus is used to classify the microinvasion. (Do not use the sum of all the individual foci.) The presence of multiple foci of microinvasion should be noted, as it is with multiple larger invasive carcinomas.

### **Multiple Simultaneous Ipsilateral Primary Carcinomas**

The following guidelines are used when classifying multiple simultaneous ipsilateral primary (infiltrating, macroscopically measurable) carcinomas. These criteria do not apply to one macroscopic carcinoma associated with multiple separate microscopic foci: (1) Use the largest primary carcinoma to classify T. (2) Enter into the record that this is a case of multiple simultaneous ipsilateral primary carcinomas. Such cases should be analyzed separately.

### **Simultaneous Bilateral Breast Carcinomas**

Each carcinoma is staged as a separate primary carcinoma in a separate organ.

### **Inflammatory Carcinoma**

Inflammatory carcinoma is a clinicopathologic entity characterized by diffuse brawny induration of the skin of the breast with an erysipeloid edge, usually without an underlying palpable mass. Radiologically there may be a detectable mass and characteristic thickening of the skin over the breast. This clinical presentation is due to tumor embolization of dermal lymphatics. The tumor of inflammatory carcinoma is classified T4d.

### **Paget's Disease of the Nipple**

Paget's disease of the nipple without an associated tumor mass (clinical) or invasive carcinoma (pathologic) is classified Tis. Paget's disease with a demonstrable mass (clinical) or an invasive component (pathologic) is classified according to the size of the tumor mass or invasive component.

### **Skin of Breast**

Dimpling of the skin, nipple retraction, or any other skin change except those described under T4b and T4d may occur in T1, T2, or T3 without changing the classification.

### **Chest Wall**

Chest wall includes ribs, intercostal muscles, and serratus anterior muscle, but not pectoral muscle.

## **DEFINITION OF TUMOR, NODE, METASTASIS CLASSIFICATION**

Definitions for classifying the primary tumor (T) are the same for clinical and for pathologic classification ( [Table 37.2-9](#)). The telescoping method of classification can be applied. If the measurement is made by physical examination, the examiner will use the major headings (T1, T2, or T3). If other measurements, such as mammographic or pathologic, are used, the telescoped subsets of T1 can be used.

These data demonstrate that survival for most breast cancer patients is not dependent on choice of local therapy. In addition to the results of these trials, numerous reports from centers in Europe and North America on the use of CS and RT have demonstrated high rates of local tumor control with satisfactory cosmetic results.<sup>249,250,251,252</sup> and <sup>253</sup>

**FIGURE 37.2-2.** Overview analysis of trials of conservative surgery and radiotherapy versus mastectomy. The squares represent the odds ratio of the annual death rate in the radiotherapy group compared with the control group. The vertical line is an odds ratio of 1, and the 99% confidence interval (CI) is shown by the horizontal line. Squares to the right of the vertical indicate a survival benefit for mastectomy. (Reprinted from Anonymous. Effects of radiotherapy and surgery in early breast cancer. An overview of the randomized trials. Early Breast Cancer Trialists Collaborative Group. *N Engl J Med* 1995;333(22):1444, with permission.)

Despite the consistency of the evidence, the use of BCT in the United States has shown relatively slow acceptance and considerable geographic variation.<sup>230,231</sup> Studies indicate that fewer than 50% of women with stage I and II breast carcinoma are treated with BCT.<sup>230,231</sup> The available data indicate that a minority of patients have contraindications to BCT,<sup>254,255</sup> and that these are readily identified with standard clinical tools, such as physical examination and mammography including magnification views.<sup>256</sup> National studies indicate that physicians continue to use inappropriate selection criteria for BCT.<sup>230</sup>

The rates of recurrence in the breast at 7 to 18 years ranged from 7% to 19% in the randomized studies using widely varying surgical and RT techniques.<sup>241,242,243,244,245,246</sup> and <sup>247</sup> In the corresponding patients treated with mastectomy, 4% to 14% of patients developed local recurrence, emphasizing that mastectomy does not guarantee freedom from local recurrence, even in women with clinical stage I and II breast carcinoma. The nonrandomized studies with the longest follow-up describe a persistent risk of recurrence in the breast through 20 years of follow-up.<sup>251,252</sup> and <sup>253,257</sup> These results have been contrasted to those seen after mastectomy, in which most local failures occur in the first 3 years following surgery. The annual incidence rate for a recurrence at or near the primary site is constant for years 2 through 7 after treatment, and then decreases to a low level by 10 years after treatment.<sup>253</sup> In contrast, the annual incidence rate for recurrence elsewhere in the breast increases slowly to a rate of approximately 0.7% per year at 8 years and remains stable.<sup>253</sup> Recurrences in the skin of the treated breast are a rare event associated with a poor prognosis.<sup>258</sup> Whole breast irradiation is effective at eradicating multicentric breast carcinoma, but it does not prevent the subsequent development of new cancers.

A number of factors have been identified that influence the risk for local recurrence after BCT. Young age has consistently been observed to be associated with an increased risk of local recurrence after breast-conserving surgery and RT.<sup>259,260,261,262</sup> and <sup>263</sup> However, young age has similarly been associated with a worse outcome after mastectomy.<sup>264,265</sup> In young women with a family history suggestive of an inherited breast cancer susceptibility, BCT is associated with a higher rate of opposite breast cancer compared with young women without such a family history.<sup>266</sup> This is consistent with the findings of an increased risk of opposite breast cancer in young patients with mutations undergoing mastectomy.<sup>31,267</sup> The rate of local recurrence in young patients with a positive family history is, if anything, lower than in patients with a negative family history. This might be explained by the findings linking BRCA1 and 2 with radiation repair genes,<sup>268,269</sup> or by a greater likelihood of localized (extensive intraductal component–negative) cancers in patients with mutations compared with patients without mutations.<sup>270</sup> However, patients with mutations appear to be at risk for late new primaries in the treated breast.<sup>271</sup> Of note, patients with a mutation do not appear to be at an increased risk for adverse effects from RT.<sup>272,273</sup> Thus, BCT appears to be an acceptable option for patients with a suspected or known mutation, although these patients need to be apprised of the increased risk of a second breast cancer, either in the opposite or, over time, in the treated breast. Many of these patients, particularly those with favorable presentations, elect bilateral mastectomy. A modeling study suggests that bilateral mastectomy may be associated with a modest gain in survival.<sup>127</sup>

An extensive intraductal component has been shown to be an important risk factor for local recurrence when margins of resection are not evaluated.<sup>274</sup> An extensive intraductal component has been found to be a marker for a large residual tumor burden in the involved quadrant of the breast<sup>236,275</sup> such that moderate-dose RT is not able to eradicate it. In such patients, a larger breast resection is commonly required to ensure adequate removal. Results have shown that the microscopic margins of resection are the major selection factor for BCT ([Tables 37.2-11](#) and [37.2-12](#)). Patients with negative margins of excision (typically defined as the absence of either invasive or ductal *in situ* disease directly at an inked surface) have generally been observed to have low rates of local recurrence following treatment with CS and RT.<sup>276,277,278,279,280,281,282,283,284</sup> and <sup>285</sup> In particular, patients with an extensive intraductal component, but with negative inked margins of excision, are not at an increased risk of local recurrence.<sup>279,280</sup> and <sup>281,286</sup> The outcome of patients with close margins of excision has been less clear. In part, this reflects variability in the definition of *close margins* and, perhaps, the effect of institutional policies calling for escalated radiation doses based on the proximity of cancer cells to the margin of resection. In the Joint Center for Radiation Therapy (JCRT) experience shown in [Table 37.2-12](#), there was no significant difference in recurrence rates between patients with close margins (less than or equal to 1 mm) compared with patients with margins greater than 1 mm using similar doses.<sup>279</sup> Some studies have suggested a high rate of local recurrence at 10 years in patients with close margins; however, the number of patients in these series and the actual follow-up time is limited.<sup>278,281</sup>

**TABLE 37.2-11.** Recurrence Rates (%) following Conservative Surgery and Radiation Therapy by Margin Status

Margin Status	No. of Patients	Percentage Local Recurrence	Percentage with Distant or Regional Failure or Opposite Breast Cancer Recurrence	Percentage with Ipsilateral Recurrence	Percentage with No Evidence of Disease
Negative	54	7	5	4	84
Clear <sup>a</sup>	54	7	5	6	83
Focally positive <sup>b</sup>	122	14	5	7	74
Greater than focally positive	66	27	5	3	55

<sup>a</sup>Key in situ or invasive disease within 1 mm of resected surface, but not present at surface.  
<sup>b</sup>In situ or invasive disease at resected surface, but in three or fewer low-power fields.

**TABLE 37.2-12.** Eight-Year Outcome Related to Margins of Resection (Joint Center for Radiation Therapy)

Long-term data on the use of BCT in patients with positive margins are more limited. In most analyses, positive margins have been associated with a high risk of breast cancer recurrence.<sup>276,277,278,279</sup> and <sup>280,283,284</sup> and <sup>285</sup> At the JCRT, patients with positive margins had a considerably higher risk of breast cancer recurrence than patients with negative margins.<sup>279</sup> The 8-year crude rate of breast recurrence was 18% for patients with positive margins. However, patients with focally positive margins (any invasive or *in situ* ductal carcinoma at the margin in three or fewer low-power microscopic fields) had a 14% rate of recurrence compared with a 27% rate in patients with greater than focally positive margins. These data suggest that patients with focally positive margins can be considered for BCT. As discussed in this section, the use of adjuvant systemic therapy results in a large reduction in local recurrence in patients treated with CS and RT. In the JCRT series, among the 45 patients with focally positive margins who received adjuvant systemic therapy, the 8-year local recurrence rate was 8% (95% confidence interval, 1% to 18%).<sup>279</sup> Additional experience is needed to confirm this finding. Patients with more than focally positive margins require more surgery given the significantly higher rate of breast cancer recurrence.

The use of *adjuvant systemic therapy* is an important factor associated with recurrence in the breast when used in conjunction with CS and RT. This is most clearly demonstrated in three randomized clinical trials. In the NSABP B-13 trial, node-negative, ER-negative patients were randomized to chemotherapy or to a no-treatment control group. Among the 235 patients treated with CS and RT, the 8-year rate of recurrence in the ipsilateral breast was 13.4% without chemotherapy and only 2.6% with chemotherapy.<sup>287</sup> Similar results are seen with adjuvant tamoxifen. In NSABP trial B-14, node-negative, ER-positive patients were randomized to tamoxifen or to a placebo. Among the 1062 patients treated with CS and RT, the 10-year rate of recurrence in the ipsilateral breast was 14.7% without tamoxifen and only 4.3% with tamoxifen.<sup>288</sup> A similar result was seen in the Stockholm Breast Cancer Study Group among node-negative patients randomized to tamoxifen or to a placebo.<sup>289</sup> Among the 432 patients treated with CS and RT, the 10-year rate of recurrence in the ipsilateral breast was 12% without tamoxifen and only 3% with tamoxifen.

### GUIDELINES FOR PATIENT SELECTION

Based on the extensive information available from prospective and retrospective studies, there is a general consensus on the criteria for patient selection for the use of BCT. It is now established that, in most cases, BCT results in a cosmetically satisfactory breast and that it provides survival rates equivalent to those seen after mastectomy. The American College of Surgeons, the American College of Radiology, the College of American Pathologists, and the Society of Surgical Oncology have jointly provided standards of care for BCT and most recently published their report in 1998.<sup>290</sup> Key portions of this report are summarized here and additional comments are provided in parentheses.

### CONTRAINDICATIONS FOR BREAST-CONSERVATION TREATMENT WITH RADIATION THERAPY

#### Absolute Contraindications

- Women with two or more primary tumors in separate quadrants of the breast or with diffuse malignant-appearing microcalcifications are not considered candidates for breast-conservation treatment.
- A history of previous therapeutic irradiation to the breast region that, combined with the proposed treatment, would result in an excessively high total radiation dose to a significant volume is another absolute contraindication.
- Pregnancy is an absolute contraindication to the use of breast irradiation. However, in many cases, it may be possible to perform breast-conserving surgery in the third trimester and to treat the patient with irradiation after delivery.
- Finally, persistent positive margins after reasonable surgical attempts absolutely contraindicate BCT with radiation. The importance of a single focally positive microscopic margin needs further study and may not be an absolute contraindication (see updated results from the JCRT in [Local Management of Invasive Breast Cancer](#), earlier in this chapter).

#### Relative Contraindications

- A history of collagen vascular disease is a relative contraindication to BCT because published reports indicate that such patients tolerate irradiation poorly.<sup>291</sup> Most radiation oncologists will not treat patients with scleroderma or active lupus erythematosus, considering either an absolute contraindication. In contrast, rheumatoid arthritis is not a contraindication.<sup>292</sup>
- Patients with multiple gross tumors in the same quadrant and indeterminate calcifications must be carefully assessed for suitability because studies in this area are not definitive.
- Tumor size is not an absolute contraindication to BCT, although few reports have been published about treating patients with tumors larger than 4 to 5 cm. However, a relative contraindication is the presence of a large tumor in a small breast in which an adequate resection would result in significant cosmetic alteration.
- Breast size can be a relative contraindication. Women with large or pendulous breasts can be treated by irradiation if reproducibility of patient setup can be ensured and it is technically possible to obtain adequate dose homogeneity.

### NONMITIGATING FACTORS

- The presence of clinical or pathologic involvement in axillary nodes should not prevent the treatment.
- Concern about not being able to detect a recurrence is not a contraindication. The changes associated with recurrence can usually be detected at an early stage by physical examination and mammography.
- The delivery of irradiation to the breast does not result in a meaningful risk of second tumors in the treated area or in the untreated area.
- Tumor location is not a factor in the choice of treatment. Tumors in a superficial subareolar location occasionally may require the resection of the nipple-areolar complex so that negative margins can be achieved, but this does not affect outcome. The patient and her physician need to assess whether such a resection is preferable to mastectomy.
- A family history of breast cancer is not a contraindication to breast conservation. Little is known about the risk of breast recurrence in patients with hereditary breast cancer, but currently this is not a contraindication to BCT. (However, such patients should be apprised of their increased risk of a second breast cancer.)
- A high risk of systemic relapse is not a contraindication for breast conservation, but is a determinant of the need for adjuvant therapy.

### CONSERVATIVE SURGERY WITHOUT RADIATION THERAPY

An unresolved question is whether RT is necessary in all patients with invasive breast cancer after CS. Six randomized clinical trials with published results have compared CS alone with CS and RT in patients with early-stage breast cancer.<sup>241,242,293,294,295</sup> and <sup>296</sup> These trials vary with regard to patient selection, the details of the surgery and RT, the use of adjuvant systemic therapy, and the length of follow-up. The results of these various trials are shown in [Table 37.2-13](#). These trials all show a large reduction in the rate of local recurrence after RT, with an average crude rate of reduction of approximately 75% (range, 63% to 89%). None of the six trials shows a significant survival benefit for RT; however, in the trials with published data, the survival rate is slightly better for irradiated patients than for nonirradiated patients. A large trial (or perhaps a metaanalysis of multiple smaller trials) is necessary to detect a small, but clinically significant difference in survival, if it in fact

exists.

Trial	Median Follow-Up (mo)	Local Recurrence		Survival		Analysis
		Conservative Surgery (%)	Conservative Surgery + Radiation Therapy (%)	Conservative Surgery (%)	Conservative Surgery + Radiation Therapy (%)	
National Surgical Adjuvant Breast and Bowel Project B-20 <sup>297</sup>	104	35	11	58	62	Overall

Ontario <sup>299</sup>	81	35	11	75	79	Overall
Milano <sup>300</sup>	12	37	2	No difference	No difference	Overall
Scottish <sup>301</sup>	10	25	1	No difference	No difference	Overall
English <sup>302</sup>	71	35	11	No difference	No difference	Overall

**TABLE 37.2-13.** Outcome in the Trials Comparing Conservative Surgery with and without Radiation Therapy

Attempts have been made to identify a subgroup of patients (based on various clinical and histologic features) that has a low risk of local recurrence after CS alone. It was not possible to identify such a subgroup within the Ontario and NSABP randomized trials. Local recurrence rates are generally lower in trials using more extensive surgery than in those using lumpectomy and in older patients than in younger patients. The JCRT attempted to identify such a subgroup in a prospective single-arm trial in which patients with favorable disease were offered the option of CS alone. The criteria for entry onto this protocol were tumor size of 2 cm or less, histologically negative axillary nodes, absence of both lymphatic vessel invasion and an extensive intraductal component in the cancer, and no cancer cells visualized within 1 cm of inked margins.<sup>297</sup> All but one patient had a negative reexcision. This trial was stopped shortly before reaching its accrual goal of 90 patients because of stopping rules ensuring against an excessively high local recurrence rate. The latest analysis includes the results in 81 patients. The median age of patients in this trial was 66 years, and median pathologic size of the cancers was 9 mm. With a median follow-up of 92 months, 19 of the patients have developed a recurrence in the ipsilateral breast, for a crude local recurrence rate of 23%. Based on the results of this prospective study, it was concluded that, even in a highly selected group of breast cancer patients, there is a substantial risk of early local recurrence after treatment with wide excision alone.

The use of adjuvant systemic therapy substantially reduces the rate of local recurrence in patients treated with CS and RT,<sup>287,288 and 289</sup> but does not seem to reduce greatly the rate of local recurrence after CS alone. There are no published trials directly comparing CS with and without either chemotherapy or tamoxifen. Information on this is available from indirect comparisons within randomized clinical trials for both adjuvant chemotherapy and tamoxifen. In the NSABP trial B-06, an indirect comparison of the effect of adjuvant chemotherapy can be made. Node-positive patients treated with lumpectomy and adjuvant chemotherapy but without RT had a 12-year rate of recurrence in the breast of 41% compared with only 5% for node-positive patients treated with lumpectomy, RT, and chemotherapy ( $P < .001$ ).<sup>241</sup> In comparison, node-negative patients treated with lumpectomy without RT had a 12-year rate of recurrence in the breast of 32% compared with 12% for node-negative patients treated with lumpectomy with RT. A similar observation, suggesting that systemic therapy further decreases the rate of local recurrence when combined with RT, but not in its absence, is also seen in indirect comparisons within the Milan trials.<sup>242</sup> In the Scottish trial, patients with ER-negative cancers were treated with adjuvant cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) chemotherapy. With a median follow-up of approximately 5.7 years, the crude rate of local regional recurrence was 44% among patients treated with CS, but without RT, compared with only 14% among patients treated with RT.<sup>295</sup>

There is particular interest in avoiding RT in older patients. It is often less convenient for such patients to receive RT, and their local recurrence rate appears lower after CS alone compared with younger patients.<sup>298,299 and 300</sup> The results of retrospective studies of CS alone with or without adjuvant tamoxifen have shown variable results.<sup>301,302</sup> The Cancer and Leukemia Group B (CALGB) and other groups in North America have completed a prospective randomized clinical trial testing the value of RT in older breast cancer patients treated by CS and tamoxifen; at this time there are no results from the trial. In NSABP B-21, women with tumors smaller than 1 cm with negative axillary lymph nodes were randomized to tamoxifen alone, breast irradiation alone, or breast irradiation plus tamoxifen. With an average follow-up of 73 months, 24.4% of women in the tamoxifen-only arm had an ipsilateral recurrence, compared to 11.7% of women who received breast irradiation plus tamoxifen. The difference was highly statistically significant. Based on these results, the investigators thought it unlikely that tamoxifen could be substituted for radiation in this patient population.<sup>300a</sup>

In conclusion, the use of breast irradiation after CS is associated with a large reduction in the rate of local recurrence. The available data from the randomized trials do not show a survival benefit; however, none of the available trials has the statistical power to eliminate a small survival difference. A subset at low risk of local recurrence following CS has not been clearly identified, and RT is currently considered standard. The addition of adjuvant systemic therapy to CS alone has not been demonstrated to decrease local recurrence. In elderly patients, particularly those with significant comorbidity, RT is commonly omitted because of the practical difficulties of delivering such therapy in this group of patients.

## PREOPERATIVE CHEMOTHERAPY

The successful application of preoperative chemotherapy in locally advanced breast cancer has led to a number of studies in patients with stage I and II breast carcinoma to determine if the use of preoperative chemotherapy would allow breast conservation in patients who would otherwise be treated with mastectomy. Early studies demonstrated a high response rate to preoperative chemotherapy with conversion of patients initially thought to be unsuitable for BCT to be considered reasonable candidates for breast conservation.<sup>303,304</sup> In addition to increasing the number of patients who can undergo BCT, a second goal of preoperative therapy is to improve survival. The available randomized trials suggest that the use of preoperative chemotherapy does reduce the use of mastectomy, but does not improve survival.<sup>305,306 and 307</sup> Of note, however, in the NSABP trial B-18,<sup>306</sup> an analysis of breast recurrence rates among patients initially eligible for lumpectomy and those who were eligible only after down-staging by chemotherapy demonstrated a local failure rate of 6.9% in those thought to be candidates for lumpectomy before chemotherapy compared with 14.5% in those who required down-staging ( $P = .04$ ). Similar findings were noted in a trial from France.<sup>308</sup> Further experience is therefore needed to identify down-staged patients who can be effectively managed by BCT. A major practical problem with the use of preoperative chemotherapy to increase rates of BCT is the determination of the extent of residual viable tumor that must be resected. The clinical assessment of response is relatively inaccurate using clinical examination and mammography. Given this, we approach these patients by initially resecting any clinically or mammographically abnormal tissue. If viable tumor is present throughout the specimen, a reexcision is carried out even if the initial margins are negative. If further viable tumor is present in the reexcised specimen, a reevaluation of the patient's suitability for BCT is undertaken. Marking the extent of the tumor before chemotherapy with stereotactically placed clips or skin tattoos is useful for determining the tumor location in patients who have a complete clinical response and may aid in assessing the need for resection of residual abnormalities in patients with a partial response.

The definitive role of neoadjuvant therapy in operable breast cancer remains undefined. There appears to be no rationale, outside of a clinical trial, for its routine use in patients who are suitable candidates for BCT. Initial chemotherapy is appropriate when a large tumor in a small breast would necessitate mastectomy and the patient desires BCT. However, in the study of Morrow et al.,<sup>254</sup> this contraindication to BCT was present in only 6% of 336 patients with stage I and stage II carcinoma. The potential for a higher risk of breast recurrence should be discussed with the patient, and the pathology carefully reviewed before deciding that the patient is a suitable candidate for BCT.

## TECHNIQUE AND COMPLICATIONS OF BREAST-CONSERVING SURGERY

The goal of breast-conserving surgery is to minimize the risk of local recurrence while leaving the patient with a cosmetically acceptable breast. The most common form of breast-conserving surgery used in the United States is referred to as *lumpectomy*. The surgical technique of lumpectomy differs from that used for mastectomy in that lumpectomy is not an *en bloc* cancer operation. Quadrantectomy is another type of breast-conserving surgery that is designed to remove an anatomic segment of breast tissue and frequently includes removal of the overlying skin and underlying pectoral fascia. Because excision of a large amount of breast tissue is the major factor responsible for a poor cosmetic outcome after BCT, lumpectomy is considered the appropriate initial surgical approach in the United States. Other surgical factors that influence the cosmetic appearance are the size and placement of the incision, the management of the lumpectomy cavity, and the extent of axillary dissection.

A number of technical aspects of lumpectomy are worth emphasizing. In general, the incision should be placed directly over the area of the tumor. This is true even when a biopsy is performed for a mammographically detected lesion. In the upper part of the breast, incisions should be curvilinear or transverse and follow the natural skin creases (Langer's lines) of the breast. In the lower part of the breast, the choice of a curvilinear or radial incision depends on the contour of the patient's breast, the distance from the skin to the tumor, and the amount of breast tissue to be resected. It is not necessary to remove skin (except for superficial tumors) or to remove needle tracks from core-needle biopsies or FNAs. Preservation of the subcutaneous fat and the avoidance of thin skin flaps is also important in maintaining normal breast contour. Raising flaps is necessary only to allow access to the tumor. Meticulous hemostasis is important because a large hematoma distorts the appearance of the breast and makes reexcision and follow-up evaluation more difficult. The presence of a postbiopsy hematoma, however, is not a contraindication to BCT. It is best to avoid reapproximation of the breast tissue since this can result in distortion of the breast contour, which may not be apparent with the patient supine on the operating table. The best cosmetic results usually are obtained by allowing the lumpectomy cavity to fill in with serum and fibrin. Drainage of the lumpectomy cavity should be avoided. Finally, the incision should be closed with a subcuticular suture to avoid cross-hatching of the skin.

A critical step in lumpectomy is the evaluation of the completeness of excision of the tumor. To allow adequate histologic evaluation, the specimen should be removed as a single piece of tissue and should not be transected unless the pathologist is present. The use of marking sutures to orient the specimen for the pathologist allows reporting of the status of individual margins. Gross inspection of the specimen in the operating room allows identification of positive or close margins, facilitating immediate reexcision. Frozen-section histologic study is sometimes useful to evaluate grossly suspicious areas, but the routine use of frozen sections to evaluate grossly normal margins is of doubtful value. The ideal amount of grossly normal breast tissue around the tumor that should be resected as part of a lumpectomy is uncertain. A resection of 0.5 to 1.0 cm of grossly normal breast tissue results in histologically negative margins in a large percentage of patients.<sup>136</sup> Larger resections may be necessary for invasive ductal carcinomas with an extensive intraductal component<sup>309</sup> and for infiltrating lobular carcinomas.<sup>310</sup>

When axillary dissection is performed as part of breast-conserving surgery, a separate incision should be used, except in patients with tumors high in the tail of the breast. A curvilinear incision at the edge of the hair-bearing axillary skin provides the best cosmetic result. The incision should not extend anterior to the fold of the pectoralis major or posterior to the latissimus dorsi.

The primary indications for a reexcision are positive or unknown histologic margins of resection on the initial excision. Several studies have demonstrated residual carcinoma in approximately one-half of cases when reexcision is performed for positive or unknown margins.<sup>308,311</sup> No consensus exists on the best technique for reexcision. When reexcision is done within 1 to 2 weeks of the biopsy, it is not usually possible to reexcise an entire biopsy cavity as a single specimen without sacrificing large amounts of breast tissue. One author's (M. M.) technique of reexcision in most cases is to reexcise each of the walls of the biopsy cavity separately. If the initial specimen is marked with orienting sutures, reexcision can be limited to the involved margins. Otherwise, thin pieces of tissue are shaved off each wall of the biopsy cavity and sent as separate specimens, with the new margin surface marked for the pathologist. When longer intervals have elapsed between the biopsy and the time of reexcision, contraction of the biopsy cavity may allow excision of the entire cavity as a single specimen without sacrificing excessive amounts of breast tissue. The status of the final margin should be used to determine the patient's suitability for BCT. Kearney and Morrow<sup>136</sup> found that 86 of 90 patients undergoing reexcision for positive or unknown margins were satisfactory candidates for BCT.

There are relatively few complications of breast-conserving surgery. Wound infection is infrequent, although rates of infection may be increased when reexcision is performed. The late occurrence of breast abscess after BCT has been reported.<sup>312</sup> The median time to abscess development was 5 months (range, 1.5 to 8.0 months). The only factor found to correlate with abscess formation was larger size of the lumpectomy specimen. Cellulitis of the breast occurring at a median of 4 months after BCT also has been reported in approximately 3% of cases.<sup>313</sup>

## TECHNIQUE AND COMPLICATIONS OF MASTECTOMY

Modified radical mastectomy involves the complete removal of the breast tissue, the underlying fascia of the pectoralis major muscle, and the removal of some of the axillary lymph nodes. Modified radical mastectomy is performed through an elliptical transverse incision, which encompasses the nipple-areola complex and the biopsy scar if an open biopsy has been performed. The nipple-areola complex and the biopsy incision must be removed, but the remainder of the skin of the breast can be preserved in early-stage breast cancer if needed for breast reconstruction. With a skin-sparing procedure, additional exposure to allow complete excision of the breast tissue is achieved by incision rather than excision of the skin. Skin flaps are created in the plane between the subcutaneous fat and the underlying breast tissue. Because of the variability in the amount of subcutaneous fat, no single thickness is appropriate for all skin flaps. To encompass all breast tissue, the dissection should extend superiorly to the inferior border of the clavicle, medially to the lateral border of the sternum, inferiorly to the superior extent of the rectus sheath, and laterally to the latissimus dorsi muscle. The fascia of the pectoralis major muscle can safely be preserved when needed for breast reconstruction. In general, however, excision posterior to the fascia provides a convenient plane for ensuring removal of most of the breast tissue. With the breast attached inferiorly and laterally, axillary dissection is carried out. Closed suction drains are then placed in the apex of the axilla and beneath the inferior skin flap. Skin closure is accomplished with a subcuticular suture. Pressure dressings are not needed with suction drains and may compromise blood supply.

The term *total mastectomy* refers to the removal of the entire breast including the axillary tail of Spence, with preservation of both pectoral muscles and the axillary nodes. The indications for total mastectomy include (1) patients with DCIS who elect mastectomy, (2) patients undergoing prophylactic surgery to prevent the development of breast cancer, (3) patients who develop a recurrence in the breast after BCT that had included an axillary dissection, and, on rare occasion, (4) patients with metastatic disease undergoing mastectomy for local control of the primary tumor.

Mastectomy is an extremely safe operative procedure.<sup>314</sup> For patients with serious comorbid conditions who are at an unacceptably high risk for general anesthesia, mastectomy can be done using a combination of local anesthesia, intercostal blocks, and intravenous sedation. The reported incidence rate of wound infection with mastectomy ranges from 6% to 14%.<sup>315,316</sup> The most common organisms are streptococcus or *Staphylococcus aureus*.<sup>316</sup> Factors that predispose to infection include the use of a two-step procedure (i.e., open biopsy preceding mastectomy) and prolonged suction catheter drainage.<sup>316,317</sup> A single dose of antibiotics (86% cephalosporin) has been shown to reduce the incidence of wound infection by 38%.<sup>318,319</sup> However, because the overall incidence of infection in these patients is so low, the cost effectiveness of routine antibiotic prophylaxis for all patients undergoing mastectomy has not been established. A selective policy of antibiotic administration to high-risk patients (e.g., prior biopsy, anticipation of long operating time) seems to be most appropriate. Necrosis of the skin flaps is a relatively uncommon problem today, but was reported in 8% to 60% of cases, particularly in earlier series of patients undergoing radical mastectomy.<sup>320,321</sup> Factors associated with skin-flap necrosis include denuding the subcutaneous fat from the flaps, closure under tension, infection, and use of a vertical incision and occlusive pressure dressings.<sup>315,316,322</sup> Skin incisions should be planned to allow tension-free closure. Pressure dressings are not necessary when suction drains are used, and suspected cellulitis should be promptly treated with antibiotics. Seroma formation occurs in 100% of patients after mastectomy and should be considered a side effect, rather than a complication, of the procedure. Prolonged lymphatic drainage after mastectomy is primarily related to extensive node involvement followed by obesity and the performance of a two-step procedure.<sup>323</sup> Prolonged seroma formation, in addition to requiring multiple physician visits, may be associated with delayed wound healing and an increased risk of infection.<sup>315,316,320</sup> Seroma formation can be minimized by leaving drains in place until their combined output is less than 40 mL/24 hours. Fluid collections should be managed by aspiration every other day. Some advocated the use of tacking sutures to obliterate the axillary dead space and attach the skin flaps to the pectoral muscle,<sup>321</sup> but this has not been established. Phantom breast syndrome has been long recognized.<sup>324</sup> In one prospective study,<sup>325</sup> phantom pain was reported in 13% of patients at 3 weeks, and nonpainful phantom sensations were present in an additional 15%. Similar incidences were seen at 1 year and at 6 years. The cause of this syndrome is unknown.

## ONCOLOGIC CONSIDERATIONS IN IMMEDIATE RECONSTRUCTION

The switch from radical mastectomy to modified radical mastectomy and advances in plastic surgical technique have made immediate breast reconstruction an option for most patients who undergo mastectomy. A number of concerns about immediate reconstruction have been raised and the available information addressing these concerns comes from retrospective studies. The incidence of local failure in patients undergoing breast reconstruction appears to be comparable with patients treated by mastectomy alone.<sup>326,327</sup> and <sup>328</sup> Similarly, the ability to detect local recurrence does not appear altered by immediate reconstruction.<sup>329,330</sup> and <sup>331</sup> There is, however, a greater risk of problems in patients undergoing immediate reconstruction who require postmastectomy RT, specifically among patients receiving implants.<sup>332,333</sup> This includes patients in whom the implants are placed beneath latissimus dorsi or transverse rectus abdominis myocutaneous (TRAM) flaps. In contrast, patients reconstructed with the TRAM flap without an implant appear to tolerate postoperative RT better.<sup>334,335</sup> Immediate reconstruction does create technical problems in the administration of RT. With immediate reconstruction, it can be more difficult to treat the internal mammary nodes and to boost the chest wall. Communication before mastectomy between the surgeon and the radiation oncologist is useful to make decisions on an individual basis. In summary, immediate breast reconstruction has not been shown to increase the incidence of local failure or impede the detection of local recurrence. In the hands of an experienced reconstructive surgeon, the incidence of complications associated with the procedure is low, and the need for postoperative systemic therapy should not be considered a contraindication to

immediate reconstruction. In patients with larger tumors or clinically positive nodes, in whom there is a high likelihood that postoperative chest wall RT will be administered, it may be prudent to avoid implant reconstruction or forego immediate reconstruction altogether.

## INDICATIONS FOR POSTOPERATIVE RADIATION THERAPY

*Postoperative RT* refers to the use of irradiation to the chest wall and draining lymph node regions as an adjuvant treatment after mastectomy. Postoperative RT has been clearly shown to reduce the rate of local regional tumor recurrence (i.e., recurrence on the chest wall or in the axillary, internal mammary, or supraclavicular lymph nodes) by treating residual microscopic disease that has spread beyond the margin of surgical resection. In the absence of postoperative RT, there is a substantial risk of local recurrence after modified radical (or even radical) mastectomy, principally related to the presence and extent of axillary nodal involvement. If axillary nodes are involved, local recurrence is seen in 10% to 30% of patients, whereas if axillary nodes are uninvolved, local recurrence is seen in only approximately 5% of patients.<sup>336,337</sup> Once a local recurrence is clinically manifest, it can be effectively controlled in only approximately one-half of patients.<sup>338,339</sup> and <sup>340</sup> Therefore, postoperative RT can benefit high-risk patients simply by preventing local recurrence.

Despite the clear-cut improvement in local control with adjuvant RT,<sup>341</sup> its effect on survival remains controversial. Assessing the survival value of postoperative RT requires evaluation within large, prospective randomized clinical trials. There are six published trials in which patients were randomized after radical, modified radical, or total mastectomy to postoperative RT or no further treatment in the absence of systemic therapy.<sup>342,343,344,345,346,347,348,349,350</sup> and <sup>351</sup> Some of these are among the earliest clinical trials performed in medicine. In many of these trials, RT was given using orthovoltage equipment and in most trials techniques were used that delivered considerable doses to the heart and are now considered outmoded. Despite this, the use of postoperative RT clearly reduced the incidence of local recurrence, but none of these trials demonstrated a clear-cut improvement in the survival rate. In addition, some of these trials showed a late increase in cardiac mortality in patients treated with RT compared with unirradiated patients.<sup>342,343</sup> The most modern of these trials was conducted at the Radiumhemmet in Stockholm between 1971 and 1976.<sup>345,346</sup> In this trial, 644 patients with operable breast cancer were treated with modified radical mastectomy and randomized to postoperative RT or no further treatment. With a median follow-up time of 16 years, node-negative patients had a decreased rate of local recurrence with postoperative RT, but there was no effect on distant metastases or survival. For node-positive patients, the use of postoperative RT was associated with not only a decrease in local recurrence, but also a decrease in distant metastasis ( $P = .02$ ). An overview of randomized trials of postoperative RT after mastectomy with or without axillary dissection showed no difference in survival when patients treated with RT were compared with those treated without RT over the first 10 years after surgery.<sup>352</sup> After 10 years, however, there was a lower rate of survival associated with the use of RT, but this was not statistically significant. When cause-specific mortality data were examined, there was an excess of cardiac deaths among patients treated with RT, but this was offset by a reduced number of deaths from breast cancer, especially in the more recent trials. An overview reanalysis published in 2000 showed similar results.<sup>353</sup> These studies suggest that if increased cardiovascular mortality associated with adjuvant irradiation can be avoided by the use of appropriate techniques, a benefit in survival will be seen.

There are a number of studies that have examined the rate of local recurrence in patients treated with mastectomy and adjuvant chemotherapy, but without RT.<sup>354,355,356</sup> and <sup>357</sup> In the largest of these, the rate of local recurrence in 2016 node-positive patients entered into Eastern Cooperative Oncology Group adjuvant systemic therapy trials was examined.<sup>356</sup> The 10-year rate of local regional recurrence (with or without simultaneous distant failure) was 12.9% for patients with one to three positive nodes and 28.7% with greater than or equal to four positive nodes. Similar results are observed in the other studies.<sup>354,355,357</sup> These studies, as well as the trials described here, demonstrate a moderate risk of local regional recurrence in node-positive patients treated with mastectomy and adjuvant systemic therapy, particularly when four or more nodes are involved.

A number of studies have examined the issue of adding postoperative RT to adjuvant chemotherapy (Table 37.2-14).<sup>357,358,359,360,361,362,363,364,365,366</sup> and <sup>367</sup> The two largest of these are from the Danish Breast Cancer Cooperative Group (DBCG). In DBCG trial 82b, 1708 premenopausal patients who had undergone mastectomy for pathologic stage II or III breast cancer were randomly assigned to eight cycles of CMF plus local regional RT or to nine cycles of CMF alone.<sup>357</sup> With a median follow-up of 114 months, the 10-year rate of local regional recurrence was reduced from 32% to 9% with RT, and overall survival was improved from 45% to 54% with RT (both  $P$  values  $<.01$ ) (Fig. 37.2-3). In DBCG trial 82c, 1375 postmenopausal patients who had undergone mastectomy for pathologic stage II or III breast cancer were randomly assigned to tamoxifen for 1 year plus local regional RT or to tamoxifen alone.<sup>358</sup> With a median follow-up time of 123 months, the 10-year rate of local regional recurrence was reduced from 35% to 8% with RT, and overall survival was improved from 36% to 45% with RT (both  $P$  values  $<.05$ ) (Fig. 37.2-4). In a smaller trial from British Columbia, 318 node-positive premenopausal patients treated with modified radical mastectomy were similarly randomized to adjuvant CMF chemotherapy and postoperative RT or to chemotherapy alone. The results of the British Columbia trial were similar to those of the DBCG trial 82b.<sup>359</sup> Of note, the magnitude of the improvement seen in these trials is similar to that seen with adjuvant systemic therapy (chemotherapy, hormonal therapy, or both) and suggests that all node-positive patients should receive postmastectomy RT. A metaanalysis published in 2000 showed a survival benefit for local regional RT in node-positive women treated with modified radical mastectomy and adjuvant systemic therapy.<sup>368</sup> For a number of reasons, however, these trials have not resulted in the universal use of postoperative RT in node-positive patients, particularly those with only one to three positive nodes. One reason is that the worldwide overview of all trials of postoperative RT only shows a small, but not statistically significant survival benefit.<sup>344</sup> A more substantial reason relates to the issue of generalizing from these results due to differing surgical and systemic treatments. The extent of axillary surgery performed in these trials was less than that performed in the United States, and the rates of local regional recurrence, especially axillary recurrences, observed in the Danish trials were greater than observed in U.S. series. In particular, as noted previously, series of patients with one to three positive nodes treated by modified radical mastectomy and adjuvant chemotherapy from the United States show rates of local regional recurrence in the range of 10%,<sup>352,353,354,355</sup> and <sup>356</sup> compared with approximately 30% in the two Danish trials. Also, systemic therapy in the Danish trials may have been suboptimal by current standards. What seems clear is that these trials address an important principle about the value of establishing local regional control in the presence of systemic therapy. Without detracting from the importance or validity of the principle, it is legitimate to question the clinical implications of these results for practice in the United States. The final reason for the failure of these trials to translate directly into clinical practice is the concern about long-term complications of postoperative RT, especially late cardiac mortality. This is especially relevant in patients receiving chemotherapy with potential cardiac toxicity, such as doxorubicin (Adriamycin). To address the issues raised by the available data on postoperative RT, the American Society of Therapeutic Radiology and Oncology sponsored a symposium on postoperative RT and invited a panel to hear the latest information on this topic and to develop a Consensus Summary Statement. The panel was composed of three radiation oncologists, a medical oncologist, a surgical oncologist, and a consumer activist.

Study	Year	RT	Systemic Therapy	Local Recurrence (%)	Distant Recurrence (%)	Overall Survival (%)
DBCG 82b	1977-1980	RT + CMF	CMF	9	25	54
DBCG 82b	1977-1980	CMF	CMF	32	25	45
DBCG 82c	1980-1983	RT + Tamoxifen	Tamoxifen	8	25	45
DBCG 82c	1980-1983	Tamoxifen	Tamoxifen	35	25	36
British Columbia	1980-1983	RT + CMF	CMF	10	25	54
British Columbia	1980-1983	CMF	CMF	32	25	45

TABLE 37.2-14. Randomized Trials Testing the Value of Postoperative Radiation Therapy Used in Conjunction with Adjuvant Systemic Therapy

**FIGURE 37.2-3.** Survival results in the Danish Breast Cancer Cooperative Group trial 82b comparing cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) chemotherapy and radiation therapy with chemotherapy alone in premenopausal patients treated with mastectomy.

**FIGURE 37.2-4.** Survival results in the Danish Breast Cancer Cooperative Group trial 82c comparing tamoxifen (TAM) and radiation therapy (RT) with tamoxifen alone in postmenopausal patients treated with mastectomy.

The panel agreed to the statements outlined in the next sections. <sup>369</sup>

### Patient Selection

Postoperative RT may be given to improve local control or to improve survival. Patients with four or more positive lymph nodes should receive postoperative RT to improve local control. There may also be a survival benefit in these patients. The data regarding patient selection for survival advantage are less clear, but the most recent evidence suggests that the greatest survival benefit is seen in node-positive patients with low tumor burdens (i.e., fewer positive nodes or smaller tumors). Radiation therapy in these patients for survival benefit is worthy of consideration, pending more definitive data. To establish the survival benefit of postoperative RT in patients with one to three positive nodes, a large randomized clinical trial should be performed. (Such a large Intergroup trial was subsequently approved.)

### Technique

Although both recent trials demonstrating a survival benefit with postoperative RT included treatment to the chest wall, axilla, supraclavicular area, and the internal mammary nodes, there is controversy about what sites require treatment. In all patients, the chest wall should be treated. The value of including the internal mammary nodes is uncertain and is currently being studied in a large European randomized controlled trial. In patients with positive axillary nodes, the internal mammary nodes are known to be also involved in approximately 30% of cases. Treatment of this area is, therefore, worthy of serious consideration, provided that it can be done with acceptable morbidity. Following a level I and II axillary dissection, the use of a third field to treat the axillary apex and supraclavicular area is appropriate for selected node-positive patients, particularly those with four or more positive nodes. A posterior axillary radiation field is not routinely indicated after a level I and II axillary dissection. However, if there is concern about the completeness of surgery, the addition of a posterior axillary field may be appropriate. Careful attention must be paid to the morbidity of treatment. In particular, postoperative RT has the potential to cause late cardiac mortality in patients with left-sided cancers. Therefore, the amount of heart (and also lung) in the treatment field must be minimized and documented. Computed tomographic (CT) treatment planning is useful in accomplishing this goal.

### COMPLICATIONS OF RADIATION THERAPY

Possible complications of RT include arm edema, brachial plexopathy, decreased arm mobility, soft tissue necrosis, rib fractures, radiation pneumonitis, carcinogenesis (e.g., contralateral breast cancer and sarcoma), and radiation-related heart disease. Information on heart toxicity and carcinogenesis is reviewed here. The data on complications after both postmastectomy RT and RT administered as part of BCT are reviewed.

Injury to the heart is a possible complication after RT. The long-term results from the early trials on postoperative RT using outmoded techniques show an increased risk of cardiac mortality. A more recent population study showed an increased risk of fatal myocardial infarctions for patients receiving left-sided breast RT compared with right-sided breast RT <sup>370</sup>; however, the techniques of RT are not described. A large institution study on patients treated with modern techniques (without adjuvant chemotherapy) did not show an increased risk with long follow-up. <sup>371</sup> In the Stockholm postmastectomy trial discussed previously, late cardiac mortality was seen, but this was clearly related to the amount of heart irradiated. <sup>372</sup> Late cardiac mortality has not been seen in institution-based studies using limited cardiac irradiation with CMF chemotherapy, <sup>373,374</sup> but may possibly occur with RT and high-dose doxorubicin. <sup>375</sup> CT simulation allows for three-dimensional visualization of anatomic structures including the heart and can be useful in selecting techniques to greatly limit the volume of irradiated heart. <sup>376</sup>

One possible complication of RT for breast cancer is the induction of another breast cancer. Breast tissue is known to be sensitive to radiation carcinogenesis. The latency period between exposure and the detection of induced cancers is at least 5 years, and this risk persists for many decades. The risk of carcinogenesis increases with doses up to 10 Gy, then seems to level off and decline so that for doses in the therapeutic range (greater than 45 Gy), the risk seems to be small. <sup>377,378</sup> Because the dose to the opposite breast from a course of RT is in the range of 1 to 3 Gy, tumor induction in the contralateral breast is of greater potential concern than in the ipsilateral breast. Age at exposure to radiation is the other important risk factor for carcinogenesis in human breast tissue. <sup>378,379</sup> and <sup>380</sup> The highest risk occurs in female subjects exposed at the youngest age. With increasing age, the risk of carcinogenesis declines. The risk for women older than 40 years of age seems to be negligible, but not zero. A number of studies have addressed the risk of contralateral breast cancer after postoperative RT. Boice and colleagues conducted a case-control study in a cohort of 41,109 patients diagnosed with breast cancer between 1935 and 1982 in Connecticut. <sup>381</sup> Among women who survived for at least 10 years, RT was associated with a small, but marginally significant, elevation in the risk of a contralateral breast cancer (relative risk, 1.33). The increased risk associated with RT was evident among women who were younger than 45 years of age when they were treated (relative risk, 1.59), but not among older women (relative risk, 1.01). In another case-control study from Denmark, <sup>382</sup> the incidence of a second primary breast cancer in the contralateral breast was examined among 56,540 women with a first primary breast cancer diagnosed between 1943 and 1978. In that study, RT was not associated with an increased risk of contralateral breast cancer (relative risk, 1.04). It is possible to estimate the increased absolute risk of contralateral breast cancer given the elevated relative risk for patients aged 45 or younger seen in the study by Boice et al. <sup>381</sup> The risk may actually be lower, as is suggested by the Danish study. For patients aged 45 years or younger, the risk of contralateral breast cancer within 15 years is approximately 11% without RT and increased to approximately 12% to 13% with the addition of RT. The risk of contralateral breast cancer within 30 years is approximately 22% without RT and increases to approximately 25% to 26% with RT. Thus, the risk of contralateral breast cancer in young patients, which is already higher than that for older patients, is likely to be further increased to a small extent by the use of RT.

Sarcomas of soft tissue or bone are a rare, but well-documented complication of RT. In a report from Memorial Sloan-Kettering Cancer Center, a total of 48 patients with a prior history of breast cancer and subsequent treatment-related sarcomas were seen at the institution over a 43-year period. <sup>383</sup> Lymphangiosarcoma of the extremity accounted for 22, or 46%, of the series. Most of these patients had been treated with radical mastectomy and postoperative RT. The other 26 sarcomas occurred within a RT treatment field and were considered radiation related. Twenty-one of these 26 patients were diagnosed with a soft tissue sarcoma and 5 with a bone sarcoma. The median latency interval between the diagnosis of breast cancer and the development of sarcoma was 11 years (range, 4 to 44) and was similar for the two types of sarcomas. The survival of these patients was poor. In a registry study from Sweden, 13,490 patients with breast cancer diagnosed between 1960 and 1980 were followed through 1988. <sup>384</sup> Nineteen sarcomas were reported, whereas 8.7 were expected (relative risk, 2.2; absolute risk, 1.7/10<sup>4</sup> person-years). Twelve of the sarcomas appeared within the radiation fields. Of particular interest is that a high percentage of sarcomas after treatment with CS and RT are angiosarcomas. <sup>385,386</sup> The typical initial clinical appearance of this sarcoma is as reddish, purplish, or bluish nodules or as skin discoloration. There are often many such areas. These initial findings can be subtle, and diagnosis is commonly not made until more advanced signs are present. Of note, the latency period for this

radiation-induced sarcoma is shorter than for other sarcomas, with some occurring before 5 years.

Lung cancer also appears to be increased in patients irradiated for breast cancer. The latency period from RT to diagnosis is approximately 10 years. In a case-referent study reported by Inskip and others<sup>387</sup> using the Connecticut Tumor Registry, there was a small increased risk of lung cancer among 10-year survivors of breast cancer associated with the use of postoperative RT (relative risk, 1.8; 95% confidence interval, 0.8 to 3.8). The relative risk for the period 15 years or more after RT was 2.8 (95% confidence interval, 1.0 to 8.2); however, it can be difficult to distinguish a late metastasis of breast cancer to lung from a new primary lung cancer even with a tissue specimen. This increased relative risk suggests that there would be approximately nine cases of RT-induced lung cancer per year among 10,000 breast cancer patients who survived at least 10 years. Similar findings were noted in a study using the SEER database.<sup>388</sup> Another study from this same group suggested that the effects of smoking and RT are multiplicative,<sup>389</sup> although this relation has not been established with certainty.<sup>390</sup> These studies all examined the risk of lung cancer after local regional irradiation, and the risk may be less after more localized breast irradiation.

### **Sequencing of Systemic Therapy and Radiation Therapy**

Clinicians are now commonly faced with the necessity of combining systemic therapy and RT in patients after CS and after mastectomy. Given (1) the variable agents, duration, and intensity of CT regimens, (2) variations in RT and surgical techniques, and, chiefly, (3) the limited data from randomized clinical trials addressing this question, the optimal sequencing approach is unresolved. The major goal in sequencing is to obtain the highest rate of survival; however, additional important goals are to maintain a low rate of local recurrence and a low rate of complications. The options for combining RT and CT are (1) CT first followed by RT; (2) RT first followed by CT; (3) RT and CT simultaneously; or (4) some number of cycles of CT, then RT, and then more CT (commonly referred to as *sandwich* therapy). In considering this issue, it would be useful to know whether a delay in either CT or RT decreases its effect, what the complication rate is for each sequence option, and whether prior RT affects the ability to give maximal doses of CT. It seems plausible that delays in the initiation of CT will decrease its effectiveness; however, firm data demonstrating this are not available. As previously described, the use of preoperative CT has not clearly improved survival compared with conventionally timed adjuvant chemotherapy.<sup>391</sup> Retrospective reviews of patients treated either with mastectomy or BCT examining the influence of the delay of CT on outcome have demonstrated conflicting results.<sup>392,393 and 394</sup> The information available on whether a delay in the initiation of RT to give CT first leads to an increased local recurrence rate is also conflicting.<sup>394,395,396,397,398,399,400 and 401</sup> The results from two NSABP adjuvant studies in node-positive breast cancer (B-15 and B-16) did not show any effect with delays of 12 weeks.<sup>402</sup>

Prospective randomized clinical trials are required to test formally the effect of sequencing of CT and RT on outcome. The Dana-Farber/Beth Israel/JCRT trial is the only published trial specifically designed to address this issue. In this trial, 244 patients at moderate or high risk for relapse (almost all node-positive) were randomly assigned to receive either (1) RT followed by cyclophosphamide, doxorubicin, methotrexate (with leucovorin), fluorouracil, and prednisone given every 21 days for four cycles or (2) CT followed by RT.<sup>403</sup> With a median follow-up of 58 months, the 5-year crude incidence of first sites of recurrence suggested that local recurrence was greater with delayed RT and distant recurrence was greater with delayed CT. The overall actuarial rate of distant failure was higher in the RT-first arm (37% vs. 25%;  $P = .05$ ), thus favoring the CT-first arm. This trial does not specifically address the question of sequencing in node-negative patients or with longer than 12 weeks of chemotherapy. One can hypothesize that the effect of delay in the initiation of RT is related to the extent of the breast surgery and the final margin status; namely, a delay of 12 to 16 weeks is important only for patients with limited breast surgery and close or positive margins. This hypothesis is suggested by a subset analysis of the JCRT trial; however, this trial was not large enough to allow for such analysis. At this writing, there are two ongoing unpublished trials in France. In the Arcosein trial, approximately 700 patients treated with breast-conserving surgery will be randomized either to (1) mitoxantrone, cyclophosphamide, and fluorouracil given every 3 weeks for six cycles followed by RT, or (2) concurrent CT and RT using the same drugs. In the other trial, patients are randomized either to (1) epirubicin, cyclophosphamide, and fluorouracil followed by RT, or (2) concurrent mitoxantrone, cyclophosphamide, and fluorouracil and RT.

Another important question regarding sequencing is whether RT and CT can be given simultaneously without an increase in complications or a decrease in the cosmetic outcome. The use of simultaneous RT and CT has the advantage of eliminating the necessity for delaying one of the modalities and perhaps providing an additive or synergistic interaction between the RT and CT. It has been reported, however, that the concurrent use of CMF chemotherapy and full-dose RT can result in greater skin reactions compared with patients treated sequentially,<sup>404,405</sup> as well as a decrease in the long-term cosmetic result.<sup>404</sup> It may be possible to combine CMF and RT in other, more tolerable ways. At the University of Pennsylvania, 210 patients were treated with concurrent CF and RT, followed by six cycles of CMF, with excellent results.<sup>406</sup> The JCRT has conducted a prospective pilot study of a modified concurrent CMF and RT regimen using reduced doses of RT designed to lessen treatment side effects by anticipating the known interaction of CMF and RT.<sup>407</sup> One hundred twelve patients with zero to three positive lymph nodes were entered into this prospective study. Patients received six cycles of CMF given every 28 days. On day 14 of cycle 1, patients started tangential field RT, consisting of 39.6 Gy in 22 fractions to the whole breast and a 16-Gy boost to the tumor bed using electrons. The most common acute toxicity observed during or shortly after RT was moist desquamation (seen in 50% of patients). Grade 4 neutropenia was noted in 16 patients during RT, but only one patient required hospitalization. Radiation pneumonitis (grade 2) was noted in only one patient. Fifty-one patients were evaluable for cosmetic scoring by JCRT physicians 2 years ( $\pm 6$  months) after the end of CT: 47% had excellent, 43% had good, and 10% had fair cosmetic scores. Seventy-nine percent of patients (89 of 112) were evaluable for CT dosages delivered; overall, 93% of patients received at least 85% of all drug doses. Thus, it seems feasible to consider the administration of concurrent treatment with CMF and reduced doses of RT; however, longer term data are required to substantiate this.

Doxorubicin and cyclophosphamide (AC) given every 3 weeks for four cycles are currently used more widely than CMF, given its shorter course and at least equivalent outcome. With the substantial interaction between doxorubicin and RT, it does not seem feasible to combine these modalities concurrently even with reduced doses of RT. When AC is used, the results of the JCRT Upfront-Outback trial provide strong support for the use of AC  $\times$  4 followed by RT in all moderate- and high-risk patients. Preliminary results suggest that AC  $\times$  4 followed by Taxol  $\times$  4 may further improve outcome compared with AC  $\times$  4 alone; the optimal timing of RT in this setting is uncertain. Given that the positive results in this trial were obtained using RT after completion of Taxol, it generally seems best to use this approach.<sup>408</sup> Studies are under way testing the feasibility of AC  $\times$  4 followed by concurrent Taxol and RT; however, there is a report of early-onset pneumonitis using this approach<sup>503</sup> and another report showing none.<sup>409</sup>

### **Axillary Treatment**

Axillary treatment in the form of a complete dissection was, for many years, standard management in patients with invasive breast cancer. As dictated by the Halstedian concept of breast cancer spread, axillary dissection was considered a critical component of the surgical cure of the disease. The axillary nodes were considered the *filter* before spread of cancer cells to distant sites. Axillary dissection is also known to be useful in assessing prognosis and ensuring local tumor control in the axilla. By the 1970s, there was increasing evidence that axillary dissection had a limited effect on survival. This was most convincingly demonstrated in the NSABP trial B-04. In this trial, patients with clinically negative axillary nodes were randomized to radical mastectomy, total mastectomy with observation of the axillary nodes and a delayed dissection if positive nodes appeared, or total mastectomy with RT to the regional lymphatics.<sup>234</sup> No statistically significant difference in the 10-year survival rate was found among the groups, despite the fact that approximately 40% of the patients undergoing axillary dissection had positive nodes and a similar percentage were presumed to have positive nodes in the observation-only arm. While this study emphasizes that axillary dissection is not of survival benefit for the majority of patients, the number of patients in this trial was insufficient to rule out a small, but clinically important survival benefit.<sup>410</sup> Also of note is that 25% to 30% of the 20-year survivors reported in a series of patients treated with radical mastectomy alone had positive axillary nodes,<sup>411,412,413 and 414</sup> suggesting that, for a small number of patients, axillary dissection may be therapeutic. The therapeutic potential of axillary dissection is also supported by the survival benefits noted in the more recent trials of postmastectomy RT.<sup>415,416 and 417</sup>

With the general recognition that axillary dissection was principally a prognostic, rather than therapeutic, procedure, a number of studies were undertaken to determine the extent of axillary surgery needed to determine whether nodes were positive or negative. Many of these studies examined the likelihood of skip metastases (i.e., involvement of nodes in the upper axilla; level III) in the absence of involvement in the lower (level I or II) nodes. Involvement of level III is clearly rare when both levels I and II are negative.<sup>418,419</sup> There is considerable variability in the literature on the risk of skip metastases to level II. Much of this variability may be due to variations in the definition of which nodal tissues constitute levels I and II. These disparate observations have led some authors to conclude that a level I dissection provides accurate staging information,<sup>420</sup> while most have concluded that removal of both levels I and II is required.<sup>421,422</sup> A level I and II dissection is effective at providing local control in the axilla. Among patients treated with a level I and II dissection as part of BCT, axillary recurrence rates of less than 3% have been reported.<sup>423,424,425 and 426</sup> When patients undergo more limited random axillary sampling procedures, the likelihood of local recurrence is related to the number of lymph nodes removed. The 5-year probability of an axillary recurrence is approximately 20% in patients with no lymph nodes examined and approximately 10% when only one to two negative nodes are removed. At least six to ten nodes need to be removed to avoid misclassification and to optimize local control in the axilla.<sup>234,426,427,428 and 429</sup> While a level I and II dissection is generally well tolerated, there are occasionally complications. Major complications, including injury or thrombosis of the axillary vein and injury to the motor nerves of the axilla, are infrequent. Minor complications are more common and include seroma formation,

shoulder dysfunction, loss of sensation in the distribution of the intercostobrachial nerve, and edema of the arm and breast.

A number of developments have led to a reexamination of the need for axillary dissection in all patients. Under discussion is the routine use of adjuvant systemic therapy in many patients with node-negative breast cancer, the increasing use of BCT, and the increasing number of patients with small, mammographically detected cancers with a low risk of axillary metastases. One approach to avoiding axillary dissection is to identify cancers with a low risk of nodal metastases. The incidence of axillary nodal involvement is known to be related principally to tumor size. However, axillary node metastases are still seen in 12% to 37% of cancers measuring 1 cm or less,<sup>170,429,430,431,432,433,434</sup> and <sup>435</sup> and in a number of studies, the incidence of metastases does not decrease appreciably even with cancers 0.5 cm or smaller.<sup>429,432,434</sup> The only groups of patients with invasive carcinoma regularly identified as having nodal metastases in fewer than 5% of cases are those with microinvasive tumors, those with grade 1 tumors less than 5 mm,<sup>415</sup> and those with pure tubular carcinomas less than 1 cm.<sup>436,437</sup> However, most patients continue to undergo axillary dissection, even in these favorable groups. A Patterns of Care study examining axillary surgery in 17,151 patients with stage I and II carcinoma undergoing BCT in 1994 found that overall, 93% had an axillary dissection. Even in patients with grade 1 tumors, favorable histologic subtypes, or tumors less than 5 cm, 88% or more underwent axillary dissection.

The new technique of lymphatic mapping and sentinel node biopsy offers the possibility of reliably identifying patients with axillary node involvement with a low-morbidity operation, allowing axillary dissection to be limited to patients with nodal metastases who can benefit from the procedure. The sentinel node is defined as the first node receiving lymphatic drainage from a tumor, and the absence of metastases in the sentinel node reliably predicts the absence of metastases in the remaining axillary nodes. This concept was popularized by Giuliano et al. in malignant melanoma and later adapted to breast cancer.<sup>438</sup> Multiple studies have now confirmed that a sentinel node can be identified in more than 90% of cases, with experience, and predicts the status of the remaining nodes with 90% to 95% accuracy.<sup>439,440,441,442,443</sup> and <sup>444</sup> (Table 37.2-15).

Study	No. of Patients	Sentinel Node Technique	Sentinel Node Identified (%)	Node Positive (%)	False-Negative Rate (%)
Giuliano et al. <sup>438</sup>	307	B	94	42	0
Vernoni et al. <sup>440</sup>	376	R	97	49	6.7
Shoush et al. <sup>441</sup>	253	B + R	92	—	0.5
Coombes et al. <sup>442</sup>	345	B	71	50	3.0

Krag et al. <sup>444</sup>	443	R	91	28	11.0

B, blue dye; R, radioactivity

**TABLE 37.2-15.** Studies of Lymphatic Mapping and Sentinel Node Biopsy

The sentinel node can be identified using isosulfan blue dye, radiolabeled colloids, or a combination of the two agents. Similar success rates are reported for the techniques, and a randomized trial demonstrated no difference in the rate of sentinel node identification, predictive value of the sentinel node, or learning curve for isosulfan blue dye alone compared with the blue dye plus technetium sulfur colloid.<sup>445</sup> Approximately 20 to 30 cases appear to be necessary to master the sentinel biopsy technique, with individual learning curves varying widely.<sup>444,445</sup> and <sup>446</sup>

A number of contraindications to sentinel node biopsy have been identified, including the presence of suspicious axillary adenopathy, evidence of locally advanced breast cancer, use of preoperative chemotherapy, multifocal or multicentric tumor, prior axillary surgery, and a pregnant or lactating patient. In addition, virtually no information on accuracy of the procedure for tumors larger than 5 cm is available. Lymphatic mapping and sentinel node biopsy have prompted renewed interest in the role of the internal mammary nodes in breast cancer. A small number of internal mammary node biopsies have been reported in patients whose lymphoscintigraphy results have failed to demonstrate axillary drainage, but the need for internal mammary node biopsy remains to be defined.

Sentinel node biopsy offers the pathologist the opportunity to perform a much more detailed examination of one or two nodes than is possible when evaluating an entire axillary specimen. It has been known for more than 30 years that approximately 20% of lymph nodes in which no tumor is seen after routine processing and light microscopy contain tumor cells that can be identified by serial sectioning or immunohistochemistry.<sup>447,448,449</sup> and <sup>450</sup> Early studies did not find these micrometastases to be prognostically significant, and these techniques were not practical for use on an entire axillary specimen. With the ability to examine only one or two sentinel nodes, there is renewed interest in the possibility of using immunohistochemistry for ultra staging. However, prospective confirmation of the significance of tumor cells detected by immunohistochemistry is lacking. The retrospective studies that indicate prognostic significance show a wide variation in the magnitude of this effect,<sup>451,452</sup> and <sup>453</sup> making patient counseling difficult. The results of two prospective clinical trials being carried out by the American College of Surgeons Clinical Oncology Group and the NSABP to address these issues will provide important information regarding the clinical significance of micrometastases.

An additional important unresolved issue is the need for completion axillary dissection when a positive sentinel node is identified. The initial sentinel node studies demonstrated that the sentinel node is the only tumor-containing node in 40% to 60% of cases, and fewer than 20% of patients have more than three involved nodes.<sup>438,439,440,441,442,443,444</sup> and <sup>445</sup> A positive sentinel node establishes the need for systemic therapy, and, in patients undergoing breast-conserving surgery, radiation of the breast includes a significant portion of the low axilla, helping to maintain local control. However, the possibility that axillary dissection has some therapeutic benefit for patients with involved nodes cannot be excluded, making abandonment of completion axillary dissection unwise. The need for axillary dissection in sentinel node–positive patients is being addressed in a prospective randomized trial by the American College of Surgeons Clinical Oncology Group.

The initial results of lymphatic mapping and sentinel node biopsy are extremely promising. However, data on the long-term outcome of sentinel node biopsy alone in unselected populations and information on the ability of surgeons outside of centers of expertise doing a low volume of breast surgery are needed before it can be determined if sentinel node biopsy will replace axillary dissection as the standard of care for the node-negative or node-positive breast cancer.

## LOCAL RECURRENCE

### LOCAL RECURRENCE AFTER MASTECTOMY

Local recurrence following mastectomy usually presents as one or more asymptomatic nodules in or under the skin of the chest wall, typically located in or near the scar of the mastectomy.<sup>454</sup> A few patients present with diffuse chest wall involvement, more commonly seen in patients with locally advanced tumors originally. *Carcinoma en cuirasse* is a distinct form of diffuse infiltration of the skin or subcutaneous tissues of the chest wall with woody induration and spread of tumor well beyond the limits of standard surgical or RT boundaries. Approximately 80% of local recurrences appear by 5 years after mastectomy and nearly all occur by 10 years.<sup>264,367,455</sup> However, local recurrences occurring 15 to 50 years after initial surgery have been reported. It is possible that some of these late recurrences may represent new secondary cancer arising in residual breast tissue.<sup>456</sup>

It is unclear how often chest wall recurrences progress to be symptomatic. In some series, only 25% to 30% of patients develop significant morbidity.<sup>367,457</sup> However, in one series of 100 patients with local regional recurrence, 62 had one or more significant symptoms before death.<sup>458</sup> Despite aggressive local treatment, most patients with an isolated local recurrence following mastectomy eventually manifest distant metastases. In a series of patients with local, regional, or both local and regional recurrence treated at the JCRT, the 5- and 10-year actuarial rates of freedom from distant metastases were 30% and 7%, respectively.<sup>459</sup> The corresponding rates of overall survival were 50% and 26%. However, patients surviving without disease 15 or more years after treatment with RT have been described. More recent series appear to include patients with more favorable disease and suggest that favorable subsets of patients with local recurrence can be identified based on factors discussed here.<sup>460,461,462</sup> and <sup>463</sup>

A number of prognostic factors for survival following local recurrence have been identified.<sup>459,460,461,462,463,464</sup> and <sup>465</sup> The interval between mastectomy and local recurrence (called the *disease-free interval*) is the most reliable indicator of the time to subsequent distant failure and overall survival. This likely reflects the intrinsic

growth rate of the tumor. For example, at the JCRT, the relapse-free survival at 3 years was 20% for patients treated with aggressive RT who had isolated local recurrences less than 24 months after initial surgery, compared with 36% in patients who had isolated local recurrences at 24 months or longer after surgery.<sup>459</sup> The respective 10-year survival rates were 7% versus 36%, with similar results found in nearly all RT series. Lymph node status at the time of mastectomy and the number of sites and the size of recurrence also appear to influence prognosis. In patients with a long disease-free interval, limited disease capable of being resected, limited initial axillary involvement, or both limited disease and involvement, the prognosis may be favorable.<sup>460,461,462 and 463</sup>

Patients undergoing skin-sparing mastectomy do not appear to be at a greater risk of local recurrence than patients undergoing more conventional mastectomy,<sup>466</sup> but further experience is needed to confirm this.

Patients with local recurrence after mastectomy should have a complete restaging to rule out distant metastases. In particular, a CT scan of the chest and abdomen and a bone scan is recommended since many patients have additional sites of involvement only discovered in this manner.<sup>467</sup> MRI or positron emission tomography scans may provide additional information.<sup>468,469</sup> Limited local excision has been used in some patients, with further local failure occurring in over one-half of patients so treated.<sup>338</sup> For highly selected patients, local control rates in excess of 75% have been reported with wide local excision of skin and subcutaneous tissue or partial or full-thickness chest wall resection, with some patients surviving 5 years or more.<sup>470,471 and 472</sup> RT has been the standard form of local treatment for patients with local recurrence after mastectomy. The volume of disease remaining at the time of RT is a critical determinant of the likelihood of achieving long-term local control, and gross excision is recommended if feasible. In patients with initially unresectable disease, the use of initial systemic therapy should be strongly considered. Patients with a recurrence in one portion of the chest wall or draining lymph node areas should receive RT to the entire chest wall. Patients with chest wall recurrence may subsequently have recurrences in the supraclavicular region (and the axillary region if not previously dissected) if only the chest wall is irradiated.<sup>464,465</sup> In general, the higher the dose of RT delivered, the less likely is an in-field failure, and doses in the range of 60 Gy to the site of recurrence are recommended, even following gross excision. However, even with technically optimal RT, further local recurrence is seen in a significant minority of patients. Attempts to improve this have included the addition of hyperthermia; however, this treatment is still limited by technical limitations, complications, and inconclusive support for its use in randomized trials.<sup>473,474</sup> The use of hyperfractionated, accelerated RT has not shown improved results.<sup>475</sup> Photodynamic therapy has shown some utility in previously treated patients,<sup>476</sup> but its role in the primary treatment of local recurrence has not been established.

It is not clear whether using adjuvant systemic therapy in conjunction with local treatment can prolong disease-free or overall survival time. While a number of retrospective studies have suggested a benefit to adjuvant systemic therapy,<sup>464,465,477,478</sup> the only randomized trial addressing this issue is from Switzerland and has only a limited number of patients (n = 167).<sup>479,480</sup> Entry in this trial was restricted to patients with a positive or undetermined ER assay, disease-free interval greater than 1 year, and three or fewer nodules, each 3 cm or smaller in diameter, without fixation. Randomized patients underwent complete gross tumor resection and RT and were randomly allocated to receive either tamoxifen until relapse or to observation. With a median follow-up of 6.3 years, the 5-year relapse-free survival rates were 59% and 36% in the tamoxifen and observation arms, respectively ( $P = \text{NS}$ ). However, this difference had nearly disappeared by 8 to 9 years, and the overall survival rates were the same in both groups. This trial was not large enough to suggest a clinically important advantage for adjuvant systemic therapy.

At present, the available information does not clearly identify which patients benefit from the different available treatments or at what point in the course of the disease treatment should be instituted. Local treatment of patients with no evidence of distant metastases reduces morbidity for many and may increase survival time for some patients and is, therefore, generally recommended. This is particularly true in patients with favorable prognostic factors. In patients with a hormone-receptor–positive cancer, hormonal therapy is often considered in addition to local treatment, given the suggestion of benefit in some studies and the limited toxicities associated with such treatment. While the value of adjuvant chemotherapy in this situation is not established, it appears reasonable to use it for patients who have not been previously treated. In patients with an inoperable recurrence, it is reasonable to use *neoadjuvant* systemic therapy to facilitate definitive local treatment. No information is available regarding the benefits of reapplying chemotherapy in patients who had received initial adjuvant systemic therapy. In patients with concurrent or prior distant metastases, appropriate systemic therapy should be used, with RT reserved for patients with persistent local symptoms.

## BREAST RECURRENCE AFTER BREAST-CONSERVING THERAPY

As previously noted, the large majority of recurrences in the treated breast following CS and RT are at or near the site of the primary tumor.<sup>253</sup> The risk of this type of recurrence is relatively constant from years 2 to 7 following treatment and then declines. Recurrences at a distance from the primary tumor are more common at longer follow-up times. Both mammography and physical examination are useful in detecting a recurrence in the breast following CS and RT, with the majority of recurrences evident on mammography with or without findings on physical examination.<sup>481,482</sup> The findings on physical examination associated with a recurrence may be subtle, especially when the primary tumor was of infiltrating lobular histology. Changes in the physical examination that occur more than 2 years following the completion of RT should be viewed as suspicious. Recurrence in the nipple alone, presenting as Paget's disease, can also occur.

There can be substantial overlap in the radiologic appearance between benign and malignant lesions following treatment. Ultrasound is sometimes helpful in distinguishing benign and malignant masses. MRI scans may also be useful, but this is not yet established.<sup>483,484</sup> In patients with suspicious findings, prompt biopsy is recommended. Mammographic or ultrasound-directed core-needle biopsy is an increasingly used approach to confirm the diagnosis.

The large majority of breast recurrences are operable, and the majority of patients are alive 5 years after recurrence.<sup>244,485,486,487,488 and 489</sup> The results appear to be better than for patients with local recurrence after mastectomy, except possibly for patients with early recurrence for whom prognosis is equally poor after mastectomy and BCT.<sup>490</sup> Factors that influence prognosis in patients with operable disease are not well established. The most important prognostic factor in patients undergoing mastectomy in the JCRT experience was the histology of the recurrence.<sup>485</sup> There was no further evidence of disease among the 24 patients with only noninvasive cancer or predominantly noninvasive disease with only focal areas of invasion. In contrast, 38% of patients (38 of 99) with predominantly infiltrating tumors developed a further recurrence, usually distant. A small minority of patients present with skin involvement following BCT, and these patients have a poor prognosis.<sup>258</sup>

In patients with a breast recurrence, appropriate staging for distant metastases should be performed before definitive therapy. The standard treatment for an isolated breast recurrence is mastectomy. Subsequent chest wall recurrences occur in fewer than 10% of patients treated with mastectomy. Postoperative complications following mastectomy are rare. Wide local excision alone is associated with a substantial risk of further breast failure and uncontrolled local disease.<sup>485,488,491</sup> There is limited experience with reirradiation for patients with a breast recurrence.<sup>492,493 and 494</sup> Many patients treated with mastectomy for local recurrence desire breast reconstruction. Immediate reconstruction with a myocutaneous flap is psychologically advantageous and also promotes tissue healing. The risk of complications following reconstruction is slightly greater than in patients who have not had prior RT, and the overall cosmetic results may not be quite as favorable. Previously irradiated patients have tolerated submuscularly placed tissue expanders poorly.

The role of adjuvant systemic therapy following breast recurrence has not been established. In patients with an invasive recurrence, the risk of distant recurrence is substantial, and the use and concerns of adjuvant systemic therapy are similar to those described previously (see [Local Recurrence after Mastectomy](#), earlier in this chapter).

## BREAST RECONSTRUCTION

As discussed, breast reconstruction is an important option for a breast cancer patient undergoing mastectomy to consider and should routinely be discussed with the patient before definitive surgery. The only contraindications to breast reconstruction are the presence of significant comorbid conditions that would interfere with the patient's ability to tolerate a longer operative procedure in the case of immediate reconstruction or additional procedures in the case of delayed reconstruction. In patients who may require postoperative chest wall irradiation, implant reconstructions should be avoided since the risk of implant loss is high after RT.<sup>495</sup> However, TRAM flap reconstructions appear to tolerate postoperative RT well.<sup>334</sup> Patient age,<sup>496</sup> need for adjuvant chemotherapy,<sup>330</sup> or poor long-term prognosis are not contraindications to reconstruction.

The simplest technique for breast reconstruction involves the use of available tissue and placement of an implant. This approach is best for women with small or moderate-sized breasts with minimal ptosis and requires adequate skin to cover an implant of a size similar to the contralateral breast. The use of limited skin excision, with operative exposure gained by incision, usually leaves enough skin to cover an implant. Oncologic surgeons now generally agree that the only skin that it is necessary to excise for reasons of cancer control is the nipple-areola complex and the biopsy scar. If insufficient skin is available to achieve symmetry with the contralateral breast or for larger or ptotic breasts, a tissue expander may be employed. This technique involves placement of a prosthesis that is only partially inflated beneath the pectoral muscle. Using a subcutaneous injection port, the prosthesis is gradually filled with saline over a period of weeks to months until the desired

breast size and shape are achieved.

Silicone breast implants have been available for over 30 years. In January 1992, the U.S. Food and Drug Administration (FDA) declared that silicone gel-filled implants could not be used until more information was available about their long-term safety. This moratorium, however, did not apply to saline-filled implants, and the FDA later recommended that gel-filled implants be allowed in breast cancer patients pending the results of further study. The major recognized complication of implants is the development of capsular contracture, an excessive scar formation around the implant that may lead to deformity and pain of the breast. Other complications of implants include rupture of the implant and leakage of silicone through the intact implant capsule. The incidence of these complications is uncertain. A major concern regarding the use of silicone implants arose after uncontrolled reports suggested an increased incidence of connective tissue disease in women with implants.<sup>497,498 and 499</sup> However, in 1995 the American Society of Rheumatologists concluded that scientific evidence does not support an association between implants and connective tissue disease. A metaanalysis of 13 epidemiologic studies and other publications on this topic identified a relative risk of 0.76 for any connective tissue disease and 0.98 for scleroderma in patients with breast implants.<sup>500</sup> Similar risks were reported by Silverman et al.<sup>501</sup> after a metaanalysis of 4000 cases.

Another technique of reconstruction is the use of myocutaneous flaps to transfer skin, fat, and muscle from distant parts of the body. The most commonly used flaps are the latissimus dorsi and TRAM flaps. The use of a flap for reconstruction requires a more lengthy and involved operative procedure than the implant method, and postoperative recovery is somewhat longer because there are two separate incision sites. The latissimus flap is often used in conjunction with a prosthesis because, in most cases, the flap alone provides insufficient bulk to achieve symmetry. With the latissimus flap, there is only a 1% incidence of complete flap loss.<sup>502</sup> The TRAM flap usually allows an adequate breast mound to be fashioned without the use of a prosthesis, but its blood supply is more tenuous than that of the latissimus flap, with major necrosis reported in 5% of patients and partial necrosis in as many as 31% of patients.<sup>330,503</sup> For some patients, the removal of extra tissue from the lower abdomen is an advantage to this procedure. Abdominal wall herniation is seen in 2% to 5% of patients following this procedure, but this percent is dependent on the skill and experience of the operator. Long-term cigarette smoking (more than 20 pack-years) has an acute and chronic effect on microcirculation and, in many centers, is a contraindication to the procedure. If these myocutaneous flaps are not available or suitable for use, it is possible to transfer composite tissues from distant sites and to perform a microvascular anastomosis to nearby vessels.<sup>504</sup> This technique, known as a *free flap*, requires a skilled microsurgeon and prolonged operating time and is only occasionally chosen for primary reconstruction. The potential benefits and complications of the various reconstructive procedures are listed in [Table 37.2-16](#).

Type	Advantage	Disadvantage
Implant	One-stage procedure; short operative time; minimal postoperative hospitalization and recovery; and low cost	Capsular contracture; possible rupture or leakage; poor cosmetic outcome; change in pain; breast
Tissue expander	Short operative time; low cost; hospitalization and recovery not prolonged	Multiple physician visits; possible rupture or leakage of implant
Latissimus dorsi flap	Multiple flap; autogenous tissue; natural contour	Donor-site scar; moderate prolongation of hospitalization and recovery; usually requires an implant
Transverse rectus abdominis flap	Autogenous tissue; natural contour; debulking option	Donor-site scar; significant prolongation in hospitalization and recovery; possible flap loss and abdominal wall hernia

**TABLE 37.2-16.** Types of Reconstruction after Mastectomy

Regardless of the technique of reconstruction chosen, the creation of a breast mound is the chief goal in breast reconstruction. Surgery on the contralateral breast, such as reduction or mastopexy, may be required to achieve symmetry. Reconstruction of a nipple-areola complex is another secondary procedure that some patients elect to undergo in order to improve cosmetic appearance. The patient's own nipple should *not* be used for this purpose because recurrent carcinoma due to persistence of breast tissue on the nipple has been reported. Microscopic involvement of the nipple is seen in 30% of mastectomy specimens, but is frequently not apparent at the time of gross pathologic examination. The nipple can be reconstructed using a variety of local flap techniques or by the use of full-thickness skin grafts. Tattooing of the grafts produces a color match to the patient's own areola and allows any site to be used as the donor.<sup>505</sup> Tissue from the contralateral nipple should not be used for nipple reconstruction because of the concern of transferring breast tissue to the reconstruction site.

## SPECIAL THERAPEUTIC PROBLEMS

### PAGET'S DISEASE OF THE NIPPLE

Paget's disease of the nipple is a rare form of breast cancer that is characterized clinically by eczematoid changes of the nipple. Associated symptoms include itching, erythema, and nipple discharge.<sup>506,507 and 508</sup> Paget's disease is diagnosed histologically by the presence of large cells, with pale cytoplasm and prominent nucleoli (known as Paget's cells) involving the epidermis of the nipple. In approximately 45% of women with Paget's disease, a breast mass is detected at presentation, and in most of the remainder, infiltrating or intraductal carcinoma is identified in the mastectomy specimen.<sup>506,507,508 and 509</sup> The average age of women with Paget's disease does not differ from that of women with other forms of breast cancer, but symptoms are frequently present for 6 months or more before diagnosis.<sup>506,509</sup> The relation between the changes observed in the nipple and the underlying breast cancer remains a matter of controversy. One theory suggests that the nipple involvement represents the migration of malignant cells from the underlying breast tumor. The alternate hypothesis suggests that Paget's cells are a separate disease process originating in epidermis.

Paget's disease has traditionally been treated with mastectomy. The rationales for this approach are the need to sacrifice the nipple-areola complex, the fact that the subareolar ducts may be diffusely involved with tumor, and the observation that carcinoma may be found at a considerable distance from the nipple.<sup>506,507,508 and 509</sup> A limited experience with breast-conserving procedures in the management of Paget's disease has been described. Paone and Baker reported five patients who underwent excision of the nipple with a wedge resection of underlying breast tissue, who remained free of disease at 10-year follow-up.<sup>508</sup> Lagios and coworkers reported five patients with no palpable breast mass and negative mammogram results treated by excision of the nipple-areola complex, who remained free of parenchymal recurrence at a mean follow-up of 50 months.<sup>510</sup> One patient, treated with only partial nipple excision, developed recurrent Paget's disease at 12 months, which was resected. In contrast, four of ten patients treated by Dixon et al. with excision alone had local recurrences after a median follow-up of 40 months.<sup>511</sup> Twenty selected patients with Paget's disease without clinical or radiologic evidence of parenchymal breast cancer were treated with RT alone or excision plus RT at the Institut Curie from 1960 to 1984.<sup>512</sup> At a median follow-up of 7.5 years, three patients had recurrent disease in the nipple-areola region and were treated with mastectomy. The 7-year actuarial probability of survival with the breast preserved was 81%. Bulens et al., using similar selection criteria, reported no local or distant failures in a group of 13 patients treated with breast irradiation alone.<sup>513</sup> Osteen collected a total of 79 patients treated by local excision with or without RT, with nine local recurrences.<sup>514</sup>

When considering therapeutic options in Paget's disease, it is helpful to think of the condition as DCIS involving the nipple, usually associated with additional intraductal or invasive carcinoma in the underlying breast parenchyma. The extent of the underlying involvement determines the patient's suitability for BCT. Detailed mammographic evaluation (including magnification views of the subareolar region) and histologic evaluation with margin assessment are essential components of this evaluation. For patients with evidence of diffuse involvement or disease at a distance from the nipple, mastectomy remains the standard therapy. In patients with disease localized to the subareolar area or the nipple-areola complex, BCT can be considered. This treatment requires removal of the entire nipple-areola complex and some of the underlying ductal region. In carefully selected patients, local failure rates with this approach appear to be similar to those reported for other breast carcinomas. The prognosis in Paget's disease is related to the stage of the disease and appears to be similar to that of women with other types of breast carcinoma. If invasive breast cancer is found, adjuvant systemic treatment should follow the same guidelines used for other patients with invasive cancer.

### MALE BREAST CANCER

Cancer of the male breast is an uncommon disease, accounting for less than 1% of all cases of breast carcinoma.<sup>515,516</sup> According to SEER data, approximately 1600 cases of male breast cancer and 400 deaths were expected to occur in 1999.<sup>2</sup> In one study, a family history of female breast or ovarian cancer was reported in 30% of men with breast cancer.<sup>517</sup> As described previously (see [Inherited Predisposition to Breast Cancer](#), earlier in this chapter), studies have demonstrated that germline

mutations of BRCA2 are associated with an increased risk of male breast cancer, as well as early-onset breast cancer in women. In the absence of a family history, however, a BRCA2 mutation is unlikely to be found in a man with breast cancer. An initial report suggested that BRCA2 might account for approximately 15% of male breast cancer; however, a high percentage of patients in this study had a family history of female breast cancer.<sup>518</sup> The only population-based study using male patients from a cancer registry found a much lower (4%) incidence of BRCA2 mutations.<sup>517</sup> Other factors that increase the risk of male breast cancer include Klinefelter's syndrome, hepatic schistosomiasis, and radiation exposure.<sup>519,520</sup> and <sup>521</sup> Except for men with Klinefelter's syndrome, the presence of gynecomastia does not seem to be associated with an increased risk of breast carcinoma; however, microscopic changes of gynecomastia are commonly seen histologically in male breast cancer.<sup>522,523</sup>

Male breast cancer typically presents as a mass beneath the nipple-areola complex.<sup>523,524</sup> Ulceration of the nipple is a frequent sign, although isolated nipple discharge is uncommon. The mean age of men with breast carcinoma is between 60 and 70, slightly higher than that of women with the disease.<sup>525</sup> Infiltrating ductal carcinoma is the most common tumor type, but Paget's disease of the nipple and inflammatory carcinoma have been reported in men.<sup>522,525</sup> LCIS is not seen in the male breast, and infiltrating lobular carcinoma is rare.<sup>522,523</sup> and <sup>524</sup> As many as 80% of male breast carcinomas are hormone-receptor positive,<sup>526,527</sup> and an inverse correlation exists between receptor positivity and age, similar to that seen in women.<sup>527</sup>

The standard local treatment for male breast carcinoma is mastectomy. If the tumor is not fixed to the pectoral muscle, a modified radical mastectomy can be performed. If muscle involvement is limited, a portion of this structure can be removed. For patients with extensive involvement of the pectoral muscle, a radical mastectomy may be required.<sup>524</sup> BCT for male breast carcinoma is rarely feasible given the small size of the breast and the subareolar location of the cancer in most men. Patients may, however, occasionally express an interest in this approach to therapy.

The survival rate of men with breast cancer is similar to that of women after controlling for differences in stage.<sup>528,529</sup> As in women, axillary nodal status is the major predictor of outcome.<sup>523,524,530</sup> In a report of 335 cases of male breast cancer, 84% of node-negative patients survived 10 years, compared with 44% of those with one to three positive nodes and 14% with four or more positive nodes, not dissimilar to that seen with female patients.<sup>531</sup> Age at diagnosis and tumor size were also significant in a multivariate analysis of prognostic factors in the study of Hulthorn et al.<sup>530</sup> Borgen and coauthors<sup>524</sup> found that only duration of symptoms and axillary nodal status were significant predictors of outcome.

The benefit of adjuvant systemic therapy in male breast cancer has not been evaluated in randomized clinical trials, although men with metastatic breast cancer are thought to have a similar course and response to treatment as women with the disease.<sup>532</sup> By extrapolation, this experience has guided the approach to adjuvant therapy in men with early-stage disease. The administration of adjuvant tamoxifen to men with stage II and III disease resulted in a 55% 5-year survival, compared with 28% in historic controls receiving no systemic treatment.<sup>533</sup> Two small retrospective studies<sup>534,535</sup> suggest that survival is improved by adjuvant systemic chemotherapy. In the absence of definitive data, guidelines for the use of adjuvant therapy in men should be the same as those employed in women and guided by prognosis and hormone receptor status. Similarly, decisions about the use of radiation should parallel the treatment of female breast cancer. For those men who choose to have CS, radiation is mandatory. Postmastectomy radiation appears to decrease local regional recurrence, but does not have a substantial effect on survival.<sup>536</sup> Two trials that report an overall survival for women undergoing postmastectomy radiation<sup>357,359</sup> suggest that radiation should be considered following mastectomy in men with nodal involvement.

The use of systemic therapy in male patients with metastatic breast cancer should also follow the guidelines set for female patients. Tamoxifen, megestrol acetate (Megace), aromatase inhibitors, and surgical castration are the principal treatments, although antiandrogens and luteinizing hormone-releasing hormone agonists have been reported to be effective.<sup>537</sup> Response rates of 50% to 80% to hormonal therapy are reported, and responses to second-line therapy are commonly seen.<sup>538,539</sup> and <sup>540</sup> The traditional method of hormonal manipulation has been orchiectomy. A literature review found a 67% response rate to this treatment, which increased to 80% when only receptor-positive cancers were considered.<sup>538</sup> Tamoxifen has a similar response rate and has become increasingly popular as a first-line hormonal manipulation, but tamoxifen may not be as well tolerated in men as in women.<sup>541</sup> Orchiectomy is now often reserved for patients who have failed multiple other therapies.<sup>539,540,542</sup> Chemotherapy is useful as palliative treatment. In general, the spectrum of activity with chemotherapeutic agents is similar to what has been seen in women with breast cancer, although much of the information is anecdotal.

## BREAST CANCER DURING PREGNANCY

Breast cancer is not a common complication of pregnancy; however, when the two occur simultaneously, it presents a complex clinical challenge. Older studies indicated that approximately 7% to 14% of breast cancer occurring in women of childbearing age was complicated by a concurrent pregnancy.<sup>543,544</sup> A review of 416,441 pregnancies found an incidence of 2.2 breast cancers per 10,000 pregnancies.<sup>545</sup> The demographic changes that have led to delays in childbearing have increased the proportion of breast cancer cases that are now associated with pregnancy. It has been suggested that breast cancer may complicate 1 in 1000 pregnancies.<sup>546</sup>

The clinical presentation of breast cancer during pregnancy is typically a palpable mass. The mass or thickening may initially be attributed to the breast changes expected with pregnancy. Nipple discharge, including a thin, sometimes bloody discharge from multiple ducts, may be a normal accompaniment of pregnancy. On the other hand, a persistent, unilateral, bloody discharge during pregnancy requires further investigation.

Mammography is not as useful in pregnant patients as in those who are not pregnant because of the increased density in breast parenchyma associated with pregnancy.<sup>546</sup> Moreover, the increase in breast size during pregnancy also may make detection more difficult. As is the case with nonpregnant patients, an unremarkable mammogram should not lead to a decision to forego biopsy in a patient with a palpable mass. Delays in diagnosis are not uncommon in pregnant women, most likely due to the difficulty of examining the breast of a pregnant woman and the reluctance of many physicians to suspect breast cancer in a relatively young, gravid patient.

Breast cancer during pregnancy has been thought to be a particularly virulent disease, but much of the poor prognosis may be due to advanced disease at the time of diagnosis. Petrek et al. compared 56 pregnant breast cancer patients treated at Memorial Hospital from 1960 to 1980 with 166 nonpregnant women of the same age treated in the same period.<sup>547</sup> Sixty-one percent of the pregnant women and 38% of the nonpregnant women had positive lymph nodes; 31% of the pregnant women had T1 tumors compared with 50% of their counterparts.

After correction for tumor stage and age, most studies indicate that survival in women treated during pregnancy is similar to that seen in nonpregnant women.<sup>547,548,549</sup> and <sup>550</sup> In the series by Petrek et al.,<sup>547</sup> node-negative pregnant patients had a 77% 10-year survival compared with 75% for nonpregnant patients. The corresponding 10-year survival figures for node-positive patients were 25% and 41%, respectively, and were not statistically different. In contrast, a multiinstitutional study of 407 patients aged 20 to 29 at the time of cancer diagnosis found a relative risk of cancer death of 2.83 (95% confidence interval, 1.24 to 6.45) for the 26 patients whose cancer was diagnosed during pregnancy compared with those who had never been pregnant.<sup>551</sup>

After a diagnosis is made, the pregnant patient with breast cancer should meet with a multidisciplinary team, including a medical, surgical, and radiation oncologist, as well as with her obstetrician.<sup>552</sup> In addition, psychosocial support for the patient and her family is critical. An initial evaluation should include an assessment of the extent of the disease, with an emphasis on symptoms suggestive of advanced disease and a thorough physical examination. Mammography can be performed safely throughout the course of pregnancy. Diagnostic studies, such as bone scans and CT scans, should be avoided early in the pregnancy, particularly during the period of organogenesis. These studies are not essential in the initial evaluation of most women with localized breast cancer.

For women in the first or second trimester, the question of pregnancy termination is inevitably raised. While some treatment approaches are feasible during pregnancy, others are contraindicated. Depending on the patient's specific situation, continuing the pregnancy may or may not compromise the usual breast cancer treatment. Even when deviations from the usual treatment are required, it is unclear to what extent such changes or delays affect a woman's odds of remaining free from recurrent breast cancer. The concerns about compromising care must be balanced, by the woman, her family, and her physicians, with the desire to continue the pregnancy. The woman facing these issues must also consider the possibility that if she receives chemotherapy, her ability to conceive another child could be compromised.<sup>553,554</sup> There is no clear evidence that pregnancy termination changes overall survival,<sup>548</sup> but the limitations of all studies that have examined this issue should be recognized. In general, clinicians and patients must understand that the disease outcomes for pregnant women with breast cancer are less well understood than for the general population of women with breast cancer.

In the setting of a pregnancy, options for local therapy need to be considered carefully. Radiation to the breast is contraindicated at all times during pregnancy because of the inability to shield the developing fetus from scatter. If a woman is in her third trimester, the use of CS is reasonable as radiation can be administered after the delivery with only a minimal delay in treatment. For women who are in their first or second trimesters, delaying radiation for 3 to 8 months is of far greater concern as it may increase the risk of local recurrence.<sup>403</sup> However, if a woman is going to receive a course of adjuvant chemotherapy during pregnancy, radiation may not be planned for several months. If the inability to administer radiation during pregnancy leads to a substantially longer time to the initiation of radiation than would usually be the case, serious consideration should be given to proceeding directly to mastectomy. Reconstruction with a TRAM flap is contraindicated because of the effect on the abdominal wall.<sup>555</sup> Other forms of reconstruction are not generally recommended because of the additional anesthesia time required by reconstruction and the difficulty achieving symmetry in a pregnant woman.

The vast majority of young women with breast cancer receive some type of adjuvant systemic therapy as part of their treatment. Such treatment decisions are particularly complex in the pregnant patient. The potential benefits of treatments for the mother must be considered within the context of risks to the fetus. In general, all chemotherapeutic agents should be avoided during the first trimester because of the risk to the fetus. When chemotherapy is administered during the first trimester, there is an increased risk of spontaneous abortion, compromised fetal viability, and major organ malformations.<sup>556,557</sup> Certain agents, such as methotrexate and 5-fluorouracil, appear to be particularly problematic in terms of fetal malformation.<sup>558,559</sup> Cyclophosphamide and other alkylator agents have also been associated with fetal malformation in the first trimester.<sup>558</sup> Exposure of the fetus to chemotherapy after the first trimester does not appear to increase the risk of major fetal malformation.<sup>556</sup> However, there are reports of low birth weight, growth retardation, and fetal demise when exposure occurs after the first trimester.<sup>560</sup> Chemotherapy does cross the placenta, so there is the potential for fetal bone marrow suppression and other organ toxicity. Fetal myocardial necrosis has been reported with the third-trimester administration of an anthracycline,<sup>561</sup> but other fetal abnormalities have not been reported with this agent.<sup>562,563</sup> Many clinicians remain concerned about the potential late cardiac effects of *in utero* anthracycline exposure to the fetus. There are no data concerning the safety of *in utero* taxane exposure.

When adjuvant chemotherapy is administered during pregnancy, many clinicians opt for an anthracycline-based regimen, such as four cycles of doxorubicin and cyclophosphamide. Chemotherapy should not be administered until the second trimester, and even then many physicians try to delay chemotherapy for as many weeks as possible to allow for further fetal development.<sup>556</sup> Adjuvant chemotherapy for women in their third trimesters is often delayed until after delivery, often with the plan of delivering the baby several weeks early.

A regimen of fluorouracil, Adriamycin, and cyclophosphamide chemotherapy has been used by investigators at M. D. Anderson Cancer Center in a total of 24 pregnant women during their second and third trimesters.<sup>552</sup> Birth weights, Apgar scores, and general health of the newborns were reported to be normal. In France, generally favorable short-term outcomes (median follow-up, 42.3 months) have been reported for children exposed to a range of chemotherapy regimens during the second and third trimesters.<sup>564</sup> Adjuvant tamoxifen has not been shown to be safe in women during pregnancy.

In the rare situation that a gravid patient has metastatic disease, treatment decisions are even more difficult and must be tailored to the individual situation. For women with rapidly progressive disease, there may be few options apart from proceeding with systemic therapy, regardless of gestational age.

### OCCULT PRIMARY WITH AXILLARY METASTASES

It is relatively uncommon for breast cancer to present as an axillary nodal metastasis without a palpable lesion in the breast. In a study of over 10,000 patients treated for primary breast cancer at Memorial Sloan-Kettering Cancer Center between 1975 and 1988, occult primaries with axillary metastases accounted for 0.35% of the cancers.<sup>565</sup> Similarly, 0.5% of 12,000 breast cancers treated at the National Cancer Institute in Milan were found to be occult primaries with axillary metastases.<sup>566</sup>

Although malignant axillary adenopathy may be secondary to a variety of primary solid tumors, as well as lymphoma, breast cancer is by far the most common diagnosis in a woman presenting with isolated axillary adenopathy. Before undergoing biopsy, a woman should have a complete physical examination and bilateral mammography. Chest radiography should be obtained, particularly in those with a smoking history. Once a diagnosis is established, additional radiologic studies looking for another primary tumor are rarely helpful in the absence of specific symptoms.<sup>565,566</sup> and <sup>567</sup> The presence of positive hormone receptors further suggests a diagnosis of breast cancer, although other primary tumors (i.e., lung carcinoma) can also be positive for ER.

Several series suggest that MRI may be able to detect otherwise occult cancers in the breast and may be helpful in planning local therapy.<sup>568</sup> In one small series, MRI identified the primary cancer in 9 of 12 patients presenting with axillary disease.<sup>569</sup> In another series from the University of Pennsylvania, MRI of the breast detected occult cancers in 19 of 22 women with a mean size of 17 mm.<sup>570</sup> A German study using MRI detected occult invasive cancer in 6 of 14 women.<sup>571</sup> Case reports also describe the use of positron emission tomography scanning to identify occult lesions.<sup>572</sup> The absence of a lesion on either mammography or MRI does not rule out the possibility of disease within the breast.

In the past, it was generally recommended that women with axillary disease (in the setting of an occult primary) undergo mastectomy.<sup>573</sup> Table 37.2-17 summarizes the results of mastectomy in 228 patients. Overall, a primary tumor was found in 64% of patients, with the highest rate of detection in some of the older studies in which patients did not routinely undergo mammography. The size of the cancers identified at mastectomy has varied. Contrary to what some might expect, some of the cancers identified are of moderate size. Rosen and Kimmel reported a median tumor size of 1.5 cm (range, 0.1 to 6.6 cm),<sup>579</sup> and Baron et al. noted that 45% of the cancers were multifocal.<sup>565</sup> These findings have important implications for BCT in these women, although it is likely that the use of MRI to detect occult cancers would decrease the proportion of women identified with unsuspected tumors at the time of mastectomy.

Investigators	Patients	Cancers/ Mastectomies	5-Y Survival Rate (%)
Ashikari et al. <sup>575</sup>	42	22/34 (65%)	79
Baron et al. <sup>565</sup>	35	22/33 (67%)	75
Ellerbroek et al. <sup>567</sup>	42	1/13 (8%)	72
Fitts et al. <sup>578</sup>	13	11/13 (85%)	71
Haagemer <sup>574</sup>	18	13/14 (93%)	57
Kemeny et al. <sup>580</sup>	20	5/11 (45%)	Not stated
Owen et al. <sup>575</sup>	25	15/25 (60%)	50
Patel et al. <sup>576</sup>	29	16/29 (55%)	28
Vezzoni et al. <sup>586</sup>	49	33/44 (75%)	84
Westbrook and Gallagher <sup>577</sup>	18	9/12 (75%)	61
Total		147/228 (64%)	

**TABLE 37.2-17.** Results of Mastectomy in 228 Women with Axillary Disease in the Setting of an Occult Primary Tumor

There are a number of reports of using BCT in patients with occult primaries.<sup>566,580,581,582</sup> and <sup>583</sup> The obvious objection to this approach is that there may be a relatively large tumor, multifocal disease, or both in the breast that might not be well controlled with radiation. Results with this approach have been mixed. A series of 44 patients treated at the Institut Curie with relatively high-dose whole breast irradiation (median dose, 60 Gy) reported a 9% risk of ipsilateral breast recurrence at 8 years.<sup>581,582</sup> Ellerbroek et al. reported a 17% 5-year actuarial rate of ipsilateral breast recurrence in a group of 16 women treated with breast conservation.<sup>567</sup> There has been no apparent survival difference associated with breast conservation in comparison with mastectomy, but randomized trials in women with occult primaries have not been performed. Furthermore, the series are sufficiently small that it would be misleading to draw anything but the most tentative conclusions regarding the survival equivalence of this approach. Whether or not a mastectomy is performed, some form of axillary surgery should be performed in women presenting with palpable axillary disease because of the limited ability of radiation to control gross axillary disease.

Overall survival for women with occult primary tumors is similar to the survival of patients with comparable axillary involvement in the setting of known primary tumors. Some investigators have suggested that survival may even be slightly better for those with occult primary tumors.<sup>582</sup> Given the fact that tumor size is of prognostic significance even in patients with positive nodes, it is not surprising that those with occult primary tumors (often with minimal disease in the breast) could have a slightly better prognosis than the general population of node-positive patients. Systemic treatment for patients with occult primary tumors and axillary involvement

should reflect the current standard of care for patients with node-positive breast cancer.

### **Phyllodes Tumor**

The term *phyllodes tumor* includes a group of lesions of varying malignant potential ranging from completely benign tumors to fully malignant sarcomas. Clinically, phyllodes tumors are smooth, rounded, multinodular lesions that may be indistinguishable from fibroadenomas. Skin ulceration is seen with large tumors, but this is usually due to pressure necrosis rather than invasion of the skin by malignant cells. Histologically, phyllodes tumor, like fibroadenoma, is composed of epithelial elements and a connective tissue stroma.

Phyllodes tumors are classified as benign, borderline, or malignant based on the nature of the tumor margins (pushing or infiltrative) and presence of cellular atypia, mitotic activity, and overgrowth in the stroma.<sup>584</sup> There is disagreement about which of these criteria is most important, although most experts favor stromal overgrowth. The percentage of phyllodes tumors classified as malignant ranges from 23% to 50%.<sup>585,586</sup> Axillary metastases are reported in less than 5% of cases, but are a poor prognostic sign when present. Metastases more commonly follow the pattern seen with sarcomas (with the lung as the most common site) and histologically resemble sarcomas. They occur in 6% to 22% of cases and are considerably more common in the malignant subtype.<sup>584,585,586</sup> and <sup>587</sup> Approximately 20% of phyllodes tumors recur locally if excised with no margin or a margin of a few millimeters of normal breast tissue, regardless of whether they are benign or malignant.<sup>588</sup> A wide excision with a 2-cm margin of normal breast tissue is appropriate therapy for benign and borderline phyllodes tumors unless they are so large that this is not cosmetically feasible. In the past, many authors have advocated mastectomy for the management of malignant phyllodes tumors.<sup>588,589</sup> Since phyllodes tumors are not multicentric, there is no clear-cut biologic rationale for mastectomy, and series have reported the successful treatment of malignant phyllodes tumors with wide excision.<sup>590,591</sup> The use of systemic therapy for malignant phyllodes tumors is based on the guidelines for treating sarcomas.

### **PROGNOSTIC AND PREDICTIVE FACTORS**

Some of the key decisions in the current management of primary breast cancer involve the need for prognostication and the optimal selection of therapy. A *prognostic factor* is defined as a biologic or clinical measurement that is associated with disease-free or overall survival in the absence of adjuvant systemic therapy. A *predictive factor* is any measurement associated with response or lack of response to a particular therapy. Estrogen receptor status has been clearly shown to be a predictive factor for hormonal therapy, in both the adjuvant and metastatic disease settings. Prognostication is especially important in identifying patients whose prognoses are so favorable that adjuvant systemic therapy is unnecessary. Prognostic factors can also be useful in identifying patients whose prognoses with conventional treatment are so poor as to warrant consideration of more aggressive investigational therapies.

It should be stressed that evaluating potential prognostic and predictive factors requires caution. Individual studies often evaluate many factors and report only the statistically significant ones. To be useful, potential factors require validation in a separate large data set in which multivariate analysis allows for the assessment of the potential factor when adjusted for other known factors.<sup>592,593</sup> and <sup>594</sup> It has also been recognized that certain prognostic factors may only be important in the first 5 years after primary treatment, but not with long-term follow-up.

The most established prognostic factor is the number of positive axillary lymph nodes based on at least a level I or II axillary dissection and a detailed histologic evaluation. An adequate axillary dissection usually contains at least ten lymph nodes. As the number of involved lymph nodes increases, relapse rates increase, and survival rates decrease.<sup>595</sup> Patients are often grouped as having negative nodes, one to three positive nodes, four to nine positive nodes, or ten or more positive nodes. Given the morbidity of axillary dissection and controversies about its therapeutic value, many patients are now undergoing sentinel node biopsy or no axillary surgery (see [Axillary Treatment](#), earlier in this chapter).

Tumor size, one of the first prognostic variables accurately quantified, is also a valuable prognostic factor. Tumor size refers to the maximal size of the invasive component measured on microscopic sections. Tumor size correlates with the number of histologically involved nodes, but has independent prognostic significance. Tumor size is particularly useful in patients with pathologically negative nodes. Patients with negative nodes and tumor size less than 1 cm have a favorable prognosis.<sup>432,596,597</sup> This appears true even for patients with mammographically detected cancers, except perhaps those showing casting-type calcifications.<sup>598</sup>

Tumor grade is commonly provided on pathology reports, and several investigators have demonstrated that it is an important prognostic factor in individual series. The use of tumor grade, however, has been limited by poor reproducibility.<sup>599,600</sup> The most widely used grading systems for breast cancer are the Scarff-Bloom-Richardson classification and Fisher's nuclear grade, although both systems are frequently used in modified versions.<sup>601,602</sup> Other pathologic factors, such as lymphatic and vascular invasion and the presence of necrosis, have been found to be important prognostic factors in individual series, but are similarly limited by poor reproducibility.

Among clinical factors, young patient age has been reported to be an adverse prognostic factor by some,<sup>260,603</sup> but not all, investigators. In two large studies, breast cancer patients younger than 35 years of age had a worse prognosis than older patients. In both studies, young patients were more likely than older patients to have adverse prognostic factors, but young age remained a significant prognostic factor in multivariate analysis. At the 1998 Sixth International Conference on Adjuvant Therapy of Breast Cancer, young patient age was first recognized as an adverse prognostic factor.<sup>604</sup>

Of the biochemical measurements, the most important is the presence or absence of ER and PR in the tumor. In the past, the receptor status was determined by a dextran-coated charcoal biochemical assay. More recently, nearly all laboratories are using an immunohistochemistry assay (estrogen and progesterone receptor immunohistochemical assay, ERICA and PRICA). ERICA is preferable in that it does not require fresh tissue, allows correlation with histology, and can be performed even on very small lesions. Although hormone receptor status correlates with prognosis, it does so only weakly. Furthermore, several studies have reported that ER is a prognostic factor for 5-year disease-free survival, although the curves tend to merge with longer follow-up.<sup>605,606</sup> This suggests that ER status is a measure of proliferative capacity, rather than metastatic potential. Despite this, hormone receptor determination is of critical importance as a predictive factor for hormonal therapy. In addition, the 1998 Overview on the use of adjuvant chemotherapy [see [Adjuvant Drug \(Systemic\) Therapy](#), later in this chapter] showed that its effectiveness was somewhat greater in ER-poor cancers than in ER-positive cancers, thus establishing ER as a weak predictive factor for adjuvant chemotherapy.

The identification of micrometastases in bone marrow using antibodies to various epithelial antigens has also been evaluated for its prognostic significance. A metaanalysis of 20 published studies reported in 1998, including 2494 patients using a variety of techniques, concluded that the presence of micrometastases did not contribute independent prognostic information.<sup>607</sup> More recently, a group using a monoclonal antibody to bind an antigen on cytokeratins not present on bone marrow cells showed a strong correlation between the presence of cytokeratin-positive cells in the bone marrow and 4-year survival.<sup>608</sup> This study raised the possibility that standardized procedures for (1) the preparation of bone marrow specimens, (2) the use of antibodies and staining technique, and (3) the criteria for defining positively stained cells may allow for the routine use of this procedure. Additional follow-up and future studies are needed to establish this before its use in routine clinical practice.

Measures of proliferation have been another area for the evaluation of prognostic factors. This includes mitotic index, thymidine labeling index, flow cytometry, and several antibodies to cell-cycle-associated antigens. One of the concerns in the use of these various measures of proliferation is ensuring standardization. The most thoroughly evaluated of these in the United States has been DNA flow cytometry. Flow cytometry can be performed on fresh tissue specimens, frozen biopsy samples, needle aspirates taken directly from the tumor, or paraffin-embedded tissues. The technique produces a measure of DNA content (DNA ploidy) and the distribution of cells in the cell cycle. Of particular interest has been the percent of cells in the S phase. In 1997, a review of the experience with S-phase fraction determined by flow cytometry concluded that standardization and quality control must be improved before it can be routinely used.<sup>609</sup>

Studies are also under way to determine whether S-phase fraction is a predictive factor for the use of chemotherapy. Studies using antibodies to Ki-67 and proliferating cell nuclear antigen have shown encouraging early results but are not established. To date, there have been relatively few studies that have directly compared different measures of proliferation.

There has also been interest in the prognostic value of growth factors and their receptors. Of these growth factors, the greatest interest has been in HER-2/ *neu*. The gene is located on chromosome 17q21 and is transcribed into a 4.5-kb mRNA, which is translated into a 185-kD glycoprotein. While multiple studies have demonstrated the negative impact of HER-2/*neu* overexpression on the progress of node-positive patients, the role of HER-2/ *neu* in node-negative patients is less clear.<sup>610</sup> There is evidence, however, that HER-2/*neu* may be a useful predictive factor. Several retrospective studies suggest that only patients whose tumors have little or no detectable levels of HER-2/ *neu* derive considerable benefit from cyclophosphamide (Cytoxan), methotrexate, and 5-fluorouracil regimens, and, in a study

from CALGB, that patients whose tumors have high levels of HER-2/*neu* derive greater benefit from dose-intensive Cytosin, Adriamycin, and 5-fluorouracil regimens.<sup>611</sup> A study from the NSABP that compared adjuvant treatment with and without Adriamycin demonstrated that patients with HER-2/*neu*-negative tumors had the same outcome with or without Adriamycin, whereas patients with HER-2/*neu*-positive tumors who did not receive Adriamycin had significantly worse prognoses.<sup>612</sup> Similar results were also seen in a trial from the Southwest Oncology Group study.<sup>613</sup> With the growing use of HER-2/*neu* testing, the most reliable method to determine HER-2/*neu* status must be established.<sup>614</sup>

It has also been suggested that HER-2/*neu* status may predict response to endocrine therapy.<sup>615</sup> Among patients treated with adjuvant tamoxifen, those with HER-2/*neu*-positive tumors tend to have shorter disease-free and overall survival times compared with patients with low HER-2/*neu* levels.<sup>616</sup> However, the data supporting an interaction between HER-2/*neu* expression and adjuvant tamoxifen therapy is not conclusive, and patients with ER-positive and HER-2/*neu*-positive cancers should still receive adjuvant hormonal therapy. Ongoing trials are testing the combined use of tamoxifen and trastuzumab (Herceptin) in these patients.

There are a large number of investigations of other potential prognostic and predictive factors; however, it is beyond the scope of this chapter to review each of them. None has been established for routine use in clinical care, including nm23, p53, cathepsin D, and other measures of tumor invasiveness, measures of angiogenesis, and evolving microarray technology.

## ADJUVANT DRUG (SYSTEMIC) THERAPY

It is thought that occult metastases (or *micrometastases*) are commonly present when patients first present with operable breast cancer. This view is based on the fact that, even following effective local treatment, many patients develop metastatic involvement over time and improvements in local control have been shown to provide, at best, only a small decrease in distant metastases.<sup>248,617</sup> Given this, improving the long-term outlook for newly diagnosed breast cancer patients with early-stage disease can only be accomplished with improvements in systemic therapy.

Beginning more than three decades ago, many clinical trials were organized to test the value of various drugs as an adjunct or *adjuvant* to local treatment. These trials, described in detail here, have demonstrated significant improvements in survival for treated patients compared with controls. Adjuvant chemotherapy, hormonal therapy, or both are now in widespread use around the world. Since its introduction, there has been a decrease in the death rate from breast cancer, suggesting a beneficial effect on public health. In many populations, it has been difficult to distinguish the life-saving effects of screening mammography from those of adjuvant systemic therapy since these two interventions were introduced at approximately the same time. In one large population-based study from British Columbia in which this issue was studied, the use of adjuvant systemic therapy by itself had a direct beneficial effect on the death rate from breast cancer.<sup>617</sup>

Over 100 prospective randomized clinical trials of adjuvant therapy have been conducted. More than 15 years ago, the Early Breast Cancer Trialists' Collaborative Group was formed to organize this vast body of information. This group has provided a composite analysis of all randomized trials of the treatment of primary breast cancer performed worldwide.<sup>618</sup> The major portion of this activity has focused on adjuvant drug therapy; the results of the 1995 Overview are summarized in [Table 37.2-18](#).<sup>110,619</sup> The 1995 Overview (published in 1998) provided important new insights related to the value of tamoxifen in premenopausal women and the utility of chemotherapy in postmenopausal women.

Patient Age (y)	Therapy	Reduction in Annual Odds of Recurrence (%)	Reduction in Annual Odds of Death (%)
<50	Tamoxifen × 5 y vs. no therapy	45 ± 8	32 ± 10
50-59	Tamoxifen × 5 y vs. no therapy	37 ± 6	11 ± 8
60-69	Tamoxifen × 5 y vs. no therapy	54 ± 5	33 ± 6
<40	Polychemotherapy vs. none	37 ± 7	27 ± 8
40-49	Polychemotherapy vs. none	35 ± 5	27 ± 5
50-59	Polychemotherapy vs. none	22 ± 4	14 ± 4
60-69	Polychemotherapy vs. none	18 ± 4	8 ± 4

(Adapted from ref. 110 and 619.)

**TABLE 37.2-18.** Adjuvant Drug Therapy: Percentage Reduction in the Annual Odds of Either Recurrence or Death (from Any Cause)

In the Overview, the number of events (either relapse or death) in the treatment and control arms of individual trials are scored to determine an expected-minus-observed value and an odds ratio indicative of the value of the treatment. When a treatment is beneficial in a given trial, the expected-minus-observed value is negative, and the odds ratio is less than 1.0. Similar studies are grouped together, and a combined expected-minus-observed value and overall odds ratio can then be calculated. In combining the results of similar studies, each expected-minus-observed value and odds ratio are weighted by the relative size of each experiment so that a large study with more events counts more. This statistical method provides an estimate of the effectiveness of a certain therapy based on the entirety of all available data from randomized trials (see [Table 37.2-18](#)).

In examining the results of the Overview, it is important to distinguish those results that are generated from a direct comparison of randomized arms and those results that are indirect comparisons of treatment results across different studies. For example, an indirect comparison would use data from trials comparing chemotherapy versus no treatment with trials comparing ovarian ablation versus no treatment to compare the relative benefits of chemotherapy versus ovarian ablation. The results of direct comparisons provide solid information for use in making treatment decisions, whereas the results of indirect comparisons should be used in generating hypotheses to be tested in additional studies.

The results of the breast cancer metaanalysis suggest an important principle; namely, that the proportional reduction in the risk of relapse as a result of a treatment is generally constant regardless of the patient's absolute risk of relapse ([Table 37.2-19](#)). To illustrate this, assume that a therapy reduces the annual odds of relapse by one-third. If we treat patients who are expected to have recurrences at a rate of 15% per year, only approximately 20% of patients would be free of disease at the end of 10 years without therapy. Reducing the rate of recurrence by one-third with therapy reduces the annual relapse rate to 10%. At this reduced recurrence rate, 35% of patients would be free of disease at 10 years, for an absolute improvement of 15%. If we apply the same therapy to a group of patients expected to develop recurrent disease at 1.5% per year, we would lower the recurrence rate to 1.0% per year with therapy. In turn, the percentage of patients who develop recurrence would decline from 14% to 10% at 10 years. In this situation, the absolute improvement is only 4%. In some situations, such as a woman with a tumor that is less than 1 cm with negative nodes, the absolute benefits might be even smaller.

	Proportional Reduction in Annual Mortality (%)		
	.50	.30	.10
Estimated mortality at 10y with no therapy			
70% (multiple positive nodes)	23 (70 47)	15 (70 57)	4 (70 66)
30% (moderate risk, node-negative)	12 (30 18)	7 (30 25)	2 (30 28)
10% (<1-cm tumor, node-negative)	5 (10 5)	3 (10 7)	1 (10 9)

(Adapted from ref. 110.)

**TABLE 37.2-19.** Absolute Reduction in Mortality at 10 Years per 100 Patients Treated

Clinicians should consider the effect of an adjuvant therapy in terms of both disease-free and overall survival. Ultimately, the goal of adjuvant treatment is to prolong survival. Some clinicians would argue that an improvement in disease-free survival, in and of itself, justifies the use of adjuvant treatment since recurrence is often associated with substantial morbidity. Any improvement in disease-free survival must be considered in the context of the short- and long-term toxicity of adjuvant treatment. In general, improvement in disease-free survival usually translates into survival benefits as well. For this reason, it is reasonable to consider disease-free survival in making treatment decisions, particularly if the studies in question have a sufficiently short follow-up such that an overall survival advantage would not yet emerge.

## ADJUVANT TAMOXIFEN

Tamoxifen was initially considered a promising candidate for adjuvant treatment because of its efficacy against advanced disease and relative lack of toxicity. In the Overview analysis, over 37,000 patients were randomized in 55 trials examining the effect of adjuvant tamoxifen at a dose of 20 to 40 mg/d for at least 1 year. The trial has yielded no clear evidence that 40 mg is superior to 20 mg, in addition to which, the higher dose is more expensive and possibly more toxic. As a result, the standard dose of tamoxifen is 20 mg/d.

As shown in [Table 37.2-18](#), the benefits of tamoxifen are substantial and are seen in both premenopausal and postmenopausal women. Tamoxifen, taken for approximately 5 years, reduces the annual odds of disease recurrence by 47% and the annual odds of death by 26%. The degree of benefit is similar in younger and older women. The benefits of tamoxifen administered for 5 years were similar despite the presence or absence of chemotherapy. This finding represented a change from the previous Overview, at least for premenopausal women. Importantly, the benefits seen with tamoxifen were only seen in women with ER-positive tumors. There appeared to be no benefit from adjuvant tamoxifen in ER-poor patients in terms of either recurrence or death ([Table 37.2-20](#)).<sup>110</sup>

Estrogen-Receptor Level	Reduction in Annual Odds of Recurrence (%)	Reduction in Annual Odds of Death (%)
Poor (<20 fmol/mg)	6 ± 11	-3 ± 11
Unknown	37 ± 8	21 ± 9
Positive	50 ± 4	28 ± 5
10-99 fmol/mg	43 ± 5	23 ± 6
≥100 fmol/mg	60 ± 6	36 ± 7

(Adapted from ref. 110.)

**TABLE 37.2-20.** Effects of Tamoxifen for 5 Years According to Estrogen-Receptor Level

In terms of duration of tamoxifen therapy, 5 years of treatment is the standard of care ([Table 37.2-21](#)).<sup>110</sup> Once women with ER-poor tumors were excluded from the analysis, indirect comparisons indicated that 5 years were superior to 2 years or less. This finding is supported by the results of two individual studies comparing 2 years versus 5 years of tamoxifen.<sup>620,621</sup> It remains uncertain whether more than 5 years of tamoxifen could be superior to 5 years. In both the NSABP B-14 trial and a trial from Scotland, patients randomized to more than 5 years of therapy appeared to have a greater risk of recurrence.<sup>288,622</sup> An Eastern Cooperative Oncology Group trial suggested that the continuation of tamoxifen beyond 5 years may delay relapse in ER-positive patients; however, there was no difference in survival in this study.<sup>623</sup> At present, the available data would support stopping tamoxifen at 5 years. Of note, there are both preclinical and clinical data (withdrawal responses in the metastatic setting) to suggest that tamoxifen may act as a growth agonist after variable periods of exposure.<sup>624</sup> If this is the case, it is not difficult to imagine that the withdrawal of tamoxifen could, in and of itself, be of benefit. Tamoxifen lowers the risk of disease recurrence even after it has been discontinued.<sup>110</sup> Women randomized to 5 years of tamoxifen had a 33% annual reduction in recurrence after 5 years (when they were no longer taking tamoxifen) compared with women who never took tamoxifen. For mortality, the proportional reduction after 5 years was similar to the proportional reduction seen during the first 5 years.

Group	Reduction in Annual Odds of Recurrence (%)	Reduction in Annual Odds of Death (%)
Tamoxifen 1 y		
<50	2 ± 7	-2 ± 8
50-59	28 ± 6	21 ± 6
All	20 ± 5	11 ± 5
Tamoxifen 2 y		
<50	14 ± 5	10 ± 6
50-59	32 ± 4	19 ± 5
All	29 ± 5	17 ± 5
Tamoxifen 5 y		
<50	45 ± 8	32 ± 10
50-59	37 ± 6	11 ± 8
All	47 ± 5	26 ± 4

(Adapted from ref. 110.)

**TABLE 37.2-21.** Duration of Tamoxifen

In general, tamoxifen appears to have greater benefit in women with strongly positive ERs.<sup>110</sup> In the trials evaluating 5 years of tamoxifen, the proportional reduction in annual recurrence was 43% for patients who had moderately ER-positive tumors (less than 100 fmol) and 60% for women with strongly ER-positive tumors (greater than 100 fmol). Similar trends were seen for mortality. Despite the predictive value of progesterone receptors (PR) in patients with advanced disease, PR status did not appear to affect the benefits of tamoxifen in patients with ER-positive tumors. There were insufficient numbers of patients with ER-negative, PR-positive tumors in the Overview to draw any definite conclusions about the benefits of tamoxifen in this subgroup. In clinical practice, such patients are usually considered to have hormonally responsive disease, and similar recommendations for adjuvant tamoxifen therapy should be made for ER-negative, PR-positive patients as for those with ER-positive tumors.

As noted previously, the substantial benefits of adjuvant tamoxifen appear to be confined to patients with positive hormone receptor results. This finding represents a change from previous publications of the Overview. A total of 8000 women with ER-poor tumors were randomized to tamoxifen or no tamoxifen. Although the 10% reduction in the annual odds of recurrence is statistically significant, the absolute benefit is of small magnitude. The proportional reduction in terms of mortality is even smaller, and there is no trend for improved outcome with longer duration of treatment. Given these results, women who are shown to have negative hormone receptor status should not be treated with tamoxifen to prevent a systemic recurrence.

With growing interest in the measurement of HER-2/ *neu* or c-erbB-2, there has been concern raised about the role of tamoxifen in women with both positive hormone receptors and HER-2/ *neu* overexpression. In the metastatic setting, trials have suggested relative resistance to hormonal therapy in patients with HER-2/ *neu* overexpression.<sup>625</sup> In the adjuvant setting, a retrospective analysis of the Italian GUN-1 trial suggested that patients with ER-positive, HER-2/ *neu* overexpressing tumors had a worse outcome with tamoxifen than those who received no hormonal intervention.<sup>626</sup> A retrospective analysis of a large CALGB trial failed to detect a negative interaction between tamoxifen and HER-2/ *neu*.<sup>627</sup> At this time, HER-2/ *neu* overexpression does not preclude the use of adjuvant tamoxifen in a patient who is otherwise an appropriate candidate.

In addition to its effect on recurrence and mortality in trials of 5 years of therapy, tamoxifen has also been shown to reduce the incidence of contralateral tumors. There was a 47% reduction in the annual odds of developing a contralateral cancer. The reduction in contralateral tumors was independent of the hormone receptor status of the primary tumor. These findings are consistent with the results of individual trials,<sup>288</sup> the NSABP tamoxifen prevention trial,<sup>113</sup> and the results seen with the

use of tamoxifen in women with DCIS.<sup>204</sup>

The serious toxicities of tamoxifen and the common side effects are listed in [Table 37.2-22](#). In individual trials, the Overview, and the tamoxifen prevention trial, there has been an unequivocal increase in the incidence of endometrial cancer in women taking tamoxifen. The excess risk over 10 years is estimated to be four cases of endometrial cancer per 1000 women. In NSABP B-14, there was a 0.16% annual risk of developing endometrial cancer on tamoxifen.<sup>113</sup> The breast cancer prevention trial has strongly suggested that endometrial cancer is primarily a problem for women over 50.<sup>113</sup> Thromboembolic complications were also seen more frequently in older women.

<i>Serious, but Rare</i>	<i>Less Serious, but More Common</i>	<i>Not Proven, but a Concern for Many Patients</i>
Thromboembolic events	Hot flashes	Depression
Endometrial cancer	Vaginal discharge	Weight gain
Cataracts	Sexual dysfunction	

**TABLE 37.2-22.** Adverse Effects of Tamoxifen

Tamoxifen has been reported to have positive effects on bone density in postmenopausal women.<sup>628</sup> In the NSABP prevention study, there was a reduction in osteoporotic fractures with tamoxifen that almost reached statistical significance.<sup>113</sup> The clinical significance of this finding is uncertain, and the effects of tamoxifen on bone have not been compared with the bone effects of agents approved to prevent or treat osteoporosis. In premenopausal women, there has been concern raised about accelerated bone loss.<sup>629</sup> Although tamoxifen does lower cholesterol levels,<sup>630</sup> there was no improvement in cardiac or vascular events with tamoxifen in the Overview.<sup>110</sup> In the NSABP prevention study, there was no difference in the frequency of fatal myocardial infarction, nonfatal myocardial infarction, or angina requiring surgical intervention.<sup>113</sup>

In patients who are receiving chemotherapy, tamoxifen can be administered either following the completion of treatment or concurrently with chemotherapy. While there have been theoretical concerns raised about tamoxifen reducing tumor growth rates and interfering with the effects of chemotherapy,<sup>631</sup> this has not been observed clinically. Clinical studies indicate that thromboembolic complications are increased when the two treatments are administered concurrently.<sup>632</sup> Outside of a clinical trial, either approach is reasonable. A similar concern has been raised about a potential negative interaction of tamoxifen and radiation, but this has not been supported by clinical data. Tamoxifen, which was administered concurrently with radiation, lowered the rate of ipsilateral breast recurrences by 61% in NSABP B-14.<sup>113</sup>

Which patients with invasive breast cancer should receive tamoxifen? It is possible to answer this question with less equivocation than in the past. All women who have positive lymph nodes or tumors greater than 1 cm in the setting of positive hormone receptors should receive adjuvant tamoxifen for a period of 5 years. For women with small tumors (T1a or T1b) and negative lymph nodes, the risk of a systemic recurrence is relatively low, and decisions about tamoxifen need to be considered carefully. For the majority of such women, the benefits of tamoxifen probably outweigh the risks. This is particularly the case for a woman who has undergone CS plus radiation and in whom tamoxifen will not only decrease the risk of a systemic recurrence but will also lower the chance of an ipsilateral recurrence or a new contralateral primary. Since the life-threatening toxicities of tamoxifen (endometrial cancer and thromboembolic disease) are more common in women over 50, these toxicities should be considered when making decisions about tamoxifen in this older group of women who are at low risk of recurrence. The decision to continue tamoxifen needs to be reevaluated in women who experience unpleasant side effects. While tamoxifen is usually well tolerated, some patients have a more difficult time with side effects than others. In summary, it is reasonable to consider the use of tamoxifen and to discuss the pros and cons of treatment in any woman diagnosed with a hormone receptor–positive or unknown breast cancer. Tamoxifen should not be administered to women with negative hormone receptor status unless the main goal of treatment is to prevent a second primary tumor. It should be recognized, however, that for the majority of women with invasive breast cancer, the risk of a systemic recurrence is far higher than the risk of developing a second primary tumor.

### HORMONAL INTERVENTIONS OTHER THAN TAMOXIFEN

Although tamoxifen is the mainstay of adjuvant hormonal therapy for patients with breast cancer, questions still remain about the role of ovarian ablation in the management of women with stage I or II disease. If anything, this area has become even more complex in recent years as a result of new findings from clinical trials.

Twelve randomized trials using either surgical or radiation ablation were judged to be of adequate quality to be included in the Overview.<sup>633,634</sup> Of these studies that included 3456 women, seven evaluated ovarian ablation as the sole adjuvant treatment and five looked at ovarian ablation in combination with chemotherapy. Many of the trials were underpowered; some included both premenopausal and postmenopausal women, and only the trials that included chemotherapy had information on ER assays. Despite the fact that most of the individual trials had failed to detect a difference in overall survival, the combined analysis of the 12 studies indicated a highly significant improvement in both recurrence rates and survival for ovarian ablation ([Table 37.2-23](#)).<sup>634</sup> Not surprisingly, this benefit was confined to women who were under 50 at the time of randomization. There was no significant benefit seen with ovarian ablation in the 1354 women who were over 50, most of whom would have already experienced menopause. The absolute improvement in survival at 15 years associated with ovarian ablation in the older subgroup was 2.5%, a difference that was not statistically significant. Of interest, the benefits of ovarian ablation appeared to be far less dramatic in women who also received chemotherapy. The explanation for this finding may lie in the fact that at least some of the benefit associated with chemotherapy may be due to treatment-induced menopause that occurs in a substantial proportion of premenopausal women.

<i>Group</i>	<i>Reduction in Annual Odds of Recurrence (%)</i>	<i>Reduction in Annual Odds of Death (%)</i>
Ovarian ablation vs. no adjuvant therapy (age <50)	25 ± 7	24 ± 7
Ovarian ablation + chemotherapy vs. chemotherapy	10 ± 9	8 ± 10

(Adapted from ref. 634.)

**TABLE 37.2-23.** Metaanalysis of the Effects of Ovarian Ablation

A U.S. Intergroup Trial prospectively studied the value of adding a luteinizing hormone–releasing hormone agonist to a course of adjuvant cyclophosphamide, Adriamycin, and 5-fluorouracil in premenopausal, receptor-positive, node-positive patients.<sup>635</sup> Women were randomized to chemotherapy alone, chemotherapy plus 5 years of goserelin, or chemotherapy plus 5 years of goserelin and 5 years of tamoxifen. The addition of goserelin and tamoxifen resulted in an improvement in 5-year relapse-free survival from 67% to 78% ( $P < .01$ ), a difference that is likely attributable to tamoxifen. The addition of goserelin alone resulted in much smaller improvement in relapse-free survival that was not statistically significant. In a subset analysis, there was the suggestion of greater benefit with goserelin in women

under the age of 40, who would be less likely to experience chemotherapy-induced menopause. <sup>635</sup>

Several European studies have also addressed the role of ovarian ablation in women with early-stage breast cancer. Investigators in Sweden randomized 732 premenopausal women with positive hormone receptors to nine cycles of intravenous CMF every 3 weeks or ovarian ablation. After a median follow-up of 68 months, there was no difference in either disease-free or overall survival. <sup>636</sup> In another trial, the combination of goserelin for 3 years and tamoxifen for 5 years was compared with six cycles of intravenous CMF (day 1, 8 every 28 days) in 1045 premenopausal women with hormone receptor-positive breast cancer. <sup>637</sup> There was no difference in survival between the two arms, although patients on the hormonal therapy had a statistically significant improvement in relapse-free survival after a median follow-up of 42 months. Finally, in a smaller but more mature trial, there was no difference seen between intravenous CMF (every 3 weeks for six to eight cycles) and ovarian ablation in approximately 300 premenopausal women. <sup>638</sup> In women with higher levels of ER expression, there was the suggestion of a better outcome with ovarian ablation; conversely, women with low ER expression appeared to have a better outcome with chemotherapy.

The results of these studies are of great interest, and indirect comparisons in the Overview suggest that ovarian ablation and chemotherapy are similar in the magnitude of their effects. It remains unclear where ovarian ablation fits into the treatment paradigm for women with early-stage breast cancer. Any conclusions must be tempered by the recognition that the database on ovarian ablation is far less extensive than on either chemotherapy or tamoxifen. While ovarian ablation may be comparable with chemotherapy in selected premenopausal patients, there are insufficient data to suggest that ovarian ablation should be substituted for chemotherapy as a routine practice. The potential negative consequences of ovarian ablation in women with breast cancer have not been fully investigated and could be even greater in some women than a course of chemotherapy. It also remains unclear to what extent ovarian ablation adds to benefits seen with tamoxifen in premenopausal women. For many clinicians, the pressing clinical question is whether ovarian ablation is of additional benefit in the premenopausal woman who has received chemotherapy, is taking tamoxifen, and continues to have menstrual cycles. In the absence of additional data, there are insufficient data to recommend such a treatment approach at this time.

Far more limited data are available about other adjuvant hormonal therapies. While toremifene has been shown to be equivalent to tamoxifen in the metastatic setting, <sup>639</sup> its activity in the adjuvant setting has not been established. There are insufficient data to support the use of any other antiestrogens as adjuvant treatment for early-stage breast cancer, including raloxifene.

In postmenopausal women, ongoing studies are evaluating aromatase inhibitors in place of tamoxifen, in conjunction with tamoxifen, and following 2 to 5 years of tamoxifen. Given the activity of aromatase inhibitors in the metastatic setting, these agents may ultimately play a role in the adjuvant therapy of postmenopausal women.

## ADJUVANT CHEMOTHERAPY

The first trials of adjuvant chemotherapy were launched in the 1950s, but it was not until the late 1960s that the first modern trials of combination chemotherapy were initiated. Since the 1970s, randomized trials have addressed many fundamental questions related to adjuvant chemotherapy. Adjuvant chemotherapy initially was administered to women with positive nodes; a series of trials published in the late 1980s extended the use of adjuvant chemotherapy to node-negative women as well. <sup>640,641</sup> and <sup>642</sup>

Two early trials had a major effect on the care of women with breast cancer and the design of future studies. <sup>643,644</sup> The NSABP compared the use of melphalan for 2 years versus no adjuvant therapy in 349 women with node-positive disease. At the same time, Bonadonna and colleagues in Milan evaluated 12 months of CMF versus no adjuvant treatment in 386 women. Both studies showed a statistically significant improvement in disease-free survival, with subset analyses strongly suggesting most of the benefit was in women under the age of 50. The studies demonstrated a trend toward improved survival with chemotherapy, although the survival comparisons did not reach statistical significance. CMF quickly became the standard care for node-positive patients, particularly those who were premenopausal at the time of diagnosis. Twenty-year follow-up of the Milan trial has demonstrated a persistent advantage for the premenopausal women who received CMF, with a difference in survival of 47% versus 22%. <sup>645</sup>

Additional randomized trials have been completed since 1980. Many of these trials have been substantially larger than the early studies, thereby increasing the power of the trials to detect small but clinically meaningful differences. These trials have contributed to our understanding of the optimal duration of therapy, <sup>646</sup> the role anthracyclines play, <sup>647,648</sup> and the benefits of treatment in both node-negative <sup>640</sup> and postmenopausal patients. <sup>649,650</sup>

There are many unanswered questions about the optimal use of adjuvant chemotherapy in women with operable breast cancer, however, one can argue that more is known about adjuvant chemotherapy for women with breast cancer than almost any other topic in clinical oncology. At the present time, there is no woman with invasive breast cancer for whom we can say there is no benefit associated with adjuvant chemotherapy, but for many women the absolute benefit is exceedingly small. In such settings, the potential benefits of treatment need to be carefully balanced against the side effects and potential risks of treatment. Breast cancer is a heterogeneous malignancy with a highly variable natural history. While the extent of disease (or stage of disease) partially reflects the underlying biology of the cancer, a more comprehensive understanding of the molecular biology and genetics of breast cancer is needed. Ultimately, this understanding will allow us to tailor therapies for specific patient subgroups and to target therapies to different tissue types. Until we gain a better understanding of subgroup differences, we are forced to consider the risks and benefits of treatments across broad populations, as best exemplified by the Overview analysis. <sup>619</sup>

It is difficult to overestimate the importance of the Oxford Overview analysis <sup>618,619</sup> in furthering our understanding of the role that adjuvant chemotherapy plays in women with breast cancer. The results of 69 randomized trials involving approximately 30,000 women were included in the third and most recent analysis and publication of the Overview. <sup>619</sup> Although any metaanalysis has limitations, the large number of women included in the analysis allows for comparisons that cannot be made in individual trials.

[Table 37.2-24](#) outlines the benefits of polychemotherapy (combination chemotherapy) in comparison with no chemotherapy in a total of 47 trials involving 17,000 women. In some of these trials, women received additional treatment (i.e., tamoxifen) as well, but all study participants were randomized to receive multiple courses of combination chemotherapy or no chemotherapy. As can be seen, there is a highly significant benefit for combination chemotherapy compared with no chemotherapy. For the population as a whole, polychemotherapy reduced the annual odds of recurrence by approximately 25% and the annual odds of death by approximately 15%. The reduction in recurrence as a result of chemotherapy was greatest during the first 5 years following diagnosis, although there was still a significant, although smaller, proportional reduction in recurrence as a result of chemotherapy even after 5 years. The effect of chemotherapy on survival was seen during the first 5 years and persisted to an equal or greater extent during the next 5 years. The fact that the survival curves continued to separate after 5 years is not surprising; recurrences of breast cancer during the first 5 years after a diagnosis may lead to death from breast cancer during the subsequent 5-year period. This finding underscores the importance of following women with early-stage breast cancer for an extended period of time to obtain a full picture of the effect of a therapy on long-term survival. The effect of adjuvant chemotherapy on women under age 50 is illustrated in [Figure 37.2-5](#).

Regimen	Total No. of Patients Analyzed	Reduction in Annual Odds of Recurrence (%)	Reduction in Annual Odds of Death (%)
All polychemotherapy regimens	1678	25% (±1); P<0.001	15% (±1); P<0.001
Cyclophosphamide, methotrexate, and 5-fluorouracil	859	26% (±1); P<0.001	16% (±1); P<0.001
Cyclophosphamide, methotrexate, and 5-fluorouracil + additional agents	819	24% (±1); P<0.001	14% (±1); P<0.01
Other polychemotherapy	740	25% (±1); P<0.001	17% (±1); P<0.001

**TABLE 37.2-24.** Effects of Combination Chemotherapy across Entire Patient Population in Overview Analysis

**FIGURE 37.2-5.** Effect of polychemotherapy on recurrence and mortality in women less than 50 years of age. (From ref. 619, with permission.)

In the Overview analysis, the proportional reductions in recurrence and mortality are similar in node-negative and node-positive patients.<sup>619</sup> Given the better prognosis of node-negative patients, especially those node-negative patients with small tumors (i.e., less than 1 cm), the absolute benefit of therapy in women with negative lymph nodes is much smaller than in those who have positive nodes. It is estimated from the Overview data that an average node-negative patient under age 50 would have an absolute improvement in survival at 10 years of 7% (an improvement from 71% to 78%). In contrast, the absolute improvement for a node-positive patient under age 50 is estimated to be 11% (an improvement from 42% to 53%).<sup>619</sup> Given the mix of trials included in the Overview, the actual benefits of chemotherapy may be somewhat greater in a compliant patient population without significant comorbidity in whom full doses are delivered.<sup>651</sup>

There is a strong relationship in the Overview between age and the magnitude of benefit seen with chemotherapy, with younger women having a proportionally greater reduction in both recurrence and mortality than women aged 50 to 69. The Overview includes data on only approximately 600 women aged 70 or older, thus limiting any conclusions that can be drawn regarding this subgroup. Since over one-third of all women diagnosed with breast cancer in the United States are over the age of 70,<sup>1</sup> it is unfortunate that additional data are not available. The reductions in recurrence and mortality by age are detailed in [Table 37.2-25](#). Although the benefit of chemotherapy is less in older women, the Overview shows a statistically significant advantage for chemotherapy across all age groups (up to age 69).

Age (y)	Reduction in Annual Odds of Recurrence (%)	Reduction in Annual Odds of Death (%)
<40	37 ± 7	27 ± 5
40-49	34 ± 5	27 ± 5
50-59	22 ± 4	14 ± 4
60-69	18 ± 4	8 ± 4

(Adapted from ref. 619.)

**TABLE 37.2-25.** Effect of Age on Outcome with Adjuvant Chemotherapy

The age-related findings in the Overview are consistent with observations made in the earlier trials<sup>643,644</sup> (i.e., that the benefit of chemotherapy is greater in younger women than in an older patient population). The more substantial benefit of chemotherapy in younger patients, as well as the established benefits of ovarian ablation in premenopausal women,<sup>634</sup> suggests that adjuvant chemotherapy may be working both through a direct cytotoxic effect on the tumor and an endocrine effect by way of the induction of menopause (which occurs in a substantial number of premenopausal women receiving chemotherapy).<sup>553</sup> It should be noted, however, that not all studies show a consistent relationship between the induction of menopause secondary to chemotherapy and disease outcome.<sup>652,653</sup> It has been difficult to separate the effects of age and menopausal status because of their high degree of correlation. It is of interest, however, that in the Overview, postmenopausal women under the age of 50 appeared to derive a similar benefit from chemotherapy as did premenopausal women under 50.<sup>619</sup> This finding would suggest that chemotherapy-induced ovarian ablation is not the primary factor leading to improvement in disease-free survival and overall survival with chemotherapy. If chemotherapy is less effective in older women, there are multiple possible explanations for this phenomenon apart from the ovarian ablation hypothesis. Women over the age of 50 may have a different biologic mix of tumors; the fact that there are age-related differences in tumor biology is suggested by the differences in hormone receptor status across age. Older women may also tend to receive lower doses of therapy and are more subject to competing causes of mortality. Finally, it should be noted that several studies<sup>640,642,643</sup> have suggested that the age-related differences in outcome with adjuvant chemotherapy may be less significant than was previously thought.

Other subjects addressed in the 1998 Overview include the influence of hormone receptor status on decisions regarding therapy and the utility of tamoxifen in conjunction with adjuvant chemotherapy.<sup>619</sup> While chemotherapy was beneficial to a highly significant degree in patients with both ER-negative and ER-positive tumors, there was a trend for greater benefit in women with ER-negative tumors. This finding was seen particularly in women aged 50 to 69 in whom the proportional reduction in recurrence was almost twice as great (30% ± 5 vs. 18% ± 4) in patients with ER-negative tumor compared with those who had ER-positive tumors. The administration of tamoxifen (in addition to chemotherapy) did not appear to have a substantial effect on the benefits of chemotherapy. In other words, the proportional risk reductions from chemotherapy were similar whether or not a woman received tamoxifen; however, the number of younger women receiving chemoendocrine therapy in the Overview was small.<sup>619</sup>

The Overview has provided additional findings of clinical significance. Among these findings, shorter duration therapy (3 to 6 months) appears to be as effective as longer therapy. In addition, anthracycline-containing regimens appear to be superior to non-anthracycline-containing regimens. A total of 11 randomized trials involving 5942 patients compared CMF with an anthracycline-containing regimen. Overall, anthracycline-containing therapy resulted in a proportional recurrence reduction of 12% and a proportional mortality reduction of 11%. The mortality reduction, which resulted in an absolute improvement in survival at 5 years of 2.7%, was of borderline statistical significance.<sup>619</sup> Finally, the Overview did not demonstrate a preponderance of deaths from other causes as a result of chemotherapy, including deaths from other neoplasms and deaths from vascular events.<sup>619</sup>

### USE OF ANTHRACYCLINES IN THE ADJUVANT SETTING

The use of anthracycline-based therapy merits further comment. The finding from the Overview, suggesting a small incremental benefit with anthracyclines, has been seen in some individual trials as well.<sup>654</sup> A U.S. Intergroup trial involving almost 2700 patients compared six cycles of CMF with six cycles of cyclophosphamide, doxorubicin, and fluorouracil (CAF) in high-risk, node-negative patients.<sup>648</sup> The trial demonstrated a 2% improvement (one-sided  $P = .03$ ) in survival for the Adriamycin-containing arm in both premenopausal and postmenopausal women. A Canadian trial comparing CMF and CEF (cyclophosphamide, epirubicin, fluorouracil) demonstrated an improvement in both disease-free and overall survival for the epirubicin-containing arm.<sup>647</sup> This trial led to the Food and Drug Administration's approval of epirubicin as adjuvant therapy in the United States. To date, epirubicin-containing adjuvant regimens have been much more popular in Europe than in the United States.

NSABP B-15 randomized node-positive patients to CMF or four cycles of AC administered every 3 weeks. Although there was no difference in disease-free survival or overall survival between the two arms, the AC arm has been widely adopted as a standard of care. The shorter duration of the treatment of the regimen and the relative ease of administration has led to the regimen's popularity. Whether or not four cycles of AC (lasting approximately 3 months) is equivalent to one of the longer anthracycline-containing regimens (which have often included fluorouracil) remains uncertain. Of interest, using a nonanthracycline regimen, the International Breast

Cancer Study Group demonstrated that three cycles of CMF was inferior to six.<sup>655</sup>

Retrospective analyses from a number of studies suggest that the HER-2/*neu* status of the tumor may influence the relative benefit of anthracycline-containing regimens. Studies have suggested that either more intensive anthracycline-containing regimens<sup>611</sup> or the mere addition of an anthracycline to a non-anthracycline-containing regimen<sup>612,613</sup> may be particularly beneficial in patients whose tumors overexpress HER-2/*neu*. Patients who were HER-2/*neu*-negative in these studies appeared to derive far less benefit from the addition or intensification of an anthracycline.<sup>612,613</sup> Small retrospective studies have also suggested relative resistance of HER-2-positive disease to CMF-type regimens.<sup>656</sup> Given the retrospective nature of all of the analyses described previously, it remains uncertain to what extent the benefit of anthracyclines reported in individual trials and in the Overview is a function of HER-2/*neu* status. The use of an anthracycline-containing regimen has become the standard of care in patients with HER-2/*neu* overexpression (who are receiving chemotherapy) and in most patients with multiple positive lymph nodes. In women with HER-2/*neu*-negative tumors who are at low to moderate risk of recurrence, CMF-type regimens represent a reasonable standard of care. CMF-type regimens are also appropriate for patients who cannot tolerate an anthracycline. There is great interest in investigating the newer nonanthracycline regimens in this population as well.

## DOSE INTENSITY AND DOSE DENSITY IN ADJUVANT TREATMENT

Dose intensity in adjuvant therapy has been of major interest since 1980. A retrospective review of the initial Milan CMF study suggested that patients who received a greater proportion of the intended chemotherapy dose had a superior outcome to those who had more extensive dose reductions.<sup>657</sup> This study, as well as trials in the metastatic setting and preclinical models, led to the development of a series of prospective randomized trials that tested the hypothesis that more dose-intensive treatment would improve clinical outcome for patients with node-positive breast cancer.

The Cancer and Leukemia Group B compared three doses and schedules of CAF chemotherapy. Approximately 1550 patients were randomized to either (1) four cycles of low-dose CAF; (2) six cycles of moderate-dose CAF; or (3) four cycles of high-dose CAF. The total doses in the moderate- and high-dose arms were identical, and the low-dose arm received one-half of the total dose of either of the other groups. The high-dose arm used doses of cyclophosphamide and Adriamycin (600 mg/m<sup>2</sup> and 60 mg/m<sup>2</sup>, respectively) that are now considered the standard of care.<sup>653,658</sup> A statistically significant improvement in disease-free survival and overall survival at a median follow-up of 9 years in favor of the moderate- or high-dose arms in comparison with the low-dose arm ( $P < .0001$  and  $P < .004$  for the two comparisons) was seen. The absolute improvement in 5-year survival between the high- and low-dose arms was 7% (79% vs. 72%). These results are consistent with either a dose-response relationship (progressive improvement in outcome with dose escalation) or a threshold effect.<sup>653</sup>

Three additional trials have evaluated dose escalations with either cyclophosphamide, doxorubicin, or both. In an Intergroup trial, four cycles of AC chemotherapy were administered to over 3100 women with node-positive breast cancer. The dose of cyclophosphamide was fixed at 600 mg/m<sup>2</sup>, but women were randomized to Adriamycin doses of 60 mg/m<sup>2</sup>, 75 mg/m<sup>2</sup>, and 90 mg/m<sup>2</sup>. Despite increased acute toxicity with higher doses of doxorubicin, there was no evidence of an improvement in either disease-free survival or overall survival.<sup>659</sup> Although the median follow-up from the trial is relatively brief, the results do not support the use of more than 60 mg/m<sup>2</sup> per cycle. In two NSABP trials (B-22 and B-25), the dose of Adriamycin was kept constant at 60 mg/m<sup>2</sup>, and women were randomized to receive 600 or 1200 mg/m<sup>2</sup> of cyclophosphamide. Despite the increased dose, there was no improvement in disease-free survival or overall survival.<sup>660</sup> In B-25, the cyclophosphamide dose was escalated from 1200 to as high as 2400 mg/m<sup>2</sup> for four cycles. Toxicity on the higher dose arms appeared to be greater, including an increased number of cases of acute leukemia and myelodysplasia. Although a subset analysis of women with four to nine nodes suggested a slight improvement for the high-dose arm in terms of disease-free survival and overall survival, this was not seen in other nodal subgroups. Dose escalation of cyclophosphamide beyond 600 mg/m<sup>2</sup> as part of combination adjuvant therapy is unlikely to be of substantial benefit and does not appear to be worth the added toxicity. While other studies have used higher than standard doses of cyclophosphamide, at present there is no established role for escalating doses above the 600 mg/m<sup>2</sup> cycle range in clinical practice.<sup>661</sup>

The ultimate test of dose intensity has been the use of very high doses of chemotherapy, usually alkylating agents, in combination with autologous bone marrow or peripheral stem cell support. An initial report from Peters et al. suggested that this approach, when used in women with ten or more positive nodes, improved disease-free survival in comparison with historical controls.<sup>662</sup> A series of randomized trials have been conducted over the past decade comparing high-dose chemotherapy with less intensive treatment programs. Many of these trials have been reported, while others are still accruing or maturing.

To date, there is little evidence that the use of high-dose chemotherapy with autologous bone marrow or peripheral stem cell support improves disease outcomes in the adjuvant setting. In the largest of the adjuvant trials, Peters et al. randomized over 800 women with ten or more positive lymph nodes to four cycles of CAF chemotherapy followed by an intermediate-dose consolidation versus the same induction therapy followed by high-dose cisplatin, carmustine, and cyclophosphamide with stem cell support.<sup>663</sup> With a median follow-up of 37 months, there was no significant difference in either event-free or overall survival (Table 37.2-26). Of note, the overall survival in the intermediate-dose group was 70%, far higher than many would have anticipated from the historic controls. While there were fewer relapses in the high-dose arm, this difference was offset by an increase in the number of toxic deaths on the high-dose arm. Additional follow-up is still needed, but other randomized trials have failed to demonstrate a significant benefit for treatment with high-dose chemotherapy administered with bone marrow or stem cell support.<sup>664,665</sup> It is premature to draw definite conclusions, but at this time, high-dose chemotherapy with peripheral stem cell support cannot be recommended as adjuvant therapy outside of controlled clinical trials.

	Intermediate-Dose Chemotherapy	High-Dose Therapy with Bone Marrow Support	P
Event-free survival	64%	68%	.7
Overall survival	80%	78%	.1
Relapses	28%	20%	
Toxic deaths	0	29	

(Adapted from ref. 663.)

**TABLE 37.2-26.** Results of Adjuvant Trial Comparing High-Dose Chemotherapy with Bone Marrow Support versus Intermediate-Dose Chemotherapy

## INCORPORATION OF THE TAXANES INTO ADJUVANT THERAPY

Because of the demonstrated activity of the taxanes in the treatment of metastatic breast cancer,<sup>666,667</sup> both paclitaxel and docetaxel have been incorporated into adjuvant chemotherapy trials. While the results of trials with docetaxel are not yet available, four cycles of paclitaxel have been shown to improve disease-free and overall survival in node-positive patients. Henderson et al. randomized women to AC × 4 followed by paclitaxel (175 mg/m<sup>2</sup> every 3 weeks × 4) or no additional treatment. The addition of paclitaxel resulted in a 22% proportional reduction in the risk of recurrence and a 26% proportion reduction in mortality. These data were recently updated at an FDA hearing; at 36 months' follow-up, 73% of patients randomized to AC were alive and disease-free compared with 77% of women who received paclitaxel. The absolute improvement in survival was 3% (84% to 87%). The benefit of paclitaxel was similar in premenopausal and postmenopausal women, but patients with hormone receptor-negative tumors appeared to have a greater reduction in risk than those with positive hormone receptor status [Taxol (paclitaxel) package insert].

Although four cycles of AC followed by four cycles of paclitaxel have become a widely accepted standard program for node-positive breast cancer, there are many questions remaining about this regimen. First, is the improvement in women who received paclitaxel entirely due to paclitaxel itself or is it related to the longer duration of therapy? Second, is the benefit of paclitaxel in hormone receptor-positive patients sufficiently large that it should be a routine component of the adjuvant regimen? This question is particularly relevant in the woman with positive receptors who has a small tumor, generally favorable prognostic factors, and a small number of positive lymph nodes. Finally, how will the use of other paclitaxel schedules (i.e., weekly treatment) and the use of docetaxel compare with the benefit seen in the study described previously? Ongoing trials are addressing these issues.

## SELECTION OF ADJUVANT REGIMEN AND DECISION MAKING ABOUT ADJUVANT TREATMENT

There is no single adjuvant regimen that has emerged as the treatment of choice for all women with breast cancer. Although anthracycline-containing regimens have gained tremendous popularity in clinical practice and are, in some cases, superior to CMF, [619,647,648](#) there remains a role for CMF-type regimens in many women with breast cancer. [Table 37.2-27](#) lists the adjuvant regimens that are acceptable in a nonprotocol setting.

---

FAC × 4–6 cycles  
AC × 4 cycles  
AC × 4 cycles followed by paclitaxel × 4 cycles  
CEF × 6 cycles  
CMF × 6 months (preferably oral)<sup>680,681</sup>  
A × 4 cycles followed by CMF × 8 cycles (rarely used)<sup>681</sup>

---

AC, doxorubicin and cyclophosphamide; CEF, cyclophosphamide, epirubicin, fluorouracil; CMF, cyclophosphamide, methotrexate, and 5-fluorouracil; FAC, fluorouracil, Adriamycin, and cyclophosphamide.

---

**TABLE 37.2-27.** Acceptable Adjuvant Regimens Outside of a Clinical Trial

It is impossible to identify a group of women with invasive breast cancer in which there is absolutely no benefit to be gained from adjuvant chemotherapy. In some patient subgroups, the benefits are of extremely small magnitude and should be carefully considered in light of the risks associated with treatment. Women with tumors less than or equal to 0.5 cm (T1a) with negative lymph nodes should not be treated with chemotherapy because of their favorable natural history. [669](#) Because of the limited toxicities associated with tamoxifen, the reduction in recurrence risk as a result of tamoxifen treatment, and the possibility that chemotherapy may be somewhat less effective in patients with ER-positive tumors, [619](#) the decision to add chemotherapy to tamoxifen in a woman who is at relatively low risk of recurrence can be particularly difficult. The acute side effects of chemotherapy (e.g., myelosuppression, emesis, mucositis, infection, fatigue) can have a substantial effect on short-term quality of life. In addition, the persistent or late effects of treatment, such as premature menopause, weight gain, and a slightly increased risk of leukemia, must also be considered. [670](#)

Patient preferences play an important role in decision making about adjuvant therapy. Surveys have demonstrated that some women are willing to accept the side effects of chemotherapy for small improvements in their risk of recurrence or death from breast cancer. [671,672](#) In one survey, the median acceptable life extension in exchange for a course of chemotherapy was 3 to 6 months, and over one-half of those surveyed indicated that they would take chemotherapy for a survival benefit of 1% or less. [672](#) It is unclear to what extent such surveys are representative of the general population, but there are clearly many women who accept the short-term toxicity and inconvenience of chemotherapy in exchange for a small improvement in outcome. In most preference studies, there is considerable variability across patients. [671,672](#) Ultimately, it is hoped that adjuvant therapy will be better tailored to the tumor, so that women do not need to consider such tradeoffs (i.e., a toxic treatment for a small benefit). Until we succeed in this endeavor, it is incumbent on oncologists to describe the potential advantages and disadvantages of adjuvant treatment to their patients.

### PREOPERATIVE CHEMOTHERAPY

For the past two decades, preoperative chemotherapy has been administered to patients with locally advanced breast cancer. More recently, a number of randomized trials have been performed in which preoperative therapy has been administered to women with operable disease. [307,673,674](#) In general, preoperative therapy has been successful in downstaging tumors, both decreasing the size of the tumor and decreasing the number of axillary lymph nodes involved with tumor. It is extremely rare for tumors to progress during preoperative therapy, and the proportion of women who can undergo CS following preoperative treatment is increased. [306](#) The response to preoperative therapy is a predictor of disease-free and overall survival. [673](#) To date, however, there is no evidence that preoperative therapy improves overall survival when compared with postoperative treatment. [306,675](#) Ongoing studies may be helpful in determining whether the response to preoperative therapy can be used to individualize postsurgical treatment. Until additional data are available, the primary advantage of preoperative therapy is to increase the chance of breast-conserving CS in women who are otherwise borderline candidates for this procedure.

### THERAPY OF LOCALLY ADVANCED AND INFLAMMATORY BREAST CANCER

The term *locally advanced breast cancer* encompasses a heterogeneous group of patients including those with neglected, slow-growing tumors as well as those with biologically aggressive disease. Locally advanced breast cancer is a relatively uncommon presentation in the economically developed world, accounting for only 5% of cases in major centers, and no more than 20% in other locations. In most other parts of the world, however, locally advanced breast cancer is more common, accounting for at least one-half of all cases. This difference is thought to be due to variations in public awareness and attitudes, as well as the availability of medical resources, including screening mammography. Biologic differences between populations may also play a role (as discussed later, in [Inflammatory Breast Cancer](#)). The relative infrequency of locally advanced breast cancer has limited the speed of clinical progress in this area.

The definition of locally advanced breast cancer is variable. All investigators include patients with inoperable stage IIIB, while some also include patients with operable stage III, stage IV by virtue of positive supraclavicular lymph nodes, or both. Management recommendations and prognosis might vary according to which of these definitions is used. For example, it might not be necessary to recommend preoperative chemotherapy for a patient with IIIA breast cancer that could be removed surgically. A reader of this literature needs to be certain which of the various definitions is used.

### ROLE OF SYSTEMIC THERAPY

Historically, the results in treating patients with locally inoperable breast cancer using surgery and RT were uniformly poor. More aggressive local treatment did little to improve survival rates, but did result in increased complications. The results, however, improved greatly with the development of effective chemotherapy. [676,677,678](#) and [679](#) This is related in part to the ability of chemotherapy to convert most cases of inoperable primary breast cancer to operable disease. In addition, these patients likely experience the same benefit in decreasing rates of recurrence and death as do patients with stage I and II disease treated with postoperative chemotherapy. Since systemic therapy results in a proportional reduction in the risk of systemic recurrence, the absolute benefit in patients with locally advanced disease may be considerable. In the Overview analysis, the benefit of systemic therapy was equally apparent in adjuvant trials that included stage III patients.

The response rates to preoperative chemotherapy are high, possibly related to the presence of an intact blood supply. The use of preoperative treatment allows (1) the early initiation of systemic therapy in a disease with a high distant failure rate, (2) a reduction in the extent of the operative procedure needed to render the patient grossly free of disease, and (3) the opportunity to observe directly the response to treatment (an *in vivo* chemosensitivity assay). Should the tumor not respond to the initial chemotherapy regimen, substitution with other drugs or the timely initiation of RT may be beneficial. Clinical response is usually determined by physical examination, but can be supplemented by mammography and/or ultrasonography. It is important to note, however, that clinical response does not always correlate with pathologic response. [680](#) Up to one-third of patients found to be histologically free of disease have residual abnormalities by palpation or imaging after induction chemotherapy. Conversely, approximately one-third of patients thought to be in complete remission on clinical grounds still have residual disease on pathologic examination. Pathologic response is the best indicator of response to treatment, and patients with a complete pathologic response have a favorable prognosis. [681](#) Newer imaging methods, such as MRI, [682](#) may improve the ability to judge response.

A wide variety of chemotherapy regimens have been used as preoperative treatment, with most incorporating doxorubicin. These regimens generally produce response rates in at least two-thirds of patients with a complete pathologic remission rate of approximately 10% to 20%. There is no evidence that one doxorubicin-containing regimen is better than another; neoadjuvant treatment is generally given to maximal response. The optimal duration and sequencing of

preoperative and postoperative therapy has not been determined.<sup>683</sup> Attempts are under way to determine if there are molecular predictors of response to neoadjuvant therapies.<sup>684,685</sup> and <sup>686</sup> Tamoxifen is used in patients with hormone receptor–positive cancers, although it is generally administered following the completion of chemotherapy.

## INTEGRATION OF SYSTEMIC AND LOCAL THERAPIES

Following successful neoadjuvant chemotherapy, a variety of options for local treatment have been investigated. These include RT alone, simultaneous RT and chemotherapy, and surgery alone. In many but not all cases, further chemotherapy is employed after local treatment. Surgery following neoadjuvant chemotherapy permits a pathologic assessment of response, the rapid reintroduction of chemotherapy, and the use of lower doses of RT. The most typical approach is to use an anthracycline-containing chemotherapy as induction, followed by modified radical mastectomy, additional chemotherapy, and then consolidative RT. It appears feasible to do an immediate breast reconstruction using a flap in this setting,<sup>687</sup> although it may delay the initiation of adjuvant chemotherapy and make RT technically more difficult. Clinical trials and experience have confirmed that a combined modality approach is an effective way to achieve local control and also to provide a substantial rate of long-term survival.<sup>676</sup>

The high response rates seen with induction chemotherapy have stimulated interest in the use of BCT for selected patients with locally advanced breast cancer. Good results have been reported in some series,<sup>676,688,689</sup> but the experience using this approach is still limited, and data from randomized, prospective trials are not available. Should breast conservation be contemplated, all of the usual considerations apply, including a mammographic evaluation that does not demonstrate diffuse disease. The conservative resection should obtain clear margins with an acceptable cosmetic result. Criteria for determining the extent of surgery in a conservative resection following induction chemotherapy have not been established, and the long-term local control rates remain uncertain.

In general, prognostic factors predictive of good outcome in patients with locally advanced breast cancer are the same as in lower stages of primary breast cancer; namely, smaller tumor size, slower growth rate, better differentiation, and fewer involved axillary lymph nodes. In addition to these classical factors, the response of locally advanced cancers to preoperative chemotherapy is an additional important prognostic factor. As noted, evidence from many series indicates that patients with rapidly responding cancers and those who achieve a complete remission have a better outcome than patients who do not have a good response to chemotherapy. Patients with inflammatory breast cancer appear to have a different clinical course than other patients with locally advanced cancer. An important distinction should be drawn between locally advanced disease by virtue of rapid growth and those that are locally advanced by virtue of neglect of a slowly growing cancer. Patients with these neglected cancers have a more indolent course than similarly staged patients with rapidly growing cancer. This distinction is better discerned by a careful history than by any laboratory study including flow cytometry.

## INFLAMMATORY BREAST CANCER

Although frequently grouped with other locally advanced cases, inflammatory breast cancer is a distinct clinical and pathologic entity. It is defined by the presence of diffuse brawny edema of the skin of the breast with an erysipeloid edge, usually without an underlying palpable mass. The clinical presentation is due to tumor embolization of dermal lymphatics. While dermal lymphatic invasion is required for the diagnosis as specified by the current AJCC staging system, patients with the clinical presentation, but without evidence of dermal lymphatic invasion, also have a poor prognosis with local treatment only. It is common for patients with inflammatory breast cancer to give a history of having been treated unsuccessfully with antibiotics before their referral to a breast cancer specialist. Inflammatory breast cancer is uncommon in the United States and in most of Europe, but is seen much more frequently in North Africa. European women living in Morocco have presented with this particularly virulent form of primary breast cancer, suggesting the existence of a specific etiologic agent. The identity of such a putative agent remains elusive. Inflammatory breast cancer has become more common in the United States. Data from SEER show that between 1975 and 1977 and 1990 and 1992, the incidence doubled, increasing among whites from 0.3 to 0.7 cases per 100,000 person-years and among African Americans from 0.6 to 1.1 cases.<sup>690</sup>

Nearly all patients with inflammatory breast cancer are dead within 5 years in the absence of systemic therapy. In addition, the historic results of surgical treatment demonstrate a difficulty in obtaining clear margins and a high local recurrence rate. Preoperative chemotherapy in patients with inflammatory breast cancer produces a response rate in the vicinity of 80%, and most patients can go on to surgical resection with clear margins. As in other patients with locally advanced breast cancer, the most typical approach is to use an anthracycline-containing chemotherapy as induction, followed by surgery, then additional chemotherapy, and then consolidative RT. With the combined modality approach, over 70% of patients achieve local tumor control. This is particularly true in patients whose tumors respond well to initial chemotherapy. In patients with inflammatory breast cancer who successfully complete a combined modality treatment, prognosis is dramatically improved when compared with the prechemotherapy era. Currently, approximately one-half of patients treated with combined modality treatment survive for 5 years and approximately 35% of the patients have been reported to be disease free at 10 years.<sup>676,691</sup> This improvement may reflect the biology of rapidly growing disease and its preferential effect of chemotherapy.

Improving the results in locally advanced breast cancer can be achieved by a number of means. It may be possible to decrease the incidence of locally advanced breast cancer by diminishing any socioeconomic factors that impede early diagnosis. Further improvements in the results of treating patients with locally advanced breast cancer require even better systemic therapy. In this regard, there is great interest in including patients with locally advanced disease in clinical trials of novel systemic therapies. Locally advanced disease affords a special research opportunity (i.e., the ability to obtain primary tumor tissue before and after chemotherapy to correlate with response and other clinical parameters).

## FOLLOW-UP AFTER PRIMARY TREATMENT

There are over 2 million breast cancer survivors in the United States. As screening programs identify more patients with earlier stage disease, and as the number of women diagnosed with DCIS continues to rise, there will be even more women living with a personal history of breast cancer. Women with a history of invasive breast cancer are at risk of developing metastatic disease. Most recurrences are detected within 5 to 10 years after diagnosis, but later recurrences can occur.<sup>692</sup> Women with both invasive and noninvasive breast cancer face a 0.5% to 1.0% annual risk of developing a contralateral cancer,<sup>693</sup> and this risk is even higher in women diagnosed with a first breast cancer at a younger age and those with an inherited predisposition.<sup>694</sup> In addition, women who have been treated for breast cancer are at risk for complications related to their treatment and face a variety of health-related decisions (e.g., pregnancy, hormone replacement therapy, prevention of osteoporosis) that may need to be carefully considered in light of their breast cancer history.<sup>671</sup>

Although extensive testing to identify early presentations of metastatic disease is probably not warranted, there is a strong rationale for having a physician knowledgeable about breast cancer care follow the patient after completion of treatment. While many follow-up visits after breast cancer treatment may seem routine to the physician, the visit provides both the clinician and the patient with the opportunity to address a wide range of issues. [Table 37.2-28](#) outlines the specific goals of follow-up care.

Area of Concern	Rationale and/or Goal
Identification of second primary breast cancer or ipsilateral breast recurrence	Women with a personal history of breast cancer are at increased risk of new primary, early detection may improve survival, similar principles apply to ipsilateral recurrence
Identification of recurrent disease	Thorough identification of recurrent disease may prevent women from suffering progressive symptoms of advanced disease (e.g., bone pain) without treatment; rare recurrences, such as distant sites, may be treated with systemic therapy
Identification of complications related to breast cancer treatment	Support, chemotherapy, hormonal therapy, and radiation can all result in toxic, but serious complications
Health knowledge/able advice about other health issues	Many health issues (e.g., the decision to use hormonal replacement therapy) may be affected by a woman's history of breast cancer; a balanced view of these issues may assist women in making optimal health decisions
Provide psychosocial support	A diagnosis of breast cancer and subsequent treatment is a major event in many patients' lives; recognition of the psychosocial and psychosocial aspects of breast cancer with initiation of care, as needed, is part of comprehensive clinical care

**TABLE 37.2-28.** Goals of Follow-Up Care after Treatment for Early-Stage Breast Cancer

Contrary to what many patients expect,<sup>695</sup> early diagnosis of metastatic disease by performing frequent, extensive, or both kinds of testing has not been shown to

improve survival. Two randomized trials have compared simple follow-up regimens consisting of periodic physical examination and routine mammography with more intensive evaluation including radiographic studies (chest radiography, bone scan, liver ultrasound) and laboratory studies (complete blood counts and liver function tests) in women after treatment of early-stage breast cancer.<sup>696,697</sup> More intensive follow-up resulted in a slightly earlier time at which systemic recurrences were detected; however, there was no difference in overall survival. Some physicians have argued that more intensive follow-up schedules might improve quality of life by providing patients with added reassurance, allowing treatment of metastatic disease before a patient develops symptoms, or both. These arguments are not supported by quality-of-life assessments performed as part of one of the large randomized follow-up studies.<sup>696</sup> With the development of ever more accurate methods of detecting low-volume metastatic disease (i.e., spiral CT or positron emission tomographic scanning), there is the potential to detect metastatic disease even earlier than in the randomized trials discussed previously. The routine monitoring of tumor markers may also allow for the detection of metastatic disease at an earlier point in a patient's clinical course.<sup>698</sup> There is little reason to believe that early detection of metastatic disease as a result of monitoring tumor markers would result in an improvement in either survival or quality of life; the routine use of tumor markers in patients who have completed breast cancer therapy is generally not recommended and can be particularly problematic.<sup>699</sup> An elevated marker may be the first sign of an impending recurrence, but a thorough search for metastatic disease may be negative even in the presence of an elevated marker.<sup>700</sup> There is no treatment that has proven to be of benefit to patients with elevated tumor markers who have no evidence of disease, and such situations are almost always anxiety provoking for patients. Early intervention in asymptomatic patients with metastatic breast cancer has not been demonstrated to improve clinical outcome. For this reason, the identification of metastatic disease in an asymptomatic patient could theoretically lead to the initiation of toxic therapy that could have a negative effect on a patient's quality of life and, at the same time, not improve her overall survival.<sup>700</sup>

The American Society of Clinical Oncology has published evidence-based recommendations for follow-up care after a diagnosis of breast cancer.<sup>701</sup> A physical examination and history (emphasizing symptoms that could be due to metastatic disease) are recommended every 3 to 6 months for the first 3 years after diagnosis and every 6 to 12 months for the subsequent 2 years. Even for patients who are 5 or more years postdiagnosis, annual follow-up is recommended. Women should be advised to do breast self-examinations on a monthly basis and to have annual mammography and gynecologic examinations. Routine laboratory testing (including tumor markers) and radiologic studies are not recommended. Patients with signs or symptoms of recurrent disease should be rigorously evaluated. These recommendations have been issued in the context of the presently available therapies for patients with recurrent breast cancer. If treatments become available in the years ahead that can prolong the lives of women diagnosed with asymptomatic, low-volume, metastatic disease, recommendations for follow-up care will need to be altered.

## MANAGEMENT OF PATIENTS WITH METASTATIC BREAST CANCER

The management of patients with metastatic breast cancer is a topic familiar to most medical oncologists. Although the majority of women diagnosed with breast cancer today will never experience a systemic recurrence, approximately 41,000 women in the United States will die of metastatic breast cancer in 2000.<sup>1</sup> The median survival for women with metastatic breast cancer is in the range of 2 to 3 years, but there is great variability. Indeed, there are even a small number of patients with metastatic disease who will receive a course of chemotherapy and remain relapse-free for a decade or longer (Fig. 37.2-6).<sup>702</sup>

**FIGURE 37.2-6.** Overall survival curves of 1544 patients (excluding 37 patients with insufficient information to determine response status) with metastatic breast cancer receiving front-line chemotherapy according to response to therapy. Deaths from any cause were included. CR, complete response; MR, minimal response; NC, no change; PD, progressive disease; PR, partial response.

The heterogeneity of patients with metastatic breast cancer must be emphasized. Rarely, patients with metastatic breast cancer succumb to their disease within weeks of a diagnosis; others live with the disease for many years. Many patients have metastatic involvement that is confined to bone or soft tissue, while others have predominantly visceral disease. CNS involvement is relatively unusual as a presenting sign or symptom of metastatic disease.<sup>703</sup> It is important, both in the approach to individual patients and in considering clinical trial results, to have an understanding of the variability of metastatic breast cancer. Table 37.2-29 outlines the clinical and laboratory characteristics of patients with metastatic breast cancer who have an indolent versus aggressive clinical course. No single factor explains the heterogeneity that is seen clinically. It is uncertain to what extent the administration of prior adjuvant therapy affects a patient's prognosis in the setting of advanced disease. There are reports of patients responding to chemotherapy in the metastatic setting even after receiving the identical therapy in the adjuvant setting.<sup>704</sup> On the other hand, a patient who develops an early recurrence following treatment with an effective adjuvant regimen (i.e., CA followed by paclitaxel followed by tamoxifen) almost certainly has a relatively poor outlook in the metastatic setting.

Indolent Progress (Indolent Clinical Course)	Aggressive Progress (Aggressive Clinical Course)
Long disease-free interval (usually considered at least 2 years from initial diagnosis) <sup>a</sup>	Short disease-free interval (usually considered less than 2 years from initial diagnosis) <sup>a</sup>
Response to prior therapy	Lack of response to prior therapy
Lack of visceral involvement	Presence of visceral involvement, CNS involvement, or both
Limited sites and bulk of disease	Multiple sites of disease and extensive involvement at these sites
HER2/neu negativity	HER2/neu positivity <sup>b</sup>

<sup>a</sup>Although 2 years is often used as an arbitrary cutoff in separating early recurrences from later recurrences, the longer the disease-free interval, the more indolent one can expect in terms of future behavior.  
<sup>b</sup>It is not clear that HER2/neu positivity remains an adverse prognostic factor with the availability of trastuzumab.

**TABLE 37.2-29.** Factors That Affect Prognosis in Patients with Metastatic Breast Cancer

## GOALS OF THERAPY IN PATIENTS WITH METASTATIC BREAST CANCER

The two primary goals in the treatment of patients with metastatic breast cancer are (1) improvement or maintenance of quality of life and (2) prolongation of survival. The measurement of response rates in either clinical trials or clinical practice is useful only to the extent that response is a surrogate for survival, quality of life, or both. Maintenance of quality of life is achieved by controlling disease-related symptoms, minimizing toxicity from treatment, and limiting the intrusion of the patient's disease and treatment on her life. Historically, it has been difficult to demonstrate that treatment prolongs survival, but there has been an assumption on the part of many medical oncologists that treatment of metastatic breast cancer extends survival. More recently, several trials have demonstrated that more effective therapy has been able to prolong survival in women with metastatic breast cancer. These trials have included studies of hormonal agents, chemotherapeutic agents, and combinations of chemotherapy and Herceptin.<sup>666,667,705,706</sup> While the median prolongation in survival has been a matter of months, these trials have demonstrated an important principle (i.e., more effective treatment of metastatic breast cancer can extend the lives of our patients). In selecting a treatment program, close attention must be paid to the patient's symptoms, the pace of her disease, and her preferences and ability to tolerate the therapy.

## EVALUATION OF PATIENTS WITH SUSPECTED METASTATIC BREAST CANCER

All patients who are thought to have metastatic breast cancer should undergo a careful physical examination and a thorough history. Historically, it was considered mandatory to biopsy a first site of metastatic disease to confirm the diagnosis. In the case of patients with chest wall or lymph node involvement, pleural effusions, or other easily assessable disease, obtaining biopsy or cytologic proof of metastatic disease can be accomplished with minimal difficulty. If a more complicated procedure is needed, which could place the patient at greater discomfort or risk, physician judgment must be exercised. In the patient with a history of breast cancer who has unequivocal radiologic evidence of advanced breast cancer, a biopsy can often be deferred. If there is any question as to whether the patient has cancer or any suspicion that the patient may have a second primary (i.e., widespread pure lytic bone lesions and anemia suggestive of multiple myeloma) that would require alternative treatment, a biopsy is essential. In the case of a woman with a history of breast cancer who presents with a solitary pulmonary nodule, a resection of the lesion is usually required since a high percentage of these lesions may be primary lung cancers.<sup>707</sup> A biopsy to establish metastatic disease provides an opportunity to reassess the hormone receptor status of the tumor. While few tumors evolve from ER negative to ER positive, more frequently there can be loss of hormone receptors over time.<sup>624</sup> With the availability of Herceptin, the result of a HER-2/ *neu* assay is often important in making treatment decisions, although this can often be assessed from specimens of the primary tumor.

Recommendations for the laboratory and radiographic evaluation of patients with newly diagnosed metastatic breast cancer have been established by the National Cancer Center Network.<sup>120</sup> Routine blood work consisting of complete blood counts and liver function tests are recommended. In addition, chest radiographs and bone scans are recommended. The decision to proceed with other radiographic studies can be based on symptoms, although many physicians obtain a baseline assessment of liver involvement with a CT scan or MRI, particularly if the presence of liver metastases would change treatment. Since intracranial involvement is extremely rare in newly diagnosed patients in the absence of CNS symptoms, a CT or MRI of the brain is not usually recommended for a woman with a new diagnosis in the absence of symptoms.<sup>700</sup> The use of tumor markers in the management of patients with breast cancer remains controversial.<sup>708</sup> It is reasonable to obtain a carcinoembryonic antigen and CA 27-29 level, looking for an elevation in either of these proteins. If elevated, they can be followed to determine if rising or falling levels correlate with the patient's disease status. Caution should be used in changing a treatment regimen based on tumor makers alone. If tumor makers are negative at the time of diagnosis, they can be checked again when the patient has disease progression, as they are more commonly elevated in patients with more extensive disease.

### LOCAL VERSUS SYSTEMIC THERAPY

Patients with a chest wall recurrence, a single site of bone involvement, pleural disease, or other localized sites can often be managed with local therapy alone. In such situations, systemic therapy may be delayed until there is evidence of disease progression. There is a small group of patients with isolated metastatic disease who remain disease-free for an extended period of time after local therapy to the involved site. This situation is best exemplified by the patient who presents with an isolated chest wall recurrence. Although patients with isolated chest wall recurrence should receive definitive local treatment, local therapy is not mandatory in minimally symptomatic patients who present with isolated sites of distant disease (i.e., a single bone lesion). As previously mentioned, isolated pulmonary nodules generally should be resected because these often represent a second primary. There are reports of resection of hepatic metastases,<sup>709</sup> but this approach cannot be recommended as standard practice.

In certain situations, patients treated with local therapy for an isolated recurrence may also be considered for adjuvant systemic therapy. A phase II trial of fluorouracil, Adriamycin, and cyclophosphamide chemotherapy for patients with stage IV but no evidence of disease suggested an improvement in relapse-free survival in comparison with historic controls. It should be noted, however, that the majority of these patients had not received prior adjuvant chemotherapy.<sup>710</sup> A retrospective review of 96 patients with isolated recurrence demonstrated an improvement in disease-free survival and overall survival for those patients who received some form of systemic therapy although the majority received hormonal therapy as opposed to chemotherapy.<sup>711</sup> Other investigators have reported less promising results with the use of chemotherapy in this setting.<sup>464</sup> In such situations, the toxicity of a course of chemotherapy must be balanced against the largely theoretical benefits. The use of chemotherapy in the patient with stage IV but no evidence of disease has its greatest appeal in the patient with a hormone receptor-negative tumor who has never received cytotoxic chemotherapy, but the benefits in this setting remain uncertain. In contrast, it is reasonable to have a lower threshold to prescribe a hormonal therapy in the patient with positive hormone receptors, with the hope that treatment will delay the time to progression. A randomized trial in 167 ER-positive patients with locoregional recurrence demonstrated an improvement in median disease-free survival (26 vs. 82 months) with the addition of tamoxifen to locoregional treatment.<sup>479</sup> This difference was largely related to a reduction in local recurrence; there was no difference in 5-year overall survival. The role of second-line hormonal therapy in women who develop a breast recurrence on tamoxifen is unknown.

In patients with widespread disease, local therapy is often used to provide palliation for specific symptoms. Radiation to bone lesions, CNS disease, or, less commonly, soft tissue disease, can be effective in controlling disease. At times, local therapy is administered in conjunction with systemic therapy, although one must be careful about the potential increase in toxicity that may be seen with the concurrent administration of chemotherapy and radiation. Decisions about the use of local therapy in the patient with advanced disease can be complex. Such decisions should be guided by the patient's symptoms or impending symptoms, the extent to which those symptoms can be relieved by supportive care, and the chance that a change in systemic therapy will provide effective palliation for the local disease.

### Administration and Choice of Systemic Therapy

The vast majority of patients with metastatic breast cancer receive some form of systemic therapy. The initial question is whether to consider hormonal therapy or chemotherapy. Because of the limited toxicity with most hormonal therapies, patients who have hormone receptor-positive tumors and a limited to moderate disease burden should generally receive hormonal therapy. Patients with both estrogen and progesterone receptor positivity are more likely to respond to hormonal therapy than are those with ER-positive/PR-negative or ER-negative/PR-positive tumors.<sup>624</sup> A trial of hormonal therapy may be justified even in the presence of negative hormone receptors since a small number of patients with ER-negative/PR-negative tumors respond to a hormonal intervention.<sup>712</sup> The key issues that the clinician must consider in proceeding with initial hormonal therapy are whether or not the patient is likely to respond to the treatment and whether the patient would be adversely affected if she did not respond to treatment and was started on chemotherapy 2 to 3 months later. Visceral disease, particularly low-volume and asymptomatic disease, is not a contraindication to the use of hormonal therapy; however, the patient with extensive visceral disease is probably better served by chemotherapy. If a patient with a hormone receptor-positive cancer is initially treated with chemotherapy, the clinician should consider returning to hormonal therapy at some point in the future.

[Table 37.2-30](#) lists the commercially available hormonal therapies for premenopausal and postmenopausal women. In general, there is little evidence that one hormonal therapy is substantially more effective than another. As a result, the ease of administration and tolerability usually dictates the choice of treatment.

Premenopausal	Postmenopausal
Tamoxifen	Antiestrogens
Ovarian ablation	Tamoxifen
Oophorectomy	Toremifene
Luteinizing hormone-releasing hormone agonist	Aromatase inhibitors
Progestins	Anastrozole
Androgens	Letrozole
High-dose estrogens	Exemestane
	Progestins
	Androgens
	High-dose estrogens

**TABLE 37.2-30.** Hormonal Therapy for Women with Metastatic Breast Cancer

In premenopausal women who have never received hormonal therapy, tamoxifen is generally the treatment of choice. A small randomized trial has suggested that tamoxifen and ovarian ablation are equivalent in efficacy.<sup>713</sup> In patients who respond to tamoxifen, the duration of response is often in excess of a year and may

extend for several years in a minority of patients.<sup>714</sup> Medical or surgical ovarian ablation is usually the second-line hormonal therapy of choice in women who are premenopausal, particularly those who have responded to tamoxifen. European trials have evaluated the use of a combination of ovarian ablation and tamoxifen in patients with metastatic breast cancer. In some studies, there has been a suggestion of an improved overall response rate,<sup>715,716</sup> but it remains unclear if this approach is superior to sequential therapy. Aromatase inhibitors are not active in premenopausal women because of the high levels of circulating estrogen from the ovaries. Aromatase inhibitors can be used in conjunction with ovarian ablation, although there is little published information about this combination. Megestrol acetate remains the usual third-line hormonal therapy. The subgroup of premenopausal women with hormone receptor–positive tumors can, at times, have an extended survival in the metastatic setting. Faulkson et al. have reported a median survival of approximately 5 years in a group of hormone receptor–positive, premenopausal women who were initially treated with chemotherapy plus oophorectomy.<sup>717</sup> If anything, many clinicians may tend to undervalue the benefits of hormonal therapy in premenopausal women with positive hormone receptor status.

In postmenopausal women, tamoxifen remains the usual first-line therapy. In the metastatic setting, toremifene is an acceptable alternative based on the equivalence demonstrated between the two agents in randomized trials.<sup>625</sup> Since many women with metastatic breast cancer have either developed disease progression on tamoxifen or have had a recent course of adjuvant tamoxifen, there are fewer and fewer patients receiving antiestrogens when they present with metastatic disease. The aromatase inhibitors (i.e., anastrozole, letrozole, and exemestane) have all been demonstrated in randomized clinical trials to be equivalent or superior to megestrol acetate.<sup>718,719</sup> Exemestane, a steroidal aromatase inhibitor that irreversibly inhibits aromatase activity, has been shown to have a survival advantage in comparison with Megace.<sup>719</sup> All three agents are generally well tolerated and are not associated with the bothersome weight gain that is seen with Megace.<sup>718</sup> It is unknown, at this time, if one aromatase inhibitor is superior to another. A randomized trial demonstrated the equivalence of anastrozole (Arimidex) and tamoxifen in patients who had had no prior hormonal therapy,<sup>720</sup> making it reasonable to consider these agents as first-line therapy even in patients who have never received tamoxifen. Objective response rates to the aromatase inhibitors have been in the 10% to 20% range, but a substantial number of patients in these trials have had disease stabilization for 6 months or longer.<sup>718,719,721</sup> Megestrol acetate remains a third-line therapy, and patients rarely are treated with either androgens or high-dose estrogen as fourth- and fifth-line therapy.

In both premenopausal and postmenopausal women, occasional responses can be seen with withdrawal of either high-dose estrogen (now rarely used), tamoxifen, or progestins.<sup>722,723</sup> Withdrawal responses are relatively rare and are more commonly seen when a patient has had a prior response to the hormonal manipulation. The possibility of withdrawing tamoxifen (without additional therapy) can be considered in the patient with low-volume, indolent, ER-positive disease who has either been on adjuvant tamoxifen for several years or has had a documented response in the metastatic setting.

Assessing the response of patients to hormonal therapy can be complex. Many patients treated with hormonal therapy have bone-only disease, making response assessment complex. In addition, it can take up to several months to see a response in some patients, whereas others have more rapid disease regressions. A flare phenomenon with worsening bone pain, increasing soft tissue lesions, hypercalcemia, or all three is seen in a small percentage of patients who are started on hormonal therapy.<sup>724,725</sup> Flares have been seen with high-dose estrogen, tamoxifen, progestins, and androgens and occur within the first days to weeks of treatment. A portion of patients who have a flare go on to respond to endocrine therapy. With either hormonal therapy or chemotherapy, there can be a rise in tumor marker levels, alkaline phosphatase, or both early in the course of therapy, with a subsequent decline. Clinicians should not continue hormonal therapy in patients with rapid or unequivocal evidence of disease progression. In the minimally symptomatic patient, it is often prudent to continue therapy for several months if there is an uncertainty concerning the response to treatment. In these situations, it is important to explain to patients that a change in therapy in the near future may be necessary, but that there is little to be lost by continuing the hormonal approach with close monitoring of disease status.

A question that often arises is how many hormonal regimens to administer before moving on to chemotherapy. In a patient who has had a prior response to (or extended disease stabilization with) hormonal therapy, there is a reasonable chance of observing a response with another hormonal approach. There are patients who respond to a second hormonal therapy, even if their disease progressed through a first agent.<sup>721</sup> In making a clinical decision as to whether to consider a second, third, or even fourth hormonal approach, the clinician needs to weigh the therapeutic index of another hormonal agent versus that of chemotherapy. The chance of observing a response with each successive hormonal regimen decreases. However, if the patient continues to have relatively indolent disease and will not be harmed by delaying therapy that may have a higher chance of producing an objective response (i.e., chemotherapy), it is reasonable to try another hormonal therapy, even if the likelihood of obtaining a response is small. For that matter, it is important to reconsider the potential advantages of another trial of hormonal therapy, even in a patient who has received intervening chemotherapy.

Resistance to hormonal therapies ultimately develops in virtually all patients with advanced disease. The mechanisms responsible for resistance to hormonal therapy are not fully understood<sup>726</sup> and are currently being investigated. Identifying new hormonal agents, such as pure antiestrogens, new selective ER modulators, and antiprogestins, is a priority. Ongoing studies are also addressing the potential of using hormonal therapies with other agents, such as differentiating compounds, to enhance disease control.

## CYTOTOXIC CHEMOTHERAPY FOR METASTATIC BREAST CANCER

Although hormonal therapy is usually the treatment of choice for patients with hormone receptor–positive cancer, almost all patients eventually develop hormone-refractory disease, and many patients with metastatic breast cancer have negative hormone receptor status. For these patients, chemotherapy is the treatment of choice, with the goal of ongoing symptom control and modest prolongation of survival. The use of chemotherapy for metastatic breast cancer has evolved since 1990. Multiple new agents are now available,<sup>727</sup> many of which have a favorable toxicity profile. Clinical trials have addressed a variety of fundamental issues related to the administration of chemotherapy to patients with metastatic breast cancer, such as the value of single agents versus combination therapy and the appropriate duration of therapy.

Table 37.2-31 lists the agents commercially available for patients with advanced breast cancer. While some of these have official Food and Drug Administration approval for the treatment of breast cancer, others have simply become part of the standard armamentarium as a result of general clinical acceptance. There is no rigid order in which agents or regimens should be administered. CMF and CAF were long considered the standard of care for initial chemotherapy treatment of advanced disease, but the development of the taxanes and a variety of other agents has given physicians and patients far greater flexibility in making treatment decisions. The taxanes and doxorubicin are usually considered the most active agents for the treatment of advanced disease, but the activity of any agent is most dependent on the characteristics of the patient population, particularly the extent of prior therapy. There are few compelling data that one regimen is markedly superior to another or promotes improved long-term survival.<sup>728</sup> The precise order in which treatments are administered is unlikely to affect overall survival. The CALGB has demonstrated that initial treatment with an investigational agent (in patients who did not have visceral crisis) does not compromise either overall survival or response to a subsequent doxorubicin-based regimen.<sup>729</sup> The availability of new agents, such as the taxanes, has improved overall survival,<sup>666,667</sup> but the order in which treatments are delivered (i.e., taxane as first-line vs. second-line therapy) is unlikely to have a major effect on long-term outcome.

<sup>c</sup>Usually administered with other agents in first-line therapy.

TABLE 37.2-31. Active Chemotherapeutic Agents in the Treatment of Metastatic Breast Cancer

In patients who have received no prior chemotherapy in the metastatic setting, objective response rates of 25% to 55% have been seen in multicenter randomized trials.<sup>667,730,731</sup> and <sup>732</sup> Higher response rates are seen in single-institution, phase II trials.<sup>733,734</sup> It is likely that the percentage of patients who derive some palliative

benefit from chemotherapy is higher than the reported response rates in multicenter trials. The median duration of response with most first-line chemotherapy regimens is in the range of 6 to 12 months, with a shorter duration of response seen in patients who are treated in the second- and third-line setting.

## COMBINATION VERSUS SINGLE-AGENT CHEMOTHERAPY

For several decades, the use of combination chemotherapy was considered the standard of care. More recently, several trials have compared combination therapy with the use of single agents in the treatment of advanced breast cancer.<sup>666,667,730,735</sup> In a large Eastern Cooperative Oncology Group trial, Sledge and colleagues randomized patients to one of three arms: single-agent Adriamycin, single-agent paclitaxel, or a combination of the two. Patients initially randomized to the single-agent arms were crossed over to the alternate agent at the time of progression. Although there was a statistically significant improvement in response rate and time to progression on the combination arm, there was no difference in either survival or quality of life.<sup>730,736</sup> If one considers the secondary responses with the crossover therapy, there is even less reason to view combination therapy as a superior approach. A Finnish trial that randomized patients to combination or single-agent therapy in both the first- and second-line setting also failed to show any appreciable difference in disease outcomes.<sup>735</sup> A major advantage of single-agent therapy is the ability to assess whether a given agent is of benefit to the patient. When a patient responds to combination therapy, it is never clear whether she is benefiting from a single drug in the regimen or from all of the agents. While the administration of combination therapy remains a common practice, it is most appropriate in highly symptomatic patients in whom the higher response rate seen with combination therapy may be worth the added toxicity. Numerous trials have also compared the use of chemotherapy alone versus the combination of chemotherapy and hormonal agents.<sup>737,738</sup> In general, these trials have demonstrated either higher response rates, longer time to progression, or both with the combination treatment, as well as a benefit in terms of survival.

## DURATION OF CHEMOTHERAPY

Several trials have examined how long chemotherapy should be continued in patients with stable or responding disease. Muss and colleagues treated 250 patients with initial CAF chemotherapy and randomized almost 150 women with stable or responsive disease to maintenance chemotherapy or observation. Although there was a 6-month prolongation in time to disease progression for women on maintenance therapy, there was no difference in overall survival.<sup>739</sup> Findings from other investigators have been quite similar.<sup>740</sup> Of note, a very brief course of treatment may not only shorten time to progression, but it may also compromise quality of life.<sup>741</sup> Coates and colleagues randomized Australian patients to continuous chemotherapy versus intermittent therapy (three cycles only) with reinstatement of treatment at the time of disease progression.<sup>741</sup> The two groups had an equivalent overall survival, but the intermittent group had a lower response rate, shorter time to progression, and inferior quality of life. Since the maximal response to chemotherapy often occurs after approximately 4 to 6 months of treatment, one interpretation of this trial is that the failure to treat patients until they achieved a maximal response to therapy perhaps compromised quality of life.

The question of how long to continue chemotherapy is frequently raised in discussions with patients. Assuming a patient has had 4 to 6 months of chemotherapy and has stable or responsive disease, there is no evidence that continuing treatment will have an effect on her overall survival. When a patient experiences progression of disease, treatment (at times with the same regimen) can always be resumed. In the patient who was initially symptomatic, has had excellent palliation of her symptoms, and has minimal toxicity with treatment, chemotherapy can be continued with the goal of delaying disease progression.

## DOSE AND SCHEDULE OF CHEMOTHERAPY

A large number of trials have addressed questions that relate to either the dose or schedule of chemotherapy. In general, higher response rates have been seen with regimens that are in the standard-dose range than those in which the doses are reduced substantially. Low-dose CMF has been found to be inferior to standard-dose therapy (600 mg/m<sup>2</sup>; 40 mg/m<sup>2</sup>; 600 mg/m<sup>2</sup>).<sup>742</sup> Lower response rates or more rapid disease progression have been demonstrated with other agents when doses have been reduced below the usually accepted range.<sup>743,744</sup> The clinician must balance the potential benefits and toxicities of different dose levels. To date, there is little convincing evidence to show that escalating doses of chemotherapy to levels that require growth factor support has a substantial effect on disease outcome. In addition, some of these regimens result in a marked increase in toxicity.<sup>745</sup>

Questions exist about the optimal schedule for many cytotoxic agents. By changing the schedule of many agents, there is the suggestion that both efficacy and toxicity can be altered. The NSABP compared 3-hour versus 24-hour paclitaxel administration in patients with locally advanced or metastatic disease.<sup>746</sup> Although a significantly higher response rate was observed with the longer infusion (54% vs. 44%), there was no difference in survival, and the longer infusion was much more inconvenient. Initial reports of weekly taxanes<sup>734,747</sup> have been encouraging, and these dose-dense schedules are being compared with the standard every 3 week regimens in randomized trials of interest. A European trial compared classical CMF (day 1 and 8 with oral cyclophosphamide) with an every 3 week regimen. The classical regimen, which is more dose dense, resulted in a higher response rate and an improvement in overall survival.<sup>748</sup> With the availability of oral fluorouracil agents<sup>749</sup> and liposomally encapsulated agents, such as doxorubicin (Doxil),<sup>750</sup> it is possible to increase the duration of exposure to cytotoxic agents without committing patients to ambulatory infusion pumps or frequent clinic visits.

## HIGH-DOSE CHEMOTHERAPY WITH HEMATOPOIETIC SUPPORT

Beginning in the mid-1980s, trials were initiated evaluating the role of high-dose chemotherapy with autologous bone marrow support. These studies were based on preclinical models and the hope that dose escalation would result in prolongation of survival.<sup>751</sup> Multiple phase I and II trials in women with metastatic breast cancer suggested that high-dose chemotherapy resulted in high response rates, generally in excess of 70%. In addition, a small proportion of patients (approximately 10% to 15%) remained free of disease progression for several years following therapy.<sup>752,753 and 754</sup> In general, patients with a low disease burden, long disease-free interval, and absence of visceral involvement appeared to have the most favorable outcome after high-dose therapy.<sup>755,756 and 757</sup> Based on preliminary trials, thousands of women in the United States underwent treatment with high-dose chemotherapy throughout the late 1980s and 1990s.

More recently, the mature results of a randomized trial comparing high-dose chemotherapy with prolonged conventional chemotherapy have been published. Stadtmauer and colleagues enrolled 553 women with metastatic breast cancer onto a trial designed to determine if high-dose chemotherapy would improve disease outcomes.<sup>758</sup> Of the original cohort, 310 women had a response to initial chemotherapy, and 199 of these women were ultimately randomized to receive either high-dose chemotherapy with stem cell support versus prolonged treatment with CMF. With a median follow-up of 37 months, there was no evidence that high-dose therapy improved either time to progression or overall survival. Subgroup analyses looking at demographic variables, response (complete vs. partial response) to induction treatment, and disease characteristics failed to identify a population of patients that had a better outcome with high-dose therapy than with CMF. In another study, Berry et al. retrospectively compared the outcomes of 560 women registered with the Autologous Bone Marrow Transplant Registry with 657 patients who participated in a series of CALGB trials using conventional dose chemotherapy.<sup>759</sup> All patients included in the analysis were 60 years of age or younger and had chemotherapy-sensitive disease. In a multivariate model, there was no difference in survival between the two groups of patients. The investigators could not identify any patient subgroup who had a better outcome with high-dose therapy. Thus, despite the initial enthusiasm for high-dose chemotherapy for metastatic breast cancer, this approach appears unlikely to have a substantial effect on the natural history of the disease.<sup>760</sup>

## TRASTUZUMAB (HERCEPTIN)

The development of Herceptin has been a major advance in the treatment of HER-2/ *neu*-positive metastatic breast cancer. As previously noted, approximately 25% to 30% of all breast cancers overexpress HER-2/ *neu*, a 185-kD transmembrane glycoprotein receptor. These tumors have a more aggressive natural history, a higher risk of recurrence, a higher frequency of visceral disease at first recurrence, and a lower likelihood of ER positivity. Herceptin, a humanized recombinant anti-HER-2/ *neu* antibody, has been evaluated in a series of clinical trials as both a single agent and in combination with chemotherapy.

In a multinational trial, women with HER-2/ *neu*-overexpressing metastatic breast cancer were randomized to receive chemotherapy alone or chemotherapy plus Herceptin.<sup>705,761</sup> Patients who had not received an anthracycline in the adjuvant setting were randomized to AC with or without Herceptin. Those patients who had received an adjuvant anthracycline-containing regimen received paclitaxel with or without Herceptin. Chemotherapy was continued in stable or responding patients for a minimum of six cycles. In the absence of disease progression, Herceptin was administered weekly at a dose of 2 mg/kg for 1 year or longer. [Table 37.2-32](#) summarizes the results of the trial.

	Chemotherapy	Chemotherapy + Herceptin	P Value
Response rate	29%	45%	<.0001
Time to progression	4.5 mo	7.2 mo	<.0001
Median survival	20.3 mo	25.4 mo	=.025

(Adapted from refs. 705 and 761.)

**TABLE 37.2-32.** Benefit of Herceptin When Added to Chemotherapy

The benefit of Herceptin was seen both in patients who received AC and in those who received paclitaxel. In addition, the survival benefit was noted despite the fact that approximately two-thirds of the women randomized to chemotherapy alone ultimately received Herceptin on an open-label extension protocol at the time of disease progression. While Herceptin was generally well tolerated, there was a 19% incidence of grade III or IV cardiac dysfunction on the AC plus Herceptin arm; with the combination of Herceptin and paclitaxel, the frequency of serious cardiac toxicity was only 4%.<sup>705</sup>

In a large single-agent trial, Cobleigh and colleagues treated 222 women with refractory metastatic breast cancer (one or two prior chemotherapy regimens).<sup>762</sup> As a single agent, Herceptin was well tolerated. Five percent of the study population developed cardiac dysfunction; however, all these patients had either received prior anthracyclines or had preexisting cardiac disease. The overall response rate in this group of pretreated patients was 15%, with a median duration of response of 9.1 months. In another single-agent trial, Vogel et al. reported a response rate of 25% in 112 women with HER-2/ *neu*-overexpressing metastatic breast cancer.<sup>763</sup> Although none of these patients had received chemotherapy in the metastatic setting, over one-half had received prior doxorubicin in the adjuvant setting. Taken together, these two trials clearly demonstrate the activity of Herceptin administered as a single agent.

There is compelling evidence to consider the use of Herceptin in the initial management of women with HER-2/ *neu*-positive, hormone-refractory metastatic breast cancer; however, there are a multitude of unanswered questions about the use of Herceptin in clinical practice. It is unknown how long Herceptin should be administered, whether it should be continued with second-line chemotherapy after disease progression, or if single-agent therapy (followed by chemotherapy) is better or worse than combination treatment. Many of these questions will be answered through future clinical trials; others will depend on gaining a fuller understanding of the complex mechanism of action of Herceptin and its probable role in sensitizing breast cancer to the effects of chemotherapy. It is unlikely that there is any role for Herceptin in patients whose tumors do not overexpress HER-2/ *neu*. Discussions continue regarding the optimal methods to assess HER-2/ *neu* overexpression. Additional trials are needed to test combinations of Herceptin with other cytotoxic agents. Promising preliminary reports have appeared using combinations of Herceptin plus vinorelbine,<sup>764</sup> Herceptin plus docetaxel,<sup>765</sup> and Herceptin plus weekly paclitaxel.<sup>766</sup> Finally, the role of Herceptin in both the neoadjuvant and adjuvant setting will be the focus of a number of clinical trials in the years ahead.

#### QUALITY OF LIFE AND SUPPORTIVE CARE ISSUES

A growing emphasis has been placed on quality-of-life issues in women with metastatic breast cancer. This interest has been reflected by an increasing effort to measure quality of life in clinical trials.<sup>736,741,767,768</sup> Although only a small number of randomized trials in women with metastatic breast cancer have demonstrated differences in quality of life,<sup>741,769</sup> this research has likely led to a greater awareness of quality-of-life issues in clinical practice.

Many of the newer chemotherapy and hormonal agents have fewer side effects, or at least a more manageable side-effect profile than agents that were available a decade ago. In many ways, the emphasis on single-agent therapy can be viewed as a step forward from a quality-of-life standpoint. There is also an ongoing effort to make breast cancer treatment more convenient for patients. Virtually all therapy is administered in the outpatient setting, and there is a growing interest in the development of oral chemotherapeutic agents. Patient surveys have documented a strong preference for oral treatment, but only if the oral therapy can be administered without compromising efficacy.<sup>770,771</sup>

With the heightened interest in quality-of-life issues, there has also been a greater emphasis on supportive care measures. The use of bisphosphonates in women with lytic bone lesions has become a standard of practice.<sup>772</sup> Treatment with bisphosphonates does not improve survival, but does have an important effect on the frequency of bone-related complications such as pain, the need for palliative radiation, and hypercalcemia. There is a growing awareness of fatigue, its relationship with anemia, and the potential benefits of treatment with erythropoietin.<sup>773</sup> Nausea and vomiting, while still a problem with many chemotherapy regimens, are far better controlled with the judicious use of some of the newer antiemetic agents.<sup>774</sup> While the availability of these newer supportive care measures represents a major advance in the care of women with breast cancer, the clinician needs to weigh carefully the advantages and disadvantages of each of these supportive care interventions.

#### NEW TREATMENT APPROACHES

It is difficult to know which of the therapies currently in development will have a future role in the treatment of women with breast cancer. There is renewed interest in immune-based treatments, including vaccines, monoclonal antibodies, and approaches using dendritic cells. Ongoing trials are evaluating a range of novel therapeutics, including differentiating agents and angiogenesis inhibitors. As our basic understanding of breast cancer grows, it is likely that there will be a whole new generation of targeted molecular therapies, allowing clinicians to increase the efficacy and decrease the toxicity of treatment for women with breast cancer.

#### INTRODUCTION

Breast reconstruction after mastectomy has grown in popularity since the 1970s. The era of diagnosis with less extensive cancers has ushered in less extensive total mastectomies, including “skin sparing” with an incision only around the areola. Presently, the typical patient has many choices, not only regarding the cancer management but also regarding multiple surgical options after mastectomy.

The first consideration after mastectomy is whether to reconstruct the breast. Not performing breast reconstruction is the simplest approach. The patient then faces postmastectomy appearance and the need, in most women, for an external prosthesis to restore appearance and weight balance. Mastectomy forms first began as individually made cotton fluff-filled forms. Then foam rubber forms were manufactured with holes in the back for metal weights to add stability and gravity. Now almost all weighted breast prostheses are made of solid silicone materials. The variably shaped breast forms are also available in several skin colors. It is very rare, but possible, to require custom manufacturing of the form for irregular mastectomy defects.

The external prosthesis is completely concealed in a bra with an adjustable built-in pocket specially constructed to accommodate it. Wearing the weighted prosthesis should help the body maintain its posture and balance and may prevent back and neck strain. With the concern that the prosthesis could become dislodged, even with such a specially fitted bra or swimsuit, adherent forms have now become popular. Using a variety of surgical adhesives, the form adheres to the chest wall or to a backing on the skin of the chest wall, so that the form can be removed every night while the backing can remain for a week or more. In retrospective studies,<sup>1,2</sup> the differences among those opting for breast reconstruction, those wearing external prostheses, and those doing neither were explored.

The American Cancer Society sponsors the program Reach to Recovery (1-800-ACS-2345), which began in 1952, a time in which all volunteers had undergone mastectomy. Today, the survivor-to-patient outreach and support include volunteers who have had breast conservation and postmastectomy reconstruction. At the physician's request, trained volunteers meet with the patient to discuss several aspects of recovery, including physiologic, psychological, and cosmetic rehabilitation. Resources for the patient include breast prostheses information with knowledge of local resources, clothing suggestions, and even an exercise booklet and aids.

#### DELAYED VERSUS IMMEDIATE RECONSTRUCTION

If breast reconstruction is elected, the next decision is timing, immediate (at the time of the mastectomy) or delayed. The traditional concept of performing the mastectomy, proceeding with adjuvant therapy, and delaying reconstruction until the completion of adjuvant therapy is being supplanted by the increasing use of immediate reconstruction. In a mastectomy without immediate reconstruction, it is difficult to “save” any extra native breast skin because, with the volume of the breast missing, there is excess skin folding and wrinkling. The first large report of immediate reconstruction was in 1982 by Georgiade et al.<sup>3</sup> In their series of 62 patients, the authors concluded that immediate breast reconstruction in selected patients offered the advantages of improved aesthetic results, decreased cost, less morbidity, and no adverse effect on cancer management.

Because the mastectomy and reconstruction are performed under a single anesthetic, the total hospital costs and convalescent time are reduced when compared to mastectomy and delayed reconstruction.<sup>4</sup> Immediate reconstruction reduces physical morbidity by limiting the total number of anesthetics and reducing the need for a symmetry procedure on the opposite breast.<sup>5</sup> Critical landmarks for optimizing breast form and symmetry are the inframammary fold, which is preserved, and the breast skin envelope, which can be preserved and maintained in its native state with immediate reconstruction.

Current methods of reconstruction can be broadly classified into autologous tissue or prosthetic material. Autologous tissue reconstruction uses the patient's own tissue (skin, subcutaneous tissue, and muscle) from another site to reconstruct the missing breast. Prosthetic reconstruction uses a process known as *tissue expansion* to create a “pocket” for the ultimate placement of a breast implant. There are occasional indications for a combination of both autologous tissue and an implant. The selection of the reconstructive technique is based on anatomic patient factors, including the laxity and thickness of the remaining chest wall skin, the condition of the chest wall musculature, the size of the opposite breast, and the availability of suitable autologous tissue donor sites. To identify the appropriate method of reconstruction, the anatomic factors are considered with cancer treatment goals and the patient's expectations, as well as, most important, clinical factors (diabetes, obesity, other chronic illnesses) because operative complexity and postoperative recovery varies.

#### PROSTHETIC RECONSTRUCTION

Breast reconstruction using prosthetic materials involves the use of tissue expanders and permanent breast implants. Initially, implants were placed directly under the skin in the mastectomy space, but the results were limited by the available skin envelope and capsular contracture.<sup>6,7</sup> The development of tissue expanders allowed for greater control over the size of the skin envelope, thus resulting in the ability to use larger prostheses for symmetry. Current techniques use a complete submuscular placement of the tissue expander, with coverage by pectoralis major, serratus anterior, and occasionally the anterior rectus sheath.<sup>8</sup>

A bidimensional textured surface tissue expander is placed either at the time of mastectomy, which increases the operative time of less than 1 hour, or in a delayed fashion, during a separate later operation. The area is allowed to heal for approximately 10 to 14 days, at which time fluid expansion is commenced. Using an integrated valve within the expander, saline is injected into the expander percutaneously until the appropriate size is reached ( [Fig. 37.3-1](#)). Adjuvant chemotherapy can be commenced during the expansion process. The exchange to a permanent breast implant takes place after the chemotherapy course. Using a two-stage method of implant reconstruction allows for maximum control of the implant pocket and optimal symmetry with the contralateral breast ( [Fig. 37.3-2](#)). When indicated, contralateral symmetry procedures such as augmentation mammoplasty, reduction mammoplasty, or mastopexy (breast lift), are accomplished when the tissue expander is exchanged to a permanent implant.

**FIGURE 37.3-1.** Complete submuscular placement of the tissue expander at the time of mastectomy (*left*). Percutaneous approach to expansion using a complete submuscular integrated valve tissue expander (*right*).

**FIGURE 37.3-2. A:** After expansion is complete, the pocket is overexpanded relative to the normal breast to maximize ptosis and implant projection. **B:** The same patient subsequent to exchange of the tissue expander to a permanent saline breast implant followed by nipple-areola reconstruction and tattooing.

The author (J. J. D.) reported results with 770 consecutive patients undergoing tissue expansion over a 10-year period. In this series, premature removal of the tissue expander secondary to wound-related complications or persistent disease was necessary in only 1.8% of the patients.<sup>8</sup> The advantages of tissue expander implant reconstruction are the simplicity, reliability, and avoidance of donor site morbidity. The disadvantages of this technique relate to the use of prosthetic material and include infection, leakage of the implant, capsular contracture, and differences in texture and symmetry when compared to the contralateral breast, which can lead to multiple surgical procedures on the opposite breast.

Breast implants available for reconstruction vary in size, shape, surface texturing, and fill material. In general, implants are either round or anatomic in shape, with a smooth or textured surface, and saline or silicone gel-filled. Currently, saline-filled breast implants are available, and use of silicone gel implants requires enrollment in a silicone adjunct study sponsored by the implant manufacturers, U.S. Food and Drug Administration, and the Institution Review Board where the procedure is being performed. Despite the moratorium placed on the general use of silicone gel implants, to date there is no convincing cause and effect between “human adjuvant disease” and the use of silicone gel implants.<sup>9</sup>

### AUTOLOGOUS TISSUE RECONSTRUCTION

The most predictable results in breast reconstruction involve the use of autologous tissue. In general, use of the patient's own tissue results in a reconstruction that can closely match the opposite breast in size, shape, and texture. Depending on the volume of the tissue transferred and the volume of the contralateral breast, autologous tissue breast reconstruction sometimes also requires an implant.

Methods of autologous tissue breast reconstruction include local flaps and distant flaps. Local flaps, including the latissimus dorsi myocutaneous flap and the pedicled transverse rectus abdominus myocutaneous (TRAM) flap, rely on transposition of muscle, subcutaneous tissue, and skin into the mastectomy defect based on the attached native blood supply of the muscle. Distant flap breast reconstruction mandates the use of microvascular free tissue transfer. The most common distant tissue donor site is the free TRAM flap. Other donor sites include the inferior gluteal flap, the superior gluteal flap, the deep inferior epigastric artery perforator flap, and the Rubens flap. Reconstruction using these tissues relies on harvesting the flap with its discrete vascular pedicle. The vascular pedicle is then anastomosed using microsurgical technique to appropriate recipient vessels in the mastectomy site, usually the thoracodorsal and internal mammary vessels.

The latissimus dorsi myocutaneous flap with an overlying skin island can be transposed from the back into the mastectomy defect ( [Fig. 37.3-3](#)). The advantages of the latissimus flap are in its ease of harvest and minimal donor site morbidity, compared to other sites.<sup>10</sup> The chief disadvantage of the latissimus flap is that concomitant use of a breast implant is often necessary due to the limited volume of tissue provided ( [Fig. 37.3-4](#)). Without a simultaneous implant placement, the latissimus dorsi flap is reserved for small breasts.

**FIGURE 37.3-3.** Design of the latissimus flap and skin island (*left*). Transposition of the myocutaneous latissimus dorsi flap into the mastectomy defect (*center*). Latissimus flap breast reconstruction with the placement of a breast implant underneath the latissimus dorsi flap (*right*).

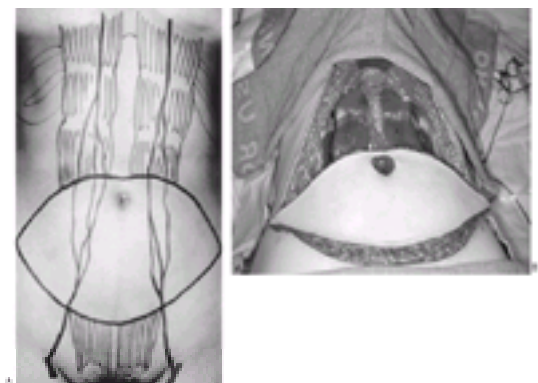

**FIGURE 37.3-4.** Right breast reconstruction with latissimus dorsi myocutaneous flap and permanent implant. The implant was necessary to achieve symmetry with the opposite breast.

The most common method of autologous tissue breast reconstruction is with the TRAM flap<sup>11</sup> because of the texture and the large volume, both of which match the other breast (Fig. 37.3-5). The blood supply to the skin island and lower abdominal fat is derived from perforating vessels through the underlying rectus abdominus muscle. Depending on the increasing volume necessary to match the other breast, the TRAM flap can be transferred on a single pedicle (usually the contralateral superior epigastric), double pedicle (using both rectus muscles and their associated superior epigastric vessels), or as a free flap (based on the deep inferior epigastric vessels)<sup>12</sup> (Fig. 37.3-6).

**FIGURE 37.3-5.** Design of an unipedicled transverse rectus abdominus myocutaneous (TRAM) flap on the lower abdomen ( *left*). Elevation of the TRAM flap based on the left rectus abdominus muscle ( *center*). Right breast reconstruction with unipedicled TRAM flap after closure of donor site and inset of flap ( *right*).

**FIGURE 37.3-6. A:** Anatomy of transverse rectus abdominus myocutaneous (TRAM) flap on the lower abdomen. The flap is centered over the rectus abdominus muscles and is supplied by the superior epigastric vessels and the deep inferior epigastric vessels. **B:** Intraoperative appearance of a bipedicled TRAM flap after harvest and before transposition into the mastectomy defect.

The TRAM flap allows the reconstructive surgeon the most versatility and design. Thus, the flap can be sculpted to closely match the contralateral breast in unilateral reconstruction, or itself in bilateral reconstruction ( Fig. 37.3-7). The use of a breast implant is rarely indicated with a TRAM flap, because an ample amount of tissue exists in properly selected patients. The lower abdominal donor site scar is easily hidden with conventional clothing. Despite the obvious advantages of the TRAM flap, not everyone is a candidate. Thin patients may not have an adequate amount of tissue at the donor site, whereas obese patients have a much higher risk for local and systemic complications.<sup>13</sup> Total flap loss with the free TRAM flap can occur, but the risk is generally accepted to be less than 2%.<sup>14,15</sup> Use of the rectus abdominus muscle results in 10% loss in abdominal wall strength in unilateral reconstruction and 40% loss when both muscles are harvested.<sup>16</sup> Lower abdominal bulging and hernia formation occurs in fewer than 10% of patients and can be minimized by surgical techniques that maximize preservation of the rectus muscles.<sup>17</sup>

**FIGURE 37.3-7.** Bilateral breast reconstruction with transverse rectus abdominus myocutaneous flaps and subsequent nipple-areola reconstruction. The use of autologous tissue conveys a natural appearance to the breast reconstruction.

Other methods of autologous tissue reconstruction include the gluteus free flap based on the superior or inferior gluteal vessels, and the Rubens flap based on the deep circumflex iliac artery. These techniques are technically demanding and do not offer the same high-quality tissue available with a TRAM flap. Therefore, their use is reserved for patients desiring breast reconstruction that are not candidates for more conventional methods.

## POSTMASTECTOMY AFTER BREAST IRRADIATION

Breast reconstruction after local failure in the irradiated breast presents a unique challenge for both the oncologic and reconstructive surgeon. The late effects of radiation are characterized clinically by a loss of skin elasticity, fibrosis, and decreased blood supply. The postradiation fibrosis severely limits the ability of the tissue expander to create a satisfactory pocket for the permanent implant. There is an increased incidence of infection, skin necrosis, and expander extrusion when attempting to expand the irradiated skin and muscle chest wall, as well as a high rate of capsular contracture in the final result. The lack of projection of the permanent implant and capsular contracture detracts from the final aesthetic result. <sup>18,19</sup>

Increasing the success of breast reconstruction after prior irradiation involves the use of autologous tissue. Depending on the method, this procedure can be performed with or without a breast implant. The transfer of the ipsilateral latissimus dorsi muscle with a cutaneous skin island into the mastectomy defect delivers a large volume of healthy nonirradiated tissue into the defect. In conjunction with a tissue expander, the flap can be expanded without difficulty, and ultimately a permanent implant can be placed with improved aesthetics and a decreased incidence of complications. <sup>20</sup>

In a series <sup>21,22</sup> of 680 consecutive patients who underwent TRAM flap breast reconstruction, 108 patients had had previous irradiation, and no difference was found in flap survival in the two groups. There was, however, increased incidence of infection and fat necrosis in the radiated group, which detracts from the final aesthetic result. The effects of irradiation on the mastectomy flaps predisposes to ischemia and may increase scar formation. <sup>20</sup>

### SKIN-SPARING MASTECTOMY WITH IMMEDIATE RECONSTRUCTION

Although autologous tissue breast reconstruction can create a breast mound that resembles the breast in shape and consistency, one drawback is the color difference between the native breast skin and the flap skin (from the distant site), which conveys a "patch-like" appearance ( Fig. 37.3-8). The technique of skin-sparing mastectomy is accomplished through one incision around the areola with preservation of the entire breast skin envelope. When necessary, a counterincision in the axilla is used to expose blood vessels, to remove lymph nodes, or for microsurgical flap transfer. The skin island from the flap is confined to the zone of the nipple-areola complex ( Fig. 37.3-9A,B). Subsequent nipple reconstruction covers the skin island completely, thereby virtually eliminating all visible scars ( Fig. 37.3-9C), and the reconstructed breast is almost indistinguishable from the other. Importantly, long-term follow-up of selected patients has not shown a difference in local recurrence rates after skin-sparing mastectomy versus traditional mastectomy. <sup>23,24</sup> and <sup>25</sup> Technical advances using complete skin-sparing techniques have resulted in reconstructed breasts that are virtually indistinguishable from the native breast in terms of color, texture, and appearance. <sup>23</sup>

**FIGURE 37.3-8.** Right breast reconstruction after mastectomy for failed breast-conservation therapy with an unipedicled transverse rectus abdominus myocutaneous (TRAM) flap. The skin island on the TRAM flap has been used to replace the radiated skin from the breast mound.

**FIGURE 37.3-9.** **A:** Design of circumareolar incision for complete skin-sparing mastectomy and axillary counterincision for exposure of lymph nodes and blood vessels. **B:** Complete skin-sparing mastectomy with free transverse rectus abdominus myocutaneous (TRAM) flap and reconstruction before nipple-areola reconstruction in another patient. **C:** Right breast reconstruction with a free TRAM flap after complete skin-sparing mastectomy. The patient has undergone right nipple-areola reconstruction and tattooing. Using this complete skin-sparing approach, the periareolar mastectomy incision is barely visible.

Nipple-areola reconstruction can be accomplished simply in the outpatient setting. One method is simply tattooing a nipple and areola onto the breast mound to imitate the color and size of the opposite nipple-areola complex. Alternatively, a local flap can be raised on the breast mound to create the nipple projection, or a skin graft can be placed ( Fig. 37.3-10). Although the nipple reconstruction lacks sensation and the erectile function of the natural nipple, it provides an important visual suggestion of normalcy and decreases the stigmata of mastectomy.

**FIGURE 37.3-10.** **A:** Nipple-areola reconstruction using a tattooing technique only. **B:** Left breast reconstruction after complete skin-sparing mastectomy with a pedicled transverse rectus abdominus myocutaneous flap, and subsequent nipple-areola reconstruction using a local flap followed by tattooing.

### LYMPHEDEMA

Aside from recurrence, lymphedema is the most dreaded sequelae of breast cancer treatment. Approximately 15% to 20% of breast cancer patients have developed

lymphedema after breast cancer treatment. Therefore, of perhaps 2 million current breast cancer survivors after axillary dissection, approximately 400,000 cope daily with the disfigurement, discomfort, and disability of arm and hand swelling.

Lymphedema is the result of a functional overload of the lymphatic system in which lymph volume exceeds transport capabilities. The functioning lymph system removes large molecules that reach the interstitial space by filtration, cellular metabolism, or secretion. The buildup of interstitial macromolecules leads to an increase in oncotic pressure in the tissues, producing more edema, and the blocked lymphatic vessels raise hydrostatic pressure proximally in the system. Persistent swelling and stagnant protein eventually lead to fibrosis and provide an excellent culture medium for repeated bouts of cellulitis and lymphangitis. With dilatation of the lymphatics, the internal valves become incompetent, causing further stasis.

The reported incidence of lymphedema has varied greatly and depends in part on the extent of axillary treatment, the interval between axillary treatment and measurement, methods used to define lymphedema, and the completeness of the patient population follow-up.

All reports on the incidence of lymphedema, including the seven selected ones from a review,<sup>26</sup> are retrospective, and in each of these reports, the denominator (i.e., the number of patients at risk for developing lymphedema in a particular population) is imprecise or unknown. The incidence varied from 6% to 30%, with the lowest incidence of lymphedema having the shortest follow-up.<sup>26</sup>

## ETIOLOGIC FACTORS

Almost all previous studies find that the incidence and the degree of lymphedema is correlated to the extent of surgical dissection as more nodes are excised. However, two large studies<sup>27,28</sup> could not demonstrate this relationship, perhaps because rather small differences in extent of axillary dissection were assessed. Regardless of the number of lymph nodes excised, surgeons should attempt to carefully preserve the fatty axillary tissue containing the invisible lymphatic trunks around the vein and to dissect the tissue only inferior to the axillary vein.

In every study that has evaluated this issue, the addition of radiation therapy directed to the dissected axilla was a strong predictor of lymphedema.<sup>26</sup> Of particular importance is that even when the intent is to radiate the breast only (such as after lumpectomy), some radiation dosage may reach the axilla depending on radiotherapy technique and patient anatomy. Specific breast radiotherapy techniques with the goal to avoid the dissected axilla and the pathophysiology of radiation-related lymphedema have been reviewed.<sup>25</sup> For precise radiation technique, it may be helpful for the surgeon to mark axillary dissection by radiopaque clips, and the area can then be seen on the simulation films.

It is biologically intuitive that sentinel lymph node biopsy of one or few nodes should decrease the risk of lymphedema. However, the sentinel node operation is not always so limited, and it is theoretically possible that indeed the sentinel node may be at the level of the axillary vein (and the lymph trunks), thereby theoretically predisposing the patient to lymphedema. The risk of lymphedema has not yet been assessed in the follow-up of patients treated with sentinel lymph node technology. Furthermore, if axillary radiotherapy is added after sentinel node biopsy, there is the risk of lymphedema. In series reporting axillary radiotherapy but no axillary surgery at all, lymphedema incidence ranged from 2% to 5%.<sup>29</sup>

Beyond these two definite factors—extent of surgical dissection and radiation to the axilla—a wide range of possible etiologic factors has not been evaluated systematically. Older age at diagnosis was reported to be a significant factor in one study,<sup>30,31</sup> but was unrelated to lymphedema incidence in another,<sup>32</sup> and curiously was not noted in others. Similar disagreement holds for dominant hand on the operated side,<sup>32,33</sup> obesity,<sup>27,34</sup> surgical technique,<sup>31</sup> and postoperative course.<sup>35,36</sup>

## PREVENTION OF LYMPHEDEMA AFTER AXILLARY TREATMENT

Because controlling lymphedema requires daily attention, and because “curing” lymphedema has not been accomplished, emphasis must be placed on prevention. Nevertheless, without evidence-based knowledge of etiologic factors, the list of posttreatment arm precautions is based on intuitive reasoning. As a background, it is important to remember that each woman has a congenitally different anatomy, which also is probably uniquely prone to degenerative conditions, similar to the remainder of the vascular system. This has been studied thus far in a limited fashion with lymphoscintigraphy.<sup>37</sup> The individual patient factors, combined with surgical and radiation treatment factors, must be the main determinants, notwithstanding the fact that lymphedema may occur several years after treatment. Events or activities, such as exercise, in the subsequent years and decades have not been studied to state which are causative factors and to what degree.

Arm and hand precautions are loosely based on two overarching principles: (1) Do not increase lymph production, which is directly proportional to blood flow, and (2) do not increase blockage to lymph transport. Heat (such as that in a sauna), significant infections, and vigorous arm exercise increase blood flow in the arm and thereby increase lymph production. Obstruction of lymph flow may result from tight arm garments or from infections with ensuing fibrosis and stenosis of lymphatic vessels.

The patient is instructed as follows:

1. Avoid puncturing or injuring the skin in any way. Use meticulous skin and nail/cuticle care. Pay immediate attention and use standard first aid care.
2. Avoid vaccinations, injections, blood pressure monitoring, blood drawing, and intravenous administration in that arm.
3. Avoid constricting sleeves or jewelry and wear a padded bra strap (to avoid supraclavicular area compression).
4. Avoid heat, such as with sunburns or tanning, baths, and saunas.
5. Avoid violent exercises and strenuous exertion. Consider vigorous aerobic arm exercise only when compression garments support the arm.

No data govern any of these recommendations. In the only studies that reported on bilateral axillary dissections, there was no higher risk of lymphedema in those women over those who had unilateral axillary dissection.<sup>26,38</sup> This calls into question whether blood drawing, intravenous administration, blood pressure monitoring, and injections are proven to hasten the development of lymphedema. On the other hand, breaking the skin barrier, even during medical procedures, could theoretically predispose to infection, and blood pressure monitoring could cause soft tissue trauma. Data for any of the other arm and hand precautions are also intuitive and not evidence-based.

All patients after axillary dissection are instructed in the arm and hand care precautions, which may, however, be too severe for those at low risk and yet not aggressive enough for those at highest risk. Because lymphedema development may occur even several decades<sup>39</sup> after the axillary treatment, patients are admonished to follow these demanding precautions for the remainder of their lives.

## LYMPHEDEMA TREATMENTS

Therapeutic nihilism (i.e., no treatment at all) is deplorable, although common. The fact that the average clinician is ill-prepared to recognize early signs of lymphedema must be remedied because the sooner the treatment is started, the less treatment is required to prevent further progression.

In the past, the treatment of established lymphedema has varied from none at all to a host of aggressive surgical procedures. Between the extremes are various combined conservative treatments, the most important of which are elevation, compression garments, centripetal massage and exercises, pneumatic compression devices, and the complete (or complex) decongestive physiotherapy (CDP) program.

### **Complete Decongestive Physiotherapy**

CDP has been widely available in Europe for many years. The program was founded on the fact that lymphedema exists in an entire body quadrant, although it is most distressing in the arm or hand. The program includes skin care, gentle specific massage known as *manual lymph drainage* (MLD), low stretch multilayer compression bandaging (followed by a fitted compression garment when edema is reduced), and therapeutic exercises with the garment or bandages in place.

The modification and features of the various CDP programs by Vodder,<sup>40</sup> Leduc,<sup>41</sup> Foldi,<sup>42</sup> and Casley-Smith<sup>43</sup> have been reviewed in the 1998 American Cancer Society Workshop on Breast Cancer Treatment-Related Lymphedema. Although the principles followed are the same for each school, the massage techniques vary somewhat in the degree of pressure, motion, and timing of strokes. Additionally, the Leduc technique uses low intermittent pneumatic pressure (<40 mm Hg) pumps,

and the Casley-Smith group uses benzopyrone medication.

A typical program is given below. CDP must be performed by skilled, specially trained therapists. During the treatment phase, the patient is given one or two daily 75 to 90 minute treatments over 1 to 4 weeks. In the maintenance phase, which is continued indefinitely, the patient maintains and optimizes the results by applying some of the techniques learned in the treatment phase, such as wearing an elastic sleeve during the day, bandaging (as described below) the affected limb overnight, and exercising for 15 minutes a day while wearing the bandages.

MLD, or manual lymph therapy, is a delicate massage technique that stimulates lymph vessels to contract more frequently and that directs and channels fluid toward adjacent, functioning lymph basins. MLD begins with stimulation of the lymph vessels and nodes in unaffected and opposite basins (neck, contralateral axilla, ipsilateral groin). Edema fluid and obstructed lymphatics are made to drain toward functioning lymph basins across the midline of the body, down toward the groin, over the top of the shoulder, around the back, and so forth. Finally, in segmented order, massage of the involved trunk, then shoulder, upper arm, forearm, wrist, and hand is performed. Multilayer low-stretch bandaging is done immediately after MLD. Bandages are wrapped from the fingertips to the axilla with maximal pressure distally and less pressure proximally. This is done by using many layers of minimally elastic cotton bandages, beneath which layers of foam rubber padding are inserted to ensure uniform pressure distribution or to increase pressure in areas that are particularly fibrotic. The bandaged patient is next guided through exercises involving active range of motion with the muscles and joints functioning within the closed space of the bandaging. Isometric exercise is generally avoided.

After volume reduction has been accomplished, well-fitted custom-made compressive garments (see [next section](#)) continue ongoing control of edema. The patient should be re-measured and the garment replaced every 3 months. The prescribed exercises continue in the low-stretch multilayer bandages, which are also worn overnight. The patient and family is trained to continue the maintenance program at home. Follow-up visits to the center usually take place at least at 6-month intervals.

Although this increasingly popular technique appears more successful in reversing lymphedema than other modalities, the availability of patient services and treatment centers that can practice CDP are limited. The patient availability <sup>44</sup> and the professional education for physical therapists <sup>45</sup> has been reviewed. The theory and clinical application of the four schools of manual lymphatic technique are reviewed in the American Cancer Society monograph by their representative faculty.<sup>40,41,42 and 43</sup>

### **Elevation and Elastic Garments**

Although elevation is helpful in reducing swelling through use of gravity, it is impractical. A patient with lymphedema should be fitted with an elastic sleeve from wrist to axilla, if the edema is mild, or after swelling reduction, if the edema is moderate. A separate gauntlet or handpiece allows the patient to wash her hands without removing the sleeve.

The compression classes are as follows:

- I. 20 to 30 mm Hg
- II. 30 to 40 mm Hg
- III. 40 to 50 mm Hg
- IV. 50 to 60 mm Hg

For upper extremity lymphedema, a class II or III support is generally required. The person measuring the lymphedematous arm and hand should be specifically trained in fitting such garments and in instructing the patient in proper application. A statistically significant reduction in edema has been reported in women who wore garments for 6 consecutive hours per day.<sup>46</sup> Using these garments during exercise, physical activity, and air travel is recommended.

### **Pneumatic Pumps**

The standard sequential system is a multichamber pump that delivers the compression at the same pressure in each garment section from distal to proximal tissues. The gradient sequential system delivers pressures that differ by approximately 10 mm Hg between each chamber, with the higher pressures delivered to the distal chamber. A minimum of 1 hour each pumping session with the arm elevated is required, and lower pressures for longer periods are more effective than higher pressures for a shorter time. Individualized and tailored pumping programs should be prescribed by a physical therapist, based on measurable efficacy and tolerability, as known by the serial assessment before the patient is placed on a home program.

The various devices have been reported in several controlled studies <sup>47,48 and 49</sup> to reduce lymphedema. Although theoretically attractive to use machinery for the pumping action on the arm lymphatics, pumping has not been as clinically effective as would be hoped. It has been hoped that pneumatic compression devices or "pumps" could duplicate the beneficial effects of massage.<sup>50</sup> However, the pumps force protein-rich edema fluid toward the shoulder but not through the axillary blockage. Rationale and controversies about pumps have been reviewed.<sup>50,51</sup>

### **MEDICATIONS**

Diuretics are not effective in high-protein edemas such as lymphedema. Although the diuretics can temporarily mobilize water, the osmotic pressure from the increased protein in the interstitial space causes rapid re-accumulation of edema.

Benzopyrones belong to a group of drugs that include the bioflavonoids and the coumarins. The former occurs widely in nature, especially in fruits and vegetables. Benzopyrones may improve chronic lymphedema by stimulating macrophage activity for increased proteolysis and thereby removal of stagnant, excess protein in the tissue spaces, which results in less oncotic pressure and edema fluid. In 1993, a randomized, double-blind, placebo-controlled, crossover trial of 5,6-benzo-a-pyrone demonstrated its efficacy in an Australian study.<sup>52</sup> Although the effect was mild, it was statistically significant. However, in a similar study design, a larger number of breast cancer patients in an American multicenter study led by the Mayo Clinic were reported. No value was found with the benzopyrone beyond the placebo effect.<sup>53</sup> Furthermore, 6% of these study subjects had serious elevation of liver function tests.

## INTRODUCTION

The transformation of a cell from the normal to the malignant phenotype is a result of a stepwise accumulation of genetic defects that render the cell unresponsive to or independent of normal cellular growth signals. Defects in a variety of oncogenes and tumor suppressor genes have been described in endocrine neoplasms. Characterization of these specific molecular defects has yielded insight into the mechanisms of tumorigenesis in these tissues and, in some cases, provided clinically applicable diagnostic or prognostic information. Identification of the germline mutations associated with the multiple endocrine neoplasia types 1 and 2 (MEN 1, MEN 2) syndromes has led to the advent of direct DNA testing for individuals at risk. In patients with a hereditary form of medullary thyroid carcinoma (MTC), early thyroidectomy may be performed on the basis of DNA mutational analysis at a time when the MTC is occult and likely curable. Finally, the molecular defects that occur in tumors arising in the familial endocrine neoplasia syndromes have been found to play an important role in tumorigenesis of sporadic neoplasms arising in the same endocrine tissues.

## MULTIPLE ENDOCRINE NEOPLASIA SYNDROMES

### MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

#### *Clinical Features*

MEN 1 is characterized by the development of parathyroid hyperplasia, neuroendocrine tumors of the pancreas and duodenum, and adenomas of the anterior pituitary gland.<sup>1</sup> In addition, affected patients develop bronchial and thymic carcinoids, benign thyroid and adrenocortical tumors, subcutaneous lipomas, cutaneous angiofibromas,<sup>2</sup> and spinal ependymomas<sup>3</sup> with increased frequency. More than 90% of patients inheriting a *MEN1* gene mutation develop hyperparathyroidism (HPT) by the second or third decade of life. Depending on the method of study, 35% to 75% of mutation carriers develop neuroendocrine tumors of the pancreas and duodenum that are frequently malignant. The neuroendocrine tumors in patients with MEN 1 result in symptoms due to either excess secretion of a specific hormone product or the effects of the tumoral process itself. The malignant duodenopancreatic tumors and intrathoracic tumors account for the majority of the disease-related morbidity and mortality in *MEN1* gene mutation carriers.<sup>4,5</sup>

#### *Genetics*

**MEN1 TUMOR SUPPRESSOR GENE.** In 1988, the *MEN1* predisposition gene was mapped to chromosome 11q13 by a combination of studies of the loss of chromosome sequences in tumor DNA and genetic linkage analysis using markers from chromosome 11.<sup>6</sup> The frequent occurrence of chromosome deletions encompassing the 11q13 interval in tumor DNA supports the hypothesis that the *MEN1* gene is a classic tumor suppressor gene. The normal protein encoded by a tumor suppressor gene is presumed to function as a negative control or “brake” on unregulated cellular growth and proliferation, such that complete elimination of its function by mutation or deletion of both homologous copies would be expected to result in unregulated cell growth. The multifocal involvement characteristically observed in affected endocrine tissues presumably reflects the chance occurrence of multiple “second hits.”

The *MEN1* tumor suppressor gene encodes a predicted 610–amino acid protein product termed *menin*.<sup>7</sup> The structure of the *MEN1* gene consists of ten exons, with the first exon being untranslated. The 2.8-kilobase *menin* messenger RNA (mRNA) transcript is ubiquitously expressed and may be detected in lymphocytes, thymus, pancreas, thyroid, the gonads, and other tissues. Similar to the protein products of most previously described tumor suppressor genes, evidence has been provided that *menin* is a nuclear protein.<sup>8</sup>

The diverse array of reported *MEN1* mutations includes missense, nonsense, frameshift, and mRNA splicing defects that are distributed throughout the nine coding exons as well as the intervening intronic sequences. The *MEN1* gene mutations in a series of 25 separate kindreds with MEN 1 are depicted graphically in [Figure 38.1-1](#). To date, more than 100 germline *MEN1* mutations have been reported in the literature,<sup>7,9,10,11,12,13,14,15</sup> and there are almost as many distinct mutations as there are separate families. Approximately two-thirds of the reported mutations in the *MEN1* gene result in truncation of the C-terminal portion of the *menin* protein. No specific genotype-phenotype correlations have been established to date.

**FIGURE 38.1-3.** Photomicrograph of medullary thyroid carcinoma showing nests and sheets of small, uniform cells with scant to moderate amounts of amphophilic cytoplasm infiltrating around normal thyroid follicles. (Reprinted from Moley JF, Lairmore TC, Phay JE, Hereditary endocrinopathies. *Curr Probl Surg* 1999;36:653, with permission.)

Patients with MEN 2A develop multifocal, bilateral MTC, associated with C-cell hyperplasia. Approximately 42% of affected patients develop pheochromocytomas, which may also be multifocal and bilateral and usually are associated with adrenal medullary hyperplasia. HPT develops in 25% to 35% of patients and is due to hyperplasia, which may be asymmetric, with one or more glands becoming enlarged.<sup>20</sup> Parathyroid carcinoma has been reported in one patient with MEN 2A.<sup>21</sup> Cutaneous lichen amyloidosis has been described in some patients with MEN 2A.<sup>22</sup> In this entity, macular amyloidosis presents as brownish plaques of multiple tiny papules, usually in the interscapular area. Microscopically, these lesions demonstrate a hyperplastic epidermis, acanthosis, lymphocytic infiltrate, and amyloid goblets. Hirschsprung's disease is infrequently associated with MEN 2A.<sup>23,24</sup> and<sup>25</sup> This disease is characterized by the absence of autonomic ganglion cells within the distal colonic parasympathetic plexus, resulting in obstruction and megacolon.

In MEN 2B, 40% to 50% of patients develop pheochromocytomas, and all individuals develop neural gangliomas, particularly in the mucosa of the digestive tract, conjunctiva, lips, and tongue. MEN 2B patients also have megacolon, skeletal abnormalities, and markedly enlarged peripheral nerves. MEN 2B patients do not develop HPT. MTC develops at a very young age (infancy) and appears to be the most aggressive form of hereditary MTC, although its aggressiveness may be related more to the extremely early age of onset than to the biologic virulence of the tumor. MTC in MEN 2B is rarely curable.

FMTC is characterized by the development of MTC without any other endocrinopathies.<sup>26</sup> MTC in these patients has a later age of onset and follows a more indolent clinical course than MTC in patients with MEN 2A and MEN 2B. Occasional patients with FMTC never manifest clinical evidence of MTC (symptoms or a lump in the neck), though biochemical testing and histologic evaluation of the thyroid usually demonstrates MTC.

### Genetics

**THE RET PROTOONCOGENE.** In 1987, the gene for MEN 2A was localized to the pericentromeric region of chromosome 10 (10q11.2) by linkage analysis.<sup>27,28</sup> Subsequent studies demonstrated that the predisposition gene for MEN 2B and FMTC mapped to the same region as MEN 2A.<sup>29,30</sup> The *RET* protooncogene resides within this critical region, which made it an obvious candidate gene for the MEN 2 syndromes.

The *RET* protooncogene was first discovered based on its ability to transform mouse NIH 3T3 fibroblasts in culture.<sup>31</sup> The transforming *RET* sequences first identified represented a rearrangement of *RET* that occurred *in vitro* during the transfection assay.<sup>32</sup> Sequence analysis of the *RET* protooncogene showed that it is a member of the receptor tyrosine kinase gene family.<sup>33</sup> *RET* was mapped to the proximal region of the long arm of chromosome 10 in 1989<sup>34</sup> and was shown to be expressed at high levels in both MTCs and pheochromocytomas.<sup>35</sup>

*RET* mutations were identified in the constitutional DNA of MEN 2A and FMTC patients in 1993.<sup>36,37</sup> Mulligan et al.<sup>36</sup> identified *RET* mutations in association with MEN 2 using an expression-based mutational analysis system. Analysis of genomic DNA from MEN 2A family members proved that the variants identified in the complementary DNAs (cDNAs) were also in the constitutional DNA of affected family members and not in individuals unaffected by MEN 2A. All mutations resulted in substitution of cysteine residues clustered near the transmembrane domain of *RET*. In all but one, MEN 2A tumor heterozygosity for the mutant and wild-type *RET* allele was retained. Mulligan et al.<sup>36</sup> suggested a dominant or dominant-negative mechanism for *RET* mutation in the development of MTC and pheochromocytomas in MEN 2A.<sup>36</sup>

Donis-Keller et al.<sup>37</sup> used single-strand conformational variant (SSCV) and sequence analysis to identify mutations in *RET* in the constitutional DNA of patients with MEN 2A and FMTC. Both MEN 2A and FMTC were shown to be associated with mutations that result in substitution of cysteine residues in the extracellular portion of *RET* immediately adjacent to the transmembrane domain. Unexpectedly, the same mutations were found to characterize MEN 2A and FMTC kindreds.

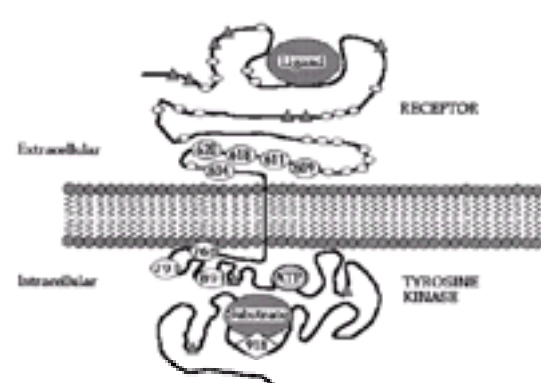

Subsequent investigations demonstrated mutations of *RET* in MEN 2B patients.<sup>38,39</sup> In 95% of cases of MEN 2B, the *RET* protooncogene mutation is a missense methionine-to-threonine (ATG to ACG) change at codon 918 in exon 16. This codon is positioned within the tyrosine kinase catalytic core of the intracellular domain. Two families with MEN 2B have been described that have a codon 883 mutation in the tyrosine kinase domain of *RET*.<sup>40</sup>

More than 30 missense mutations have been described in MEN 2A and FMTC kindreds (Table 38.1-2).<sup>41,42</sup> Most of these mutations result in nonconservative changes in cysteine residues, although changes in Glu, Val, Met, Leu, and Tyr have also been described. Several of these mutations have been shown to result in "gain-of-function" in the *RET* protein product, with increased intrinsic tyrosine kinase activity or alterations of substrate recognition (or both) and transforming capability.<sup>43</sup> The *RET* protooncogene encodes a protein with three domains: a cysteine-rich extracellular receptor domain, a hydrophobic transmembrane domain, and an intracellular tyrosine kinase catalytic domain (Fig. 38.1-4). The *RET* gene consists of at least 20 exons<sup>44</sup> and is expressed as five major mRNA species.<sup>45,46</sup> The *RET* gene product is expressed in a limited number of cell types in the normal individual, including the thyroid C cells, the adrenal medulla, and parts of the brain. The gene is important in the embryonic development of the enteric nervous system and the kidneys.<sup>47</sup>

**TABLE 38.1-2.** *RET* Mutations in Hereditary Medullary Thyroid Carcinoma

**FIGURE 38.1-4.** Diagram of *RET* gene product delineating locations of germline mutations found in multiple endocrine neoplasia type 2A and familial, non-MEN medullary thyroid carcinoma (ovals), germline mutations in multiple endocrine neoplasia type 2B (diamonds), and mutations in hereditary Hirschsprung's disease

(triangles). As mentioned in the text, the RET gene product is thought to create a dimer that forms a complex with glial-derived neurotrophic factor receptor- $\alpha$  or neurturin. The RET gene product is divided into the intracellular, transmembrane, and extracellular domains. ATP, adenosine triphosphate. (Adapted from Moley JF, Kim S, Molecular genetics in surgical oncology. Austin: RG Landes, 1994, with permission.)

Glial-derived neurotrophic factor (GDNF) and neurturin are ligands to the receptor domain of the RET gene product.<sup>48,49,50,51,52,53</sup> and<sup>54</sup> GDNF is a 32-kD protein dimer that was first purified from glial cell lines and is a potent neurotrophic survival factor for motor neurons. A glycoposphatidylinositol-linked protein called GDNF receptor- $\alpha$  (GDNFR- $\alpha$ ) is a cofactor in the signaling heterodimeric complex with RET. Current evidence suggests that GDNF binds directly to GDNFR- $\alpha$  and indirectly with RET. When triggered by ligand, wild-type RET dimerizes with another RET molecule, and this dimerization is responsible for phosphorylation and activation of the tyrosine kinase domain, with subsequent downstream signal transduction events. RET molecules that contain MEN 2A-type mutations are constitutively dimerized and therefore activated. In contrast, the mutation responsible for MEN 2B does not result in constitutive dimerization but changes the substrate specificity of the tyrosine kinase domain, which results in transformation.

**OTHER RET GENOTYPE-PHENOTYPE CORRELATIONS.**

*Cutaneous Lichen Amyloidosis.* Interscapular lesions of cutaneous lichen amyloidosis (CLA) have been described in several families with MEN 2A.<sup>22</sup> The total number of patients described with this entity is fewer than 100. In a 634@Tyr mutation was reported in one family with MEN 2A and CLA, and in two other families, a 634@Arg mutation was described that segregated with both MEN2A and CLA.<sup>55</sup>

*Hyperparathyroidism.* HPT in MEN 2A is caused by parathyroid hyperplasia; the hypercalcemia is mild and often asymptomatic. HPT clusters in some families with MEN 2A. Whether specific MEN2A mutations are associated with a higher incidence of HPT remains controversial. Mulligan et al.<sup>56</sup> previously described a strong correlation between C634R mutation and HPT in families with MEN 2A, but other studies have been unable to confirm this relationship definitively.<sup>57,58</sup> and<sup>59</sup>

*Hirschsprung's Disease.* Hirschsprung's disease is characterized by absence of autonomic ganglion cells within the distal colonic parasympathetic plexus, resulting in obstruction and proximal megacolon. Approximately 80% of Hirschsprung's disease cases are sporadic, and the remainder are familial. A subset of familial Hirschsprung's cases have been found to be associated with germline mutations of RET.<sup>24,56</sup> Most of these are inactivating and loss-of-function (frameshift and nonsense) mutations and are not associated with the MEN 2A phenotype. Several families, however, have been described in which Hirschsprung's disease cosegregates with either MEN2A or FMTC (missense codon 618 or 620 mutations).<sup>60</sup> Additionally, a few Hirschsprung's disease patients have been described with missense mutations in codon 609 or 620 who have no evidence of MEN 2A or MTC.<sup>23,25,56</sup> It is interesting to note that the Hirschsprung's disease phenotype can be associated with either loss-of-function or gain-of-function mutations of RET. All patients with MEN 2B (missense codon 918 mutation) have megacolon and chronic colonic motility disturbances, though they usually do not require surgery for this (see Fig. 38.1-2C).<sup>61</sup>

*RET Mutations in Sporadic Tumors.* Mutations in the RET protooncogene have also been found in sporadic MTCs.<sup>37,40,62,63</sup> and<sup>64</sup> The most frequent mutation in sporadic MTCs is the M918T mutation found in MEN 2B. Mutations have been found in other regions of the extracellular and intracellular domains. Missense, deletions, and insertion mutations have been described.<sup>41,65</sup> Somatic RET mutations in sporadic pheochromocytomas are unusual but have also been described.<sup>41</sup>

*Other Dominant Oncogenes in Medullary Thyroid Carcinomas and Pheochromocytomas.* Absence of amplification of N-MYC, C-MYC, and ERB-B2 has been reported in MTCs and pheochromocytomas. Roncalli et al.<sup>66</sup> reported that N-myc expression in more than 10% of tumor cells, as detected by immunohistochemistry, was associated with poorer survival, sporadic disease, and male gender. These investigators found no evidence of gene amplification and did not determine the basis for the overexpression.<sup>66</sup> Our group reported absence of mutation of the H-RAS, N-RAS, and K-RAS genes in a series of pheochromocytomas and MTCs analyzed by direct sequencing.<sup>67</sup> Likewise, examination of nerve growth factor and nerve growth factor receptor (p75) showed no abnormality at the DNA or RNA levels.<sup>68</sup>

*Other Tumor Suppressor Genes in Medullary Thyroid Carcinoma and Pheochromocytoma.* Several studies have evaluated loss of heterozygosity (LOH) at tumor suppressor loci in pheochromocytomas and MTCs; these are summarized in Table 38.1-3. The cumulative data indicate a higher-than-background incidence of LOH in pheochromocytomas on chromosome arms 1p, 3p, 17p, and 22q.<sup>69,70</sup> In MTCs, the report by Mulligan et al.<sup>70</sup> suggests a significant incidence of 1p LOH; however, evaluation of other chromosomal arms yielded no consistent findings. Lack of significant LOH on 10q, at the RET locus, supports the hypothesis that the RET protooncogene acts as a dominant oncogene as opposed to a tumor suppressor gene.<sup>71</sup> Chromosome 1 is the largest chromosome, and LOH analysis on 1p in pheochromocytomas suggests a very large region of deletion. Our studies have indicated that the entire short arm of 1p is lost in pheochromocytomas from patients with MEN 2A and MEN 2B.<sup>69</sup> Fine mapping of the region of deletion suggests a possible common breakpoint in the centromeric region defined by the markers D1S514 and D1S442.<sup>72</sup>

**TABLE 38.1-3.** Loss of Heterozygosity in Pheochromocytomas and Medullary Thyroid Carcinomas

The high rate of LOH on 3p in pheochromocytomas suggests an as-yet undefined tumor suppressor locus.<sup>70,73</sup> LOH on 17p suggests possible involvement of the TP53 gene.<sup>74</sup> Existing reports on TP53 mutations in pheochromocytomas are conflicting. Two Japanese groups reported no evidence of TP53 mutations in pheochromocytomas.<sup>75,76</sup> In contrast, a Chinese group reported TP53 mutations in five of six tumors tested.<sup>77</sup> Four of these mutations were in exon 4. Our group reported a series of 22 pheochromocytomas and 29 MTCs that were screened with four different markers for LOH on 17p.<sup>74</sup> SSCV analysis of exons 4 through 9 of the TP53 gene was performed in 20 of the pheochromocytomas and in 22 of the MTCs. The expression of p53 was determined by immunohistochemistry in 19 pheochromocytomas and in 17 MTCs, using two different antibodies (D01 and D07) on both frozen and paraffin-embedded tissues. LOH was demonstrated on 17p in 4 of the 22 pheochromocytomas and in none of the MTCs. No mutations were detected in any of the tumors screened by SSCV analysis. Immunohistochemical staining of frozen and paraffin-embedded tumor sections did not show p53 overexpression in any of the tumors examined. These findings indicate that mutations in the TP53 gene are an uncommon event in the tumorigenesis of hereditary and sporadic pheochromocytomas and MTCs.<sup>74</sup>

Pheochromocytomas also occur in neurofibromatosis type 1 (NF1) and von Hippel-Lindau (VHL) disease, both of which are caused by mutations in tumor suppressor genes. NF1 gene expression was decreased or absent in 7 of 20 pheochromocytomas from patients with MEN 2 and sporadic disease.<sup>78</sup> Because NF1 is ubiquitously expressed, its lack of expression indicates that NF1 may play a role in the development or progression of pheochromocytomas from patients who do not have NF1. Because of the extremely large size of the NF1 gene, mutational analysis has not yet been performed. Mutational analysis of the VHL gene in non-VHL pheochromocytomas has not been reported.

There have been no reports of the involvement of DNA repair genes (MLH1, MSH2) in development or progression of pheochromocytomas or MTCs, and replication error or repeats have not been a consistent finding in these tumors (J. F. Moley, unpublished data).

## Preventive Surgery for MEN 2A Gene Carriers

Individuals with MEN 2A and FMTC are virtually certain to develop MTC at some point in their lives (usually before age 30 years). Therefore, at-risk family members who are found to have inherited a *RET* gene mutation are candidates for thyroidectomy, regardless of their stimulated plasma calcitonin levels. In a series from Washington University in St. Louis, Wells et al.<sup>79</sup> reported the performance of preventive surgery in 13 asymptomatic *RET* mutation carriers. One hundred thirty-two individuals from seven different kindreds affected by MEN 2A were screened. Of the 132 individuals, 48 had an established diagnosis of MEN 2A, and 58 were at 50% risk for inheriting the disease but had no clinical evidence of endocrine neoplasia. Twenty-six unaffected spouses of MEN 2A kindred members served as controls. All individuals were evaluated for the presence of *RET* gene mutations. PCR- and sequence-based direct mutation analysis of genomic DNA from the 58 individuals at 50% risk for MEN 2A identified 21 individuals who had inherited a *RET* mutation associated with disease. The other thirty-seven family members had two normal *RET* alleles. All 26 unaffected control individuals had normal *RET* alleles. After meeting with genetic counselors, who informed them of the pattern of disease inheritance and the basis for the genetic tests, total thyroidectomy was offered to all 21 individuals who were found to have inherited a *RET* mutation. The patients ranged in age from 6 to 21 years (mean, 13.2 years). In 12 of the 21 patients (mean age, 12 years; range, 6–21 years), the stimulated plasma calcitonin levels were within normal limits. In the remaining nine patients (mean age, 15.1 years, range, 8–20 years), the stimulated plasma calcitonin levels were elevated.

Of the 12 genetically positive individuals with normal stimulated plasma calcitonin levels, 6 patients (or, in the case of minors, their parents) decided against having an immediate thyroidectomy, for reasons of convenience of timing or because they preferred to wait until calcitonin levels were elevated. Of the nine family members with elevated stimulated plasma calcitonin levels, two wished to delay thyroidectomy for several months for personal reasons. In the remaining 13 individuals (six with normal plasma calcitonin levels and seven with elevated levels), total thyroidectomy, lymph node dissection, and parathyroid autotransplantation were performed. After thyroidectomy and parathyroid autotransplantation, patients were placed on thyroid hormone, calcium, and vitamin D supplementation. Approximately 8 weeks after the operation, the oral calcium and vitamin D were stopped. Two weeks after the oral calcium and vitamin D replacement were stopped, the serum calcium concentration was within the normal range in each patient. Of the seven patients whose preoperative plasma calcitonin levels were elevated, each had microscopic evidence of MTC on histologic examination. Two of the seven had macroscopic disease. Of the six patients with normal preoperative plasma calcitonin levels, macroscopic MTC (n = 1), microscopic MTC (n = 2), or C-cell hyperplasia only (n = 3) was evident. A total of 212 lymph nodes were resected from the central zone of the neck (14.5 per patient), none of which was found, on histologic examination, to contain metastases. In each of the 13 patients, the stimulated plasma calcitonin levels were normal after total thyroidectomy.

Lips et al.<sup>80</sup> in a series from the Netherlands, identified 14 young members of families affected by MEN 2A who had normal calcitonin testing but who were found to be *MEN2A* gene carriers by DNA testing. Thyroidectomy was performed on 8 of these 14, and foci of MTC were identified in all 8.

In a later report of preventive thyroidectomies in *RET* mutation carriers, Wells et al.<sup>81</sup> at Washington University in St. Louis reported a series of 49 children with MEN 2A and MEN 2B. In this series, 14 children had a prophylactic thyroidectomy based on genetic testing. The average age of the children at the time of surgery was 10.5 years. Postoperative calcitonin levels were all undetectable, and no evidence of recurrent MTC was found during a mean follow-up of 1.3 years. In an interim report of 3-year follow-up of the earliest group of 18 patients, no recurrence of disease was noted.<sup>82</sup>

The finding of carcinoma in the thyroid glands of many of these young patients with normal stimulated calcitonin testing indicates that the operation was therapeutic, not prophylactic.<sup>81,83</sup> There is some urgency, therefore, to applying this genetic test to other at-risk individuals and performing thyroidectomy on those who test positive genetically. The ideal age for performance of thyroidectomy in those patients found to be genetically positive has not been determined unequivocally. It is reasonable to perform surgery in 6-year-old patients with MEN 2A and FMTC. Patients with MEN 2B should undergo thyroidectomy during infancy, because of the aggressiveness and earlier age of onset of MTC in these patients.<sup>61,84</sup> Patient follow-up over the next decades will determine whether there is a significant rate of recurrence after preventive thyroidectomy. At present, it is advisable to follow up these patients with stimulated plasma calcitonin levels every 1 to 2 years. These patients must also continue to be followed for the development of pheochromocytomas and HPT.

## MOLECULAR PATHOGENESIS OF SPORADIC THYROID NEOPLASMS

The thyroid follicular cell is highly differentiated, with the ability to concentrate iodide and synthesize thyroglobulin. Thyroid-stimulating hormone (TSH) is the major regulator of differentiated function of follicular cells and also functions as a growth factor for follicular cells via a cyclic adenosine monophosphate-mediated signal transduction pathway. In addition, thyroid cell growth and proliferation are influenced by a variety of growth factors and cytokines, as well as by the amount of iodine in the diet. Presumably, a host of genetic and environmental factors may result in unregulated growth or loss of differentiated function and confer a proliferative advantage to certain follicular cells, resulting in nodule formation.<sup>85</sup> Progression of benign adenomatous nodules to differentiated carcinoma is speculative at present, but good evidence exists for the development of anaplastic carcinomas from well-differentiated tumors.<sup>86,87 and 88</sup> A schematic model of the proposed events in thyroid follicular cell tumorigenesis is shown in [Figure 38.1-5](#).

**FIGURE 38.1-5.** Flow diagram of proven and postulated events in thyroid follicular cell tumorigenesis. Mutations in the RAS oncogene are believed to be early events in the genesis of follicular neoplasms. Activation of the RET and TRK receptor tyrosine kinases is specific to papillary thyroid carcinomas. The association of mutations in the TP53 tumor suppressor gene with undifferentiated thyroid tumors suggests that mutations in TP53 are a critical event in the progression of follicular carcinoma to anaplastic carcinoma.

## EPIDEMIOLOGIC AND GENETIC FACTORS ASSOCIATED WITH THYROID NEOPLASIA

Papillary thyroid carcinoma accounts for 85% of differentiated thyroid carcinomas in iodine-sufficient countries.<sup>89</sup> In areas of iodine deficiency or endemic goiter, an overall increased incidence of thyroid cancer is noted, attributable to a higher proportion of follicular carcinomas and anaplastic thyroid carcinomas (which often arise from preexisting follicular carcinomas).<sup>90,91,92 and 93</sup> The incidence of thyroid neoplasia is also increased in certain hereditary syndromes, including familial adenomatous polyposis coli, Cowden's disease, and MEN 1. Exposure to external radiation in childhood is a strong risk factor for the subsequent development of benign and malignant thyroid nodules.<sup>94,95,96,97 and 98</sup> Point mutations of K-RAS have been detected in 60% of radiation-related thyroid tumors.<sup>99</sup>

## FOLLICULAR ADENOMAS

A local proliferative advantage may be provided to a thyroid follicular cell by genetic mutational events, environmental factors, or the local influence of cytokines or growth factors. Clonal expansion of cells with a growth advantage leads to nodule formation.

Mutations in all three members of the *RAS* oncogene family (K-RAS, N-RAS, and H-RAS) have been detected in thyroid neoplasms.<sup>100</sup> RAS mutations are detected with equal frequency in benign and malignant thyroid neoplasms<sup>101</sup> and are believed to represent an early event in follicular cell tumorigenesis.<sup>102</sup> RAS mutations occur predominantly in follicular thyroid carcinomas, with most of the mutations occurring at codon 61 of H-RAS and N-RAS.<sup>101,103,104</sup> By contrast, RAS mutations are a rare event in papillary thyroid carcinomas. It appears that RAS mutations are not sufficient for transformation of the thyroid cell; additional genetic events are required. In

cooperation with other oncogenes,<sup>105</sup> transformation of thyroid cells *in vitro* with mutant *RAS* is associated with loss of differentiation, including decreased iodide uptake and expression of thyroid peroxidase.<sup>106</sup>

Mutational events affecting receptors or intermediates along the adenylate cyclase–cyclic adenosine monophosphate signal transduction pathway may contribute to the formation of hyperfunctioning adenomas. A subset of hyperfunctioning adenomas has been shown to harbor somatic mutations in the gene encoding the TSH receptor (*TSHR*) that result in constitutive activation of downstream events.<sup>107</sup> Mutations in the G protein intracellular mediator of adenylate cyclase ( $G_s$ ) have been detected in 25% of hyperfunctioning thyroid nodules.<sup>108,109</sup> Therefore, a unifying molecular theme in the pathogenesis of hyperfunctioning nodules is inappropriate activation of the TSH signal transduction pathway, which is a result of specific gene mutations altering a key mediator of an otherwise well-balanced cascade.

Finally, deletion of chromosomal sequences from the 11q13 region has been demonstrated in 14% of follicular adenomas,<sup>110</sup> suggesting that inactivation of a tumor suppressor gene in this region may play a role in follicular cell tumorigenesis in a subset of tumors.

## PAPILLARY THYROID CARCINOMA

Activation of receptor tyrosine kinases (*RET/PTC*, *NTRK1*, *MET*), whether by chromosomal rearrangement or gene amplification, is associated with the transformation of follicular cells to papillary thyroid carcinoma.<sup>111,112</sup> The *RET* protooncogene was first discovered based on its ability to transform mouse NIH 3T3 fibroblasts in culture.<sup>31</sup> The transforming *RET* sequences first identified represented a rearrangement of *RET* that occurred *in vitro* during the transfection assay.<sup>32</sup> Fusco et al.<sup>113</sup> subsequently demonstrated that DNAs from 25% of papillary carcinomas or their lymph node metastases also were positive in transfection assays. The transforming sequences in papillary carcinomas, originally believed to be a unique oncogene termed *PTC* (for papillary thyroid carcinoma), were shown to represent *in vivo* chromosomal rearrangements that resulted in the juxtaposition of sequences encoding the intracellular tyrosine kinase domain of *RET* with 5' sequences from one of three unrelated genes.<sup>111,113,114,115,116</sup> and <sup>117</sup> The most frequent form of activated *RET/PTC* results from a paracentric inversion of chromosome 10q,<sup>116</sup> which in turn incites the gene fusion of D10S170 (H4) sequences with the catalytic domain of *RET* (Fig. 38.1-6). The frequency of *RET* rearrangements in papillary carcinomas may be as high as 33%,<sup>113,118</sup> but a lower frequency has been found in other studies,<sup>119,120</sup> perhaps reflecting either racial or environmental factors influencing thyroid tumorigenesis in different geographic regions.

**FIGURE 38.1-6.** Chromosome 10q inversion in papillary thyroid carcinoma. **A:** Two representative chromosome 10 homologues from tumor cells of patients 1 and 2 showing *inv(10)(q11.2q21)* (arrows). **B:** Schematic view of the paracentric inversion of chromosome 10q generating the transforming sequence *RET/PTC*. (From ref. 116, with permission.)

Activation of *NTRK1* (tropomyosin receptor kinase), which encodes a cell surface receptor for nerve growth factor, has also been detected in some papillary carcinomas.<sup>111</sup> The *NTRK1* oncogene is generated by a chromosomal rearrangement that juxtaposes the tyrosine kinase domain of *NTRK1* and the 5' region of the *TPR* gene, both mapping to chromosome 1q23-24.<sup>121,122</sup> Finally, the *MET* oncogene, which also encodes a receptor tyrosine kinase, is amplified and overexpressed in 70% of papillary and poorly differentiated carcinomas but in only 25% of follicular carcinomas.<sup>123,124</sup> Activation of *MET* by amplification<sup>124</sup> and the presence of a rearranged, activated form of *RET*<sup>125,126</sup> and <sup>127</sup> have been suggested as predictors of aggressive biologic behavior and poor prognosis in papillary carcinomas. However, because of the generally excellent prognosis of these tumors, larger studies will be required to confirm these observations.

Activation of receptor tyrosine kinases by the common mechanism of gene rearrangement that brings the tyrosine kinase domain under the control of inappropriate upstream regulators derived from any of several “activating genes” appears to be specific for the transformation of follicular cells into papillary thyroid carcinoma.

## FOLLICULAR THYROID CARCINOMA

Numerous chromosomal deletions have been detected in thyroid neoplasms, suggesting a role for multiple tumor suppressor genes in the initiation or progression of these tumors. Although sporadic follicular thyroid tumors exhibit allelic chromosomal loss of chromosome 11q13 sequences with increased frequency,<sup>110</sup> one study failed to find accompanying mutations in the *MEN1* gene in the remaining normal allele, suggesting that a tumor suppressor gene other than *MEN1* might be involved in tumorigenesis of these neoplasms.<sup>128</sup> In addition to the 11q13 deletions described in follicular adenomas, Herrmann et al.<sup>129</sup> have presented evidence for chromosome 3p deletions specific to follicular carcinomas and proposed that inactivation of a tumor suppressor gene on chromosome 3p is important in the progression from follicular adenoma to carcinoma.

## ANAPLASTIC THYROID CARCINOMA

Point mutations in the *TP53* tumor suppressor gene are frequent in anaplastic thyroid carcinomas but not in differentiated thyroid tumors.<sup>130,131</sup> This suggests that the *TP53* mutation is a critical event in the progression of follicular carcinoma to anaplastic carcinoma. Wild-type *TP53* encodes a nuclear phosphoprotein that functions as a transcriptional regulator believed to influence cell-cycle arrest or programmed cell death in response to genetic damage. Disruption of this protective function appears to be relevant to the progression of thyroid neoplasms to an aggressive, undifferentiated phenotype. Codons 273<sup>130,131</sup> and 248<sup>131</sup> are hot spots for *TP53* mutation in anaplastic thyroid carcinoma.

## MEDULLARY THYROID CARCINOMA

The molecular genetic alterations associated with sporadic medullary carcinoma of the thyroid were discussed earlier in [Other \*RET\* Genotype-Phenotype Correlations](#).

## GENETIC ABNORMALITIES IN PARATHYROID NEOPLASMS

### BENIGN PARATHYROID NEOPLASMS

Neoplasms of the parathyroid glands are almost always benign and occur with increased frequency in postmenopausal women, after neck irradiation, or as a component of several distinct familial syndromes. Benign parathyroid adenomas in patients with primary HPT have a proliferative defect (increase in cellular mass) as well as a defect in regulating parathyroid hormone (PTH) release in response to the extracellular calcium concentration (set-point abnormality).<sup>132</sup> In different parathyroid tumors, at least three specific genetic defects have been uncovered, including activation of an oncogene, inactivation of the *MEN1* tumor suppressor gene, and mutations in the cell surface calcium-sensing receptor.

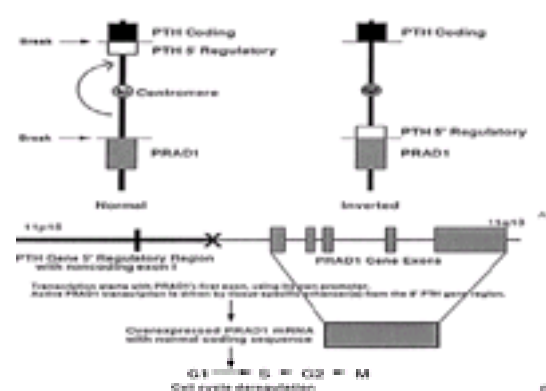

### MUTATIONS IN THE *MEN1* GENE AND ROLE OF OTHER TUMOR SUPPRESSOR GENES

Patients with MEN 1 inherit one mutated copy of the *MEN1* gene in the germline and therefore require only one chance additional somatic event (deletion, point mutation) to result in the loss of the remaining functional copy of the gene within an individual parathyroid cell. Presumably, the relatively likely combined occurrence of these genetic events leads to the asynchronous development of multiglandular parathyroid neoplasms (parathyroid hyperplasia) in affected individuals. LOH for markers in the *MEN1* gene region has been demonstrated not only in MEN 1–related parathyroid tumors but also in approximately 30% of sporadic parathyroid adenomas.<sup>133,134,135 and 136</sup> As previously suspected from studies of chromosome 11q13 LOH in DNA from sporadic parathyroid adenomas, loss of *MEN1* gene function now is known to be responsible for a subset of the parathyroid adenomas in patients with sporadic primary HPT. In this subset, the occurrence of a sporadic parathyroid adenoma presumably requires the chance occurrence of two somatic inactivating events (one involving each homologous copy of the *MEN1* gene).

A study by Heppner et al.<sup>137</sup> identified somatic mutations in one allele of the *MEN1* gene in tumor DNA from 7 of 33 parathyroid adenomas. In each of these tumors, a chromosome deletion was detected that eliminated the remaining wild-type copy of the *MEN1* gene in tumor DNA. Farbeno et al.<sup>138</sup> screened 45 sporadic adenomas from 40 patients with nonfamilial HPT by LOH and SSCV analysis. LOH for chromosome 11q13 was present in 13 (29%) of the tumors and, in six of these cases, somatic mutation was detected in the remaining copy of the *MEN1* gene. These findings suggest that a subset of sporadic parathyroid adenomas is caused by a combination of somatic genetic events within a parathyroid cell that inactivate both copies of the *MEN1* tumor suppressor gene.

### ACTIVATION OF THE PRAD1 PROTOONCOGENE BY CHROMOSOMAL GENE REARRANGEMENT

In a small subset of parathyroid adenomas (approximately 5%), a pericentromeric inversion of chromosome 11 has been detected that results in a gene rearrangement involving the PTH gene on 11p15 and the parathyroid adenoma 1 (*PRAD1*) oncogene or cyclin D1 on 11q13.<sup>139,140</sup> As a consequence of the breakpoint and rejoining in 11q13, the PTH transcriptional regulatory sequences and its noncoding exon 1 are placed immediately upstream of the *PRAD1* protooncogene intact promoter and its five exons (Fig. 38.1-7). This rearrangement results in inappropriate or unregulated expression of *PRAD1* in response to the parathyroid tissue–specific transcriptional regulatory elements of the PTH gene. It has been suggested that the subset of patients with the *PRAD1* chromosomal rearrangement tend to have larger tumors and are more often symptomatic than are other patients with this disease.<sup>132</sup>

**FIGURE 38.1-7. A:** Schematic diagram illustrating the pericentromeric inversion of chromosome 11 deduced to have caused the observed rearrangement involving the PTH gene and the *PRAD1* gene in a subset of parathyroid adenomas. The tumor's other copy of chromosome 11, which contains an intact PTH gene, is not shown. **B:** Diagram of the directly observed molecular structure of the PTH/*PRAD1* DNA rearrangement in a subset of parathyroid adenomas and its functional consequences. X represents the chromosome breakpoint between the PTH gene regulatory region, plus PTH noncoding exon 1 (solid light vertical bar) and part of its first intron, from 11p15 (left), and the intact promoter and 5 exons of the *PRAD1* gene from 11q13. (Reprinted from ref. 132, with permission.)

## OTHER GENETIC LOCI IMPLICATED IN FAMILIAL HYPERCALCEMIC SYNDROMES

### FAMILIAL BENIGN HYPERCALCEMIA

Familial benign hypercalcemia (hypocalciuric hypercalcemia)<sup>141,142</sup> is a dominantly inherited condition characterized by mild hypercalcemia, low urinary calcium excretion, and the absence of symptoms or the complications of hypercalcemia. The features of familial benign hypercalcemia are important to recognize and distinguish from other hypercalcemic disorders, because surgery fails to result in correction of the calcium level.<sup>143,144,145,146,147,148 and 149</sup>

Pollak et al.<sup>150</sup> demonstrated that mutations in the human calcium-sensing receptor gene are associated with familial benign hypocalcemia as well as neonatal severe HPT (NSHPT). Parathyroid cells from patients with familial benign hypercalcemia are characterized by an abnormally increased set point for extracellular calcium.<sup>151</sup>

The germline mutations that are associated with familial benign hypercalcemia are heterozygous, inactivating mutations in the calcium-sensing receptor gene.<sup>152</sup> The reported mutations include point mutations, nonsense mutations, or insertions that are postulated to result in varying degrees of loss of the receptor's calcium-sensing function.<sup>150,153,154,155 and 156</sup>

### NEONATAL SEVERE HYPERPARATHYROIDISM

NSHPT is characterized by severe hypercalcemia, failure to thrive, dehydration, pathologic fractures and rib cage deformities, respiratory distress, and hypotonia in the newborn. The disorder usually requires urgent total parathyroidectomy in the first few weeks of life, although some have achieved a favorable outcome with intensive medical management.<sup>157</sup>

In some cases, NSHPT results from homozygous mutations (mutations on both homologous alleles) that cause loss of function of the calcium-sensing receptor gene.

### HEREDITARY HYPERPARATHYROIDISM–JAW TUMOR SYNDROME

The autosomal dominant inheritance of HPT without any associated features and without any apparent association to the MEN syndromes has been described in several families.<sup>158,159 and 159</sup> HPT–jaw tumor syndrome (HPT-JT) is recognized as a distinct syndrome characterized by the autosomal dominant inheritance of recurrent parathyroid adenomas, fibrous jaw tumors, Wilms' tumor, and parathyroid carcinoma.<sup>161</sup> The onset of hypercalcemia typically occurs in childhood or the second decade of life. The association may not be recognized in many cases because the jaw lesions occur asynchronously in relation to the parathyroid tumors and may occur in some patients without HPT. The parathyroid tumors may be single or multiple but have a tendency toward recurrence after subtotal parathyroidectomy. The parathyroid adenomas in the familial HPT-JT syndrome often are cystic, a finding that occasionally is noted in primary sporadic HPT. The specific gene responsible for the HPT-JT syndrome remains to be identified.<sup>161,162</sup>

### PARATHYROID CARCINOMA

Molecular defects with a possible role in progression to the malignant phenotype have also been sought in tumor DNA from parathyroid carcinomas. Although one study failed to detect evidence of mutations in exons 5, 7, and 8 of the *TP53* gene in parathyroid carcinomas,<sup>163</sup> another study reported allelic loss of *TP53* in two of six informative parathyroid carcinomas.<sup>164</sup> None of 20 informative parathyroid adenomas exhibited deletions of *TP53*. Most recently, the retinoblastoma tumor suppressor gene has been shown to be inactivated in most parathyroid carcinomas but not in adenomas.<sup>165</sup>

## GENETIC ABNORMALITIES IN ADRENAL NEOPLASMS

## SPORADIC PHEOCHROMOCYTOMAS

The molecular genetic alterations associated with sporadic pheochromocytomas were discussed earlier in [Genetics under Multiple Endocrine Neoplasia Type 2 Syndromes](#).

## FAMILIAL PHEOCHROMOCYTOMAS ARISING IN PATIENTS WITH VON HIPPEL-LINDAU SYNDROME AND NEUROFIBROMATOSIS TYPE 1

Pheochromocytomas occur in association with the VHL and NF1 syndromes. VHL syndrome is characterized by the development of retinal, cerebellar, and spinal hemangioblastomas, pancreatic and renal cysts, renal carcinomas, pheochromocytomas, neuroendocrine tumors of the pancreas, epididymal cysts, and endolymphatic sac tumors. The original mapping of the *VHL* gene by positional cloning to chromosome 3p was reported in 1993.<sup>166</sup> The *VHL* tumor suppressor gene encodes a protein that regulates the transcription of DNA to mRNA by RNA polymerase II.<sup>167</sup> Clinical heterogeneity exists in patients with the VHL syndrome. In type 1, pheochromocytomas do not occur. Pheochromocytomas are associated with type 2a, but renal cell carcinomas do not occur. Finally, in type 2b, both pheochromocytomas and renal cell carcinomas develop. The preceding classification has been related also to apparent genotype-phenotype correlations associated with mutations in the *VHL* gene.<sup>168</sup>

Mutations in the tumor suppressor gene for NF1 on chromosome 17q were identified in 1990.<sup>169,170</sup> Pheochromocytomas occur in approximately 1% to 2% of patients with NF1. Bilateral tumors occur with increased frequency compared with sporadic cases of pheochromocytomas.

## ADRENOCORTICAL ADENOMAS AND CARCINOMAS

Several lines of evidence suggest a role for mutation or loss of the *TP53* tumor suppressor gene in adrenocortical neoplasms. First, LOH for markers from 17p has been consistently demonstrated in adrenocortical carcinomas but not in benign adrenocortical adenomas or hyperplasia.<sup>171</sup> Frequent LOH has also been detected for markers on chromosome 11p and 13q.<sup>171</sup> It is of interest to note that adrenocortical carcinomas occur with increased frequency in patients with the Li-Fraumeni syndrome, who have been shown to harbor germline mutations in *TP53*,<sup>172</sup> and in patients with the Beckwith-Wiedemann syndrome, which is associated with a defect on chromosome 11p15.<sup>173</sup> Sequence analysis has also demonstrated point mutations in the *TP53* gene in adrenocortical carcinomas<sup>174</sup> and in adrenal adenomas in some<sup>175</sup> but not all<sup>174</sup> studies. Point mutations of G protein genes have been detected in a variety of endocrine tumors, including adrenocortical tumors.<sup>108,175</sup> Mutations of the adrenocorticotropic hormone receptor have not been detected in adrenal neoplasms.<sup>176</sup>

In one study of 35 adrenocortical lesions (six hyperplasias, 19 adenomas, ten adrenocortical carcinomas), LOH at 11q13 was detected in 31% of the tumors analyzed.<sup>177</sup> The frequency of LOH for this region was significantly greater in adrenocortical carcinomas (60%) than in benign lesions (11%). However, inactivating mutations of the *MEN1* gene were demonstrated in almost none of the tumors with LOH at 11q13. The authors concluded that the *MEN1* gene appears not to play a significant role in the development of benign or malignant adrenocortical neoplasms.<sup>177</sup>

## SUMMARY

A variety of genetic abnormalities in both oncogenes and tumor suppressor genes have been identified in endocrine neoplasms. The study of tumors developing in the inherited endocrine cancer syndromes has provided valuable insight into genetic events that likely play a role in the genesis of sporadic tumors developing in the same endocrine tissues. The advent of direct DNA testing for germline mutations in the *RET* protooncogene that are responsible for the MEN 2 syndromes has made possible early thyroidectomy at a time when hereditary MTC is likely occult and curable. The identification of germline mutations in the *MEN1* gene will allow direct genetic testing and an enhanced understanding of the mechanisms of tumorigenesis of related endocrine tumors.

## INTRODUCTION

Cancers of the endocrine glands or organs are rare, as they will account for only 1.5% of the estimated 1.22 million new cases of non-skin cancer and 0.21% of the estimated 563,100 cancer deaths in the United States in 1999.<sup>1</sup> Thyroid cancer is overwhelmingly the most common type of endocrine malignancy, accounting for the majority of the deaths due to endocrine cancers. It was estimated that in 1999 there would be 18,100 new cases of thyroid cancer (more than 90% of the total new endocrine cancers) and 1400 deaths due to thyroid cancer, which is 60% of the total deaths due to endocrine malignancies ( [Table 38.2-1](#)).<sup>1</sup> Compared to the number of thyroid cancers, there are approximately 800 cases of endocrine pancreas tumors (not all malignant),<sup>2</sup> 550 adrenal cancers, 130 pituitary gland cancers, and 65 parathyroid gland cancers. The discrepancy between the total number of cases of all endocrine cancers arising in the thyroid (91%) and the total proportion of endocrine cancer deaths (60%) reflects the relatively indolent nature and long-term survival associated with thyroid malignancies.

	Number	Percentage of Total
All endocrine cancers*	18,100	91
Thyroid	16,500	91
Endocrine pancreas	800	4
Adrenal	550	3.0
Thyroxin	420	2.3
Pituitary gland	130	0.7
Pituitary gland	77	0.4
Parathyroid	65	0.4
Carotid body, paraganglia	55	0.3
Primary thyroid cancers*		
Well-differentiated	16,500	91
Papillary	14,500	75
Follicular	1,500	9
Hürthle cell	500	3
Anaplastic	100	0.6
Medullary thyroid cancer	500	3
Sporadic	5	0.03
Familial	5	0.03
Lymphoma	1-3	<0.01
Sarcoma and others	1-3	<0.01

**TABLE 38.2-1.** Incidence and Proportion of All Endocrine Cancers and Relative Proportions of Different Primary Thyroid Cancer Subtypes

Within the broad category of thyroid cancers, there are many types, each with a distinctive epidemiology, natural history, treatment, and prognosis. The general categories of thyroid cancer are well-differentiated malignancies, anaplastic cancer, medullary thyroid cancer (MTC), and other unusual cancers, such as lymphoma, sarcoma, and other rare malignancies.<sup>3</sup> The normal thyroid is composed histologically of two main parenchymal cell types. Follicular cells line the colloid follicles, concentrate iodine, and are involved in the production of thyroid hormone. These cells give rise to well-differentiated cancers and, almost certainly, anaplastic thyroid cancer (ATC). The second cell type is the parafollicular or C cell, which produces calcitonin and is the cell of origin for MTC. Stromal and immune cells of the thyroid are responsible for sarcoma and lymphoma, respectively. Of the 18,100 new cases of thyroid cancer each year, approximately 90% of malignant thyroid nodules are well-differentiated cancers, 5% to 9% are MTC, 1% to 2% are anaplastic cancers, 1% to 3% are lymphoma, and fewer than 1% are sarcoma and other rare tumors.<sup>3</sup>

Within the category of well-differentiated thyroid cancers, there are various histologic subtypes. These descriptive subgroupings have evolved since the 1980s with an improved understanding of the biology of these different types. Initial categories included papillary, follicular, and mixed tumor with variable areas of both papillary and follicular histology. Several studies have documented that these mixed tumors with any area of papillary features have the same natural history and prognosis as papillary thyroid cancer without follicular features.<sup>3,4</sup> This category of mixed papillary and follicular carcinoma should be grouped with papillary carcinoma; even those that are composed entirely of follicles should be included (diagnosed as the follicular variant of papillary carcinoma). The major cytologic feature shared by all members of this group, regardless of the histologic pattern, is the characteristic nucleus. A third category of lesions grouped with differentiated thyroid carcinoma is the Hürthle cell or oncocytic carcinoma. Although there are controversies about whether Hürthle cell neoplasms can behave in a benign fashion, most authors now accept the concept of benign and malignant lesions with this cytology.<sup>5</sup> The clinical behavior of these lesions is somewhat more aggressive than usual follicular carcinomas, and some authors prefer to include these lesions in the intermediate malignancy group. The distribution of well-differentiated thyroid cancer subgroups in some reports shows that 80% to 85% are papillary, with 10% to 15% of cases being follicular and 3% to 5% Hürthle cell carcinomas.<sup>3</sup> These published figures may not reflect adequate pathologic recognition of the follicular variant of papillary carcinoma, and true follicular carcinoma may represent 5% or fewer of well-differentiated thyroid cancers in countries with iodine-sufficient diets.<sup>4</sup> Therefore, as 90% of all thyroid cancers are well-differentiated and 85% to 95% of all well-differentiated tumors are papillary tumors, papillary thyroid cancer accounts for 75% to 80% of all thyroid cancers.

This chapter is organized to present the key clinical aspects of well-differentiated thyroid cancers, anaplastic cancers, MTCs, thyroid lymphoma, and secondary thyroid malignancies. As the vast majority of thyroid cancers present as thyroid nodules, yet only a minority of all thyroid nodules are malignant, a general discussion of the incidence, evaluation, and management of thyroid nodules precedes discussion of specific clinical conditions.

## THYROID NODULES

The prevalence of thyroid nodules depends on the population under study; gender, age, and history of exposure to ionizing radiation strongly influence the results of various large studies, as does the method by which the nodules are being detected (physical examination, ultrasonography, or pathology). There is clearly an age-dependent increase in thyroid nodules<sup>6</sup>; in one pathologic study, up to 90% of women older than 70 years and 60% of men older than 80 years had nodular goiter.<sup>7</sup> All studies show that women develop nodules more frequently than men, although reports of the female to male ratio vary from 1.2:1 to 4.3:1.<sup>8</sup> An increased tendency to develop thyroid nodules is demonstrated in groups exposed to ionizing radiation, especially during childhood. In a study at the Michael Reese Hospital, 38.4% of patients who received radiation before age 16 years developed palpable thyroid nodules.<sup>9</sup> In patients with Hodgkin's disease treated with mantle radiation, 3% developed thyroid nodules.<sup>10</sup>

Most thyroid nodules are found in asymptomatic patients either during routine physical examination of the neck or because the patient notices a mass in the neck. By

obtaining information from the history and physical examination, one assesses the risk of malignancy in that individual. In general, there is a 5% to 10% chance of malignancy in all thyroid nodules for the total population<sup>11</sup>; however, men and patients at the extremes of age are at higher risk for malignancy. Nodules found in a patient with a history of childhood neck irradiation carry a 33% to 37% chance of malignancy.<sup>12,13</sup> The presence of a solitary nodule is of greater concern than a thyroid with multiple nodules; however, a dominant nodule or a nodule that changes size in the setting of a multinodular goiter should be investigated to exclude carcinoma. Patients with Graves' disease who develop a nodule may have a higher risk of cancer.<sup>14,15</sup> Whether the co-occurrence of Graves' disease affects the aggressiveness of the thyroid carcinoma is a topic of controversy.<sup>16,17</sup> However, the occurrence of carcinoma in autonomously functioning nodules is extremely rare.<sup>8</sup>

Although not specific for malignancy, a history of rapid increase in size, dyspnea, dysphagia, hoarseness, and the development of a Horner's syndrome are worrisome symptoms. Tender nodules are more often associated with thyroiditis and are likely to be benign. A family history of thyroid cancer or pheochromocytoma should suggest MTC in the setting of multiple endocrine neoplasia type 2a (MEN 2A) or MEN 2B.<sup>19</sup> Other inherited disorders to be aware of are Gardner's syndrome<sup>20</sup> and Cowden's disease,<sup>21</sup> both of which are associated with benign and malignant thyroid neoplasms. On examination of the neck, attention to the firmness, mobility, and size of the nodules, their adherence to surrounding structures, and the presence of adenopathy are important clues to the presence of carcinoma. However, these features, with the exception of cervical lymphadenopathy, lack specificity for malignancy.<sup>22</sup>

Thyroid function testing should be performed to identify underlying thyroid pathology and not to differentiate benign from malignant nodules. Subclinical hyperthyroidism, sometimes seen only as a suppressed thyroid-stimulating hormone (TSH), may be secondary to an autonomously functioning nodule. In this case, one determines whether the nodule is functional with a radionuclide scan by iodine uptake. Tests of serum thyroglobulin (Tg) levels are not helpful in distinguishing benign from malignant thyroid nodules.<sup>18</sup> Routine measurement of serum calcitonin may be useful to identify patients with sporadic medullary carcinoma of the thyroid preoperatively<sup>23</sup>; however, the cost-effectiveness of this practice requires further evaluation.<sup>24</sup> The majority of both benign and malignant thyroid nodules are hypofunctional when compared to normally functioning thyroid tissue; thus, the finding of a "cold nodule" on <sup>123</sup>I or <sup>99</sup>Tc scanning is nonspecific. Radionuclide scans are also helpful in determining the functional status of nodules in patients with multinodular thyroid disease to focus a biopsy on cold nodules.<sup>18</sup> A hyperfunctioning or hot nodule is rarely malignant in an adult.<sup>18</sup>

High-resolution ultrasonography is a useful adjunct to the clinical examination for size assessment of nodules, for the detection of multiple nodules not discerned by palpation, and for assisting in fine-needle aspiration biopsy (FNAB) of nodules.<sup>25,26</sup> Despite advances in technology allowing more sensitive detection of blood flow in thyroid pathology, differences in echogenicity or vascularity cannot distinguish benign from malignant lesions.<sup>27</sup> Ultrasonography identifies whether a lesion is cystic or solid, and the vast majority of cystic lesions are benign. A more cost-effective method to identify a cyst is fine-needle aspiration (FNA) with return of fluid and disappearance of the nodule after aspiration. Cysts larger than 4 cm in size and having a partially solid component and those that recur after three aspirations may warrant biopsy, as these conditions are more likely to be associated with malignancy.<sup>3</sup>

The single most important study in the evaluation of thyroid nodules is the FNAB. The impact this procedure has had on clinical practice is reflected by a reduction of the total number of thyroid surgeries performed, a greater proportion of malignancies removed at surgery, and an overall reduction in the cost of managing patients with nodules.<sup>8</sup> The accuracy of cytologic diagnosis from fine-needle biopsy ranges from 70% to 97%<sup>25</sup> and is highly dependent on the skill of the person performing the biopsy and that of the cytopathologist interpreting it. The results of FNAB are most commonly divided into the following categories: benign or negative (colloid nodule or hyperplastic nodule), indeterminate (all follicular neoplasms, including those with Hürthle cell changes), suspicious or malignant (papillary, anaplastic, medullary, and lymphoma), and insufficient sample. Reviews of this technique provide insight into the results typically obtained at the time of fine-needle biopsy of the nodules: 70% are classified as benign (range, 53% to 90%), 4.0% as malignant (range, 1% to 10%), 10% as suspicious or indeterminate (range, 5% to 23%), and 17% as insufficient sample (range, 15% to 20%).<sup>28</sup>

The malignant potential of follicular neoplasms cannot be determined by cytologic evaluation; thus, the biopsies from all such lesions are generally classified as suspicious or indeterminate, and most come to surgical resection. The cells from follicular adenomas and follicular carcinomas appear identical; only by identifying capsular or vascular invasion can cancer be diagnosed.<sup>18</sup> Specimens with predominantly Hürthle cells must be treated in the same fashion; however, extensive Hürthle cell changes can be seen in Hashimoto's thyroiditis. Malignancy is found in 10% to 20% of follicular nodules that are classified as indeterminate biopsy.<sup>18,29</sup>

Attempts to develop more discriminating cytologic subclassifications to improve the yield of malignancy found at surgery have not proven highly successful, nor are they easily adopted at other institutions. A new technique to improve the sensitivity of FNA in this situation has been to perform polymerase chain reaction analysis for telomerase, which is an enzyme expressed in virtually all malignant cancers but not expressed in benign or normal tissue.<sup>30</sup> Preliminary studies have demonstrated increased telomerase activity in thyroid cancers, and this may serve as a useful adjunct to improve the sensitivity of this category of suspicious or indeterminate FNAB with more appropriate surgical procedures.<sup>31,32</sup>

Biopsies classified as benign or negative are safely followed up medically with the caveat that false-negative results occur in 1% to 6% of cases.<sup>28</sup> Clinical judgment should dictate the course of action in these cases; if a large, hard nodule is fixed to surrounding tissue and is painful, surgery should be performed despite a negative aspirate. Sampling error occurring during biopsy of large, cystic hemorrhagic nodules or simple misdiagnosis account for many of the false-negative results.<sup>33</sup> False-positive results for malignancy occur in 3% to 6% of all biopsies.<sup>28</sup> The cytologic features of Hashimoto's thyroiditis frequently lead to these false-positive interpretations.<sup>33</sup> With experienced cytopathologists, this false-positive rate should decrease to less than 1%.<sup>34</sup>

Benign thyroid nodules can be followed up carefully by routine physical examination or, more precisely, by ultrasonography and do not generally require repeat biopsy.<sup>18</sup> Thyroxine suppression therapy is widely used; however, randomized controlled studies have indicated that thyroxine therapy is not superior to placebo.<sup>35,36</sup> and<sup>37</sup>

Attention to potential side effects of long-term thyroxine therapy has stirred controversy. The creation of a subclinical hyperthyroid state by suppressive doses of thyroxine increases the incidence of osteoporosis.<sup>15</sup> There is evidence that postmenopausal women who are not on estrogen replacement therapy are at higher risk for bone demineralization while on suppressive doses of thyroxine.<sup>36</sup> Patients on long-term suppressive therapy may have cardiac symptoms (tachycardia, arrhythmias),<sup>39</sup> and those at high risk for recurrence of thyroid cancer may receive less aggressive suppression and judicious use of  $\beta$ -adrenergic blockers to prevent atrial arrhythmias.<sup>39</sup>

## WELL-DIFFERENTIATED THYROID CARCINOMA

### DEMOGRAPHICS AND EPIDEMIOLOGY

The incidence of both papillary and follicular thyroid carcinomas in terms of gender distribution is similar, with approximately a 2.5-fold excess in favor of female individuals as compared to male individuals (Table 38.2-2).<sup>3,40,41,42,43,44,45</sup> and<sup>46</sup> The median age at diagnosis is earlier in women than in men for both papillary and follicular subtypes and tends to be earlier for papillary cancer as compared to follicular cancer in either gender (see Table 38.2-2).<sup>42,43,44,45</sup> and<sup>46</sup> Specifically, median age at diagnosis in white women is between 40 and 41 years, whereas for white men, it is 44 to 45 years for papillary carcinoma.<sup>3</sup> For follicular thyroid carcinoma, the median age at diagnosis is 48 for white women as compared to 53 for white men.<sup>3</sup> Well-differentiated thyroid cancer has a greater incidence in whites than in blacks of both genders.<sup>7</sup> The relative proportion of age-adjusted incidence rates is slightly more than twofold higher for whites. One significant difference in the incidence in terms of race is that the proportion of well-differentiated thyroid carcinomas that are follicular is increased greatly in blacks as compared to whites. It is reported that follicular carcinoma accounts for 15% of all well-differentiated tumors in whites as compared to 34% in blacks.<sup>3</sup>

Institution	Interval	Sex	Mean Age (yr)	TSH Ratio	Papillary			Follicular

## ETIOLOGY

Radiation exposure to the thyroid gland is the only risk factor known definitively to increase the incidence of well-differentiated thyroid cancer. <sup>47,48</sup> Thyroid exposure to radiation can occur in two ways: from external sources or from ingestion of radioactive material. Data regarding external exposure to the thyroid comes primarily from two sources. One is medically administered external-beam irradiation, and the second is environmental exposure, previously related to nuclear weapons attacks or weapons testing and, more recently, from nuclear power plant accidents. Internal exposure occurs by ingestion of radioisotopes of iodine that concentrate in the thyroid gland from either medical treatment with radioactive iodine or by ingestion of these radioisotopes from the fallout from nuclear weapons explosions or power plant accidents. The relative risks of radiation exposure from these different sources has been well studied, and variables, such as age at exposure, radiation dose, and latent period to developing cancers, have been defined. <sup>48</sup> However, radiation accounts for only a small portion of the total annual cases of well-differentiated thyroid cancer. <sup>49</sup> Other potential factors that may predispose to thyroid neoplasms include diet (particularly content of iodine), effects of steroid hormones, and other occupational exposures. <sup>47,50</sup>

Case-control studies, <sup>51,52</sup> as well as detailed institutional reviews of large populations of patients <sup>9,53</sup> undergoing childhood irradiation, show that there is an inverse relationship between increased risk of thyroid cancer and age of exposure to radiation. Relative risk is also linearly related to exposure dose, at least up to 2000 rads. <sup>9,54</sup> The latent period after exposure is at least 3 to 5 years, and there is no apparent drop-off in the increased risk even after 40 years after the radiation exposure. <sup>54</sup> One of the best analyzed databases regarding childhood radiation for medical purposes comes from Schneider et al. <sup>9,53,54</sup> at the University of Chicago. They have intensively analyzed more than 3000 patients who were irradiated between 1939 and 1962. More than one-third of these patients developed thyroid nodules, and 318 patients were documented to have thyroid cancer. <sup>53</sup> The large populations studied by Schneider et al. showed that increased relative risk of thyroid carcinoma was low and thyroid cancers were rare between 5 and 10 years after radiation exposure. <sup>54</sup> The majority of cases occurred between 20 and 40 years after exposure. However, even after 40 years, the relative risk as compared to a nonirradiated population was still increased. <sup>54</sup> For these reasons, the large cohort of patients who underwent childhood irradiation for benign medical conditions between 1920 and 1960 are now between the ages of 40 and 80, and this population still has an increased risk of developing thyroid carcinoma as compared to nonirradiated patients.

Although the use of radiation for benign conditions has not been practiced since the 1960s, there is increased use of radiation treatments for neoplastic conditions, including infants, children, and young adults. <sup>55</sup> The majority of this patient population is made up of patients with either Hodgkin's or non-Hodgkin's lymphoma but also includes long-term survivors of Wilms' tumor of the kidneys or neuroblastoma in which there is some scatter to the thyroid gland. <sup>10,55</sup> The young age at treatment for neuroblastoma and Wilms' tumor (mean age, 2 and 3 years, respectively) and the relatively high-dose of thyroid exposure (660 rads and 310 rads, respectively) has led to a dramatic increase in relative risk of 350 for neuroblastoma patients and 132 for survivors of Wilms' tumors for the development of thyroid cancer. <sup>51</sup> Relative risks between 16 and 80 have been reported in this patient population of adolescents and young adults treated for lymphoma. <sup>10,55</sup> In the adult patient population treated with therapeutic radiation for malignancies, there is a drop-off in risk reflecting the importance of age at exposure. A large study of more than 150,000 women treated with radiation for cervical cancer had an estimated thyroid exposure of 11 rads, with a relative risk of 2.35, compared to nonirradiated age-matched controls. <sup>56</sup>

A second type of radiation exposure to the thyroid gland is via ingestion of radioisotopes that concentrate in the thyroid. These isotopes come from two sources: medical administration either for diagnostic or therapeutic purposes using radioactive iodine, <sup>57</sup> and environmental exposure to fallout from nuclear weapons or nuclear accidents. The most common exposure is due to <sup>131</sup>I administered for diagnostic thyroid scans. A typical nuclear medicine study exposes the thyroid to the equivalent of approximately 50 rads of external-beam radiation exposure. <sup>58</sup> A large study of more than 35,000 diagnostic scans between 1951 and 1969 showed a very minimal increase in the number of thyroid cancers, with 50 actual cases versus 39.4 cases predicted. <sup>58</sup> A second, more significant medical exposure is therapeutic <sup>131</sup>I administered for ablation of thyroid tissue, with the equivalent of 6000 to 10,000 mCi to treat Graves' disease. <sup>59</sup> Despite this high radiation dose, there is a standardized increased incidence ratio of only 1.32 for thyroid cancer, <sup>59</sup> as the high-dose <sup>131</sup>I most likely destroys the thyroid parenchyma.

A more dangerous type of ingestion of radioisotopes of iodine comes from exposure to nuclear fallout. <sup>60,61</sup> Data from fallout exposure comes from nuclear weapon-testing sites at the Marshall Islands <sup>60</sup> and Nevada in the 1950s, <sup>61</sup> as well as the 1986 nuclear power plant explosion at Chernobyl. <sup>62</sup> The positive results in these studies compared to the lack of risk of the medical use of <sup>131</sup>I is most likely due to other high-energy short-lived isotopes, such as <sup>129</sup>I and <sup>132</sup>I to <sup>135</sup>I present in fallout that are more damaging but are not present in radioisotope drugs. An early study completed 4.5 years after the event at Chernobyl suggested no increased risk of thyroid nodules. <sup>63</sup> More recent studies show a steady sequential increase in the diagnosis of pediatric thyroid cancer as early as 3 years and increasing from 5 to now 10 years since the incident. <sup>62</sup> This data reflect the importance of age at exposure, as this increased incidence occurs primarily in children.

The natural history and pathology of radiation-associated thyroid cancer has been well documented in the aforementioned epidemiologic studies. <sup>9,50</sup> The vast majority of cases have a papillary histology, and these behave in the same way as nonradiation-associated papillary cancers. <sup>9</sup>

Although the data relating radiation exposure of the thyroid gland and subsequent development of carcinoma are definitive, the majority of patients who developed well-differentiated thyroid carcinoma have absolutely no history of radiation exposure. A study from the Connecticut Tumor Registry shows that 9% of thyroid cancer could be related to radiation exposure, meaning 91% of cases have no identifiable risk factor. <sup>48</sup> Other factors, including dietary influences, sex hormones, environmental exposures, or increased genetic susceptibility, have been studied, with very mixed results and no clear associations. Dietary influences have primarily focused on the level of iodine in the diet. <sup>47,50,64</sup> Iodine-deficient diets or diets that include a large intake of vegetables from the crucifer family (which block iodine uptake) may lead to increased TSH levels and are considered goitrogenic, with a modest increase in follicular cancers. <sup>64</sup> Increased iodine intake due to shellfish occurs in the geographic areas with the highest incidence of predominantly papillary thyroid cancer, such as Iceland, Norway, and Hawaii. <sup>65</sup>

There is no clear familial syndrome or genetic disease associated with the development of well-differentiated thyroid cancer, although one study has suggested a propensity to multifocal well-differentiated thyroid cancer in a small number of families. <sup>66</sup> However, none of the described oncogenes for well-differentiated thyroid cancer (RET, MNG-1, TCO) were found to be involved in evaluation of 56 kindreds. <sup>67,68</sup> This contrasts with MTC, in which a variety of genetic syndromes now are being defined at the molecular level (see later in [Treatment of Familial Medullary Thyroid Cancer](#) and [Table 38.2-10](#)). <sup>65</sup>

## PATHOLOGY

Thyroid malignancies are derived from either follicular cells (papillary, follicular, Hürthle cell, and anaplastic carcinomas) or C cells (medullary carcinoma, described later in [Medullary Thyroid Cancer](#)). <sup>69,70</sup> The degree of clinical malignancy varies greatly among the types of carcinoma: It is convenient to consider these tumors as falling into three categories with increasing clinical aggressiveness: well-differentiated (papillary carcinoma, follicular carcinoma), intermediate differentiation (Hürthle cell carcinoma, some variants of papillary carcinoma, insular carcinoma), and undifferentiated (anaplastic carcinoma).

Papillary carcinoma constitutes approximately 80% to 85% of malignant epithelial thyroid tumors in developed countries where sufficient iodine is present in the

diet.<sup>3,71</sup> Grossly, papillary carcinomas have a variable appearance from minute subcapsular white scars to large tumors greater than 5 to 6 cm that grossly extend outside the thyroid gland. Cystic change, calcification, and even ossification may be identified.

Microscopically, papillary carcinomas are characterized by the presence of papillae, but some variants contain no papillary areas, are totally follicular in pattern, and are identified as a follicular variant.<sup>72</sup> The term *mixed papillary and follicular carcinoma* is no longer used, because the great majority of papillary carcinomas of the thyroid do contain some follicular areas (Fig. 38.2-1). Biologically, all these tumors, independent of their degree of follicular pattern, show similar clinical characteristics.<sup>68,70,73</sup> The World Health Organization defines papillary thyroid cancer as “a malignant epithelial thyroid neoplasm with a distinctive set of nuclear features. The nuclei of papillary carcinoma are enlarged and ovoid and contain thick nuclear membranes, small nucleoli often pressed against the nuclear membrane, intranuclear grooves, and intranuclear cytoplasmic inclusions.”<sup>73,74</sup> Because the nuclei are enlarged, they frequently overlap each other, which is a helpful clue in both the cytologic preparations and histologic slides. Papillary carcinoma has a propensity to invade lymphatic spaces and, therefore, leads to microscopic multifocal lesions in the gland as well as a high incidence of regional lymph node metastases.<sup>73</sup> The latter may be the presenting symptom of a thyroid papillary carcinoma as, in some cases, a primary tumor is very small (less than a few millimeters).

**FIGURE 38.2-1. A:** Classic papillary carcinoma. Note the papilla with its fibrovascular core. The nuclei are enlarged, are elongated rather than round, and have irregular nuclear outlines. (Hematoxylin and eosin,  $\times 250$ .) **B:** Follicular variant of papillary carcinoma. The tumor cells are arranged in follicles; note the characteristic nuclei throughout the lesion. (Hematoxylin and eosin,  $\times 250$ .)

Certain variants of papillary carcinoma have been shown to be more aggressive clinically, but these make up a minority of all papillary carcinomas. The more aggressive variants include the so-called tall cell variant, in which the cells are at least twice as long as they are wide<sup>75</sup>; the columnar variant, which shows a curious clear cytoplasm<sup>76</sup>; and the diffuse sclerosis variant, which is found more commonly in young individuals and adolescents.<sup>77</sup> This sclerosis variant permeates the thyroid lymphatics and has a 100% incidence of regional lymph node metastases at the time of diagnosis. All these high-risk variants are associated with significant mortality at 5 years, ranging between 25% and 90%.<sup>75,78</sup>

True follicular thyroid carcinoma is a rare tumor comprising approximately 5% to 10% of thyroid malignancies in nonendemic goiter areas of the world.<sup>3</sup> Before iodine prophylaxis via iodinated salt, follicular carcinoma was much more frequently diagnosed. In addition, the pathologic dictum—that any tumor with a pattern that is 50% or more characteristic of follicular carcinoma should be diagnostically placed in a follicular carcinoma category—has been shown to be incorrect. Indeed, most of the follicular pattern thyroid malignancies represent the follicular variant of papillary carcinoma and share its biological features, natural history, and prognosis.<sup>73</sup> Follicular thyroid carcinoma is unifocal and thickly encapsulated and shows invasion of the capsule or the vessels. Because of the diagnostic confusion, it is difficult to collect statistics about the survival rate or the metastatic potential of true follicular carcinoma.<sup>79</sup> Most studies show that if capsular invasion but not vascular invasion is present, the prognosis is excellent, with 85% to 100% of patients surviving at least 10 years of follow-up.<sup>79,80</sup>

A variant of follicular neoplasms is the Hürthle cell neoplasm. In 1894, Hürthle described a thyroid cell that was later shown to be the parafollicular C cell.<sup>5</sup> For this reason, the designation of cells and their tumors as Hürthle cells is historically incorrect as these lesions are actually derived from thyroid follicular cells.<sup>5</sup> The preferred pathologic term is *oncocytic*. However, because a large body of literature exists on the subject of Hürthle cells and Hürthle cell neoplasms, this nomenclature will be used. The Hürthle cell tumor of the thyroid is one of the most controversial lesions in this organ. Initially, all such lesions, despite the histologic features, were considered to be malignant; hence, it was recommended that they all be treated aggressively.<sup>81</sup> However, many studies have evaluated the clinical pathologic features of thyroid Hürthle cell tumors and have shown that, on average, only 33% show histologic evidence of malignancy or invasive growth and may metastasize.<sup>82,83</sup> Hürthle cell tumors that do not demonstrate invasion microscopically behave as adenomas and may be treated conservatively.

## CLINICAL FINDINGS IN WELL-DIFFERENTIATED THYROID CANCER

The typical clinical presentation for a patient with well-differentiated thyroid cancer is development of an asymptomatic thyroid nodule.<sup>8,11</sup> Other symptoms may infrequently precede or occur simultaneously with development of a nodule, including hoarseness, dyspnea, and dysphagia, reflecting local invasion of the recurrent laryngeal nerve, the trachea, and the esophagus, respectively.<sup>84,85</sup> A small subset of patients present with palpable cervical lymphadenopathy without an identifiable mass in the thyroid. Because most patients with well-differentiated thyroid cancer are euthyroid, complaints related to thyroid dysfunction are rare, and thyroid function test results tend to be normal. Certain aspects of the clinical history are relevant to the differential diagnosis, including a prior history of radiation exposure (increased risk of papillary cancer), family history (increased risk of familial MTC), and rapid rate of growth of the thyroid nodule (increased likelihood of ATC or thyroid lymphoma), but may also represent a spontaneous hemorrhage into a benign cyst. A second category of patients diagnosed with thyroid nodules consists of those in whom the nodule is not palpable but is diagnosed by imaging studies obtained for other clinical indications.<sup>86</sup> For example, patients undergoing neck ultrasonography for parathyroid disease or undergoing neck magnetic resonance imaging studies for cervical spine disease may have unappreciated nodular disease within the thyroid.<sup>87</sup>

Any new palpable thyroid nodule or any lesion larger than 1.0 cm identified by neck imaging should be initially assessed by FNAB (described previously in [Thyroid Nodules](#)).<sup>88</sup> Nodules smaller than 1.0 cm may be followed intermittently (6 to 12 months) with ultrasonography and should be subjected to biopsy only when the nodule becomes larger than 1.0 cm.<sup>18</sup> Management decisions in these patients are based on the FNA results modified by certain factors of the clinical history.<sup>8,28</sup> Potential management options include careful observation typically combined with thyroid suppression, alternative or repeat diagnostic studies, or surgical excision. The goal of management of these patients is to avoid missing an enlarging carcinoma that could be morbid to the patients if the disease is not recognized and treated balanced against the goal of avoiding unnecessary surgical procedures for benign pathology.<sup>8,89</sup> An algorithm of management based on FNA as the initial procedure is shown in [Figure 38.2-2](#). Decisions regarding patient management in four of the five categories of possible results from the FNA are relatively straightforward. Patients with malignant lesions detected by FNA should undergo surgical resection. The extent of this resection is controversial and is discussed in detail later in [Treatment of Well-Differentiated Thyroid Cancer: Surgery](#). Patients with a benign FNA result should be followed up intermittently, and nodules that enlarge should be resubmitted to biopsy.<sup>18</sup> The controversial point regarding these patients is the use of thyroid suppression.<sup>35,36 and 37</sup> Although common clinical practice is to suppress patients who have benign nodules by FNA using thyroid hormone, objective data that this practice alters the clinical course are lacking. Some investigators argue that patients with a prior history of radiation should have all thyroid lesions surgically resected once they are noted without a biopsy.<sup>3</sup> Although the proportion of these patients with carcinoma is relatively increased, the majority (65%) still do not have malignant lesions.<sup>9</sup>

FIGURE 38.2-2. A flow diagram for management of thyroid nodules based on fine-needle aspiration as the initial procedure.

Patients with an inadequate biopsy should submit to a repeat biopsy, as one-half of the time this provides definitive results.<sup>33</sup> Often, patients with small lesions that are not discrete and are difficult to palpate as well as patients with large lesions with areas of necrosis or hemorrhage have inadequate sampling results. Repeat FNA with ultrasonographic guidance to ensure that the aspiration specimen is taken from a solid component of the lesion may be helpful.<sup>26,86</sup> Nodules in patients in whom a diagnosis cannot be obtained by repeat FNA even with ultrasonographic assistance should be studied with nuclear medicine scans to determine the functional status of the nodule.<sup>27</sup> Functional nodules have a small chance of being malignant, whereas hyperfunctional nodules in adults are unlikely to harbor malignant lesions and require no further study other than close follow-up.<sup>18</sup>

Cystic lesions should be aspirated until all the fluid is removed.<sup>90</sup> After the cyst fluid aspiration, the area is studied with ultrasonography, and any residual solid component is sent for biopsy by FNA using ultrasound guidance. Cysts that have a complex cyst and solid component, are recurrent after three separate aspirations, and are larger than 4 cm may warrant open biopsy, as these conditions are more likely to be associated with malignancies.<sup>3,9c</sup> Patients who have a cyst resolve and then recur should undergo repeat cyst aspiration, with biopsy reserved for patients with recurrent lesions despite three prior successful aspirations.

Most investigators recommend surgical resection of lesions classified as indeterminate or suspicious by FNA to establish definitive diagnosis.<sup>91</sup> Analysis of subgroups in this category show the majority of aspirates “suggestive of a follicular neoplasm” and, to a lesser extent, “suspicious for papillary” or “Hürthle cell features.”<sup>92</sup> In a large series from the M. D. Anderson Cancer Center, 22% of patients with suspicious FNA eventually were shown to have cancer; of these patients, virtually all biopsies suggested papillary cancer on the initial cytology report, and the majority with follicular or Hürthle features and who were older were the patients who proved to have malignant lesions.<sup>92</sup> Analyses such as these may establish criteria for selective surgical management of patients with suspicious nodules on FNA. Any patients with an indeterminate or suspicious FNA with other risk factors, such as prior radiation exposure or local symptoms, should have nodules surgically resected. For patients with no risk factors and stable nodules, some investigators have advocated using nuclear medicine thyroid scans to determine patient management.<sup>3</sup> A cold mass clearly has a higher risk for being a carcinoma as compared to a warm or hot mass by this nuclear medicine scan, and patients with functional or hyperfunctioning nodules can be followed up clinically.

**NATURAL HISTORY AND PROGNOSIS**

The natural history and prognosis of well-differentiated thyroid cancer has been intensively studied since the 1980s.<sup>93,94,95,96,97,98</sup> and<sup>99</sup> Clear definition of risk factors associated with poor outcome have allowed more selective and less morbid treatment recommendations. In general, well-differentiated thyroid cancer is one of the most indolent solid neoplasms, with favorable long-term survival.<sup>94,96</sup> However, a small proportion of patients with papillary cancer and a slightly larger proportion of patients with follicular thyroid cancer do die from disease-related causes.<sup>94,95,97</sup> and<sup>98</sup> As opposed to other solid neoplasms, one major difference is that regional lymph node metastases appear to have no strong correlation with overall survival in most,<sup>94,95</sup> and<sup>96,99</sup> but not all, series<sup>93,98</sup> but do consistently correlate with local recurrence.

At presentation, approximately two-thirds of patients have disease that is localized to the thyroid. The median size of tumors is between 2.0 and 2.5 cm in most large series.<sup>40,41</sup> and<sup>42,100,101</sup> Patients with papillary carcinomas smaller than 1.0 cm are considered to have minimal or occult papillary thyroid cancer (papillary microcarcinoma).<sup>3</sup> In North American studies, the incidence of occult papillary tumors ranges between 0.5% and 14.0%, with a greater proportional incidence in older age groups. Studies from Scandinavia report up to one-third of patients with minimal papillary thyroid cancers.<sup>3</sup> There is clearly a large discrepancy between this incidence of one-fourth to one-third of patients having occult papillary thyroid cancer and the incidence of 40 per 1 million patient population of clinically significant disease. This discrepancy would argue strongly that these minimal lesions have a different biology than the clinically apparent thyroid cancers. For this reason, standard practice is not to investigate or submit to biopsy nodules that are smaller than 1.0 cm, except in the setting of familial MTC.<sup>88</sup> However, a proportion of patients who present with metastases to cervical lymph nodes may have a clinically occult lesion.<sup>102</sup>

Approximately 33% to 61% of patients with papillary thyroid cancer will have involvement of clinically apparent cervical lymph nodes at the time of diagnosis (see Table 38.2-2).<sup>42,43,45,100,101,103</sup> The reported incidence of positive cervical lymph node metastases in follicular thyroid cancers is much lower, ranging between 5% and 20%, with a median of approximately 10%.<sup>42,43,45,57,100,101</sup> However, this is probably an overestimate, as many series of follicular thyroid carcinomas include follicular variants of papillary carcinoma that have the natural history of papillary thyroid cancer and metastasize to lymph nodes with a high incidence. Some argue that the frequency of true lymphatic metastases from follicular thyroid carcinoma to regional lymph nodes may be extremely unusual, being less than 1%,<sup>4</sup> although one report from Memorial Sloan-Kettering Cancer Center (MSKCC) reported a 31% incidence of lymph node metastases in follicular carcinoma.<sup>103</sup> If patients with papillary cancer have lymph nodes studied in great detail, the incidence of micrometastases in lymph nodes increases to 80%.<sup>3</sup> The clinical significance of these micrometastases in some ways parallels the significance of the microscopic foci of intrathyroidal disease, as it is very common but does not progress and change clinical outcome.

Hürthle cell neoplasms generally have the same natural history and survival as follicular tumors<sup>75</sup>; however, the incidence of nodal metastases is greater than that of follicular carcinomas but not as high as papillary cancers.<sup>103</sup> Another difference that may have an impact on outcome is that these lesions do not tend to take up radioactive iodine with the efficiency of papillary tumors.<sup>104</sup>

Only a small minority of patients have metastatic hematogenous disease at the time of diagnosis.<sup>32,36,41,100</sup> In a large series from Mazzaferri and Jhiang,<sup>42</sup> 1% to 2% of papillary thyroid cancer patients and 2% to 5% of follicular thyroid cancer patients had distant metastases outside the neck or mediastinum at the time of diagnosis (Fig. 38.2-3). One series of 1038 patients from the MSKCC reported 44 patients (47%) presenting with metastases at diagnosis, including 2.3% of patients with papillary cancer and 11% with follicular cancer.<sup>105</sup> Having distant metastases at the time of presentation is a strong predictor of very poor outcome. Between 50% and 90% of these patients die secondary to their thyroid malignancy.<sup>42</sup> In the 44 patients in this category in the MSKCC series, there was a 43% long-term survival.<sup>105</sup>

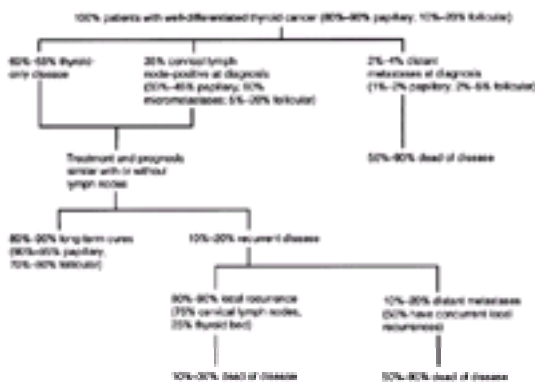

FIGURE 38.2-3. A flow diagram for well-differentiated thyroid cancer showing the extent of disease at the time of diagnosis, the natural history, and the

outcome-based specific disease patterns. (Adapted from refs. 5 and 49.)

In the overall population with papillary thyroid cancer, there is a 90% to 95% long-term disease-free survival and a 70% to 80% long-term disease-free survival for patients with follicular cancers. The 20% of patients in this group who develop recurrent disease includes a majority with local cervical recurrences either in lymph nodes or the thyroid bed and a minority of patients with distant metastases to the lung, bone, and liver.<sup>3,42</sup> Once again, patients who do develop distant metastases have a poorer outcome, with 50% to 90% disease-specific deaths, whereas patients with locally recurrent disease in the neck have long-term survivals between 70% and 90% even in the presence of persistent cervical disease.<sup>42</sup>

Overall survival in well-differentiated thyroid carcinoma from various institutional series shows a better 10-year survival for papillary cancer, ranging between 74% and 93% as compared to follicular cancer, with 10-year survivals of 43% to 94%.<sup>106</sup> Although many institutions have reported their data based on these histologic subcategories, a more meaningful system is to categorize patients according to defined risk factors more pertinent to generating prognostic information. Groups at both the Lahey Clinic<sup>41,107,108</sup> and the Mayo Clinic<sup>44,45,109,110</sup> and<sup>111</sup> have considerable databases that define prognostic risk factors for well-differentiated thyroid cancer. The two dominant factors in both series are the age at diagnosis and the presence of distant metastases.<sup>107,109</sup> All systems also include some measurement of the size of the lesion and other factors, such as local invasion or grade of the tumor, which have impact on outcome. In general, younger patients do well with well-differentiated thyroid cancer. Cady and Rossi<sup>107</sup> defined low-risk age categories as men younger than 40 and women younger than 50 years. The Mayo Clinic takes age into account using a numerical factor in a formula calculating a prognostic score (PS) that does not discriminate according to gender. Although historical data report follicular cancer as having worse outcome than papillary thyroid cancer, Donohue et al.<sup>100</sup> showed that if one corrects for age and other prognostic variables, the outcome is similar within these two pathologic subcategories.

As stated, patients who have distant metastatic disease either at presentation or with recurrence do much worse.<sup>42,106</sup> Similarly, patients with local invasion or high-grade lesions have a worse prognosis. The risk categorization schema developed by the Lahey Clinic group incorporating these components carries the acronym AMES (age, metastatic disease, extrathyroidal extension, size) (Table 38.2-3).<sup>107</sup> Using this system, low-risk patients can be identified who have a long-term overall survival of 98% and overall disease-free survival of 95% as compared to 54% and 45%, respectively, for high-risk patients (Table 38.2-4). A group from Canada added an assessment of DNA content by flow cytometry to the AMES categorization and showed that high-risk patients with aneuploid tumors have essentially zero long-term survival in a small number of patients.<sup>112</sup> The initial system developed by the Mayo Clinic group<sup>109</sup> carried the acronym AGES (age, tumor grade, tumor extent, tumor size; see Table 38.2-3). A mathematical formula to develop a PS with different weights on these factors was developed. The scoring system showed that patients with a PS of less than 4 had a 99% 20-year survival, whereas patients with a PS greater than 6 had a 13% 20-year survival, with graded categories in between (see Table 38.2-4).<sup>109</sup> A more recent modification of this system is seen in MACIS (metastasis, age at diagnosis, tumor extent subdivided into completeness of resection and invasion, and tumor size).<sup>113</sup> Using this system, the score of less than 6 yields a 20-year survival of 99%, and a score of more than 8 results in a 20-year survival of only 24%. On the basis of these scoring systems that have been verified by other institutions, the aggressiveness of treatment can be balanced against the possible treatment risks and costs. Clearly, if subgroups of patients with 99% 20-year survivals can be prospectively identified, aggressive therapy with potential life-long complications cannot be justified in this subpopulation. Sanders and Cady<sup>114</sup> reexamined the AMES criteria for a group of thyroid cancer patients treated between 1980 and 1990. Survival rate for the low-risk groups was 98% and for the high-risk group was 47%, consistent with data collected over the previous four decades. As has been published by this group before, there was no significant improvement in survival with total thyroidectomy or radioactive iodine therapy (discussed later in Radioiodine Therapy).<sup>155</sup>

	Low Risk	Intermediate Risk	High Risk
AMESS <sup>107</sup>			
Age	Male <40, female <50		Male >40, female >50
Metastases	No distant metastases		Distant metastases
Tumor	Benign or papillary or follicular with minor capsular invasion		Extrathyroidal papillary or follicular with major invasion
Size	<1 cm		>1 cm
Definitive	A. Any level of age group without metastases B. High-risk age group without metastases and with low risk tumor size		A. Any patient with metastases B. High-risk age group with either high-risk tumor size
AMES <sup>100</sup>			
Definitive	Low-risk AMES + negative lymph node	Low-risk AMES + negative lymph node	High-risk AMES + negative lymph node
AGES <sup>109</sup>			
PS	PS = 11 (age <40) or 10 (age >40) + 1 (grade II) or 2 (grade III) + 1 (extrathyroidal) or 3 (distant metastases) + 1 (size >1 cm) or 2 (size >1.5 cm) or 3 (size >2 cm) or 4 (size >2.5 cm) or 5 **TABLE 38.2-5.** American Joint Committee on Cancer Staging System for Thyroid Cancer

There is no large database that has verified this adaptation of the AMES and MACIS staging system into the TNM (tumor-node-metastasis) classification used by the American Joint Committee on Cancer. However, a very similar staging system was developed by the National Thyroid Cancer Treatment Cooperative Study registry, which initiated collection of data in 1987.<sup>117</sup> A report of more than 1500 patients analyzed by this staging system showed that 5-year disease-specific survivals for papillary thyroid cancer in stage I and II were 100%, 93.8% for stage III, and 78.5% for stage IV (<.0001).<sup>117</sup> The disease-free survival similarly showed a high correlation with stages I through IV papillary carcinoma, having survivals of 94.4%, 92.5%, 82.7%, and 30%, respectively ( *P*<.0001). A comparison of the ability of this prospective registry to predict for patients being disease-free over long-term follow-up produced slightly higher correlation values than the AMES classification but slightly lower than the MACIS and TNM classifications.<sup>117</sup>

**TREATMENT OF WELL-DIFFERENTIATED THYROID CANCER**

**Surgery**

The key decisions in the surgical management of thyroid nodules or cancers (or both) is whom to operate on and how extensive a resection to perform. The development of FNAB and the proven accuracy of those results since the mid-1980s has significantly decreased the number of patients who present with thyroid nodules and need to undergo surgical exploration for diagnosis.<sup>8,89</sup> Consequently, FNA has increased the proportion of nodules that are surgically excised and turn out to be cancer. The algorithm outlined in [Figure 38.2-2](#) is a guide for deciding which patients should undergo surgical resection based on an initial assessment by FNAB.

Before the development and widespread use of preoperative FNA of thyroid nodules, surgeons frequently relied on frozen-section test results obtained during the procedure to guide them.<sup>118</sup> The utility of frozen-section diagnosis for thyroid nodules is controversial. The situations in which the frozen section may be useful is for patients who have suspicious FNA results. Specifically, patients with suspicious cytology (e.g., follicular neoplasm or possible follicular variant of papillary carcinoma) or patients with a nondiagnostic FNA on repeated biopsies underwent surgical resection with an unknown diagnosis of malignancy. Most of the lesions in the indeterminate FNA category are follicular neoplasms, the majority of which are benign. As previously described in the section [Pathology](#), capsular and vascular invasion determine malignancy, and the ability to render an accurate interpretation on frozen-section analysis is very limited. A large series from Chen et al.<sup>119</sup> at Johns Hopkins University examined this patient population. They reported that 87% of frozen sections rendered no useful information, whereas 5% gave inaccurate results. Their conclusions were that obtaining frozen sections did more harm than good in addition to the expense incurred. A similar series from Bonner et al.<sup>120</sup> also reported that frozen-section interpretation of lesions diagnosed as follicular or Hürthle cell neoplasms on FNA is fraught with error. The recommended approach in this group of patients is to perform excision of the thyroid lobe harboring the nodule and to wait for the definitive pathologic report. If the lesion turns out to be a follicular carcinoma with characteristics that place a patient at high risk, such as significant capsular invasion or angioinvasion,<sup>18</sup> a completion total or near total thyroidectomy is performed during a second operation to remove the contralateral thyroid lobe.<sup>121,122</sup> In cases suspicious for a follicular variant of papillary carcinoma, the presence of specific nuclear features that define papillary thyroid cancer may be identifiable on frozen-section analysis. For this reason, patients with FNA results that are read as follicular neoplasm with some features of papillary nuclei should undergo lobectomy and intraoperative assessment (frozen section, touch preparation) to attempt identification of a follicular variant of papillary thyroid cancer.

A long-standing controversy among endocrine surgeons has existed regarding the extent of surgical resection for well-differentiated thyroid cancer.<sup>3</sup> This question may never be answered definitively by a clinical trial, as the expense and number of patients needed for trials of this indolent low-risk disease are overwhelming.<sup>123</sup> Acceptable surgical procedures to remove a thyroid neoplasm include a lobectomy, a subtotal thyroidectomy, a near-total thyroidectomy, and a total thyroidectomy. The entire thyroid lobe on the side of the primary cancer is taken out as completely as possible for any of these procedures. The difference comes in the management of the contralateral lobe and how this choice relates to outcome as well as operative morbidity. Arguments typically put forth for either more conservative therapy or more aggressive surgery are listed in [Table 38.2-6](#). In a thyroid lobectomy, the contralateral lobe is not dissected but is simply examined visually and by palpation for abnormalities. A subtotal thyroidectomy leaves a rim of 2 to 4 g of tissue in the upper lateral portion of the contralateral thyroid lobe.<sup>124</sup> By leaving thyroid in this location, two things are accomplished. First, the recurrent laryngeal nerve as it enters the larynx at the ligament of Berry is not dissected and consequently does not present a risk for injury. Second, the blood supply to the superior parathyroid gland on that side is less likely to be disrupted by leaving a rim of tissue in this location. A near-total thyroidectomy leaves a much smaller amount of normal tissue (<1 g) immediately adjacent to the ligament of Berry. This maneuver may offer some protection to the recurrent laryngeal nerve, but it offers minimal benefit in terms of preserving the blood supply of the upper parathyroid. A total thyroidectomy implies that every effort is made to excise all thyroid tissue, leaving no gross or macroscopic residual thyroid in either lobe. The difference between a total thyroidectomy and a near-total thyroidectomy usually depends on the particular anatomy of the thyroid in any given patient. There may be a small ledge of thyroid tissue, called the *tubercle of Zuckerkandl*, at the ligament of Berry that may limit safe resection of the entire thyroid.

Issue	Conservative Surgery	Radical (Total Thyroidectomy) Surgery
Prognostic risk factors	Seems to deliver risk as accurately through patients who have 25 percent of PTH and 25 percent of normal PTH	Occasional low-risk patients develop recurrence (small tumor size plus aggressive morphology in 25% of cases)
Safety of surgery	Risk of permanent hypocalcemia and recurrent laryngeal nerve injury greatly reduced with lobectomy or subtotal thyroidectomy	Experienced surgeons can perform these procedures with very minimal or no laryngeal complications
Therapeutic value	If necessary, 75% ablation of thyroid reserve can be accomplished with no morbidity	Thyroid ablation with 75% is complicated by pain if a gross thyroid remnant exists; decreased efficacy of 75% with residual thyroid
Local cancer control	Local recurrence able to be managed; risk of conversion to anaplastic is 0.5	Potential for local recurrence with possible differentiation to a more aggressive tumor

(From refs. 108, 111, with permission.)

**TABLE 38.2-6.** Arguments for and against Conservative or More Radical Surgery for Well-Differentiated Thyroid Cancer

The real increased risk of performing a total thyroidectomy versus a lesser resection may be in the long-term incidence of hypocalcemia ( [Table 38.2-7](#)). A study from the Mayo Clinic spanning the years between 1946 and 1970 reported a 32% incidence of permanent hypocalcemia after total thyroidectomy versus only a 0.3% incidence after a subtotal procedure.<sup>109</sup> More recent series report much less permanent morbidity and show variable results comparing the patients undergoing subtotal with those undergoing total thyroidectomy. Virtually all experienced surgeons should be able to perform total thyroidectomies with less than 1% recurrent nerve injuries, with the long-term risk of hypoparathyroidism of 2% to 9%.<sup>125</sup>

Study	Number	Hypocalcemia (%)	Recurrent Laryngeal Nerve (%)
<b>Subtotal thyroidectomy</b>

<sup>a</sup>Ref. 100 represents an older series between 1946 and 1970, as compared with other reports that are from the last two decades.

**TABLE 38.2-7.** Long-Term Complications of Total versus Subtotal Thyroidectomy

The most compelling argument for performing a unilateral lobectomy or a subtotal thyroidectomy are the data that come from the definition of prognostic factors for this disease. These rating scales identified by the acronyms AMES or AGES have been used to evaluate thousands of patients (see later in [Natural History and Prognosis](#)).<sup>107,109,113</sup> A low-risk patient defined by the AMES criteria has a 20-year survival of 99% with a 20-year disease-free survival of more than 95%.<sup>106</sup> If prognostic factors can accurately diagnose patients with such excellent outcome, the added benefit of a total thyroidectomy as well as postoperative iodine therapy may not be worth the potential morbidity for the patient. However, careful medical surveillance for cancer in the contralateral lobe as well as recurrence must be maintained. Furthermore, in situations in which a small thyroid remnant is left, the true morbidity of treating this patient with ablative doses of <sup>131</sup>I (if indicated) is relatively minimal.<sup>126</sup> In fact, it is typical for patients with a surgical report of a “total thyroidectomy” that there is residual thyroid tissue within the bed of the thyroid identified on the postresection diagnostic scan, as actually a near-total thyroidectomy was performed. This small thyroid remnant is then ablated with postoperative <sup>131</sup>I treatments. Radioiodine ablation of an intact lobe of the thyroid lobectomy is associated with considerably more symptoms.<sup>127</sup>

A very large review from the Mayo Clinic of 1685 patients with papillary thyroid cancer treated between 1940 and 1991 has been reported with a long-term follow-up.<sup>115</sup> Based on surgeons' preference, 1468 patients underwent a near-total or total thyroidectomy (87%), while 195 patients (12%) had a unilateral resection. With a 20-year follow-up, the incidence of local recurrence with unilateral resection was 14% and, for bilateral resection, it was 2%.<sup>115</sup> Similarly, the incidence of recurrent cervical lymph node metastases after unilateral resection was 19% as compared to 6% after bilateral resection ( $P=.0001$ ). Despite this very clear difference in recurrence rates, there was no translation of benefit in terms of disease-specific survival or distant metastases. The overall mortality at 30 years for patients with either unilateral resection or bilateral resection was approximately 2%. These results further confirm the excellent predictive outcome of the AMES low-risk criteria with long-term follow-up.<sup>115</sup> The authors concluded that although no survival benefit is gained from bilateral thyroid resection, the significant improvement in local recurrence with a minimal operative morbidity in the hands of experienced surgeons would lead to recommendation of near-total or total thyroidectomy for even this low-risk category of patients. Arguing with the opposing viewpoint, Sanders and Cady also provided a long-term review of their personal series and came to the conclusion that there was no benefit in performing bilateral resection versus unilateral resection for low-risk patients.

For patients in a high-risk category, there is much less disagreement regarding the extent of surgery, although there are still some proponents of less than total or near-total thyroidectomy. An analysis of 303 patients with high-risk papillary thyroid cancer showed an improvement in overall survival (relative risk ratio, 0.37) but not cancer-specific mortality or disease-free survival.<sup>128</sup> In this nonrandomized study, no effect of extent of surgery was seen in patients with follicular thyroid cancer.<sup>128</sup> A report by Wanebo et al.<sup>129</sup> in a smaller number of high-risk patients reported that 10-year disease-specific survival was 82% with total thyroidectomy, 78% with subtotal thyroidectomy, and 89% with unilateral lobectomy. Again, neither of these retrospective reviews was a prospective randomized study and, for reasons discussed later in [Radioactive Therapy](#), in terms of effectiveness of adjuvant postoperative radioiodine treatments and ease of follow-up with serum Tg measurements, the vast majority of investigators would agree that a total or near-total thyroidectomy is indicated for high-risk patients. For patients with extrathyroidal extension, the *en bloc* resection of invaded structures should be performed. If the tumor is on the anterior thyroid, this provides minimal morbidity to the patients, as resection of the overlying strap muscles, such as the sternal thyroid, causes no symptoms postoperatively. For posterior tumors, direct invasion of the trachea and esophagus should be resected with either partial tracheal resection and primary closure or resection of the esophagus muscular layer, again with closure and drainage.<sup>130</sup> This aggressive strategy for extrathyroidal extension at the first operation offers the best chance for local control.

The surgical management of lymph node metastases from well-differentiated thyroid cancer is also somewhat controversial.<sup>131,132,133</sup> Most experts agree that a procedure somewhere between “berry-picking” of clinically positive nodes and a formal modified radical neck dissection is the ideal treatment. For patients who have bulky and obviously pathologic lymph node metastases, a formal neck dissection is indicated.<sup>134</sup> As noted in [Natural History and Prognosis](#), particularly in lower-risk younger patients, the presence of metastatic disease to lymph nodes does not carry the connotation of worse prognosis of other solid neoplasms. Although lymph node metastases correlate with increased local recurrence, they do not carry a worse prognosis in several series.<sup>94,96,99</sup> The lymph nodes typically involved are the level VI on paratracheal lymph nodes in the cervical compartment and the level III and IV lymph nodes lateral to the internal jugular vein in the midneck or lower neck. During any thyroid resection, these lymph node areas should be palpated. Lymph nodes that are abnormal because they are firm or large should be subjected to biopsy with frozen-section pathologic evaluation. If positive for metastatic cancer, these lymph node areas should be completely dissected.

The technique of sentinel lymph node biopsy that has been used for melanoma and breast cancer has been applied to thyroid cancer using isosulfan blue.<sup>135</sup> Seventeen patients had thyroid mapping, with successful removal of sentinel lymph nodes in 15 (88%) and 2 failures due to retrosternal lymph nodes. Of 12 patients with cancer, 5 had positive lymph nodes (42%: 3 level VI, 2 level IV) for metastases and, in 2 patients, the sentinel node was the only node positive for cancer.<sup>135</sup> Whether this technique has a role in thyroid cancer in which the significance of nodal metastases is less than in breast cancer remains to be seen.

Some investigators have noted a positive correlation with lymph node metastases and outcome<sup>93,95</sup> and have argued for more routine formal dissections on that basis.<sup>136</sup> Tisell et al.,<sup>137</sup> who have widely promoted microdissection of all lymphatic tissue for MTC, reported their results applying the same technique to papillary thyroid cancer. In their series of 195 patients, there was a 70% incidence of lymph node metastases in men and a 4% to 5% incidence of lymph node metastases in women. With long-term follow-up, only three patients (1.6%) of this series died, partially due to locally recurrent thyroid cancer, all living more than 17 years after the initial surgery.<sup>137</sup> A different strategy was used by a group from Germany: For well-differentiated cancer, a modified radical neck dissection was performed routinely only for T4 lesions.<sup>138</sup> For other-stage primary tumors, only if there were positive cervical lymph nodes was a modified radical neck dissection performed at the time of initial surgery. After a mean of 6.5 years of follow-up, 77 patients (31%) underwent reoperation because of regional tumor recurrence. In the subgroup of patients with papillary thyroid cancer, the incidence of regional recurrence for T2 lesions was 45% in those without initial neck dissection versus 3% for those with an initial neck dissection; 77% of patients for T3 lesions without initial lymph node dissection had local recurrence as compared to 36% with initial dissection, and patients with T4 tumors had a 75% recurrence rate without initial node dissection versus 33% with an initial node dissection ( $P<.0001$ ).<sup>138</sup> It is not clear from this study with limited follow-up whether this decreased incidence of regional recurrence has an impact on survival and warrants a modified radical neck dissection for all patients with positive central neck lymph nodes at the time of initial thyroidectomy.

### Radioiodine Therapy

The postoperative treatment of patients with well-differentiated thyroid cancer, particularly relating to radioiodine therapy, is controversial. The lack of well-designed, randomized controlled studies and the low probability that any large multicenter treatment studies will ever come to fruition force the clinician to rely on retrospective studies and surveys of practice habits.<sup>139,140</sup>

All patients who have undergone a total or near-total thyroidectomy for a follicular carcinoma or a papillary carcinoma larger than between 1.0 and 1.5 cm should be considered candidates for radioiodine ablation.<sup>131</sup> I ablation of residual normal thyroid is important after what is thought to be complete resection of the primary tumor to aid in the detection of metastatic disease and to destroy residual microscopic cancer. Normal thyroid tissue takes up <sup>131</sup>I more avidly than does cancer<sup>140</sup> and thus prevents full visualization of the true extent of disease. Furthermore, <sup>131</sup>I ablation removes the contribution of normal thyroid tissue serum Tg, an important tumor marker in the follow-up of postoperative patients.<sup>141,142</sup> Most important, many studies have documented that <sup>131</sup>I ablation decreases cancer death,<sup>128,143</sup> tumor recurrence,<sup>128,144</sup> and development of distant metastases.<sup>128,145</sup> Despite such data for large patient populations, Cady and Rossi<sup>107</sup> and Sanders and Cady<sup>114</sup> observed that an enhanced survival has not been documented with the use of radioiodine ablation in the Lahey Clinic series, particularly in “low-risk” patients defined by AMES criteria.

The dose of <sup>131</sup>I for ablation is not standardized. Some recommend low-dose ablation with less than 30 mCi given on an outpatient basis. This approach should be reserved for low-risk young patients who may benefit from an overall lower radiation exposure and who accept the fact that several low radioiodine doses may be necessary before successful ablation. Several studies demonstrating proper diagnostic scan preparation with sufficiently elevated TSH and adherence to a low-iodine diet describe disparate rates of successful ablations using less than 30 mCi ranging from 27% to 83%.<sup>146,147</sup>

Higher ablative doses ranging from 100 to 150 mCi should be used for older, high-risk patients, particularly those known to have an incomplete resection of the primary tumor, an invasive primary tumor, or metastases. Beierwaltes et al.<sup>148</sup> demonstrated that 87% of their patients were ablated with an initial dose of 100 to less than 200 mCi. No significant differences were noted when doses from 100 to 200 mCi or more were used, leading to a recommendation of an optimal ablative dose of

100 to 149 mCi.<sup>148</sup> The goal of dosimetry is to derive the dose of <sup>131</sup>I that will deliver no more than 200 cGy to the blood, with no more than 120 mCi retained at 48 hours or 80 mCi in the presence of pulmonary metastases. This decreases the risk of bone marrow damage and radiation fibrosis in patients with metastatic lung disease. The methods used to perform dosimetry are generally modifications of the protocol developed by Benua and Leeper<sup>149</sup> and others. One recommended approach is for all patients with metastatic disease treated with repeated therapeutic doses of <sup>131</sup>I to undergo dosimetric quantification of the highest, safe dose, using a ceiling of 300 mCi. Other investigators recommend a standard fixed dose that may vary according to the site of uptake.<sup>150</sup> For example, a dose of 150 mCi is given for residual or recurrent thyroid bed carcinoma with or without metastases, up to 200 mCi for bone metastases, and a reduced dose of 75 mCi for diffuse pulmonary metastases to prevent radiation pneumonitis and fibrosis.

Lymph node metastases were found in up to 42% of patients at time of initial therapy in one large study by Mazzaferri and Jhiang.<sup>151</sup> Radioiodine is indicated in these patients to decrease recurrences that may have an impact on long-term survival.<sup>77,152</sup>

Pulmonary metastases are frequently detected exclusively on radioiodine scanning. Scumberger reported an increase in this observation, noting the rate of negative chest radiograph results in patients with metastatic disease to have increased from 13% to 43%.<sup>141</sup> Earlier detection of pulmonary metastases before development of gross chest film abnormalities is thought to be due to the use of Tg screening and the enhanced sensitivity of <sup>131</sup>I scanning. This same group reported on 23 patients who had diffuse pulmonary metastases seen only on radioiodine scanning, of which almost 90% had no further uptake and a decrease in the serum Tg after <sup>131</sup>I therapy. Bone metastases may require several modalities for adequate therapy. Surgery may be needed for orthopedic stabilization or palliation of pain. External radiation may be used in combination with radioactive iodine in difficult cases.<sup>154</sup>

Ablation of residual thyroid is typically performed at approximately 6 weeks after near-total or total thyroidectomy. Most, but not all, centers perform a diagnostic scan followed by ablative <sup>131</sup>I therapy. To optimize uptake by both residual thyroid and thyroid cancer, patients are rendered hypothyroid with a goal of increasing TSH. To accomplish this, thyroid replacement after thyroidectomy is triiodothyronine, as it has a much shorter half-life than thyroxine, and it is discontinued 2 weeks before treatment. In response to this hypothyroid state, TSH must achieve levels of greater than 25 to 30  $\mu$ U/mL to obtain optimal uptake of radioiodine. A low-iodine diet is instituted 1 to 2 weeks before scanning to enhance the uptake and retention of radioiodine.<sup>155</sup>

Just as there is lack of consensus regarding ablation and therapeutic doses of <sup>131</sup>I, the diagnostic scanning dose is as controversial. The ideal dose achieves high sensitivity in detecting residual thyroid tissue, thyroid cancer, and metastatic foci and reduces the potential for sublethal radiation “stunning” of thyroid tissue that prevents optimal uptake of future <sup>131</sup>I therapy. Although it is clear that higher scanning doses improve visualization of thyroid remnants and metastases,<sup>156</sup> even conventional scanning doses of 4 to 5 mCi of <sup>131</sup>I were found to diminish therapeutic radioiodine uptake.<sup>157</sup> Park et al.<sup>158</sup> have suggested that diagnostic scanning with <sup>123</sup>I may prevent the stunning effect. One strategy is to use a 5-mCi <sup>131</sup>I diagnostic dose followed by a whole body scan at 48 hours, with treatment following in most cases in 24 to 96 hours after whole body scanning. A posttherapy whole body scan is obtained after 5 to 7 days to determine the extent of disease.<sup>159</sup> Follow-up diagnostic scanning should be performed at 6- to 12-month intervals, and treatment should continue until there is no further uptake, the serum Tg is in the “athyreotic” range, or complications of <sup>131</sup>I therapy arise.

Medical management of malignant lesions includes thyroxine therapy to suppress TSH, which is invaluable in preventing tumor recurrences. The degree to which one suppresses TSH is a point of debate. It is advisable to keep the TSH at or below the normal range (range, 0.5 to 5  $\mu$ U/mL) in patients who are thought to be without evidence of disease and to maintain a lower TSH (0.1  $\mu$ U/mL) in patients with residual neck disease, metastases, or recurrent disease. A large review by the National Cancer Treatment Cooperative Registry of 693 patients reported for all papillary thyroid patients that TSH levels did not predict disease progression.<sup>160</sup> In high-risk papillary cancer, patient TSH was a predictor of risk ( $P=.03$ ) but not when radioiodine therapy was included in the analysis ( $P=.004$ ).<sup>160</sup> The degree of thyroid suppression in these cases is dictated by balance of the risk of recurrent thyroid cancer and the overall medical condition of patients, particularly their cardiovascular status.

**THYROGLOBULIN MEASUREMENTS.** Tg, an important tumor marker in the follow-up of thyroid cancer patients, is the protein that provides a matrix for thyroid hormone synthesis within thyroid follicles and is critical in the storage of thyroid hormone within the thyroid gland.<sup>161</sup> After successful thyroidectomy and ablation of residual normal or cancerous thyroid tissue by radioiodine, the Tg will be in the athyreotic range. Levels above the athyreotic range are indicative of persistent, functioning residual thyroid tissue or carcinoma. If there is detectable serum Tg in the circumstance of suppressive thyroxine therapy, it is a true indicator of persistent or recurrent thyroid carcinoma. However, thyroxine may suppress Tg in patients with metastatic disease; therefore, the test is more sensitive in the setting of thyroid hormone suppressive therapy withdrawal and frank hypothyroidism documented by an elevated TSH.

At the time of thyroid hormone withdrawal for both initial postoperative scans and for subsequent follow-up scans, Tg is measured in conjunction with the diagnostic whole body scan and may be more sensitive than the scan in detecting cancer, as demonstrated by several investigators.<sup>142,162</sup> Pineda et al.<sup>142</sup> treated 17 patients with 150 to 300 mCi <sup>131</sup>I who had negative diagnostic whole body scan results but serum Tg measurements above 8 ng/mL (range, 8 to 480 ng/mL) detected at the time of hypothyroidism.<sup>142</sup> Posttherapy scan results were positive in the thyroid bed or at sites of distant metastases in 16 of 17 patients. After repeated therapeutic doses given under similar conditions, 8 of 13 patients had a positive scan result after a second therapeutic dose, and five of five were positive after a third treatment. Lowering of Tg was demonstrated as was a decrease in uptake demonstrated on subsequent posttherapy scans.

Since this initial report,<sup>142</sup> there has been a great deal of debate regarding the optimal management of patients who are whole body iodine scan–negative but Tg-positive. This debate has included discussions of the false-negative rate of Tg, and alternative imaging studies, including positron emission tomography (PET) scans as well as sestamibi, technetium-sestamibi scans, and thallium 201 scans.<sup>140</sup> Without question, there are patients who have negative whole body iodine scan results but have definite recurrent and metastatic well-differentiated thyroid cancer. PET scans have been reported to have sensitivities of identifying the occult disease in 82%<sup>163</sup> and 71%<sup>164</sup> in this patient population. In the series of patients studied at MSKCC, the PET scan result changed clinical management in 19 of 37 patients.<sup>164</sup> In patients with elevated Tg levels, PET scans had a positive predictive value of 92%; in patients with a low Tg value, PET scans had a negative predictive value of 93%.<sup>164</sup> A study from the University of Southern California reported that 100% of patients imaged by PET with elevated or rising Tg had evidence of disease, although only 17 of these 24 patients had this recurrence confirmed (biopsy or alternative imaging studies).<sup>165</sup> Alternative imaging methods, including sestamibi scans as well as <sup>201</sup>Tl scans, could detect thyroid cancer metastases even in patients with false-negative normal Tg level results.<sup>140,166</sup>

The relatively routine use of radioiodine ablation in this patient population who are Tg-positive and whole body scan–negative has been debated in the literature.<sup>140</sup> Most experts agree that a selective approach incorporating prognostic features of the primary tumor (age of patient, extrathyroidal extension) should come into play regarding management of these patients. It should also be understood that a variety of patients with autoantibodies to Tg may have spurious results that are most commonly false-negative results but also have the potential for false-positive test results.<sup>167</sup> The controversy in this area speaks to the need for a randomized trial that may be conducted by one of the North American cooperative groups to answer the question of radioiodine treatment in this patient population. An even more elegant way to detect residual tumor may be use of the polymerase chain reaction technique for application of Tg messenger RNA circulating in peripheral blood.<sup>168</sup> The clinical relevance of this molecular detection method remains to be seen.

**ADJUVANTS TO RADIOIODINE THERAPY.** The success of radioiodine therapy is dependent on residual thyroid tissue concentrating iodine avidly under the stimulation of elevated TSH. In some circumstances, stimulation by endogenous TSH is impossible, as in the case of hypopituitarism, or is contraindicated, as in patients with central nervous system metastases in whom the hypothyroid state could lead to acute swelling and complications. Lithium can be used to increase the therapeutic effects of <sup>131</sup>I by decreasing its turnover and effectively increasing its half-life at oral doses of 400 to 800 mg daily for 7 days.<sup>169</sup> A study from the National Institutes of Health reported an estimated increased radiation exposure to the tumor by taking lithium of 2.29-fold after an <sup>131</sup>I treatment dose.<sup>170</sup>

The availability of recombinant human TSH has led to a large study that reported comparing diagnostic whole body iodine scans after standard thyroxine withdrawal compared to scans obtained with recombinant human thyroid-stimulating hormone (rhTSH).<sup>171</sup> In 127 patients with a diagnosis of well-differentiated thyroid cancer in this study, rhTSH, 0.9 mg, was injected once daily intramuscularly for 2 days. The day after the final injection, patients received between 3 and 5 mCi of <sup>131</sup>I and were scanned 48 hours later. At least 4 weeks later, patients underwent standard thyroxine withdrawal with an endogenous TSH at least more than 25 U/mL. The results of several parameters of this study are shown in [Table 38.2-8](#).<sup>171</sup> There were 65 patients who had concordant negative scan results (51% of the patient population). In the additional 62 patients (49% of population) who had positive scan results, both scans were positive in 41; only the standard thyroxine withdrawal study result was positive in 18, and only the rhTSH scan result was positive in 3. These results analyzed in a different way demonstrate that the rhTSH scan was equivalent to or better than the standard scan in 86% of the patients but inferior to the standard withdrawal scan in 14% ( $P<.001$ ).<sup>171</sup> This difference in scan results culminated in an alteration of therapy in 13% of the patients who were then treated with high-dose radioactive iodine based on the standard scan alone. On the other hand, there was a highly significant worsening of symptoms of hypothyroidism ( $P<.001$ ) and dysphoric mood states ( $P<.001$ ) after withdrawal of thyroid hormone as compared to

rhTSH.<sup>171</sup> The rhTSH was shown to be safe with only some mild nausea side effects. The serum Tg was studied at the point of peak TSH levels before both these scans in 35 patients. It was elevated more than 5 ng/mL in 14 of 35 patients with the standard withdrawal scan and 13 of 35 patients with the rhTSH scan. These results would indicate that in low- to moderate-risk patients, the use of recombinant thyrotropin may be indicated in follow-up annual scans, with near-equivalent efficacy of thyroid withdrawal but none of the morbidity for the patients.

	74 Withdrawal Scan	rhTSH Scan
Mean TSH level at time of <sup>131</sup> I injection	100 ± 77	132 ± 89
Negative scans	66	85
Positive scans	59	44
Uniquely positive scans	18	3
Percentage of <sup>131</sup> I uptake (mean ± SEM)	0.4 ± 0.7	0.5 ± 0.7 (P = .004)
Elevated thyroglobulin* (n = 35)	14	13

rhTSH, recombinant human thyroid-stimulating hormone; SEM, standard error of the mean.

**TABLE 38.2-8.** Comparison of Whole Body Iodine Scans and Scans Obtained after Injection of Recombinant Human Thyroid-Stimulating Hormone

**COMPLICATIONS OF RADIOIODINE THERAPY.** The most common side effects from radioiodine therapy include sialadenitis, nausea, and temporary bone marrow suppression.<sup>127</sup> Amifostine, (Ethyol) which has been used as a radioprotector of head and neck cancer, significantly reduced sialadenitis from radiation treatment for thyroid cancer.<sup>172</sup> Testicular function and spermatogenesis are transiently impaired but appear to recover with time.<sup>173</sup> In a study comparing fertility rates, birth rates, and prematurity between women treated with <sup>131</sup>I and those not treated, there were no significant differences.<sup>174</sup> One noted that three of six patients who became pregnant within the first year after radioactive treatment had children with significant congenital anomalies.<sup>175</sup>

There is a dose-dependent relationship between <sup>131</sup>I therapy and the development of leukemia. The incidence increases when the total cumulative dose is greater than 800 mCi and can be avoided by treating at widely spaced intervals (6 to 12 months) with activity between 100 and 200 mCi.<sup>176</sup> A higher incidence of bladder carcinoma has been seen in patients who have received high cumulative doses of radioiodine.<sup>177</sup> Urine dilution by adequate hydration and frequent voiding can reduce the radiation exposure to the bladder wall.

### Chemotherapy and Radiation Therapy

The most effective nonsurgical treatment for well-differentiated thyroid cancer is, without question, ablation with radioiodine.<sup>140,154</sup> Other conventional modes of neoplastic treatment—chemotherapy, and external-beam radiation therapy—demonstrate much poorer results and, consequently, are much less studied. The best single chemotherapeutic agent for this tumor is doxorubicin (Adriamycin) with partial response rates of 30% and up to 45% in some series.<sup>178</sup> Combination therapy with Adriamycin and cisplatin has produced disappointing results that were no better than single-agent trials, and the toxicity was worse.

For surgically unresectable local disease that has not responded to radioiodine, the best treatment may be a combination of hyperfractionated radiation treatments plus Adriamycin. Response rates of more than 80% have been reported using this regimen, although even in this situation, complete responses are rare and limited in duration.<sup>178</sup> Adjuvant radiation therapy for grossly resected well-differentiated thyroid cancer has not generally been thought to be beneficial<sup>179,180</sup> until one recent retrospective study. This study by Farahati et al.,<sup>181</sup> a retrospective review, analyzed patients with T4 primary lesions (evidence of extrathyroidal extension) who underwent radiation (n = 99) compared to those who did not (n = 70).<sup>181</sup> Patients received a uniform treatment course of total thyroidectomy with initial ablative radioactive iodine, with or without 5000 to 6000 rads of external-beam radiation therapy to the neck and mediastinum, followed by a second ablative dose of radioactive iodine. The group that had radiation treatments had recurrent disease in 4% of cases (3 of 75 patients), while the group who did not receive radiation had recurrences in 26% (13 of 50 patients; P = .0001).<sup>181</sup> This benefit for radiation extended only to the subgroup of patients with lymph node–positive disease. In patients with papillary thyroid cancer who were lymph node–negative, there were 1 of 47 patients (2%) with recurrence with radiation therapy and 2 of 21 patients (9.5%) without radiation therapy had recurrences, which was not statistically significant (P = .27). In patients with T4 lesions and positive lymph nodes who received radiation, there were 2 recurrences in 28 (7.1%) and there were 13 recurrences in 29 patients without radiation therapy (44.8%; P = .002). These results would suggest that patients with T4 papillary thyroid cancer, particularly with positive lymph nodes, should undergo external-beam radiation therapy to the neck. This patient population should be studied in a prospective manner to determine the benefit of that additional therapy. This retrospective review showed not only an improvement in local recurrence but an improvement in distant metastases in this subgroup.<sup>181</sup>

## ANAPLASTIC THYROID CANCER

ATC is one of the most aggressive and difficult human malignancies to treat and subsequently is one of the most lethal. As opposed to the excellent long-term survival for well-differentiated thyroid carcinoma, ATC in most series has a median survival of 4 to 5 months from the time of diagnosis, with rare long-term survivors.<sup>182,183</sup> and <sup>184</sup>

The proportional incidence of ATC compared to the total number of thyroid carcinomas is variable but appears to be declining over time. Historically, ATC was said to constitute 5% to 15% of all thyroid carcinomas in the United States<sup>182</sup> and between 10% to 50% in European series.<sup>3</sup> Current epidemiologic studies indicate that this lethal form of thyroid cancer has decreased to between 1% and 3% of the total number of cases.<sup>183</sup> Institutional reviews over a distinct period support the apparent real decrease in the incidence of ATC. One of the largest single-institution series, from the Mayo Clinic, spans the years 1946 to 1971.<sup>182</sup> During that time, 1161 patients with thyroid cancer had their primary treatment at Mayo Clinic, including 82 cases of ATC or 7.1% of the total. Later single-institution series from Loyola (1966 to 1989)<sup>185</sup> and Roswell Park (1968 to 1992)<sup>183</sup> reported respective incidences of 5% and 2.7%. The decrease over time may be partially related to iodine prophylaxis and an overall decrease in endemic iodine-deficient goiter in North America.

Patients with ATC differ epidemiologically from patients with well-differentiated thyroid neoplasms, with a median age two to three decades older and with a more equal gender distribution (Table 38.2-9).<sup>182,183,184</sup> and <sup>185</sup> Median age at diagnosis ranges between 63 and 74 years. In most series, including the largest one from the Mayo Clinic with 82 patients,<sup>182</sup> there are equal number of male and female patients, but some series show a predilection for women near the ratio that is commonly reported for well-differentiated thyroid cancer.

Institution	Year	Total Thyroid Cancer		Anaplastic Thyroid Cancer		Ratio	Survival (mo)	Survival (%)	Survival (%)
		No. Cases	Case (%)	No. Cases	Case (%)				
Mayo Clinic <sup>182</sup>	1946-1971	16	136	71	46	1.47	5	8	3

**TABLE 38.2-9.** Clinical Series of Anaplastic Thyroid Carcinomas with Demographic Data, Total Percentage of Thyroid Cancer, and Survival

ATC is commonly related to a prior or a concurrent diagnosis of well-differentiated thyroid cancer or benign nodular thyroid disease. This association of ATC with prior or concurrent well-differentiated thyroid carcinoma suggests two features of the biology of this tumor. First, ATC may arise via the dedifferentiation of prior well-differentiated thyroid cancer, and the aggressive growth pattern of this anaplastic tumor may replace all previous evidence of well-differentiated tumor. <sup>186</sup> Also, the close association between ATC and well-differentiated thyroid cancer suggests that the risk factors are similar. <sup>185</sup>

The natural history, clinical presentation, and outcome of ATC reflect the biology of this tumor as an undifferentiated, rapidly growing neoplasm with invasive characteristics. The patients uniformly present with a palpable mass that is reported to be increasing in size during the period of observation. The median tumor size in patients with ATC from Roswell Park Cancer Institute was 8 to 9 cm, with a range of 3 to 20 cm as compared to the usual size of 2 to 3 cm for well-differentiated thyroid cancer. <sup>183</sup> Invasion to the trachea, larynx, or recurrent laryngeal nerve leads to hoarseness at diagnosis and, in a subset of these patients, an invasion to the esophagus may cause dysphagia.

The majority of patients with ATC die from aggressive local regional disease, primarily with upper airway respiratory failure. At the time of diagnosis, 25% to 50% of patients may have synchronous pulmonary metastases. <sup>182,183</sup> and <sup>184</sup> However, it is usually the local growth causing obliteration of the airway that causes the patient's demise. For this reason, aggressive local therapy is indicated in all patients who can tolerate it and in whom it is technically possible. As opposed to well-differentiated thyroid cancer, <sup>131</sup>I plays no role in the treatment of recurrent or metastatic disease for this tumor. Therefore, total or near-total thyroidectomy is not as important in ATC, except as needed to obtain local control. <sup>182</sup>

Survival after the diagnosis of ATC is very poor. With the median survival in most series being less than 5 months from the time of diagnosis, this is one of the most rapidly lethal tumors known in clinical oncology. <sup>182,183</sup> and <sup>184</sup> The majority of patients die due to local recurrence, although distant metastases occur primarily in lung, bone, and liver. External radiation has been used with limited success to treat locally recurrent ATC. One study from London reported 10 of 17 patients with an objective response to accelerated radiation (three complete responses and seven partial responses) but toxicity to the esophagus was considerable. <sup>187</sup> In the mid-1980s, Kim and Leeper <sup>188</sup> reported improved responses with a combination of radiation therapy and relatively low-dose Adriamycin as an apparent synergistic agent, achieving responses in 84% of 19 patients, although still having a median survival of only 12 months. Adriamycin is the single most effective chemotherapeutic for ATC, and it has been shown that Adriamycin plus platinum is more effective than Adriamycin alone. A review from the National Cancer Database reports a 10-year survival of 14% for ATC. <sup>189</sup> Early diagnosis with aggressive surgical therapy supplemented by external-beam radiation therapy and Adriamycin-based chemotherapy is the most appropriate treatment for patients with anaplastic thyroid carcinoma.

## MEDULLARY THYROID CANCER

MTC was recognized in the 1950s by Hazard et al. <sup>190</sup> as a distinct clinicopathologic entity. Since this description, sequential pathologic, biochemical, and molecular genetic studies have progressed to render this one of the best characterized solid malignancies of the thyroid. <sup>65,191</sup> In 1959, Hazard described MTC as a solid thyroid neoplasm without follicular histology but with a high degree of lymph node metastases that accounted for 3.5% of thyroid cancers in a review at the Cleveland Clinic. <sup>190</sup> Over the next 10 years, investigators identified and described the parafollicular C cell that produces calcitonin, which lowers serum calcium. <sup>191</sup> In 1966 and 1967, Williams <sup>192,193</sup> suggested that MTC arose from this C-cell population. This hypothesis was confirmed by a number of investigators who documented elevated serum calcitonin from patients with MTC. During the decade of the 1970s, Wells et al <sup>194</sup> extended the measurement of calcitonin by defining a provocative test that rendered this hormonal tumor marker one of the most sensitive and specific in all of oncology. Understanding of the familial associations of MTC with corollary genetic studies reported in the 1980s and early 1990s <sup>191</sup> has defined molecular changes that are important for inherited MTC and may have implications for sporadic MTC as well. <sup>195</sup>

MTC constitutes as few as 3% <sup>4</sup> or as many as 12% <sup>191</sup> of most institutional series of detectable thyroid cancers. As opposed to well-differentiated thyroid cancer, MTC is not associated with radiation exposure, but it does occur in distinct familial syndromes. Sporadic or nonfamilial MTC accounts for 60% to 70% of cases, with three distinct familial syndromes accounting for the remainder. <sup>191</sup> MTC is the most prominent clinical diagnosis in MEN 2a and MEN 2B (Table 38.2-10). <sup>196</sup> In 1986, familial MTC with none of the associated features of MEN 2a or MEN 2B was described. <sup>197</sup> Appreciation of this syndrome has shifted the percentage of incidence of sporadic MTC as a function of the total number of cases of MTC from 80% to 60% and even lower in some series. In addition to the presence or absence of other associated endocrine abnormalities, each of these familial forms of MTC has a unique natural history and prognosis. <sup>191</sup> Furthermore, studies have identified specific genetic changes associated with each type (see Table 38.2-10). <sup>195</sup>

	Sporadic	Familial			
		MEN 2A	MEN 2B	MEN 2C	MTC only
Age at diagnosis	45-60	45-60	30-50*	30-50	30-50
Gender (F/M ratio)	1/1	1/1	1/1	1/1	1/1
Associated features	None	None	Pheochromocytoma, hyperparathyroidism	Pheochromocytoma, medullary thyroid carcinoma, and/or lipomas	Pheochromocytoma, medullary thyroid carcinoma, and/or lipomas
Genetic testing	None	None	None	None	None
Survival (months)	12-24	12-24	12-24	12-24	12-24
Case of MTC	1/1000	1/1000	1/1000	1/1000	1/1000
Survival in MTC	12-24	12-24	12-24	12-24	12-24
Mutation in RET or other gene	None	None	None	None	None

\*The age at diagnosis is a range representing genetic screening can be at an even younger age. Numbers reported reflect ratios based on frequency of families in risk.

(Data from refs. 191, 192, 193, 194, 196, 198 and 201.)

**TABLE 38.2-10.** Characteristics of Sporadic and Various Familial Forms of Medullary Thyroid Cancer

Parafollicular, or C cells, arise embryologically from the neural crest and have characteristics shared with other cells with a similar origin. <sup>171</sup> The C cells are located primarily in the upper and middle thirds of the thyroid lobes, with a particular concentration posteriorly. This feature is important to surgical therapy, as this is the location in which the recurrent laryngeal nerve passes under the ligament of Berry and enters the larynx. Therefore, complete thyroid resection is necessary for this condition, because MTC typically arises in this upper portion of the thyroid gland where the C cells are concentrated.

Grossly, MTC may be circumscribed or infiltrative and is usually yellow. Histologically, this tumor can be described as having a wide variety of patterns, including glandular, solid, spindle-cell, oncocytic, clear cell, papillary pattern, small cell, <sup>198</sup> and giant cell. The nuclei of MTC resemble those of neuroendocrine tumors in other areas of the body. They are usually round and have a stippled "pepper-and-salt" chromatin. <sup>198</sup> Pathologic features associated with a poor prognosis include presence of necrosis ( $P=.001$ ), squamous pattern ( $P=.002$ ), presence of oxyphil cells in the tumor and absence of cells with intermediate cytoplasm ( $P=.02$ ), and less than 50% calcitonin immunoreactivity ( $P=.04$ ). <sup>199</sup>

## CLINICAL PRESENTATION AND DIAGNOSIS

The clinical symptoms at the time of presentation vary, dependent on the situation for each patient. Patients with familial MTC who are identified by screening with stimulation tests <sup>191</sup> or with molecular analysis <sup>200</sup> are universally identified before any macroscopic mass or lesion. Sporadic patients typically present with an asymptomatic mass in the thyroid. <sup>191</sup> Patients with bulky disease with extremely high levels of calcitonin may have severe secretory diarrhea as a principal symptom. Before the definition of the molecular change for familial MTC, <sup>200</sup> basal and stimulated serum calcitonin levels were used to screen patients. <sup>191</sup> Sequential calcitonin testing is still important as a tumor marker for following up patients with MTC.

Various nuclear medicine imaging studies have been evaluated in patients with MTC to identify gross and occult metastases. MTC does not concentrate iodine, so <sup>131</sup>I thyroid scans are of no utility. <sup>201</sup> Similarly, thallium as well as technetium scans have been used with minimal benefit in this disease. <sup>131</sup>I metaiodobenzylguanidine scans have been useful in pheochromocytoma and neuroblastoma and have been studied for MTC but do not identify a large proportion of the lesions. <sup>202</sup> Other

studies have used radiolabeled anti--carcinoembryonic antigen antibody<sup>203</sup> or anticalcitonin antibody but with limited success. Several studies have used somatostatin receptor scintigraphy in the setting of MTC.<sup>204,205</sup> Like other amine precursor uptake and decarboxylation (APUD) cells, C cells may express a high level of somatostatin receptors, and pharmacologic developments of radiolabeled agents, based on analogs that bind to somatostatin receptor, have been studied for use in treating MTC. In general, the results are better than any other nuclear medicine agent; however, occult lesions smaller than 1 cm<sup>204</sup> as well as liver lesions still are missed with this technique.

## TREATMENT

### General Approaches

Chemotherapy and external-beam radiation therapy are ineffective against MTC, rendering surgical resection the only definitive therapy.<sup>206,207</sup> For patients with sporadic MTC who are not identified by biochemical or genetic screening, the appropriate operation in most cases is total thyroidectomy with central node dissection. Total thyroidectomy is indicated in this sporadic setting because a small proportion of lesions may be bilateral and because it may not be clear at the time of operation whether a patient is an index case of familial disease or the disorder is a true sporadic case. Because all familial syndromes have a high propensity for bilateral tumors, total thyroidectomy is indicated except possibly for patients having nonfamilial syndromes and small lesions (<1.0 cm).<sup>208</sup> However, one report of 80 patients with sporadic MTC smaller than 1 cm showed that 11% had clinically involved lymph nodes, 31% had pathologically involved lymph nodes, and 5% had distant metastases.<sup>207</sup> Combined with this thyroid resection, a central lymph node dissection is performed, removing lymphoid tissue from the level of the hyoid bone to the innominate vessels inferiorly and laterally to the jugular vein. Lymph nodes lateral to the jugular vein are sampled and, if there is any evidence of metastatic spread in this area, a formal modified radical neck dissection is performed.<sup>209</sup>

The incidence of positive lymph nodes correlates with the size of the primary lesion at the time of diagnosis. It has been reported that for lesions smaller than 1 cm, there can still be an 11% incidence of positive nodal disease, whereas in patients with tumors larger than 2 cm, 60% will have positive cervical lymph nodes.<sup>208</sup> Combining all cases of MTC, between 15% and 75% have spread to the lymph nodes at the time of diagnosis.<sup>191</sup> For this reason, Duh et al.<sup>208</sup> advocated a formal modified radical neck dissection for any lesion larger than 2 cm on the side in which it is located, with a central node dissection on the contralateral side.

The incidence of distant metastases at the time of diagnosis varies with the clinical setting. Twelve percent of patients with sporadic MTC have distant metastases, whereas 20% of those with MEN 2B have metastatic spread but only 3.3% of patients with MEN 2a.<sup>191,196</sup> Patients with familial non-MEN MTC also have a favorable clinical condition similar to MEN 2a, with 2% of patients presenting with distant metastases.<sup>179</sup> Moley et al.<sup>206</sup> have instituted staging laparoscopy to identify liver metastases in patients undergoing thyroid resection and lymph node dissection. For MTC, liver metastases are often the site of metastatic disease and are often radiologically occult. By performing laparoscopy, the incidence of biochemical cure has increased because patients with unresectable liver disease are eliminated from the therapy pool.

The outcome of treatment of patients with sporadic MTC has improved. An early review published in 1970 reported 5- and 10-year survival rates of 48% and 12%, respectively.<sup>191</sup> More recent studies show a 5-year survival of between 80% and 90% and 10-year survival between 70% and 80% for combined series of familial and sporadic MTC.<sup>208,209</sup> and <sup>210</sup> The series from the National Cancer Database confirms this improved survival, with a 75% 10-year survival for MTC.<sup>189</sup> It is interesting to note that the natural history and prognosis for the various subtypes of MTC correlate with described genetic changes. The two groups with the worst outcome (sporadic and MEN 2B) have similar genetic changes in the RET oncogene, as do the two types with favorable outcome (familial non-MEN and MEN 2B).<sup>200</sup>

One controversial area in the surgical management of patients with MTC is the proper approach to patients who have persistently elevated basal or stimulated calcitonin after resection of all gross disease.<sup>205,211,212,213,214</sup> and <sup>215</sup> In many of these cases, imaging studies with conventional techniques of ultrasonography, computed tomography, or magnetic resonance imaging, plus newer techniques of somatostatin receptor scintigraphy,<sup>204</sup> demonstrate no areas of disease. One strategy to identify the region from which elevated calcitonin is coming is to perform selected venous sampling with systemic pentagastrin or calcium stimulation.<sup>205</sup> The key clinical question is: In these patients, who have occult MTC with no radiographic or clinical evidence by which to localize residual tumor but with persistently abnormal calcitonin levels, is the natural history altered by aggressive attempts to excise the occult disease surgically? Excision attempts generally do not produce normalization of calcitonin levels. The best results come from Tisell, who performs meticulous 12-hour neck dissections, often removing 40 to 60 additional cervical lymph nodes in patients with occult MTC.<sup>214</sup> In a series of 11 patients, he had four that had normalized calcitonin levels, with another four that had dramatic improvement in their calcitonin levels. However, even these improvements in the calcitonin levels do not necessarily translate into improved survival. Thirty-one patients were identified, all of whom had gross disease resected at initial operation at the Mayo Clinic but had documented elevated postoperative calcitonin.<sup>215</sup> With a median follow-up of almost 12 years, only 11 patients developed clinically or radiographically apparent recurrent disease, and these 11 patients were reoperated at that time. None of these patients normalized their calcitonin levels after reoperation. Important is that the overall 5- and 10-year survival rates in this population were 90% and 86%, respectively, with only two patients dying specifically from MTC.<sup>215</sup> Both patients had sporadic MTC with very aggressive invasive primary lesions and died of distant metastases 2 to 2.5 years after diagnosis. Even though there is no alternative therapy to surgical resection for MTC, the data regarding the prognosis of occult MTC plus the lack of success even with very extensive reoperations to normalize calcitonin would argue that the best course of action in this patient population is close follow-up and operation only when clinically apparent disease is present.

For patients with metastatic MTC, surgical resection may still offer the best chance of survival as well as long-term palliation. In 16 patients with metastatic MTC at Johns Hopkins, 21 palliative reoperations were performed. These procedures included neck reoperations in 11 cases but also removal of mediastinal masses and liver metastases as well as other miscellaneous lesions. All patients had clear relief of their index symptoms, typically diarrhea and fatigue, and had a median survival rate of 8.2 years.<sup>216</sup>

The results of MTC treatment with external-beam radiation therapy<sup>217</sup> or chemotherapeutics are disappointing.<sup>218,219</sup> Radiation administered at a dose of more than 5000 rads to a large Y-shaped anterior field without laryngeal shielding necessary to treat these patients causes significant local toxicity. Dysphagia as well as dyspnea can be severe in certain individuals. Furthermore, treatment with this radiation dose has not definitively been shown to decrease local recurrences. One large study from France of 59 patients reported local recurrences within the radiation field in 30% of patients.<sup>217</sup> Chemotherapeutics used in treatment of MTC include Adriamycin, dacarbazine, streptozocin, and 5-fluorouracil.<sup>218</sup> Single-agent response rates are poor, with aggressive Adriamycin regimens producing 20% to 30% objective responses. A study of combination chemotherapy showed that a regimen of 5-fluorouracil, streptozocin, and dacarbazine produces objective responses in only 15%.<sup>218</sup> The poor outcome of treatment of metastatic disease validates the treatment recommendation to diagnose patients with MTC early and treat with initial aggressive surgery.

Due to failure of chemotherapy and radiation therapy to offer significant benefit for patients with MTC, innovative therapeutic strategies for MTC have been developed, such as the use of gene therapy. This technique primarily uses adenovirus to transduce either interleukin-2 or suicide gene, such as herpes simplex virus thymidine kinase.<sup>220,221</sup> Other more directed gene therapies would rely on the expression of calcitonin only from MTC and have use of selective promoter in front of a suicide gene or other targeted transgene.

### Treatment of Familial Medullary Thyroid Cancer

An increasing number of patients are identified in one of the three familial settings of MTC that are diagnosed using biochemical or genetic screening.<sup>200</sup> Routine use of provocative biochemical testing to diagnose MTC led to a significant decrease in the age of diagnosis, a significant decrease in the incidence of lymph node metastases, and a significant increase in the number of patients cured biochemically at these earlier operations.<sup>191</sup> This strategy has been extended to an earlier stage with the description of the mutations in the RET oncogene present in the MEN 2a.<sup>200</sup> At Washington University, Wells et al.<sup>200</sup> use a molecular genetic screening technique to identify patients who are carriers of the MEN 2a mutation as infants or young children. Before any abnormality in basal or stimulated calcitonin, these patients undergo a total thyroidectomy, a total parathyroidectomy, and a parathyroid autograft. Pathologic evaluation on these children's thyroid identifies either C-cell hyperplasia or microscopic or macroscopic MTC. In the initial trial, no patients treated with this strategy had evidence of lymph node metastases, and this surgical strategy should be curative.

The genetic test for the mutations in the RET protooncogene have become commercially available, and many individuals are reporting series based on early operation for patients identified by RET mutation. A review has noted that in a total of 209 patients treated in this manner, 3.4% had normal thyroid glands with no evidence of C-cell hyperplasia or MTC.<sup>222</sup> It was also noted that in these patients undergoing prophylactic operations, there was an 8.6% incidence of lymph node metastases. Based on these results, it is thought that a prophylactic central neck dissection should be performed at the time of this prophylactic thyroidectomy, based

on genetic testing. Because this oncogene was one of the first to be defined that led to a therapeutic procedure, there has been appropriate attention paid to the psychosocial impact of genetic testing. A study from Lyon, France suggests that patients who are in this situation of being kindreds undergoing genetic testing are frustrated regarding this stressful process.<sup>223</sup>

## THYROID LYMPHOMA

Thyroid lymphoma is a relatively rare disease constituting fewer than 1% of all lymphomas and accounting for 2% of extranodal non-Hodgkin's lymphoma (see [Chapter 45.3](#)).<sup>224</sup> Almost all these thyroid lymphomas are non-Hodgkin's lymphoma,<sup>225</sup> with the majority (70% to 90%) being intermediate grade and the remainder being high grade.<sup>226</sup> Many are considered mucosa-associated lymphoid tissue lymphomas or *MALomas* and show plasmacytic differentiation and may be associated with similar lesions in extranodal sites especially in the gastrointestinal tract.<sup>231</sup>

The majority of patients with thyroid lymphoma all have disease on one side of the diaphragm with a proportion confined to the thyroid (stage IE) and the majority with thyroid disease plus cervical or mediastinal lymph nodes (stage IIE).<sup>227</sup> The incidence of this disease may be changing, primarily due to improved recognition and diagnosis of thyroid lymphoma. Henry Ford Hospital in Detroit saw seven cases of thyroid lymphoma in 20 years before 1976 and 30 cases in the 8 years after 1976.<sup>225</sup> One hypothesis to explain the incidence increase is that these patients were previously diagnosed as having anaplastic thyroid carcinoma and, with better understanding and more sophisticated diagnostic tools, such as immunohistochemistry, these patients are being correctly categorized as having thyroid lymphoma.

In most series, there is a strong female predominance, ranging from 3:1 in the large Mayo Clinic series<sup>228</sup> to 6.5:1 from Brown University<sup>227</sup> and up to 8:1 for the Vancouver, British Columbia study.<sup>226</sup> The median age in most series at diagnosis places patients in the seventh decade of life, similar to what is seen for ATC and much older than patients with well-differentiated thyroid cancer.<sup>226,227</sup> and<sup>228</sup> Between 10% and 30% of patients report a symptom or combination of symptoms relating to local invasion, including hoarseness, dyspnea with stridor, or dysphagia.<sup>226</sup> Patients with thyroid lymphoma virtually never have hyperthyroidism but frequently have hypothyroidism. These hypothyroid patients have evidence of autoimmune thyroiditis or Hashimoto's thyroiditis, either by biopsy or from the pathologic specimen.<sup>225</sup>

The optimal treatment for thyroid lymphoma has evolved with the success of combination chemotherapy used in the treatment of non-Hodgkin's lymphoma and with the ability to obtain an accurate diagnosis without invasive surgery by large-needle or core needle biopsy. Skarsgard et al.<sup>226</sup> argued that the role of surgery in this disease is simply to obtain adequate tissue for diagnosis and that the primary treatment should be external-beam radiation combined with an Adriamycin-based chemotherapy regimen. Using this strategy at his institution, the 5-year survival was 70%, and the 4-year disease-free survival was also 70%. Others have argued that in the 20% to 30% minority of patients who have no extrathyroidal extension, excellent survival is achieved by surgical excision plus postoperative radiation therapy.<sup>224</sup> Patients with extrathyroidal disease either by direct extension or lymph node involvement should be considered to have systemic disease. Although some endocrine surgeons argue that attempts to clear the trachea to avoid airway obstruction should be performed if at all possible in all patients,<sup>224</sup> others report that the rapid use of radiation therapy (starting the day after the diagnostic biopsy procedure) produces the same beneficial results.<sup>226,227</sup> All would agree that the efficacy in long-term survival using a combination of radiation therapy and chemotherapy render aggressive surgical resection with a sacrifice of recurrent laryngeal nerve or possibly resulting in hypoparathyroidism contraindicated for thyroid lymphoma.

## SECONDARY THYROID MALIGNANCY

Involvement of the thyroid gland by malignant metastases from other sites is rare, accounting for fewer than 1% of thyroid malignancies in most clinical series involving surgical resection or FNA biopsies.<sup>229,230</sup> On the other hand, the incidence of thyroid metastases identified on autopsy series is greater and can range between 2% and 26% in autopsy series, probably depending on the thoroughness of the examination by the pathologists.<sup>229</sup> From these autopsy series, the most predominant malignancies metastatic to the thyroid are breast and lung, each accounting for 25% of the total.<sup>229</sup> Melanoma, renal cell carcinoma, and gastrointestinal tract malignancies each account for approximately 10% of these secondary malignancies from autopsy studies. A variety of other miscellaneous diagnoses account for the remainder.

For the more clinically relevant situation in which the thyroid metastasis is detected pre-mortem, the most common primary site is renal cell carcinoma, accounting for 23% of 111 such cases combined from the literature.<sup>229</sup> The next most common sites are breast (16%), lung (15%), melanoma (5%), and colon and larynx (4.5% each). Occasionally, the thyroid metastasis may be the initial presentation of an occult primary from a gastrointestinal source or renal primary. Because FNA biopsy is the diagnostic tool used to evaluate thyroid nodules as the initial step, an awareness of the potential of the secondary metastases is important for interpretation of these biopsy results.

Dependent on the clinical situation, some of these patients may need thyroidectomy for palliation of local symptoms. Thyroid metastases may grow at a rapid rate and can cause airway obstruction. In one large institutional series from Toronto, 8 of 11 patients derived benefit from a thyroidectomy after pre-mortem diagnosis of secondary metastases.<sup>230</sup>

#### INTRODUCTION

Parathyroid neoplasia is a common endocrine problem, whereas parathyroid carcinoma is exceptionally rare.<sup>1</sup> Parathyroid carcinomas, as opposed to other endocrine tumors that become less hormonally active when malignant, are hyperfunctional and characterized by severe elevations of serum calcium with associated renal and bone symptoms.<sup>2</sup> The clinical course is variable, but typically follows a pattern of local recurrence in the neck with late distant metastases to lung, bone, and liver.

The initial report of a parathyroid carcinoma was made by de Quervain in 1909.<sup>3</sup> He described a patient with a large locally invasive neck mass that was parathyroid on histologic evaluation. The tumor was definitely malignant as the patient developed lung metastases after removal of the neck mass, but no signs or symptoms of hypercalcemia were described. The initial description of severe hypercalcemia associated with parathyroid cancer was made three decades later by Armstrong.<sup>4</sup> The rarity of parathyroid carcinoma limits reports to primarily small institutional series with occasional reviews of all experience reported in the medical literature. Even institutions such as the Massachusetts General Hospital<sup>5</sup> or the Mayo Clinic<sup>3</sup> with extensive clinical interest in this disease have only one to two dozen cases in clinical reviews spanning four to five decades. A detailed review by Obara and Fujimoto<sup>2</sup> identified 270 cases of parathyroid carcinoma in the English literature between 1933 and 1991. An article from the National Cancer Database in the United States identified 286 cases of parathyroid cancer reported between 1985 and 1995.<sup>6</sup> This single report more than doubles the number of cases in the literature for this rare disease. The epidemiology, pathology, clinical course, treatment, and prognosis of this rare malignancy is described in relation to the much more common diagnoses of parathyroid adenoma and hyperplasia.

#### PRIMARY HYPERPARATHYROIDISM

The vast majority of parathyroid cancers are functional with excess production of parathyroid hormone (PTH) which results in the clinical syndrome of primary hyperparathyroidism (HPT). The pathology of HPT can be grouped into three general categories: a single parathyroid adenoma (83% to 85% of cases), multiglandular hyperplasia (15%), and parathyroid cancer (0.5% to 3.0%).<sup>7</sup> The proportion of HPT patients who truly have parathyroid cancer is likely to be well under the 2% of cases more recently quoted.<sup>2</sup> The epidemiologic and pathologic characteristics of these three general categories of HPT are shown in [Table 38.3-1](#).

Cause	Frequency	Etiologic Factors	Gender	Patient		Microscopic
				Age (y)	Course	
Adenoma	83-85%	Isolated exposure	M:F 1:1	35-60	Single enlarged nodular benign gland	Nests of parathyroid chief cells decreased; capsule may be pushed into or normal tissue
Hyperplasia	15%	Familial or multiple endocrine neoplasia 1 and 2	M:F	25-60	Asymmetric enlargement with enlargement of 3 glands	Similar to adenoma; minimal intercellular fat
Carcinoma	<1%	Familial/Isolated exposure	M:F	60-80	Single large firm white/grey mass frequently involving thyroid or strap muscle	Tubular arrangement of tumor cells divided by fibrous bands; nests by capsular invasion; capsular invasion; vascular invasion

**TABLE 38.3-1.** Comparison of the Various Causes of Primary Hyperparathyroidism

#### PATHOLOGY

Schantz and Castleman defined the pathologic criteria used to distinguish parathyroid carcinoma from benign parathyroid adenoma in a classic article in 1973.<sup>8</sup> Thick fibrous bands, pleomorphic cells in a trabecular pattern, and a high incidence of mitotic figures are the chief distinguishing features<sup>8,9</sup> ([Fig. 38.3-1](#) and see [Table 38.3-1](#)). Invasion of the glandular capsule and vascular invasion are also found with parathyroid carcinoma. However, as with other endocrine neoplasms, the diagnosis of parathyroid carcinoma strictly is difficult on histologic evaluation using the criteria outlined previously.<sup>10,11</sup> There is a spectrum of these changes present in benign adenomas, atypical adenomas, and true carcinomas. Even histologic evidence of capsular or vascular invasion is not pathognomonic for parathyroid cancer as spontaneous hemorrhage in large benign parathyroid adenomas may result in a similar histologic appearance.<sup>12</sup>

**FIGURE 38.3-1.** Pathologic characteristics that are used to define a lesion as a parathyroid carcinoma are shown in these two panels. **A:** A low-power view demonstrates dense fibrous bands with the cells arranged in a trabecular pattern (*arrowheads*) and evidence of capsular invasion (*arrows*). **B:** A high-power view documents a high number of mitotic figures (*arrows*) in one single field of view.

In addition to the histologic criteria, both the clinical course and the gross pathology observed at operation help to define a lesion as parathyroid cancer.<sup>12</sup> The typical

clinical presentation is discussed in greater detail here, but parathyroid carcinoma tends to have a higher serum calcium level, more marked symptoms of HPT, and larger lesions that may be palpable in the neck. The operating surgeon finds a large lesion that is more firm than typical adenomas.<sup>10</sup> The color of parathyroid carcinoma is frequently gray-brown versus the red-brown of benign lesions, reflecting the increased fibrous stroma within these tumors.<sup>10</sup> Most important, parathyroid carcinoma may locally invade into adjacent structures such as the ipsilateral thyroid gland or overlying strap muscles of the neck. This gross pathologic feature is infrequently seen with benign lesions.<sup>8,9</sup> and <sup>10</sup>

In the past decade, several groups have used flow cytometry to analyze DNA content in parathyroid carcinomas compared with adenomas. In three series, a consistent proportion between 31% and 56% of parathyroid carcinomas were documented to be aneuploid.<sup>13,14</sup> and <sup>15</sup> The DNA content of parathyroid adenomas is not as consistent, with one group reporting no aneuploidy in 32 patients<sup>13</sup> and other groups reporting proportions in the range of one-third aneuploid similar to parathyroid carcinoma.<sup>2</sup> A second piece of information that these studies report is that aneuploidy is a prognostic indicator for parathyroid carcinoma. August reported that four out of five patients with aneuploid parathyroid carcinoma died of disease with the fifth alive with extensive recurrence, while four of four patients with diploid parathyroid carcinoma were cured with no evidence of recurrence after parathyroid surgery.<sup>15</sup>

## EPIDEMIOLOGY

The incidence of parathyroid cancer is most commonly reported in the context of primary HPT. Most endocrine surgeons report 0.5% to 4.0% of all HPT as being parathyroid carcinoma (Table 38.3-2). Because the estimate of the annual incidence of primary HPT is reported to be 1 per 2000,<sup>1</sup> then if 1% of HPT is parathyroid cancer, the incidence of this malignancy would be approximately 0.5 per 100,000 persons. This incidence is clearly an overestimation as it would place the annual number of parathyroid cancers in the United States more than 1000 new cases, which greatly exceeds the actual number. Several tertiary institutions have reported their total experience with parathyroid carcinoma over several decades in the setting of more than 1000 cases of primary HPT. The Mayo Clinic,<sup>3</sup> the Cleveland Clinic,<sup>16</sup> and the University of Michigan<sup>17</sup> reported an overall proportion of parathyroid cancer in HPT of 0.6%, 0.47%, and 0.37% (see Table 38.3-2). However, even these numbers may be overestimates as these tertiary institutions are more likely to be referred these patients with this rare diagnosis. A review from a tertiary referral center in Padua, Italy, reported 5.2% of all patients operated on for HPT between 1980 and 1996 were parathyroid cancers.<sup>18</sup> This unusually high proportion does not appear to be an overestimation due to inaccurate pathology as 13 of 16 had metastases and two had multiple local recurrences. Thompson at the University of Michigan reported an incidence of two parathyroid carcinomas in 1450 initial parathyroid operations for HPT over the past two decades at the University of Michigan for a percentage of 0.14%.<sup>17</sup> The National Cancer Database reported 286 cases of parathyroid cancer in a 10-year period. This group believed that it captured 60% to 80% of all cancers in the United States during that time interval. If that estimate is correct, then there are only 36 to 48 cases of parathyroid cancer annually in the United States. With an incidence of 0.015 per 100,000 population, parathyroid cancer is one of the most rare of all human cancers. Because of this low incidence, there is no American Joint Committee on Cancer Staging system for parathyroid cancer.<sup>6</sup>

Institution	Year	Number of Cases		Percentage of Cancer	Age (Mean/Range)	Tumor Size (cm)	Serum Calcium (mg/dL)
		Total Parathyroid Operations	Parathyroid Carcinomas

**TABLE 38.3-2.** Demographics, Proportion of Primary Hyperparathyroidism That Is Parathyroid Cancer, Tumor Size, and Calcium Levels in More Recent Institutional Series of Parathyroid Cancer

The gender distribution is equal or has a slight female preponderance in most series and differs from benign parathyroid adenomas, which have a higher female predominance<sup>2,6,7,9</sup> (see Table 38.3-2). The age at diagnosis can vary between 19 and 81 and the median age in most series is between 45 and 51 years. The large National Cancer Database series had essentially an equivalent gender distribution (51% male and 49% female subjects) and a mean and median age of 54.5 and 55.1 years, respectively. There was also no disproportional incidence by race in this report with 76.2% non-Hispanic white, 12.2% black, 7.3% Hispanic, and 4.2% others.<sup>6</sup> There are no documented etiologic causes for this malignancy, although there is a familial association in a few series. Parathyroid cancer has been reported and documented in members of multiple endocrine neoplasia 1 kindreds.<sup>19</sup> In this autosomal dominant disease, the predominant endocrine abnormality is multiglandular benign hyperplasia of the parathyroids. Familial non-multiple endocrine neoplasia 1 associated parathyroid cancer has been reported in siblings<sup>20</sup> and in one report, several relatives across two generations had parathyroid carcinoma.<sup>21</sup> This study also reported other relatives with primary HPT who had atypical adenomas, implying a connection between this benign pathologic entity and true parathyroid carcinoma. External radiation exposure has been correlated with parathyroid neoplasms, but virtually all reports describe an association between radiation and the more common parathyroid adenoma, although there are isolated case reports of patients with parathyroid carcinoma who had a history of radiation treatments in the distant past.<sup>22</sup> Patients with renal failure typically experience secondary HPT with nonclonal hyperplasia of all parathyroid glands, but 13 cases of parathyroid cancer have been reported in the literature in this clinical setting.<sup>23</sup>

## CLINICAL PRESENTATION

Because virtually all parathyroid carcinomas are functional, meaning they produce high and unregulated levels of PTH, the signs and symptoms of this disease relate primarily to the consequences of this hormone excess. Specifically, various manifestations of renal disease associated with hypercalcemia and hypercalcuria such as renal stones, renal colic, nephrocalcinosis, renal insufficiency, or all of these manifestations occur in up to 90% of cases<sup>24,25</sup> (Table 38.3-3). Also, the prevalence of bone disease related to calcium absorption with osteoporosis and bone pain is much greater in parathyroid carcinoma than in patients with parathyroid adenoma,<sup>26,27</sup> with up to 70% of patients manifesting the symptoms. In nonmalignant parathyroid disease, it is unusual to have both renal and bone symptomatology documented at the time of diagnosis.<sup>28</sup> However, these symptoms are present simultaneously at diagnosis in up to 50% of patients with parathyroid carcinoma (see Table 38.3-3).

	Adenoma	Carcinoma (Median Percentage, Range)
Renal	18%	60% (27-90%)
Skeletal	15-20%	55% (19-64%)
Renal and skeletal	<5%	32% (0-50%)
Peptic ulcer disease	3-13%	18% (0-22%)
Palpable neck mass	<2%	38% (22-48%)
Parathyroid crisis	<2%	14% (0-27%)
Asymptomatic	38-61%	3% (0-27%)
Serum calcium (mg/dL)	11-12	14-16

(Data from refs. 1-3, 5, 8, 9, 24-27, 43, 48, and 50.)

**TABLE 38.3-3.** Comparison of the Incidence of Signs and Symptoms at Presentation in Patients with Parathyroid Carcinoma versus Parathyroid Adenoma

These amplified symptoms reflect the increased magnitude of the biochemical disturbances seen with parathyroid carcinoma. The level of total serum calcium is significantly elevated in virtually all series of parathyroid carcinoma, with the mean values between 15 and 16 mg/dL compared with 11 to 12 mg/dL seen with

parathyroid adenomas<sup>2,25</sup> (see [Table 38.3-3](#)). Similarly, the PTH level in parathyroid carcinoma is consistently higher than for benign parathyroid disease, with more than 70% of patients having a greater than fivefold increase over the upper limits of normal for PTH.<sup>2,29</sup> Because of the high degree of hypercalcemia, it is unusual for patients to be asymptomatic at presentation with parathyroid carcinoma compared with patients with benign causes of HPT who are asymptomatic in more than 50% of cases in some series.<sup>26,27</sup> Up to 14% of patients with parathyroid carcinoma may present with hypercalcemic crisis manifested by a depressed level of consciousness, dehydration, and extreme hypercalcemia.<sup>5</sup> The size of the typical parathyroid carcinoma is much larger than benign lesions. The median maximal diameter in most series is between 3.0 and 3.5 cm compared with approximately 1.5 cm for benign adenomas<sup>8,9</sup> (see [Table 38.3-2](#)). This large mass translates into a significant number of patients who present with a palpable neck mass ranging between 22% and 50% of cases.<sup>9,24,25</sup> Again, it is extremely unusual for patients with benign lesions to have palpable abnormalities in the neck, and this is a clinical sign that strongly suggests parathyroid carcinoma. In 10% of cases, patients with parathyroid carcinoma present with symptoms of hoarseness caused by compression or invasion of recurrent laryngeal nerve and vocal cord paresis.<sup>2</sup>

## NATURAL HISTORY

The best information regarding the natural history of parathyroid carcinoma comes from a detailed review of 163 cases reported between 1981 and 1989<sup>2</sup> (summarized in [Table 38.3-4](#)). At initial presentation, few patients with parathyroid carcinoma have metastases either to regional lymph nodes (less than 5%) or distant sites (less than 2%). In the National Cancer Database series of 286 patients, only 16 (5.6%) had lymph node metastases noted at the time of initial surgery.<sup>6</sup> This report did not comment on the incidence of distant metastases and has a relatively short follow-up interval. A higher proportion of parathyroid carcinomas are locally invasive into the thyroid gland, overlying strap muscles, recurrent laryngeal nerve, trachea, or esophagus. Some patients are not identified preoperatively or intraoperatively as having parathyroid carcinoma and undergo parathyroid procedures as if to treat parathyroid adenoma. Only after review of the pathology following this resection, or when these patients have either local recurrences or metastases is a correct diagnosis of parathyroid carcinoma made. The incidence of not recognizing parathyroid carcinomas at initial operation ranges between 11% from the Lahey Clinic series (one in nine),<sup>30</sup> to 36% in the M. D. Anderson series (5 of 14),<sup>26</sup> and up to 86% in the Cleveland Clinic series (six of seven).<sup>16</sup>

<b>At initial presentation*</b>	
Local invasion	98%
Thyroid	1.0%
Recurrent laryngeal nerve	3.7%
Other (trachea, trachea, esophagus)	4.6%
Lymph node metastases	4.9%
Distant metastases	1.8%
<b>Recurrence after initial resection*</b>	
Local recurrence	50%
Lymph node recurrence	17%
Cervical	14%
Mediastinal	6.1%
Distant recurrence	25%
Lung	15%
Bone	6%
Liver	4%
<b>Outcome after surgical treatment*</b>	
Alive	60%
No evidence of disease	40%
Mean follow-up	4.6 y
Alive with disease	24%
Mean follow-up	7 y
Dead	39%
Caused by parathyroid carcinoma	30%
Caused by unrelated causes	9%

**TABLE 38.3-4.** Clinicopathologic Features, Natural History, and Outcome in Patients with Parathyroid Carcinoma

After surgical treatment, 40% to 60% of patients have recurrent disease at some point typically in the range of 2 to 5 years after the initial resection.<sup>29,31</sup> Since parathyroid carcinomas are functional, serial measurements of calcium or PTH serve as ideal tumor markers for this malignancy. In patients followed closely, hypercalcemia precedes physical evidence of recurrent disease in most cases. The most common location of recurrence is regionally either in the tissues of the neck or in cervical lymph nodes, accounting for two-thirds of the recurrent cases.<sup>2</sup> Often the local recurrences in the neck are difficult to identify as they may be small, multifocal, and involve the scar from the previous procedure. Use of ultrasound, sestamibi-thallium scanning,<sup>32,33</sup> and more recently positron emission tomographic scanning,<sup>34</sup> may aid in this difficult diagnosis. Distant metastases occur in 25% of patients, primarily in the lungs but also in the bone and liver<sup>2,35</sup> (see [Table 38.3-4](#)). More recently published series have reported a higher incidence of recurrence than prior studies. In nine patients from Brazil with parathyroid cancer with long-term follow-up, five had local or nodal neck recurrence (55%), three had lung metastases (33%), and one had bone metastasis (11%).<sup>36</sup> In a study of 16 patients from Italy, 13 had distant metastases (nine lung alone, four lung plus bone) and 2 others had local neck recurrences.<sup>8</sup> The reasons for this high incidence of recurrence between 94% and 100% may be due to more accurate pathologic diagnosis excluding patients with atypical adenomas.

Patients who experience parathyroid carcinoma typically die of metabolic consequences and not directly from malignant growth.<sup>35</sup> For this reason, surgical treatment to debulk parathyroid carcinoma, if possible, is indicated as medical management of the hypercalcemia of parathyroid carcinoma is difficult (see [Treatment](#), later in this chapter). The median survival after recurrent parathyroid cancer ranges between 3 and 5 years, with isolated case reports of patients surviving several decades with intermittent surgical debulking.<sup>31</sup>

## DIFFERENTIAL DIAGNOSIS

Other non-HPT causes of hypercalcemia can be ruled out primarily by the biochemical studies of serum PTH simultaneous with total and ionized serum calcium. Secondary HPT in the setting of renal failure is clinically obvious by the concomitant renal disease. There are isolated reports of development of parathyroid carcinoma in this clinical setting as well, however.<sup>37</sup> Once the diagnosis of primary HPT is established, the histopathologic diagnosis of parathyroid carcinoma may be difficult as discussed previously.<sup>10,12</sup> Supporting evidence of malignancy comes from markedly elevated calcium levels (greater than 14.0 mg/dL) and larger gland sizes (greater than 3.0 cm). In most reported institutional series, it is likely that parathyroid carcinoma is overdiagnosed.<sup>17,38</sup> In one such study, a careful review of the pathology in the context of the clinical course identified more than one-half of the patients with previously diagnosed parathyroid carcinomas as more appropriately considered as benign or atypical adenomas.<sup>38</sup> This difficulty in correctly identifying parathyroid carcinoma is also reflected by the wide variation in clinical outcome between different series. Some series report long-term disease-free survival at rates greater than 75%. One explanation for series in which outcomes are much better than the norm is that they include in their analysis patients with atypical parathyroid adenomas that were not truly malignant.<sup>17</sup> Other investigators take an opposite approach and include only cases in their institutional reviews that recur locally or manifest distant metastases.<sup>28</sup> This approach may underestimate the true incidence of cases of parathyroid carcinoma because there is a subgroup with this disease that may be cured with an aggressive initial resection.

Local recurrence of parathyroid neoplasms after initial resection does not necessarily establish the diagnosis of parathyroid carcinoma. Two patterns of benign lesions that recur locally have been described. First, patients with a single parathyroid adenoma may have partial or incomplete resection of a gland such that there is an isolated regrowth after the initial procedure in the exact position where the first abnormal gland was removed.<sup>39</sup> The recurrent gland grows in an area of fibrosis and scar, and may well give the gross appearance of an invasive carcinoma, but detailed pathologic analysis of the initial or recurrent specimen shows no evidence of carcinoma in terms of mitotic figures, cellular appearance, or fibrous bands. A second category of nonmalignant recurrent disease is a condition called parathyromatosis.<sup>37,40</sup> Parathyromatosis is a diffuse seeding of the cervical tissue with parathyroid cells that implant and grow. This occurs when lesions that are being excised have the capsule ruptured and are spilled or when lesions are partially removed with a raw surface of the adenoma exposed to the field of dissection. This condition is much more difficult to treat than isolated local recurrence and is tantamount to a nonmetastasizing locally recurrent carcinoma, and this condition has been described with lesions that have absolutely no pathologic or clinical manifestations of parathyroid carcinoma.

## TREATMENT

The only effective treatment of parathyroid cancer is surgical resection. The most important component to achieve a favorable outcome is recognition by the operating surgeon that a lesion is likely to be a parathyroid cancer, which allows performance of the appropriate *en bloc* resection of the tumor with all potential areas of invasion at the initial operation ([Fig. 38.3-2](#)).<sup>30,31</sup> Patients with extremely high serum calcium levels (greater than 13.5 mg/dL) should lead the physician to suspect parathyroid cancer preoperatively. Other clinical features that suggest parathyroid cancer are a palpable mass and hoarseness. Intraoperatively, if a large lesion is identified, particularly if it is firm or scirrhous, then the operating surgeon should assume the lesion is parathyroid cancer and do an *en bloc* resection. The practice of minimally invasive parathyroidectomy, which is appropriate in the vast majority of patients with HPT, should be altered in these clinical situations.<sup>41</sup> Parathyroid cancer typically invades the ipsilateral thyroid lobe, and resection of the tumor with one or both thyroid lobes is frequently required to perform an adequate operation.<sup>30</sup> In most series, long-term results in terms of local recurrence are significantly improved when an *en bloc* excision including thyroid is done as opposed to cases in which

only the parathyroid cancer is removed.<sup>30,31</sup> The recognition and diagnosis of parathyroid cancer preoperatively correlates strongly with a favorable outcome. In a small series of seven patients from the Cleveland Clinic, six had parathyroid carcinomas that were not appreciated until after the procedure.<sup>16</sup> All of these patients had recurrences, whereas the one case that was known to be a parathyroid cancer preoperatively underwent an *en bloc* resection with long-term disease-free survival. The recurrent laryngeal nerve may be intimately involved or invaded by the parathyroid cancer. In these situations, patients frequently have preoperative hoarseness due to the tumor invasion of the nerve.<sup>2</sup> Because the nerve is at risk for loss of function due to the malignant process itself, it is appropriate to resect the recurrent laryngeal nerve if necessary to perform an *en bloc* excision during the initial procedure for parathyroid cancer. The increased potential for long-term local control achieved by this approach outweighs the complication of postoperative vocal cord paralysis, which can be improved with techniques such as Teflon injection into the paralyzed cord. Assessment of cervical lymph nodes, particularly level 6 paratracheal nodes and levels 3 and 4 internal jugular nodes, should be performed with node dissection only for enlarged or firm lesions.

**FIGURE 38.3-2.** *En bloc* resection of an isolated recurrence of a parathyroid carcinoma as shown after a partial dissection. The parathyroid cancer is resected together with overlying strap muscles and the left lobe of the thyroid gland. This *en bloc* specimen is being retracted laterally in clamps. The midline structure is the trachea that is completely cleared of surrounding tissues. This patient is alive and well with no evidence of recurrent disease or recurrent hypercalcemia 3 years after this resection for an isolated local recurrence.

For most cases of recurrent parathyroid carcinoma confined to the neck, the most appropriate treatment is aggressive resection. However, as opposed to the initial procedure in which the success rate is up to 40% to 60%, it is unusual to obtain long-term cures in patients who have to undergo resection.<sup>5</sup> In a large series from the Mayo Clinic, no patients who underwent resection were cured.<sup>3</sup> However, there are selective patients described in the literature who have disease-free intervals greater than 10 years after two or three local resections in the neck.<sup>11,17</sup> The benefit of sacrificing the recurrent laryngeal nerve is greatly decreased in patients undergoing resection for recurrent parathyroid cancer as most recurrences are multifocal. If a recurrent nodule involves the recurrent laryngeal nerve, there are most likely other areas of parathyroid cancer that are adherent to the trachea, esophagus, and great vessels of the neck. Since it is impossible to remove all of these vital structures, one is unlikely to obtain a cure by taking the nerve. However, in certain circumstances in which there is an isolated local recurrence that is involving the nerve, it again should be sacrificed with an *en bloc* resection as those patients' conditions, in rare instances, may be salvaged by an aggressive surgical procedure (see Fig. 38.3-2).

Nonsurgical forms of therapy for parathyroid carcinoma have generally poor results such that surgical treatment of distant metastases is appropriate in certain situations. Pulmonary metastases as well as bone metastases should be resected, if possible, primarily to debulk tumor to decrease the magnitude of the hypercalcemia.<sup>42,43</sup> However, occasionally long-term salvage is achieved in this group of patients with aggressive surgical treatment.

Radiation therapy, in general, does not result in meaningful antitumor responses.<sup>44</sup> Isolated case reports of long-term control exist, and radiation therapy should be used in patients with unresectable recurrent cervical disease.<sup>11</sup> Various chemotherapeutic agents alone or in combination have been used for treatment of parathyroid carcinoma with limited success.<sup>44</sup> Dacarbazine alone or in combination with 5-fluorouracil and cyclophosphamide have been reported to result in objective responses, including one complete response in a patient with pulmonary metastases.<sup>44,45</sup> Other combination therapies have resulted in rare responses. Part of the problem with the medical treatment of parathyroid carcinoma is that the rarity of this disease does not allow systematic evaluation of various combination therapies.

The second aspect of medical management for metastatic parathyroid carcinoma relates to the treatment of the hypercalcemia.<sup>40</sup> Acute therapy of patients with hypercalcemic crises or high serum calcium levels is similar to that used for other causes of symptomatic hypercalcemia. Volume loading with loop diuretics causing a forced diuresis is the initial therapy. For patients with parathyroid carcinoma, the ultimate management of the hypercalcemia is directed at the tumor to decrease the level of PTH, if possible, by surgical treatment. In situations in which surgical resections are no longer possible, the treatment of hypercalcemia is difficult, and this metabolic abnormality is the primary cause of death for the majority of these patients.<sup>26,27,31</sup> The most effective agents in this setting are the bisphosphonates that inhibit osteoclast bone resorption.<sup>44,46</sup> Two agents available in the United States are etidronate and pamidronate. Other agents used in other settings of hypercalcemia such as plicamycin (formerly mithramycin) and calcitonin have limited benefit.<sup>44</sup> Gallium nitrate has also been used as an inhibitor of bone reabsorption, but is limited by nephrotoxicity.<sup>17,47</sup> All agents used to date in the setting of high tumor burden from parathyroid carcinoma have a limitation that the patients become refractory after initial treatment. Newer generations of more potent bisphosphonates may hold some promise for symptomatic management of this group of patients.<sup>44</sup>

## OUTCOME

The ability to achieve long-term survival in patients with parathyroid carcinoma ranges between 18% and 78% in various series.<sup>2,5,24,25,48</sup> The 5- and 10-year overall survival rates for patients with resected parathyroid carcinoma are shown in Table 38.3-5. A summary of 251 patients analyzed shows a 5-year survival of 57% and a 10-year survival of 39%. The National Cancer Database reported a 5-year survival at 55.5% and a 10-year survival of 49.1% in 286 patients treated.<sup>6</sup> These two large series accounted for the majority of cases of parathyroid cancer in the literature and provides an accurate assessment of outcome. The majority of patients who have recurrences after initial surgery ultimately succumb to this disease because there is a much lower rate of salvage after second or third procedures. For patients with local recurrences or distant metastases, only between 0% and 15% have long-term cures after secondary resections as there is no meaningful nonsurgical therapy.

Institution	Year Interval	N	5Y Survival (%)	10Y Survival (%)

## **PATHOLOGY OF THE ADRENAL CORTEX**

### **HYPERPLASIA**

The term *hyperplasia* is defined as an increased number of cells.<sup>1</sup> It is a pathologic change associated with increased function or compensatory change. When a pituitary adrenocorticotropic hormone (ACTH)-secreting tumor produces hypercortisolism (Cushing's disease), the most common form of endogenous hypercortisolism, the adrenal gland is approximately twice normal size. The weight of each hyperplastic adrenal is between 6 and 12 g (normal adrenal weighs between 3 and 6 g). Microscopically there is a widened inner zone of the compact zona reticularis and a sharply demarcated outer zone of clear cells. Adrenal glands in ectopic ACTH syndrome are larger in size, weighing between 12 and 30 g. Macronodular adrenal hyperplasia (3-cm adrenocortical nodules weighing between 30 and 100 g) usually is a secondary response of the adrenal to ACTH, but may occur with primary adrenal pathology. Primary pigmented micronodular adrenal hyperplasia (1- to 5-mm nodules with pigmented appearance and normal glandular weight) is more likely to be autonomous and to occur in children<sup>2</sup> and can occur in a familial pattern.<sup>2</sup>

### **ADRENAL CORTICAL ADENOMA**

Adrenal adenoma is a benign neoplasm of adrenal cortical cells that may possess functional autonomy.<sup>1</sup> In general, an adenoma does not exceed 5 cm in diameter nor 100 g in weight. Some cellular pleomorphism and tumor necrosis may be present, but is rare. It is not possible to describe the exact functional type of neoplasm based solely on histology, although there are consistent differences. Adenomas produce syndromes of hypercortisolism and hyperaldosteronism and seldom produce adrenogenital syndromes. Tumors larger than 6 cm that produce adrenogenital syndromes are usually carcinoma. Pleomorphism, tumor necrosis, and mitotic activity are more common in malignant tumors. The prognosis of adrenal cortical adenoma producing Cushing's syndrome is excellent, and surgical resection invariably produces cure. The prognosis of adrenal cortical adenomas producing hyperaldosteronism may not be as favorable. Resection is followed by a favorable response in blood pressure and serum level of potassium; however, 30% of patients develop recurrent hypertension. Adenomas that produce the adrenogenital syndrome have the least favorable outcome, because many of these tumors are really carcinomas.<sup>3</sup>

### **ADRENAL CORTICAL CARCINOMA**

Adrenal cortical carcinoma is a malignant neoplasm of adrenal cortical cells demonstrating partial or complete histologic and functional differentiation. Adrenal cortical carcinomas are rare and compose between 0.05% and 0.20% of all cancers. This incidence translates to a rate of only 2 per million in the world population. Women develop functional adrenal cortical carcinomas more commonly than men. However, men develop nonfunctioning malignant adrenal tumors more often than women. There is a bimodal occurrence by age, with a peak incidence less than 5 years and a second peak in the fourth and fifth decade. Adrenal cortical carcinoma has been described as part of a complex hereditary syndrome, including sarcoma, breast, and lung cancer.<sup>4</sup> Studies suggest that loss of heterozygosity on the short arm of chromosome 11 (11p) may be important in the pathogenesis of adrenocortical cancer.<sup>5</sup> Germline P53 mutations do not appear to be involved.<sup>6</sup> In a study from a region in Brazil with a tenfold higher incidence of adrenocortical cancer, eight of nine tumors had an increase in genetic material in the chromosomal region 9q34, suggesting that these changes may also be important.<sup>7</sup> In addition, deficiency of 21-hydroxylase (P-450c21), an essential enzyme for zona glomerulosa and fasciculata function, has also been implicated. Prevalence of heterozygous germline mutations in the P-450c21 gene has been noted to be increased in patients with adrenocortical tumors.<sup>8</sup> The myriad of genetic changes seen in different studies of these tumors may explain the association of adrenocortical cancer with complex hereditary syndromes.

Adrenal cortical carcinomas are greater than 6 cm in size and weigh between 100 and 5000 g. Areas of necrosis and hemorrhage are common. Invasion and metastases also occur. Microscopically, the appearance is variable. Cells with big nuclei, hyperchromatism, and enlarged nucleoli are all consistent with malignancy.<sup>1</sup> Nuclear pleomorphism is more common in tumors larger than 500 g. Vascular invasion and many mitoses are diagnostic of malignancy. Broad desmoplastic bands are associated with metastatic potential of tumors. The diagnosis of malignancy in cortical tumors that weigh between 50 and 100 g is less certain. Furthermore, the distinction between adrenal and renal carcinoma may also be difficult. Immunostaining for vimentin, epithelial membrane antigen, cytokeratin, and blood group antigens may be used to distinguish the two diagnoses. Adrenal tumors stain positive for vimentin, whereas renal carcinoma is negative for vimentin but positive for the others.<sup>9</sup> Although the difference in natural history between benign and malignant adrenal cortical neoplasms is clear, it is not always possible to histologically separate one from the other. The only reliable, single criterion is the presence of nodal or distant metastases. The data used to differentiate benign from malignant adrenocortical neoplasms include whether and what type of hormone is produced, amount of tumor necrosis, fibrosis, inhibin, 21-hydroxylase deficiency, vascular invasion, mitoses, and tumor weight ([Table 38.4-1](#)). The detection of mitotic activity and venous invasion suggest a malignant tumor.<sup>10</sup> Aneuploidy is also associated with cancer.<sup>11</sup> Quantitative nuclear analysis demonstrates that nuclei from adrenal cancers are larger than adenomas, and DNA density is diploid in adenomas and aneuploid in carcinomas.<sup>12</sup> A final criterion is based on the observation that cells from carcinomas produce abnormal amounts of androgens and 11-deoxysteroids.<sup>13</sup> However, this is merely suggestive of malignancy, because only 10% of malignant tumors produce masculinization whereas the rest secrete cortisol, aldosterone, or nothing (see [Table 38.4-1](#)).

Attribute	Clinical Criteria	Pathologic and Genetic Criteria
Diagnosis of malignancy	Negligible necrosis, mitotic or atypical mitoses	Tumor weight > 100 g, tumor necrosis, fibrous bands, vascular invasion, number of mitoses per high-power field
Consistent with malignancy	Hyaline, Cushing's cells, no hormone production	Nuclear pleomorphism, anaplasia
Aggressive malignancy	Elevated activity of telomerase	Capillary invasion, mitosis, telomerase deficiency?
Variable	Hypercortisolism, hyperaldosteronism	Tumor giant cells, cytoplasmic size variation, ratio between compact and clear cells

*Cytokeratin immunohistochemistry*

## CLINICAL PRESENTATIONS OF ADRENAL CORTICAL NEOPLASMS

### CUSHING'S SYNDROME (HYPERCORTISOLISM)

#### Signs

Cushing's syndrome, or hypercortisolism, is the result of excessive secretion of ACTH by a pituitary tumor, cortisol by an adrenal tumor, or ACTH by an ectopic source. Determining the cause of the hypercortisolism involves performing multiple tests in a logical sequence ( Fig. 38.4-1). Treatment should aim to cure the hypercortisolism and eliminate any tumor that threatens the patient's health, while minimizing the chance of endocrine deficiency or long-term dependence on medications.<sup>14</sup> The signs and symptoms of hypercortisolism are ubiquitous and diverse; nearly every organ in the body is affected.<sup>15</sup> However, there is no single symptom or sign that is common to every patient. Although hypercortisolism is the most common presentation for adrenal cortical neoplasms, Cushing's syndrome is rare, with an estimated incidence of only 10 per million population.<sup>16</sup> Cushing's syndrome can also rarely occur in children.<sup>16</sup> The most common cause of hypercortisolism is iatrogenic administration of steroids to treat other diseases. The most common cause of endogenous hypercortisolism is a pituitary tumor that makes ACTH, or Cushing's disease. Hypercortisolism is not usually associated with multiple endocrine neoplasia type 1 (MEN 1), although it can be present in this familial syndrome. It has been reported to be present in 5% of patients with sporadic Zollinger-Ellison syndrome (ZES) and 19% of patients with ZES and MEN 1.<sup>17</sup>

**FIGURE 38.4-1.** Flow diagram for evaluation of a patient with suspected hypercortisolism. ACTH, adrenocorticotropic hormone; Bil., bilateral; cal, calcitonin; CT, computed tomography; Dex, dexamethasone; MR, magnetic resonance imaging; nl, normal; PP, pancreatic polypeptide; PPNAD, primary pigmented nodular adrenocortical disease; VIP, vasoactive intestinal polypeptide.

Progressive weight gain is the most universal symptom of patients with hypercortisolism. Obesity is usually truncal, and patients have thin extremities due to muscle wasting. Increased fat in the dorsal neck region combined with kyphosis secondary to osteoporosis gives the appearance of a “buffalo hump.” Serial photographs show a rounding of the face. Increased blood pressure is mild and caused by excess mineralocorticoid secretion. Striae are reliable clinical signs of Cushing's syndrome. Hirsutism consists of excessive fine hair on face, upper back, and arms. Virilization, including clitoromegaly, deep voice, and balding, suggest adrenocortical carcinoma. Glucose intolerance with hyperglycemia is common, and patients may present with diabetes mellitus. Weakness secondary to muscle atrophy is a common complaint and is especially common in ectopic ACTH syndrome with hypokalemia. Menstrual irregularity or amenorrhea is common in women, whereas men with Cushing's syndrome have loss of libido or impotency. In children, the most common presenting sign is obesity and an arrest of normal growth with short stature. Dilatation of blood vessels and thinning of the subcutaneous tissue give the face a ruddy appearance. Mental changes vary from mild depression to severe psychosis and appear to correlate directly with serum levels of cortisol and ACTH. Hypokalemia worsens the weakness associated with Cushing's syndrome and suggests the diagnosis of adrenocortical carcinoma or ectopic ACTH syndrome. Immunosuppression results in unusual infections, including cryptococcosis, aspergillosis, nocardiosis, *Pneumocystis carinii*, and necrotizing fasciitis.<sup>18,19,20 and 21</sup> The early diagnosis of Cushing's syndrome depends primarily on a knowledge of the many different signs and symptoms of the disorder and a high clinical index of suspicion.<sup>22</sup>

#### Workup and Diagnosis

The initial step in the workup of a patient with presumptive hypercortisolism is to establish biochemically whether hypercortisolism is, in fact, present. The second step is to determine whether the hypercortisolism is “pituitary dependent” or “pituitary independent,” and the final step is to determine the exact etiology (see Fig. 38.4-1). Current laboratory testing allows the correct diagnosis in nearly every case.<sup>14,15</sup>

**ESTABLISHING HYPERCORTISOLISM.** Urinary excretion of unmetabolized (“free”) cortisol is directly proportional to the amount of free cortisol in the plasma. As the cortisol-binding globulin becomes saturated (plasma cortisol levels of 20 µg/dL), small increases in cortisol secretion produce exponential increases in urinary free cortisol. This amplification effect makes 24-hour urinary free cortisol the single best measurement to discriminate normal from hypercortisolemic states. The overnight single-dose dexamethasone test (see Fig. 38.4-1) works because of lack of normal feedback (Fig. 38.4-2) that occurs in all forms of hypercortisolism. Normal subjects given 1 mg of dexamethasone orally at 11:00 p.m. have plasma cortisol levels of less than 5 µg/dL at 8:00 a.m. the next day. Patients with endogenous hypercortisolism do not suppress and have cortisol levels greater than 5 µg/dL. The major disadvantage of this test is a 3% incidence of false-negatives (patients with Cushing's syndrome whose levels suppress). This test may also have false-positives (3%), including depression, alcoholism, stress, and primary cortisol resistance. A normal single-dose dexamethasone test and urinary free cortisol (less than 100 µg/d in most laboratories) virtually exclude the diagnosis of hypercortisolism.

**FIGURE 38.4-2.** Model of cortisol secretion indicates the mechanism of dexamethasone suppression and corticotropin-releasing hormone (CRH) stimulation of normal cortisol secretion. ACTH, adrenocorticotropic hormone.

**ETIOLOGY OF HYPERCORTISOLISM.** Patients with pituitary tumor (Cushing's disease) respond to 1 µg/kg corticotropin-releasing hormone (CRH) by increasing plasma ACTH and cortisol levels, whereas patients with depression or other stress diseases have a blunted ACTH response to CRH<sup>23</sup> (see Fig. 38.4-1 and Fig. 38.4-2). The CRH test also distinguishes pituitary tumor from ectopic secretion of ACTH. Twenty-nine of 33 patients with Cushing's disease had increased plasma ACTH and cortisol levels after a CRH test, whereas none of 8 with ectopic ACTH responded.<sup>24</sup> Patients with Cushing's syndrome have abnormalities in the diurnal rhythm of plasma levels of cortisol and ACTH. Serial samples over days are necessary because patients with Cushing's disease can have episodic secretion of cortisol. Nevertheless, a low midnight cortisol level (less than 2 µg/dL) excludes the diagnosis of endogenous hypercortisolism. Determination of plasma ACTH levels may also be helpful. Patients with primary adrenal tumors or hyperplasia have undetectable or low plasma ACTH levels, those with pituitary-dependent hypercortisolism have intermediate levels, and those with ectopic ACTH-producing tumors have very high levels; approximately 60% of these patients have ACTH levels greater than 300 pg/mL. Radioimmunoassays for ACTH in plasma have been difficult to perform reliably and interpret because of platelet-associated proteases that degrade ACTH. Samples must be collected using recommended procedures, including prechilled tubes on ice. Urinary 17-ketosteroids can help the differential diagnosis of hypercortisolism. Low levels (less than 10 mg/d) suggest an adrenal adenoma, and very high levels (more than 60 mg/d) occur more commonly in patients with adrenal cancer and ectopic ACTH. Hypokalemia is seen in most patients with ectopic ACTH (16 of 16 in one series) and in only 10% of patients with Cushing's disease.<sup>25</sup>

The standard dexamethasone suppression test is the most useful test in establishing the cause of hypercortisolism (see Fig 38.4-1 and Fig 38.4-2). The expected results are that urinary free cortisol levels will be markedly suppressed when normal subjects receive a low dose (2 mg) of dexamethasone, but levels do not suppress in patients with Cushing's syndrome. High-dose dexamethasone (8 mg/d) suppresses urinary levels of free cortisol to less than 50% of baseline levels in patients with pituitary-dependent hypercortisolism (Cushing's disease), but it does not suppress levels in patients with primary adrenal causes of hypercortisolism or ectopic ACTH syndrome. This single test makes the diagnosis of Cushing's syndrome and determines the cause of hypercortisolism with an accuracy rate of approximately 95%.

The metyrapone test, which is a stimulation test in patients with pituitary Cushing's disease, can be complementary to the dexamethasone suppression test, and combining both tests results in greater accuracy than with either test alone.<sup>26</sup>

**RADIOLOGIC EVALUATION OF HYPERCORTISOLISM.** Computed tomography (CT) scans of the sella detect a tumor in only 0% to 15% of patients with pituitary-dependent Cushing's disease, and detect minor abnormalities in 23% to 60%. Most ACTH-secreting tumors are microadenomas (less than 5 mm). Pituitary magnetic resonance imaging (MRI) studies, even with gadolinium, have similar resolution. In patients with pituitary-dependent hypercortisolism, CT and MR may be normal, but bilateral petrosal sinus sampling for ACTH concentrations detects the side with a tumor in most cases.<sup>27</sup> Data indicate that this study is the single best method to differentiate a pituitary from an ectopic ACTH-producing tumor. The study requires bilateral sampling of the inferior petrosal sinus and peripheral veins for plasma ACTH levels before and after CRH. A petrosal sinus to peripheral plasma ACTH level of greater than 3 after CRH administration correctly identifies patients with Cushing's disease (sensitivity, 100%) with few false-positive results (specificity, 100%). Furthermore, petrosal sinus sampling provides correct localization of the ACTH-producing microadenoma in most patients.<sup>27</sup> It is the study of choice both to diagnose and localize pituitary tumors in patients with Cushing's disease.

Adrenal CT can detect normal adrenal glands in most patients. CT can reliably distinguish cortical hyperplasia from tumor.<sup>28</sup> CT has great sensitivity (more than 95%); however, it lacks specificity. In a patient with Cushing's syndrome, early detection of an adrenal neoplasm by CT simplifies the workup. CT can be used to image the primary tumor plus local and distant metastases in patients with cancer. In these cases, the primary tumor is usually greater than 6 cm.<sup>29</sup> Approximately 15% of patients with Cushing's syndrome have a primary adrenal neoplasm as the source of the hypercortisolism. Unilateral adrenal tumors require the detection of a normal adrenal gland on the contralateral side. Adrenal hyperplasia may also be detected if both glands appear enlarged. MRI may be able to add specificity to the sensitivity of CT. MRI may be able to distinguish adrenal adenoma from carcinoma and pheochromocytoma by the appearance on the T2-weighted image. Adenomas appear darker than the liver on the T2 MRI. Carcinomas, whether primary adrenocortical or metastatic, appear as bright as or slightly brighter than the liver on T2 image. Pheochromocytomas appear much brighter (three times) than the liver on T2 MRI.<sup>29</sup>

Radioisotope imaging of adrenals using labeled iodocholesterol, such as <sup>131</sup>I-6-b-iodomethylnorcholesterol, can be used to distinguish adenoma from hyperplasia.<sup>30</sup> It can help differentiate a benign cortical neoplasm (adenoma), which usually takes up iodocholesterol (images), from a malignant cortical neoplasm (carcinoma), which usually does not.<sup>31,32</sup> This is not absolute, however, because adrenal cortical carcinomas may take up iodocholesterol and be "hot" on scan.<sup>33</sup> Iodocholesterol scan can be helpful in micronodular hyperplasia in which bilateral uptake confirms the diagnosis. It can image ectopic rests of adrenal tissue. The disadvantages of radioiodocholesterol scans are exposure to radiation, limited isotope availability, and poor imaging of malignant adrenal neoplasms.

**INTERPRETATION OF WORKUP FOR CUSHING'S SYNDROME.** Once the biochemical tests confirm endogenous hypercortisolism, the remainder of the workup can pinpoint its cause. If it is caused by an adrenal cortical neoplasm, the workup will produce the following results: (1) imaging of the tumor on CT and MRI, (2) low plasma ACTH levels with elevated serum cortisol levels, and (3) no suppression of urinary free cortisol level with high-dose dexamethasone. If criterion number 1 is absent but numbers 2 and 3 are present, primary pigmented nodular adrenocortical disease should be ruled out by iodocholesterol scan (see Fig. 38.4-1). If criteria numbers 1 and 3 are present but ACTH levels are consistently elevated, urinary catecholamines, vanillylmandelic acid (VMA), and metanephrines should be measured because the patient may have an ACTH-producing pheochromocytoma.<sup>34</sup>

In ectopic ACTH syndrome, one finds (1) enlargement of both adrenals on CT, (2) elevated plasma ACTH levels, (3) no suppression with high-dose dexamethasone, and (4) no evidence of pituitary ACTH secretion on petrosal sinus sampling.<sup>35</sup> Bronchial carcinoid tumors are the most common site of ectopic ACTH secretion and are potentially curable. Lobectomy is required, because a significant proportion has nodal metastases. Some bronchial ACTH-producing carcinoid tumors may suppress with dexamethasone, but the false suppression of ectopic ACTH-producing tumors is rare.<sup>36</sup> Malignant tumors, such as Ewing's sarcoma, have been rarely determined to secrete a CRH-like factor that causes Cushing's syndrome.<sup>36</sup> Studies from the Netherlands suggest that OctreoScan (somatostatin receptor scintigraphy) may be useful to image the source of ectopic ACTH. It correctly identifies 80% of ACTH-secreting carcinoid tumors (either bronchial or thymic carcinoids).<sup>37</sup>

In Cushing's disease (pituitary adenoma), one expects to find (1) bilateral hyperplasia of the adrenal glands, (2) normal or mildly elevated plasma ACTH levels, (3) no suppression with low-dose dexamethasone and suppression with high-dose dexamethasone, and (4) localization with petrosal sinus sampling. Occasionally (less than 5% of instances) results may be confused with ectopic ACTH syndrome. This is not common,<sup>38</sup> however, and most studies show that petrosal sinus sampling eliminates the ambiguity.

## CONN'S SYNDROME (PRIMARY ALDOSTERONISM)

### Signs, Symptoms, and Diagnosis

Aldosterone overproduction with elevated plasma levels is the cause of hypertension in patients with primary aldosteronism, or Conn's syndrome. The most common cause of primary aldosteronism is an aldosterone-producing adenoma; next is idiopathic hyperplasia and last is carcinoma. Secondary aldosteronism, which occurs with renal artery stenosis, cirrhosis, and conditions of decreased kidney perfusion, is diagnosed by an increase in plasma renin activity.

Hypertension, hypokalemia, hyperaldosteronism, and decreased plasma renin levels are essential for the diagnosis of primary aldosteronism. Primary hyperaldosteronism is also associated with weakness, muscle cramps, polyuria, and polydipsia. These clinical signs are due to hypokalemia. Hypertension is usually not severe and is mostly diastolic (diastolic pressure more than 90 mm Hg).

The serum potassium level is usually less than 3.5 mEq/L.<sup>39</sup> Another possible diagnosis is essential hypertension treated with diuretics, although patients with that diagnosis seldom have potassium levels less than 3.5 mEq/L. All diuretics and antihypertensive medications should be stopped and 24-hour urinary potassium excretion measured. In most patients with primary aldosteronism, 24-hour urinary excretion of potassium is greater than 30 mEq. Patients with primary hyperaldosteronism have elevated plasma levels of aldosterone and low levels of renin activity. Measurement of messenger RNA (mRNA) in the kidney and adrenal

gland of patients with aldosteronoma also has demonstrated decreased levels of renin mRNA.<sup>40</sup> The plasma aldosterone-renin ratio is usually greater than 30. Final evidence for the diagnosis of primary hyperaldosteronism relies on the inability to lower plasma aldosterone levels and raise plasma renin activity after captopril.<sup>41</sup> The patient takes 25 mg of captopril orally in the morning. Two hours later, plasma levels of aldosterone and renin activity are measured. In normal subjects and patients with essential hypertension, captopril decreases plasma aldosterone levels and increases plasma renin activity. In patients with primary aldosteronism, plasma levels of aldosterone and renin activity do not change. A post-captopril plasma aldosterone level greater than 15 ng/dL and an aldosterone-renin ratio greater than 50 are diagnostic of primary aldosteronism (Table 38.4-2).

Measurement	Result
Blood pressure	Hypertension
Serum potassium levels	Hypokalemia (serum K <sup>+</sup> <3.5 mEq/L)
Urinary potassium levels	Elevated urinary K <sup>+</sup> excretion (>25–30 mEq/d)
Plasma aldosterone and plasma renin activity	Ratio >50 (elevated aldosterone and low renin)
Urinary aldosterone	Elevated
Captopril suppression test (25 mg orally)	After captopril, aldosterone >15 ng/mL. Aldosterone-renin ratio >50
Salt loading (9 g NaCl orally per day for 1–2 wk)	Renin suppression

**TABLE 38.4-2.** Diagnosis of Primary Aldosteronism

### Adenoma versus Hyperplasia

Once the diagnosis of primary aldosteronism is established, the next important consideration is the etiology—whether the patient has idiopathic adrenal hyperplasia (IAH) or a tumor that produces aldosterone (Table 38.4-3). The exact cause is critical because drug treatment is indicated for IAH, and surgery is indicated for a neoplasm. Measurement of plasma aldosterone concentrations with respect to postural changes is a relatively quick biochemical test to differentiate between the two. A decrease or no change in the serum level of aldosterone measured at 8:00 a.m. and noon in the upright position after overnight recumbence is consistent with an adenoma. The accuracy of this test is between 75% and 100%.

Measurement	IAH	Neoplasm
Aldosterone response to upright posture	Increases (>20 ng/dL)	No response or decrease (<20 ng/dL)
Best 18-hydroxycorticosterone	<6 ng/dL	>10 ng/dL
High-resolution computed tomography scan	Normal adrenal glands	Tumor (more <10 mm may be missed)
Iodocholesterol scan	Symmetric uptake bilaterally	Uptake of tumor by large adenoma (adipose tumor may not take up tracer)
Spironolactone	Fair response	Good response
Adrenal vein sampling	Aldosterone levels elevated from both adrenal veins and greater than simultaneous peripheral sample	Aldosterone levels elevated on side with tumor; contralateral side equal to simultaneous peripheral samples

**TABLE 38.4-3.** Etiology of Primary Aldosteronism: Idiopathic Adrenal Hyperplasia (IAH) versus Neoplasm

CT can image approximately 75% to 90% of aldosteronomas.<sup>42</sup> CT may miss small tumors. The contralateral adrenal cortex in a patient with an aldosteronoma appears thin on CT. Iodocholesterol scans with <sup>131</sup>I-b-iodomethyl-19-norcholesterol can image 88% of aldosteronomas. The advantage of these nuclear studies over CT is the provision of functional information about the neoplasm. In patients with IAH, the scan shows symmetrical uptake in both adrenal glands; and in patients with adrenal carcinoma causing hyperaldosteronism, the study may show no uptake by the tumor, whereas in adenomas tumor uptake is usually evident.

The single study of choice to determine if hyperaldosteronism is caused by a tumor or hyperplasia is sampling of the adrenal veins for aldosterone.<sup>42</sup> The procedure is performed by simultaneous selective catheterization of both adrenal veins and a peripheral vein. Serum levels of aldosterone and cortisol are measured at each site before and after ACTH. Aldosteronomas make aldosterone in response to ACTH. A unilateral elevation of aldosterone level or of the aldosterone-cortisol ratio indicates the presence of an aldosterone-secreting adenoma. Bilateral levels of aldosterone that are similar and greater than peripheral levels are consistent with IAH. Adrenal venous sampling for aldosterone (96%) is more sensitive than CT (75%) and adrenal venography (78%) in prospective comparisons.<sup>42</sup> If CT is nondiagnostic, venous sampling is the study of choice to distinguish a tumor from hyperplasia.

### Treatment

The management of primary aldosteronism depends on the diagnosis. Idiopathic adrenal hyperplasia is best managed medically with spironolactone or amiloride in conjunction with other antihypertensive drugs. Another drug with potential for managing the hypokalemia and hypertension associated with primary aldosteronism (both IAH and adenoma) is the calcium channel blocker nifedipine. Because aldosteronomas are usually small benign adenomas, it is now preferable to use a laparoscopic approach for unilateral adrenalectomy in patients with aldosteronoma. The laparoscopic approach is associated with less pain and morbidity.<sup>43,44</sup>

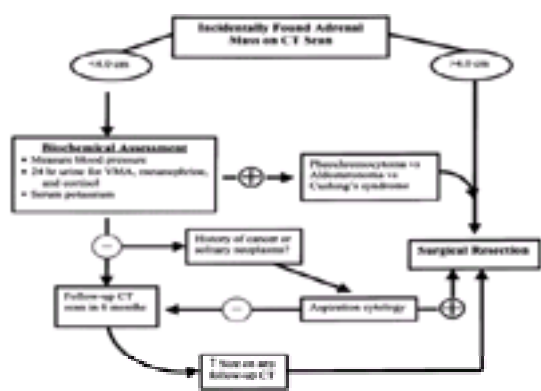

Results for resection of an aldosteronoma have not been entirely satisfactory. A high percentage of patients initially become normotensive and normokalemic postoperatively (approximately 95% dependent on accurate diagnosis). However, 20% to 30% of patients develop recurrent hypertension within 2 to 3 years. This has caused some physicians to advise against surgery and recommend long-term medical management. This therapy has been demonstrated to effectively control blood pressure and serum level of potassium in patients with aldosteronoma for periods of up to 5 years.<sup>45</sup> Aldosterone-producing adrenocortical carcinomas are rare (2% of all carcinomas).<sup>46</sup> Treatment is similar to other patients with adrenal carcinoma and is discussed later (see the section [Treatment of Adrenal Cortical Neoplasms](#)).

### INCIDENTAL ADRENAL MASS

High-resolution CT scans have resulted in a new diagnostic problem: an incidental adrenal mass detected by CT. Unexpected adrenal masses are seen in 0.6% of abdominal CT scans. The majority of these are benign adrenal cortical adenomas, which occur in 9% of autopsies.<sup>47</sup> However, one report indicates that an asymptomatic 3-cm adrenal mass that was followed subsequently was found to be metastatic adrenocortical carcinoma.<sup>48</sup> Of 311 incidentally discovered adrenal tumors, adrenocortical carcinoma was diagnosed in 21 cases (7%).<sup>49</sup>

The suggested evaluation of an incidental adrenal mass (incidentaloma) is given in [Figure 38.4-3](#). Two questions arise. Is the tumor functional? Is it cancer?

**FIGURE 38.4-3.** Flow diagram for management of incidentaloma. +, yes; -, no; CT, computed tomography; VMA, vanillylmendelic acid.

The first step in evaluation of an incidentally discovered adrenal mass is a careful history and physical examination, including blood pressure.<sup>50</sup> The clinician should examine for evidence of weight change, weakness or hypokalemia, Cushing's syndrome, hypertension, virilization, feminization, change in menstruation, and evidence of occult malignancy (stool guaiac, pap smear, anemia). Laboratory evaluation should consist of a 24-hour urine collection for free cortisol, VMA, metanephrines, and catecholamines. Twenty-four-hour urinary levels of free cortisol are indicated to rule out Cushing's syndrome. Patients with incidentalomas and no stigmata of Cushing's syndrome have been identified who have occult hypercortisolism. These individuals are fairly uncommon but can be identified by measuring a 24-hour urine sample for free cortisol or a low-dose dexamethasone suppression test.<sup>51</sup> If urinary levels of catecholamines or catecholamine metabolites are elevated, the diagnosis is pheochromocytoma (see the section regarding management in [Pheochromocytoma](#), later). In addition, the serum potassium concentration is used to exclude an aldosteronoma. Plasma levels of aldosterone and renin activity should be measured in any patient with hypertension and hypokalemia. Hormonal screening for an excess of androgens or estrogens is limited to patients with clinical signs suggestive of these disorders.<sup>50</sup>

The size of an adrenal mass on CT is an important determinant of a potentially malignant tumor. Adrenal cortical carcinomas are generally greater than 6 cm in diameter, and benign lesions are less than 6 cm. Nevertheless, a smaller lesion should not be totally ignored. Early diagnosis may lead to discovery of a small adrenal cortical carcinoma, which may lead to better prognosis and survival. Patients with primary adrenal cancers less than 5 cm in size have a better prognosis than those with larger tumors. Most recently, because of decreased morbidity with laparoscopic excision, some have advocated surgery for incidentalomas of 4 cm in size, especially in younger patients.<sup>52</sup> CT can accurately image normal glands, hyperplastic adrenal glands, and neoplasms, but it can only distinguish benign from malignant neoplasms by criteria such as size, direct invasion, or distant metastases.<sup>53</sup>

Fine-needle aspiration for cytology of an adrenal mass has limited ability to differentiate benign from malignant primary adrenal lesions. Fine-needle aspiration may be catastrophic in a patient with an unsuspected pheochromocytoma,<sup>53</sup> so urinary catecholamines are indicated to exclude a pheochromocytoma before needle biopsy. In patients with suspected metastatic disease to the adrenal or lymphoma, needle aspiration may be helpful.<sup>47</sup> In patients with known primary cancers, fine-needle aspiration can reliably diagnose adrenal metastasis.<sup>30</sup> Because it cannot distinguish between benign and malignant primary adrenal tumors, fine-needle aspiration cytology is not routinely recommended.

The suggested approach to an asymptomatic adrenal mass is outlined in [Figure 38.4-3](#). Biochemical assessment should be performed to exclude hormonal function of the tumor. The size of the tumor is assessed. Size greater than 4 cm is an indication for surgical resection, especially in a younger patient. The incidence of cancer in solid adrenal masses equal to 6 cm is estimated to be between 35% and 98%.<sup>50</sup> Laparoscopic excision of tumors smaller than 6 cm in size is recommended because of less pain and morbidity. Laparoscopic excision of large adrenal tumors (greater than 6 cm) is not recommended because a high proportion of these tumors are malignant.<sup>54</sup> However, some suggest that size is not a contraindication to the laparoscopic approach.<sup>55</sup> We prefer the open anterior approach to malignant adrenal tumors because of fewer long-term wound complications and higher likelihood of complete tumor excision.<sup>56</sup> If the tumor is hormonally functional, adrenalectomy is indicated and is usually performed laparoscopically. If the patient has a history of cancer, fine-needle aspiration can be considered to exclude adrenal metastases. If the mass is smaller than 4 cm and nonfunctional, a repeat follow-up CT examination in 3 to 6 months is indicated to again determine size. If size increases, surgical excision is necessary.<sup>50</sup> If there is no change at 6 months, it is most likely an adenoma, and subsequent CT scans are unnecessary. It is hoped that the evaluation provides early surgical intervention for functional or malignant adrenal masses and exclusion of nonfunctional benign adrenal adenomas.

## SEX HORMONE EXCESS

Adrenocortical carcinoma may present with excessive sex hormone secretion. Virilization or feminization may be combined with hypercortisolism, or the tumor may produce only estrogen or testosterone. In children, the clinical signs of increased androgen production include increased growth, premature development of pubic and facial hair, acne, genital enlargement, increased muscle mass, and deep voice. In women, the clinical signs of excess androgen production include hirsutism, acne, amenorrhea, infertility, increased muscle mass, deep voice, and temporal balding. In children, the clinical signs of increased estrogen production include gynecomastia in boys and precocious breast enlargement and vaginal bleeding in girls. In adult men, hyperestrogenism presents with gynecomastia, decreased sexual drive, impotence, and infertility. In adult women, hyperestrogenism presents primarily with irregular menses in premenopausal women and dysfunctional uterine bleeding or vaginal bleeding in postmenopausal women. The workup requires 24-hour urinary 17-ketosteroids, 17-hydroxysteroids, urinary free cortisol and, depending on virilization or feminization, serum determination of testosterone or estrogen.

Virilization secondary to an adrenal neoplasm may accompany Cushing's syndrome, and if it does occur, it usually indicates adrenal cortical carcinoma. Virilization in the absence of Cushing's syndrome may also occur due to adrenal cortical adenoma<sup>57</sup> or carcinoma.<sup>58</sup> Of course, there are many other disorders that cause virilization in women and children; however, in working up a patient with virilization, an imaging study of both adrenals, either CT or MRI, is indicated to rule out an adrenal neoplasm.

## TREATMENT OF ADRENAL CORTICAL NEOPLASMS

### ADRENAL CORTICAL ADENOMA

The definitive treatment of benign adrenal adenoma is surgical resection of the adrenal gland with the adenoma. Laparoscopic adrenalectomy is rapidly becoming the procedure of choice to remove benign adrenal tumors.<sup>43,52</sup> It is clearly indicated for smaller tumors (less than 6 cm) because it is associated with less pain and shorter convalescence.<sup>59,60</sup> In patients who are undergoing resection of an adrenal tumor that causes Cushing's syndrome, steroid replacement during and after surgery is necessary. Mineralocorticoid replacement is not required. Postoperative glucocorticoid replacement is indicated until complete recovery of the hypothalamic-pituitary-adrenal axis (see [Fig. 38.4-2](#)). Glucocorticoid replacement may be necessary for as long as 2 years.<sup>61</sup> Surgical resection of an adenoma is curative.<sup>61</sup> Larger lesions weighing between 50 and 100 g that appear benign histologically (no mitoses and no vascular invasion) need careful long-term follow-up to exclude carcinoma.

### ADRENAL CORTICAL CARCINOMA

The mainstay of treatment of adrenal cortical carcinoma is complete resection of all gross tumor. If the carcinoma is intimately associated with the kidney, liver, or diaphragm on the right or pancreas on the left, it may be necessary to remove part or all of the contiguous structures at the time of definitive surgery. It is important to consider that the best time for curative resection is the initial time. The surgeon needs adequate imaging of the extent of disease, which can be achieved by CT, MRI, or both. CT or MRI should include the chest to rule out metastatic disease above the diaphragm. If the right adrenal is involved and the inferior vena cava is compressed, either an inferior vena cava contrast study or caval ultrasound is useful to assess tumor extension into the cava. If resection of one kidney is indicated, either an intravenous pyelogram or an intravenous contrast CT is necessary to be certain the contralateral kidney is functioning. A complete bowel preparation is used in case the tumor invades the bowel. Even though patients with hypercortisolism have impaired healing, adrenal tumor resection can be performed with acceptable morbidity and an operative mortality of 3%.<sup>62</sup>

Adrenal cortical carcinoma can occur in adults and children. It occurs in children younger than 6 years, with a higher incidence in girls than boys. The median age in

children with adrenal cancer is 4 years. Virilization is the most common presenting feature (93%). Some children may also present with precocious puberty or Cushing's syndrome.<sup>63,64</sup> Some children with adrenal cancer can be cured by complete surgical resection. Approximately 65% of children with adrenocortical cancer can be cured by complete surgical resection of tumor.<sup>65</sup> In a multivariate analysis of predictors of outcome, only primary tumor size greater than 200 cm<sup>3</sup> independently identified a poor-prognosis group of children who may require more aggressive adjuvant therapy after surgery.<sup>63</sup> One study of children with adrenocortical cancer demonstrated that virilization was the most common presenting symptom, followed by Cushing's syndrome.<sup>65</sup> The overall 5-year survival rate was 49%, and when all tumor was removed, it was 70%.<sup>65</sup>

The second peak age of occurrence of adrenal cancer is between 40 and 50 years, and approximately 70% of these patients present with hormonal syndromes.<sup>46</sup> The surgical staging of adrenal carcinoma is as follows:

- I. Tumor less than 5 cm without local invasion, nodal, or distant metastases
- II. Same as stage I except tumor more than 5 cm
- III. Tumor with local invasion or positive lymph nodes
- IV. Tumor with local invasion and positive lymph nodes or distant metastases (Table 38.4-4)

Most patients (70%) present with stage III or IV disease.<sup>46,66</sup>

Stage	Criteria
<b>Tumor</b>	
T1	Tumor ≤5 cm, invasion absent
T2	Tumor >5 cm, invasion absent
T3	Tumor outside adrenal in fat
T4	Tumor invading adjacent organs
<b>Lymph nodes</b>	
N0	No positive lymph nodes
N1	Positive lymph nodes
<b>Metastases</b>	
M0	No distant metastases
M1	Distant metastases
<b>Stage grouping</b>	
I	T1, N0, M0
II	T2, N0, M0
III	T3-4, N1, M0; T3, N0, M0
IV	Any T, any N, M1; T3, T4, N1

**TABLE 38.4-4.** Staging Criteria for Adrenal Cortical Carcinoma

The definitive initial treatment for all stage disease, including locally aggressive stage III disease, is *en bloc* resection, which may include the adjacent kidney. This procedure may require a combined thoracoabdominal approach. Surgical resection of localized disease can be curative.<sup>46,66</sup> Some recommend adjuvant mitotane therapy after surgical resection to improve survival.<sup>67</sup> Doses between 1.5 and 2.0 g/d are well tolerated and may prolong survival.<sup>68</sup> However, others do not recommend mitotane therapy because it has not been proven to prolong survival.<sup>69</sup> In an analysis of 105 adult patients with adrenal cancer, only 80 were able to undergo surgery for possible cure, and the median disease-free interval postoperatively was 12 months.<sup>69</sup> The overall 5-year survival rate was 22%.<sup>69</sup> In most series, the 5-year survival rate is between 20% and 35%.<sup>70</sup> In a series from Italy, the 5-year survival rate after surgical resection in 129 cases was 35%.<sup>71</sup> In another series from Goteborg, Sweden, complete surgical resection was routinely combined with 1 year of mitotane therapy. Eighteen patients were treated, and the 5-year survival rate was 58% based on the Kaplan-Maier method.<sup>72</sup> Age over 40 years and the presence of metastases at the time of diagnosis correlated with a poor prognosis.<sup>69</sup> If complete resection of tumor cannot be achieved, tumor debulking should be attempted to decrease the amount of cortisol-secreting tissue and to minimize complications due to tumor mass. Patients who undergo definitive resection should undergo monitoring of steroid hormone levels postoperatively. Accurate measurement of urinary levels requires switching the glucocorticoid replacement therapy from hydrocortisone to dexamethasone. CT and MRI are also used to detect local recurrences and pulmonary metastases. If a recurrence is detected, it can be removed surgically. Prolonged remissions have been reported after resection of hepatic, pulmonary, and cerebral metastases from adrenal cortical carcinoma.<sup>73,74</sup> and <sup>75</sup> Patients with recurrent adrenal cortical carcinoma who can be surgically resected have improved survival over those who cannot. In 52 cases of recurrent disease, the 5-year survival rate of reoperated cases was 50% versus 8% for nonoperated cases.<sup>76</sup> When complete resection of tumor metastases is not possible, near total resection may still be helpful in some hormonally productive, slow growing adrenal cortical cancers.<sup>76</sup> Palliation of bony metastases may be achieved by radiation therapy.<sup>46</sup> Abdominal radiation therapy may be useful in 65% of patients with local recurrences not amenable to resection, and the treatment has even relieved bowel obstruction. However, it does not appear to improve the duration of survival.<sup>46</sup>

## CHEMOTHERAPY

Once the patient has recurrent or metastatic adrenal cortical carcinoma, chemotherapy with o,p-DDD (mitotane) usually is started.<sup>77</sup> Therapy is initiated at a dose of 2 to 6 g daily in two or three divided doses and increased until adverse reactions occur. Adverse reactions include gastrointestinal toxicity (anorexia, nausea, vomiting, and diarrhea), neuromuscular toxicity (depression, dizziness, tremors, headache, confusion, and weakness), and skin rash. Seventy-nine percent of treated patients develop some gastrointestinal toxicity, 50% develop neuromuscular toxicity, and 15% develop a skin rash.<sup>77</sup> Mitotane is associated with prolongation of the bleeding time and abnormal platelet aggregation.<sup>78</sup> A decrease in urinary 17-hydroxysteroids and 17-ketosteroids occurs in 67% of patients treated due to a direct effect on steroid metabolism, and a partial response occurs in approximately 35% of patients treated with mitotane. It is important to measure blood levels of o,p-DDD and achieve serum levels higher than 14 µg/mL. In one study, patients who had blood levels of less than 10 µg/mL had no demonstrable therapeutic effects, whereas seven of eight patients who had levels greater than 14 µg/mL had objective responses and subsequently lived significantly longer.<sup>79</sup> Unfortunately, the difference between efficacy and toxicity is small, and levels greater than 20 µg/mL are associated with symptoms of neuromuscular toxicity.<sup>79</sup>

Tumor responses usually occur in the first 6 weeks after the initiation of mitotane treatment. Although most patients who demonstrate an objective response to o,p-DDD subsequently relapse, there have been a few long-term survivors with metastatic adrenocortical carcinoma treated with mitotane. Mitotane may be an unpleasant drug, and when clinical toxicity is present, the dose must be adjusted to minimize side effects. Because patients with adrenocortical carcinoma are rare, there have been no controlled studies to establish that mitotane can significantly alter the natural course of adrenocortical carcinoma. Some suggest that adjuvant o,p-DDD improves survival after initial surgery for adrenocortical carcinoma,<sup>67</sup> although most experts do not recommend it as an adjuvant drug after total resection of primary adrenocortical cancer.<sup>65,80</sup> In a report of 59 patients with adrenal cancer who received mitotane therapy at a dose between 7 and 10 g/day, 37 patients were evaluable for tumor response.<sup>69</sup> Of the 37 patients, only 8 (22%) had a documented partial response.<sup>69</sup> Mitotane has been reported to have a 20% response rate.<sup>81</sup> Most experts do not recommend mitotane for the management of patients with adrenocortical cancer.<sup>76,82,83</sup> and <sup>84</sup> However, others argue that the dose of drug is critical and that the dose of mitotane must be pushed to toxicity to see reasonable response rates.<sup>85,86</sup> When one achieves a measurable serum mitotane level greater than 14 µg/mL, mitotane appears to have a more favorable impact on survival. Lower serum levels have no impact at all.<sup>86</sup> At best, the response rate with mitotane alone is 60%, and few complete responses have been reported.<sup>87</sup> Mitotane has clear benefit to help control hypercortisolism. In one retrospective review, two inoperable patients were treated preoperatively with mitotane and streptozotocin, and each had a 50% reduction in primary tumor size. One patient also had complete regression of pulmonary metastases. Tumor was resected in both patients, and both were treated with more chemotherapy postoperatively. Both patients have remained completely free of disease for 9 and 5 years postoperatively.<sup>88</sup> Chemotherapy has been combined with mitotane treatment. Eighteen patients with advanced adrenal cortical carcinoma were treated with etoposide (VP16), 100 mg/m<sup>2</sup>/day, and cisplatin, 100 mg/m<sup>2</sup>, every 4 weeks plus mitotane. A complete response was seen in three cases and a partial response in three cases, for an overall response rate of 33%.<sup>89</sup> Because of the *in vitro* finding that mitotane is able to reverse multidrug resistance, it has also combined with etoposide, doxorubicin, and cisplatin in a (n = 28) Italian multicenter trial of patients with advanced metastatic adrenal cortical carcinoma. A complete response was achieved in two patients and partial responses in 13, for an overall response rate of 54%.<sup>90</sup> Patients treated with mitotane plus chemotherapy have prolonged survival over patients treated with chemotherapy alone.<sup>91</sup>

Chemotherapy regimens besides o,p-DDD have been ineffective against adrenal cortical carcinoma. Partial responses have been reported with regimens based on doxorubicin<sup>84</sup> and alkylating agents. Promising regimens include cisplatin and etoposide. In three studies including these drugs in patients with metastatic adrenal cortical carcinoma who failed mitotane, there were seven responses in eight patients, including one complete response,<sup>92</sup> although the complete responder had a

duration of only 1 year. Another active regimen includes 5-fluorouracil, doxorubicin, and cisplatin, which has produced 3 responders in 13 patients treated.<sup>93</sup> One patient had a complete response that lasted for 42 months.<sup>93</sup> Patients who have not responded to mitotane have been effectively treated with a combination of cisplatin and etoposide.<sup>94</sup>

Suramin is known to inhibit the binding of growth factors, including epidermal growth factor, platelet-derived growth factor, and transforming growth factor-β, to tumor receptors and may reduce tumor growth by antagonizing these factors.<sup>95</sup> It has been used as a phase 1 agent in 21 patients with metastatic adrenal cortical cancer who have failed other therapy, and 3 partial responses (14%) were seen with no complete responses.<sup>95,96</sup> Suramin has toxicity related to blood coagulation, and some patients have had thrombocytopenia and hemorrhage (C. A. Stein, R. LaRocca, C. E. Myers, personal communication, 1991). In another study of nine patients with metastatic adrenal cortical carcinoma treated with suramin, cumulative doses between 8 and 30 g were administered over 1 to 15 months. One-third had a partial response, and the remainder had progression or stabilization. Toxicity included polyneuropathy, coagulopathy, and thrombocytopenia.<sup>97</sup> Suramin has had limited efficacy and serious toxicity.<sup>97</sup> Suramin does not appear to be an effective agent in adrenal cancer.

*In vitro* studies in a soft agar system suggest that the new midazole tetrazirone compound 8-carbamoyl-3-methylimidazo(5,1-d)-1,2,3,5 tetrazin-4(3H)-1 (temozolomide) is very active against adrenal cortical carcinoma.<sup>98</sup> Paclitaxel also has been shown to be effective against the adrenocortical carcinoma cell line, human NCI-H295, in *in vitro* studies.<sup>99</sup> Taxol also has been effective in *in vitro* studies against a steroid-secreting malignant adrenal cortical carcinoma cell line.<sup>100</sup>

Gossypol has been shown in experimental studies of adrenal cancer to inhibit tumor growth and prolong survival of mice.<sup>101</sup> However, in phase 1 human studies with metastatic adrenal cancer, it had a partial response rate of 20%. One 5-year-old child with metastatic adrenal cancer had a near complete response to oncovin, cisplatin, epidodophyllotoxin, and cytoxan.<sup>102</sup> Steroid hormone receptors have been detected *in vitro* in adrenal cortical carcinomas, indicating dependence on progesterone and glucocorticoid. However, *in vivo* studies of therapy related to manipulation of receptors have not been done. The available chemotherapy agents and results are summarized in Table 38.4-5. Mitotane is a first-line chemotherapy drug, and combination regimens including cisplatin and other drugs are the preferred second-line choices. Adrenal cortical carcinoma is rare and malignant. Most patients present with stage III and IV tumors (see Table 38.4-4). Metastatic sites of adrenal cancer are lymph nodes (68%), lung (71%), liver (42%), and bone (26%).<sup>103</sup> Surgical cure may only be feasible in stage I or stage II tumors (tumors confined to the adrenal gland).

TABLE 38.4-5. Chemotherapy Agents Used to Treat Adrenocortical Carcinoma

In patients with invasion of contiguous structures at presentation, median survival is 2.3 years.<sup>46</sup> Patients who present with stage I disease have a 50% 5-year survival rate compared with patients who present with either stage II or III disease, who have a 10% 5-year survival rate.<sup>82</sup> In patients with tumors confined to the adrenal gland, the mean duration of survival is 5 years.<sup>46</sup> For all patients, the 5-year survival rate is between 10% and 35%, indicating that most patients present with locally advanced or distant disease.<sup>69,104,105</sup> Most clinicians still recommend aggressive surgical resection of locally recurrent or metastatic cancer in these patients, but one study demonstrates that, even with this aggressive intervention, the 5-year survival rate is only approximately 10% to 20%.<sup>75</sup> These data indicate the poor prognosis of all patients with adrenal cortical carcinoma and support the use of adjuvant systemic chemotherapy or radiotherapy for resectable lesions (stages I to III). Based on the current evidence, however, adjuvant chemotherapy or radiation therapy is not recommended because effective regimens have not yet been documented.

Future challenges for better treatment of adrenal cortical carcinoma include earlier diagnosis and better adjuvants than o,p-DDD. Earlier diagnosis can be facilitated by an index of suspicion of hormonal excess during history and physical examinations. Changes in body appearance and menstrual history are important clues to earlier diagnosis. The use of MRI to differentiate benign from malignant incidentalomas of the adrenal may help clinicians find early resectable adrenal cortical cancers. Drugs such as cisplatin and etoposide or mitotane combined with chemotherapy<sup>106</sup> may be useful in the management of these difficult patients.

## ECTOPIC ADRENOCORTICOTROPIC HORMONE SYNDROME

The first report of a patient who exhibited features of Cushing's syndrome had an oat cell carcinoma of the bronchus secreting a peptide now called *corticotrophin*, or ACTH. Similar patients who had adrenal hyperplasia without pituitary tumors were reported over the next 30 years, but it was Christy<sup>107</sup> and Liddle<sup>108</sup> who established the presence of ACTH-like material in tumors other than pituitary tumors, in the blood, and in subnormal quantities in the pituitary itself.<sup>107,108</sup> The name *ectopic ACTH syndrome* was introduced in 1962.<sup>108</sup>

The diagnosis of ectopic ACTH syndrome is based on the metabolic evaluation of the patient who presents with hypercortisolism. An early clue to the diagnosis is the presence of Cushing's syndrome and severe hypokalemia (potassium level under 3.3 mEq/L). The diagnosis is based primarily on high plasma ACTH and cortisol levels, which do not change with high-dose dexamethasone or administration of CRH, and results of petrosal sinus sampling that demonstrate low levels of ACTH draining the pituitary gland that do not change with CRH. Once the diagnosis is established, the primary therapeutic goal is to find and eradicate the neoplasm that is secreting ACTH. When this is accomplished by surgery, chemotherapy, or radiation therapy, long-term cures can be achieved. The main clinical problems have been finding the source of ectopic ACTH in some patients and treating the aggressive underlying tumor in others. The causative tumors, in approximate order of frequency, are as follows:

1. Oat cell or small cell lung cancer
2. Carcinoid tumor of the bronchus
3. Epithelial carcinoma of the thymus or thymic carcinoids
4. Pancreatic islet cell tumor
5. Medullary carcinoma of the thyroid gland
6. Pheochromocytoma
7. Gut carcinoids
8. Ovarian adenocarcinoma
9. Pancreatic cystadenoma
10. Adenocarcinoma of unknown site

Other than small cell carcinoma of the lung, the most common cause of ectopic ACTH syndrome is either bronchial or thymic carcinoid tumors. The recommended radiographic procedures to localize ACTH-producing tumors include chest and abdominal CT, chest and abdominal MRI, urinary catecholamines to screen for pheochromocytoma, plasma levels of calcitonin to rule out medullary thyroid carcinoma, and inferior petrosal sinus sampling with CRH in patients in whom the differential diagnosis of Cushing's disease (pituitary) is unclear. Any suspicious finding in the chest or abdomen can be unequivocally confirmed by fine-needle aspiration and radioimmunoassay for ACTH in the aspirate.

The goal of therapy for patients with ectopic ACTH production is to find and treat (usually resect, unless it is oat cell carcinoma) the neoplasm that is the source of ACTH. Cancer resection is indicated for patients with bronchial carcinoid tumors (lobectomy with lymph nodes) because 50% will have positive lymph node

metastases. Despite this clear malignant potential, approximately 75% of patients are cured by surgical resection.<sup>109</sup> The proper therapy for ACTH-producing neoplasms depends on the diagnosis (exact tumor that produces ACTH) and extent of disease.

Any of these tumors may be malignant and may metastasize. Therefore, in some patients with ectopic ACTH production, the primary disease cannot be eradicated and therapy must be directed toward correcting the life-threatening metabolic and hormonal abnormalities. Hypokalemia and excess mineralocorticoid activity may be managed with potassium supplementation and spironolactone. Hypercortisolism may be managed with metyrapone, aminoglutethimide, or mitotane. Bilateral adrenalectomy is recommended for patients who have ectopic ACTH secondary to tumors that cannot be localized despite diligent radiographic efforts and for patients who have stable, but unresectable, metastatic disease whose hypercortisolism cannot be managed medically.

## PHEOCHROMOCYTOMA

Pheochromocytomas are rare tumors that rise from chromaffin cells in the adrenal medulla and elsewhere. Pheochromocytomas secrete catecholamines and cause intermittent, episodic, or sustained hypertension. Pheochromocytomas can present with either lactic acidosis or unexplained fever. In autopsy series, only 0.005% to 0.1% of persons have unsuspected pheochromocytomas.<sup>1</sup> When urinary catecholamines are measured in hypertensive patients, pheochromocytoma is present in only 0.1% of patients. Although these tumors are rare, it is important to diagnose and localize pheochromocytomas. Sustained hypertension caused by a pheochromocytoma is curable with tumor resection. Sudden death is associated with pheochromocytoma. Pheochromocytomas may be malignant. Earlier diagnosis and therapy may lessen the probability of death from malignancy and improve the prognosis. Incidence of malignancy in pheochromocytomas is as low as 5% and as high as 46% in different series.<sup>110</sup> Extraadrenal tumors may be more commonly cancerous. Pheochromocytomas may be associated with endocrine and nonendocrine inherited disorders. Bilateral adrenal medullary pheochromocytomas are components of MEN 2a and MEN 2B. Some recommend unilateral adrenalectomy in some MEN 2a patients as long as careful follow-up of the contralateral adrenal gland with urinary catecholamines is maintained.<sup>111</sup> Familial pheochromocytoma also has been described. Affected individuals have bilateral adrenal pheochromocytomas and no other manifestation of MEN syndromes. In other families, extraadrenal pheochromocytomas have been reported, sometimes in the same location (bladder, etc.) in affected individuals. Pheochromocytomas occur in approximately 25% of patients with von Hippel-Lindau (VHL) disease<sup>112</sup> and in fewer than 1% of patients with neurofibromatosis and von Recklinghausen's disease.<sup>113</sup>

Pheochromocytomas produce catecholamines, which result in clinical symptoms of anxiety attacks, episodic hypertension, or sustained hypertension. Severe, symptomatic paroxysmal hypertension with symptoms that are not related to stress or emotional distress are the most common presenting complaint of patients with pheochromocytoma.<sup>114</sup> However, pheochromocytomas may also produce other hormones, including ACTH; therefore, patients may have concomitant Cushing's syndrome. Pheochromocytomas may produce many other peptide hormones, including somatostatin, calcitonin, oxytocin, and vasopressin.

## ONCOGENE

Pheochromocytomas originate from the neural crest and may develop by arrest at various points during normal differentiation. The *ras* oncogene does not appear to be involved in the tumoral process of pheochromocytoma, because one study failed to detect any abnormality of *ras* gene sequence in ten pheochromocytomas.<sup>115</sup> Loss of heterozygosity at specific loci may help localize tumor suppressor genes involved in the formation of various familial and sporadic pheochromocytomas. Of 41 tumors tested, significant allelic losses were found on chromosome 1p (42%), 3p (16%), 17p (24%), and 22q (31%). Furthermore, there appeared to be a correlation between loss of heterozygosity on chromosome 1p with urinary excretion of metanephrine and loss of heterozygosity on chromosomes 1p, 3p, and 17p with tumor volume.<sup>116</sup> Because pheochromocytomas are part of the VHL syndrome, investigators have studied the role of the tumor suppressor gene *CUL2*, whose product interacts with the VHL tumor suppressor in the pathophysiology of sporadic pheochromocytomas. It does not appear to have a significant effect, because only 1 of 26 tumors had a mutation.<sup>117</sup>

## PATHOLOGY

Pheochromocytomas arise from chromaffin cells. Chromaffin cells are widespread and associated with sympathetic ganglia during fetal life. After birth, most chromaffin cells degenerate, and the majority remain in the adrenal medulla. This may explain why approximately 90% of pheochromocytomas are in the adrenal medulla. Extraadrenal pheochromocytomas may arise anywhere, including the carotid body, intracardiac, along the aorta (both thoracic and abdominal), and within the urinary bladder. The most common extraadrenal location is the organ of Zuckerkandl, which is near the origin of the inferior mesenteric artery to the left of the aortic bifurcation. Extraadrenal pheochromocytomas may more often be malignant. Bilateral adrenal pheochromocytomas occur in familial syndromes, including MEN 2a and MEN 2B.<sup>118</sup>

Data from series of patients with sporadic pheochromocytomas indicate that the right adrenal gland more commonly harbors a tumor than the left gland.<sup>119</sup> Pheochromocytomas resected from hypertensive patients usually measure between 3 and 5 cm in diameter and weigh approximately 100 g.<sup>120</sup> These tumors appear tan to gray in color and have a soft smooth consistency. Larger tumors may be cystic or have necrotic areas and often have calcification. Microscopically, pheochromocytomas resemble the cell of origin. Tumors are usually arranged in cords or alveolar patterns.<sup>1</sup> Tumors may be composed of cords of cells lining vascular structures that have an angiomatous appearance. Tumors are generally clearly separated from the adrenal cortex by a thin band of fibrous tissue. Extension of the pheochromocytoma into the cortex or vascular invasion may occur in benign neoplasms.<sup>1</sup>

The pathologic distinction between benign and malignant pheochromocytomas is not clear, and pathologists have relied on the reported benign natural history of most pheochromocytomas. However, some reports indicate that more pheochromocytomas than expected are malignant. In one large series, the tumor recurrence rate was 10% and most recurrences occurred within 5 years.<sup>119</sup> In another series, the recurrence rate was 23%,<sup>121</sup> and in another it was 46%.<sup>122</sup> Certainly these results partly reflect the referral pattern of tertiary institutions, but they may also reflect a true higher malignancy rate than originally suggested. Malignant tumors tend to be larger and weigh more, although this is not an absolute criterion<sup>1</sup> (Table 38.4-6). Staining for the nuclear proliferation marker MIB-1 is positive in 50% of malignant pheochromocytomas and negative in benign tumors. It is preliminary data, but it may be a useful marker for malignancy.<sup>123</sup> The only absolute criterion for malignancy is the presence of secondary tumors in sites where chromaffin cells are not usually present and visceral metastases. Benign pheochromocytomas may demonstrate marked nuclear pleomorphism, whereas paradoxically, malignant ones demonstrate less.<sup>1</sup> Malignant pheochromocytomas usually have many more mitoses than benign tumors, but capsular and vascular invasion occurs with equal frequency in both.<sup>1</sup> Nuclear DNA ploidy may be a predictive indicator of malignant potential.<sup>124</sup> Flow cytometry has been used to define a subgroup of patients with pheochromocytoma who have malignant tumor. Tumor whose DNA ploidy studies demonstrated tetraploidy or polyploidy and aneuploidy had a significantly higher chance of a malignant course than most tumors, which were normally diploid. It has been observed that neuropeptide Y gene expression by tumors may be used to distinguish benign from malignant pheochromocytomas. Neuropeptide Y mRNA was expressed in 9 of 9 benign tumors and only 4 of 11 malignant tumors, suggesting that expression of this gene is seen more often in benign pheochromocytomas.<sup>125</sup> Others have attempted to differentiate patients with benign and malignant pheochromocytomas by serum levels of neuron-specific enolase and neuropeptide Y, but observed differences were not significant.<sup>126</sup> Finally, studies indicate that size of tumor (weight) correlated best with malignant potential, as did amount of necrosis<sup>127</sup> (see Table 38.4-6).

Characteristic	Benign	Malignant
Metastases	-	+
Weight (g)	<100	>500
Occurrence (%)	50-90	10-50
Vascular invasion	+	+
Capsular invasion	+	+
Mitoses	±	+++
Nuclear pleomorphism	+	-
Ploidy	Diploid	Hyperdiploid, triploid
Necrosis	±	++
Tumors with neuropeptide Y gene expression	+	-
Proportion of patients with elevated serum levels of neuron-specific enolase (%)	-	+

+, extent present; -, extent absent.

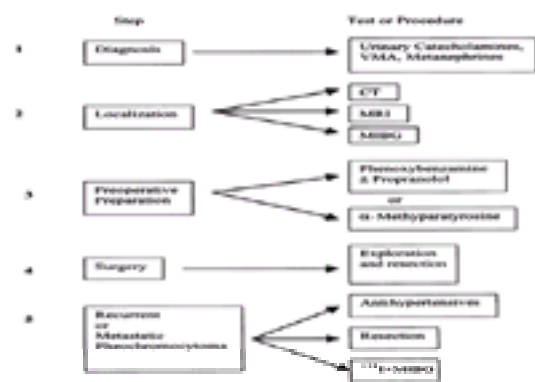

TABLE 38.4-6. Differentiation of Benign versus Malignant Pheochromocytomas

## CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with pheochromocytomas can present with a range of symptoms, from mild labile hypertension to sudden death secondary to a hypertensive crisis, myocardial infarction, or cerebral vascular accident. The classic patient describes “spells” of paroxysmal headaches, pallor, palpitations, hypertension, and diaphoresis. In 50% of patients, the hypertension is intermittent, whereas in the others it is sustained. In 90% of children with pheochromocytomas, the hypertension is sustained. Patients may have signs of chronic hypovolemia, such as orthostatic hypotension or lactic acidosis secondary to excess  $\alpha$ -catecholaminergic stimulation and vasoconstriction. Most patients have mild weight loss, but obesity does not rule out pheochromocytoma. Diabetes mellitus may be induced.

The diagnosis of pheochromocytoma is based on measuring catecholamines and metabolites in the urine ( Fig. 38.4-4). If a pheochromocytoma is suspected clinically or a patient has a history of familial pheochromocytoma, MEN 2a, or MEN 2B, the best study is a 24-hour urine test for catecholamines, metanephrine, and VMA. In a report describing the testing of 64 patients, 30 of whom had pheochromocytomas, 24-hour urine collections for VMA, dopamine, epinephrine, and norepinephrine were analyzed. The 24-hour urinary levels of VMA and norepinephrine had the greatest sensitivity (97%), whereas the levels of VMA had the best specificity (91%).<sup>128</sup> Another study also reports that urinary measurement of catecholamine, VMA, and metanephrine levels were the most sensitive screening test.<sup>129</sup> Methods are now available to measure plasma catecholamines using a radioenzymatic assay. This can provide a more direct measurement of catecholamine excess, but there have been conflicting reports comparing the value of urinary or plasma catecholamines in the diagnosis of pheochromocytoma. As the plasma studies become more reliable, they may be a more sensitive and specific method than the urinary assay. However, it depends on the laboratory and the method, because studies still report that urinary measurements are more sensitive than plasma.<sup>130</sup>

**FIGURE 38.4-4.** Flow diagram for diagnosis, localization, preoperative preparation, treatment, and follow-up of a patient with a pheochromocytoma. CT, computed tomography; MIBG, metaiodobenzylguanidine; MRI, magnetic resonance imaging; VMA, vanillylmendelic acid.

The clonidine suppression test has become the test of choice to determine whether a patient with borderline urinary or plasma catecholamine level has a pheochromocytoma.<sup>131</sup> It is the study of choice to diagnose pheochromocytomas in patients with plasma catecholamine concentrations between 500 and 2000 pg/mL.<sup>132</sup> In normal subjects and patients with idiopathic hypertension, clonidine suppresses plasma levels of epinephrine and norepinephrine. In patients with pheochromocytoma, clonidine does not suppress levels. Only two incorrect diagnoses have been reported using the clonidine suppression test: one false-positive and one false-negative.<sup>133</sup> An overnight method of this test has also been reported based on the measurement of urinary levels of norepinephrine and epinephrine.<sup>131</sup>

## LOCALIZATION STUDIES

CT and MRI are the two radiologic (nonnuclear medicine) procedures of choice to localize pheochromocytomas (see Fig. 38.4-4). Both are noninvasive and sensitive, being able to detect tumors approximately 1 cm in diameter. MRI may be more specific because of the increased signal intensity on the T2-weighted image. CT has some advantages over MRI. CT scanners currently have greater resolution and greater availability. In a Mayo Clinic study of 52 patients with pheochromocytoma, CT detected 51 of 52 tumors, including 9 of 10 bilateral tumors.<sup>134</sup> In another study, unenhanced high-resolution CT detected pheochromocytomas in six of six patients who had tumors found at surgery, including two extraadrenal retroperitoneal tumors.<sup>135</sup> MRI also has remarkable resolution. In seven patients with pheochromocytomas demonstrated on CT, MRI imaged all primary lesions as well as metastases to the chest, retroperitoneum, and liver. Because it has no radiation exposure, it can be used to image a pheochromocytoma during pregnancy. In one analysis, CT imaged 16 of 19 pheochromocytomas (84%), whereas MRI imaged 12 of 15 (75%) for comparable sensitivity.<sup>136</sup> In addition, MRI successfully imaged an intrapericardial pheochromocytoma and distinguished it from the cardiac chambers and surrounding great vessels, which could not be determined by CT.

Another important technique for the localization of pheochromocytomas is nuclear scanning after the administration of labeled metaiodobenzylguanidine (MIBG) (see Fig. 38.4-4). The compound is similar to norepinephrine and is taken up and concentrated in adrenergic tissue.<sup>137</sup> <sup>131</sup>I-MIBG has been studied in 400 patients to localize suspected pheochromocytoma.<sup>137</sup> The sensitivity of MIBG scanning was 78% in sporadic pheochromocytoma, 91% in malignant pheochromocytoma, and 94% in familial pheochromocytoma. The overall sensitivity was 87%. The specificity was nearly 100% in all categories and overall.<sup>137</sup> <sup>131</sup>I-MIBG at another institution demonstrated a sensitivity of 77% and a specificity of 96%,<sup>138</sup> and two other institutions had similar findings.<sup>139,140</sup> More recent data confirm previous studies and demonstrate that labeled MIBG is a useful diagnostic and imaging study for the detection and localization of pheochromocytoma.<sup>128</sup> In three studies from three different institutions, it had a sensitivity of 86% and correctly diagnosed and imaged tumor in 71 of 83 patients.<sup>128,136</sup> It appears that MIBG scanning is safe, noninvasive, and efficacious for the localization of pheochromocytomas, including those that arise in nonadrenal sites, and malignant disease. Metastatic bone involvement by pheochromocytoma can be imaged by <sup>131</sup>I-MIBG, but standard bone scintigraphy may be more sensitive. In summary, MIBG scanning images catecholamine-producing tumors with a high specificity and sensitivity. Whereas CT and MRI reflect changes in morphology, scintigraphic imaging relies on tissue function.<sup>140</sup> False-positive results with MIBG scintigraphy are rare (but tumors such as medullary thyroid carcinoma and neuroblastoma can image), which accounts for the high specificity (98% to 100%) of the study. False-negative results can occur and have an incidence of approximately 13% to 20%,<sup>128,136</sup> which lowers sensitivity. It appears that these false-negatives may be more common with multiple tumors and metastatic disease in the same patient.

## MANAGEMENT

### Preoperative Preparation

Once the diagnosis is established and the tumor localized, preoperative preparation includes  $\alpha$ -adrenergic blockade. Patients are started on phenoxybenzamine, 10 mg orally two or three times daily (see Fig. 38.4-4). If tachycardia develops (heart rate more than 100 beats/min),  $\beta$ -adrenergic blocking agents (propranolol) are added before surgery. Propranolol should never be started before a blockade because unopposed vasoconstriction may worsen hypertension. Phenoxybenzamine increases the total blood and plasma volume in patients with pheochromocytoma. In addition, lactic acidosis may be present in patients with pheochromocytoma related to the effect of catecholamines on peripheral circulation. The measurement and correction of arterial blood pH should be performed in all patients before the induction of anesthesia and surgery.

$\alpha$ -Methyltyrosine is a competitive inhibitor of tyrosine hydroxylase, the rate-limiting step in catecholamine biosynthesis. Treatment with  $\alpha$ -methyltyrosine (metyrosine) reduces catecholamine production by 50% to 80% in patients with pheochromocytoma. The usual dose is 250 mg four times daily, which may be increased to a maximum dose of 3 to 4 g/day.<sup>141</sup> It has been used preoperatively to prepare some patients with pheochromocytoma and unusual cardiac complications for surgery, and it may be used to treat hypertensive crisis in patients with pheochromocytoma.<sup>140,142</sup> Studies suggest that it is most effective when combined with phenoxybenzamine.<sup>143</sup> Others have successfully used the calcium-antagonist nifedipine with phenoxybenzamine or nifedipine alone (60 to 120 mg every 24 hours) to control labile hypertensive episodes in patients with pheochromocytoma.<sup>144</sup> Either of these newer drug strategies appear to work as well as or better than the more traditional strategy of phenoxybenzamine.

## Intraoperative Management

If the patient is elderly or has had cardiac complications, he or she should be transferred to the intensive care unit the day before surgery and a Swan-Ganz catheter should be inserted. This allows correction of hemodynamic imbalances and optimization of cardiac performance. The morning of operation, an arterial catheter and peripheral intravenous catheters should be inserted. Arterial blood gas should be measured to rule out acidosis. During surgery, especially during manipulation of the tumor, marked increases in blood pressure may occur; hypertensive episodes should be controlled with either  $\alpha$ -adrenergic blocking agents like regitine or agents that directly relax arterial and venous smooth muscle like sodium nitroprusside. Nitroprusside is the preferred drug because of its rapid onset and short duration. It is administered via a continuous intravenous infusion with a pump, and the blood pressure is continuously titrated to acceptable levels. The use of preoperative preparation with oral  $\alpha$ -adrenergic blocking agents and intraoperative adjustment and regulation of blood pressure with nitroprusside has greatly facilitated the surgical resection of pheochromocytoma and has reduced operative morbidity and mortality.

The operation is performed using a transabdominal incision, either a bilateral subcostal or a long midline incision. Preoperative localization studies, such as CT, MRI, and  $^{131}\text{I}$ -MIBG, guide the exploration, but the entire abdomen should be carefully visualized and palpated. Others argue that localization procedures are so sensitive and specific that more direct approaches may be preferred.<sup>145</sup> Small intraadrenal pheochromocytomas have been removed using laparoscopic techniques. Laparoscopic procedures appear to decrease pain and shorten the time to recovery. Most pheochromocytomas are well localized. However, in instances of malignant pheochromocytomas or multiple pheochromocytomas in known or unsuspected MEN syndromes, some tumors may be missed. Extraadrenal pheochromocytomas may be difficult to find. The most common locations of intraabdominal extraadrenal pheochromocytoma are in the hilar region of the kidneys and in the chromaffin tissue along the aorta from the celiac axis to the aortic bifurcation. The organ of Zuckerkandl at the aortic bifurcation is the most common extraadrenal location. Pheochromocytomas have been described within the urinary bladder. Multiple locations, metastatic potential, and multiple tumors all support the necessity for a complete exploration of the entire abdominal cavity. The "rule of ten" may be of value in the management of pheochromocytomas: Ten percent are malignant, 10% are extraadrenal, and 10% are bilateral. In patients with MEN 2, some suggest that nearly 100% either have or will develop bilateral benign adrenal medullary pheochromocytomas,<sup>146</sup> whereas others suggest that the incidence of bilaterality, although high, may be significantly less (70%).<sup>147</sup>

## MALIGNANT PHEOCHROMOCYTOMAS

Malignant pheochromocytomas are thought not to occur in MEN syndromes and to be present in approximately 10% of patients with pheochromocytoma. Two reports indicate that substantially more than 10% of sporadic pheochromocytoma may be malignant.<sup>121,122</sup> In one study, 25 of 69 (36%) patients had malignant pheochromocytomas diagnosed by recurrent or metastatic disease<sup>121</sup>; in another study using the same criteria, 81 of 176 (46%) patients with pheochromocytomas had malignant disease.<sup>122</sup> In the later study, original histologic review by blinded pathologists did not discriminate malignant versus benign neoplasms with accuracy. Pathologic analysis was not helpful in predicting which tumors were malignant.<sup>122</sup> Patients who developed metastases did not develop them until 0.2 to 28.7 years after their initial surgery. Incidence of detection for the first 9 years was 5% per year. Males were more likely to develop metastatic pheochromocytoma. Imaging with  $^{131}\text{I}$ -MIBG was usually able to detect recurrent or metastatic pheochromocytoma. Some recommend yearly  $^{131}\text{I}$ -MIBG scans to detect recurrent disease in all patients after resection of pheochromocytoma.<sup>122</sup> New studies indicate that octreotide scintigraphy may also be useful to image malignant metastatic pheochromocytoma.<sup>148</sup> If the tumor is imaged by somatostatin receptor scintigraphy, octreotide therapy may have potent antitumor effects.<sup>149</sup> Others recommend lifetime follow-up with measurement of blood pressure and urinary levels of catecholamines.<sup>121</sup> The detection of recurrent or metastatic pheochromocytoma should be based on the same methods as detection of primary or initial pheochromocytoma. These methods include urinary and serum catecholamine measurement, the clonidine suppression test, CT scanning, MRI, and  $^{131}\text{I}$ -MIBG scanning. Careful follow-up requires some, but not necessarily all, of these studies on a yearly basis (see Fig. 38.4-4). It appears that with careful follow-up the incidence of malignant pheochromocytoma may be greater than 10% and may approach 30% to 50%.

The basic principles in the treatment of malignant pheochromocytoma have been to surgically resect recurrences or metastases whenever possible and to treat hypertensive symptoms by catecholamine blockade.<sup>150</sup> Even in pediatric patients, surgical resection of metastatic and recurrent pheochromocytoma has been shown to prolong survival.<sup>151</sup> Painful bony metastases, which may be diagnosed by either  $^{131}\text{I}$ -MIBG scans or standard bone nuclide scans, respond well to radiotherapy. Soft tissue masses or bony masses generally respond well to radiation therapy if doses of 40 Gy or more can be administered.<sup>124</sup> Localized or solitary soft tissue masses, even when metastatic to the liver or lung, may be successfully resected surgically. Standard chemotherapy regimens including doxorubicin plus streptozotocin and carmustine plus doxorubicin have not had efficacy in the treatment of malignant pheochromocytomas.

Survival data of patients with malignant pheochromocytoma are difficult to obtain because of the rarity and indolence of the tumor. In a large series from the Mayo clinic, the 5-year survival rate was 36%.<sup>150</sup> Others report a 5-year survival rate of 60% in 15 patients with malignant pheochromocytoma.<sup>152</sup> In this study, patients were treated primarily by aggressive surgery and medical blood pressure control.<sup>152</sup> In a final series, patients who succumbed from malignant pheochromocytoma did so within 3 years of the appearance of metastases.<sup>153</sup>

The early success with streptozotocin in the treatment of neuroendocrine tumors of the gastrointestinal tract suggested that it might also be useful in the treatment of malignant pheochromocytomas. Streptozotocin has had mixed responses in patients with malignant pheochromocytoma. Initial work with streptozotocin was disappointing and suggested no role for it in the treatment of malignant pheochromocytoma.<sup>153</sup> However, Feldman<sup>154</sup> treated one patient with a good response and suggested that the dosage schedule might be important in obtaining a beneficial result. He provided additional 3-year follow-up on that patient and noted that the patient maintained an 85% reduction in urinary homovanillic acid levels and a 73% reduction in urinary VMA levels with normal renal function despite 66 g of streptozotocin.<sup>155</sup> Other investigators have tried this regimen and noted no response and deterioration of renal function. It may be that some patients with malignant pheochromocytoma respond to streptozotocin chemotherapy, but many do not, and it does not appear to play a major role in the treatment of patients with these rare tumors.

Because of the high sensitivity (85%) and specificity (100%) of  $^{131}\text{I}$ -MIBG to image pheochromocytomas, its use in higher doses to treat recurrent or metastatic pheochromocytomas has been implemented. Current imaging modalities of pheochromocytoma permit relatively accurate dosimetry to the tumor on the basis of the diagnostic dose of  $^{131}\text{I}$ -MIBG administered. If uptake by primary or metastases is high, it is possible to deliver very high radiation doses by increasing the administered activity. Specific activity of  $^{131}\text{I}$ -MIBG of 200 mCi in 5 mg has now been achieved. With the remarkable ability of MIBG to image tumors, one would expect its ability to treat metastatic or recurrent tumors to be equally effective; however, the results have not been very dramatic. Treatment response in patients with pheochromocytomas can be measured by catecholamine secretion and standard tumor size measurements. Blood pressure control of a few patients with malignant pheochromocytoma has been facilitated by  $^{131}\text{I}$ -MIBG therapy.<sup>156</sup> One trial reports the use of  $^{131}\text{I}$ -MIBG therapy in 15 patients with malignant pheochromocytoma. Patients were treated with  $^{131}\text{I}$ -MIBG (specific activity 740 MBq/mg) every 3 months. The typical patients received three doses. The absorbed cumulative tumor dose was 12 to 155 Gy. A beneficial response to treatment was observed in nine patients (60%), four never responded, and others had a slight response. No complete responses were observed. Five patients had measurable partial responses to treatment, and seven had clear hormonal responses. Toxicity included pancytopenia in one patient that resolved after discontinuation of therapy.<sup>156</sup> In another study of 12 patients treated with  $^{131}\text{I}$ -MIBG, 5 (42%) reduced catecholamine levels and 2 decreased tumor size (17%).<sup>157</sup> Vetter and colleagues<sup>158</sup> reported two patients with malignant pheochromocytomas treated with  $^{131}\text{I}$ -MIBG who had minor reduction in tumor size but no change in catecholamine secretion. There were no reported complete responses until more recently.<sup>156,157</sup> and <sup>158</sup> Targeted radiotherapy with  $^{131}\text{I}$ -MIBG is effective in 58% of malignant pheochromocytomas with objective responses.<sup>159</sup> One report documented a 4-year biochemical and imageable complete response with  $^{131}\text{I}$ -MIBG treatment in one patient.<sup>160</sup> Another report documents significant partial responses in three patients treated with  $^{131}\text{I}$ -MIBG.<sup>156</sup>

Neuroblastomas are aggressive tumors of neural crest origin that occur in children and have no association with hypertension. All patients with neuroblastoma have high plasma levels of dopa. Patients with benign pheochromocytomas have elevated plasma levels of norepinephrine or epinephrine, and none have elevated plasma levels of dopa. Sixty percent of patients with malignant pheochromocytomas have elevated plasma levels of dopa, in contrast to benign pheochromocytoma. The similarity between malignant pheochromocytoma and neuroblastoma is further supported by the astonishing responsiveness of malignant pheochromocytomas to therapy that is effective in treating neuroblastomas.<sup>161</sup> Combination of cyclophosphamide, vincristine, and dacarbazine has an 80% response rate for metastatic neuroblastoma<sup>162</sup> and has been used in patients with metastatic pheochromocytoma. The chemotherapy regimen consists of cyclophosphamide, 750 mg/m<sup>2</sup> intravenously, on day 1, vincristine, 1.4 mg/m<sup>2</sup> intravenously, on day 1, and dacarbazine, 600 mg/m<sup>2</sup> intravenously, on days 1 and 2, repeated every 21 days. Doses of cyclophosphamide and dacarbazine have been increased or decreased on the basis of neurotoxicity. This regimen has now been reported in 14 patients with metastatic pheochromocytoma.<sup>161</sup> The ability to respond to the chemotherapy regimen correlated with plasma norepinephrine level before therapy. One patient had a complete response (both biochemical and imageable) that lasted for 9 months. One other patient also had a biochemical complete response, and a total of eight (57%) patients had clear decreases in 24-hour levels of urinary catecholamines. Seven patients (50%) also had at least a 50% decrease in the measurable size of tumor. Biochemical response (urinary catecholamines) correlated well with response evaluated on imaging studies. The median duration of response was greater than

18 months. All responding patients have had dramatic improvement in hypertension control and performance status. The regimen has been well tolerated, and toxicity has been mild.<sup>161</sup> Hypertensive crises after cytotoxic drug therapy in patients with pheochromocytoma have been reported,<sup>162</sup> but this potentially life-threatening complication is not a problem with adequate  $\alpha$ -adrenergic blockade. Single cases have been reported to have complete responses with cyclophosphamide, vincristine, and dacarbazine (CVD).<sup>163</sup> Three additional patients have been treated with CVD, resulting in partial responses.<sup>164</sup>

Patients with malignant pheochromocytomas have been treated with both chemotherapy and radioactive MIBG in a study protocol. Six patients with metastatic pheochromocytoma were treated with three doses of <sup>131</sup>I-MIBG followed by a year of chemotherapy with CVD given in 21-day cycles. Three patients had significant partial responses to <sup>131</sup>I-MIBG, and two patients had further partial responses to chemotherapy. The combination therapy produced additive antitumor effects.<sup>165</sup> Two additional patients with metastatic pheochromocytomas also have been treated with CVD with partial responses.<sup>166</sup> Table 38.4-7 lists possible treatment regimens for metastatic pheochromocytoma.

Investigator	Compound	Patients	Response with Change in Catecholamine Secretion	Result of Therapy and/or Level of Catecholamine
Anderson et al., 1987 <sup>161</sup>	131I-MIBG	3	No change	Quantitative decrease
Bray et al., 1987 <sup>162</sup>	131I-MIBG	11	7 partial responses (63%)	1 decrease (9%)
Nakajima and Nakagawa, 1987 <sup>163</sup>	131I-MIBG	1	4 partial	1 CR
Anderson, 1987 <sup>164</sup>	131I-MIBG	1	1 partial	Marked decrease
Andrich et al., 1987 <sup>165</sup>	Cyclophosphamide Vincristine Dacarbazine	11	2 partial	1 CR 4 PR (36%)

## INTRODUCTION

Pancreatic endocrine (or neuroendocrine) tumors (PETs) are uncommon neoplasms that share a number of features.<sup>1,2</sup> Histologically, they are classified as apudomas and share cytochemical features with melanoma, pheochromocytoma, carcinoid tumors, and medullary thyroid carcinoma.<sup>2</sup> All amine precursor uptake and decarboxylation (APUD) neoplasms have the capacity to synthesize and secrete polypeptide products that have specific endocrine hormone activity. Except for insulinoma, each is malignant in most (more than 60%), if not all, cases (Table 38.5-1). Each type is a vascular tumor sharing with the other types a similar radiographic appearance and metastatic patterns of spread (primarily to regional lymph nodes and liver).

Tumor Name	Endocrine Name	Stimulus	Prevalence (All/Pancreas)	Location
PPoma	PPoma	Pancreatic polypeptide	100/100	Pancreas
Insulinoma	Insulin	Hypoglycemia	100/100	Pancreas (90-95%) Islet (5-10%)
Gastrinoma	Gastrin	Starvation	100/100	Pancreas (90%) Duodenum (10%)
Glucagonoma	Glucagon	Hypoglycemia	10/10	Pancreas (90%)
Somatostatinoma	Somatostatin	Starvation	10/10	Pancreas (90%) Other (10%)
Other	Other	Other	10/10	Pancreas (90%) Other (10%)

TABLE 38.5-1. Enteropancreatic Endocrine Tumors

PETs are considered *functiona* if they are associated with a clinical syndrome due to ectopic hormone release or *nonfunctiona* if not associated with clinical symptoms. In the latter category are pancreatic polypeptide (PP) tumors (PPomas), as the hormone causes no specific symptoms.<sup>1,3</sup> In addition, some PETs are associated with no known hormone elevation and histologically are indistinguishable from functional tumors.<sup>1</sup>

In general, PETs are uncommon. Functional PETs are reported to have a prevalence of 10 per million population.<sup>4</sup> The prevalence in unselected autopsy studies is 0.5% to 1.5%, with fewer than 1 of 1000 being functional.<sup>1,5</sup> The incidence of clinically significant PETs is 3.6 to 4 per million population per year; nonfunctional PETs or PPomas are reported to account for 15% to 30% of all PETs.<sup>3,6</sup> Gastrinomas or PPomas are the most common malignant PETs, whereas insulinoma is the most common benign PET. Gastrinomas usually are clinically recognized because of the Zollinger-Ellison syndrome (ZES) and have been studied extensively.<sup>7,8 and 9</sup> This chapter presents information in a format that reflects the many similarities of PETs, though detailed discussions of each tumor type are provided for those tumors associated with unique issues.

## PATHOGENESIS, PATHOLOGIC FEATURES, AND TUMOR BIOLOGY

### GENERALLY MALIGNANT NEOPLASMS

In 1955, Zollinger and Ellison described two patients with severe peptic ulcer disease treatable only by total gastrectomy because of extreme hypersecretion of gastric acid associated with a non-b islet cell tumor of the pancreas.<sup>10</sup> Analysis of tumor extracts via enzymatic degradation and amino acid analysis demonstrated that the secretagogue in the tumor was identical to human antral gastrin<sup>11,12</sup>; hence, these tumors are called *gastrinomas*. Studies estimate that the ZES occurs in one-half to three patients per million population per year and varies from half as common to 1.2 times as common as insulinomas.<sup>13</sup>

Almost all the early clinical manifestations are due to gastric acid hypersecretion secondary to hypergastrinemia.<sup>14</sup> Effective control of the gastric hypersecretion either medically or surgically abolishes all clinical manifestations such as peptic ulcer disease or diarrhea.<sup>14,15</sup> Along with basal gastric acid hypersecretion, hypergastrinemia causes trophic changes in the gastric mucosa,<sup>16</sup> with the result that patients with ZES have increased numbers of parietal cells and an increased maximum acid secretory capacity.<sup>14,16</sup> Many patients with ZES have diarrhea and, in some patients, it is the sole presenting manifestation. The diarrhea is a result of acid hypersecretion causing direct injury to the small intestinal mucosa, inactivation of pancreatic lipase, and precipitation of bile acids. ZES patients with diarrhea become asymptomatic when the gastric acid hypersecretion is controlled, even though the hypergastrinemia remains unchanged.<sup>14</sup>

Gastrin in both normal subjects and patients with ZES has been found in a number of different molecular sizes. In gastrinoma, gastrin 17 (G<sub>17</sub>) is the major gastrin component, composing 74% to 80% of the total immunoreactivity, with “big gastrin” or gastrin 34 (G<sub>34</sub>), making up most of the remainder.<sup>17</sup> In contrast, in sera from normal subjects and patients without gastrinoma, G<sub>34</sub> contributes more than 60% of the total gastrin immunoreactivity.<sup>14</sup> In addition to G<sub>17</sub> and G<sub>34</sub>, smaller and larger forms of gastrin have been described in sera and gastrinomas from patients with ZES.<sup>2,8,9,18,19</sup> Also, a large-molecular-weight progastrin has been described in plasma

and tumors of patients with gastrinomas.<sup>20,21</sup> High amounts of progastrin have been found in patients with gastrinoma metastatic to liver.<sup>20</sup> The relative amount of G<sub>17</sub>, the amount of NH<sub>2</sub>-terminal fragments, and the ratio of the amount of G<sub>17</sub> amino-terminal immunoreactivity to the amount of G<sub>17</sub> carboxy-terminal immunoreactivity have been shown to be predictive of the extent of the gastrinoma by some investigators<sup>22</sup> but not others.<sup>20</sup>

In recent studies, the proportion of gastrinomas found at surgery in the duodenum and in lymph nodes near the pancreatic head has increased to greater than 50%,<sup>23,24,25</sup> and<sup>26</sup> such that 65% to 90% of all gastrinomas found at surgery occur in the pancreatic head and duodenal area ( Table 38.5-2).<sup>23,25</sup> Gastrinomas have also been reported to occur occasionally in other sites such as the liver, stomach, jejunum, mesentery, common bile duct, heart, and spleen ( Fig. 38.5-1).<sup>14,28</sup> In women, ovarian gastrinomas can occur and are functionally indistinguishable from other gastrinomas.<sup>14,27,28</sup> and<sup>29</sup>

Location	Frequency (%)
Duodenal	40-50
Pancreatic	30-40
Lymph node	10-15
Ectopic (nonpancreaticoduodenal or nodal)	5
Liver	
Common bile duct	
Cardiac	
Mesentery	
Spleen	
Ovary	

**TABLE 38.5-2.** Sites of Apparent Primary Gastrinoma

**FIGURE 38.5-1.** Patient with a primary gastrinoma of the common bile duct, illustrating several important features of the disease. Computed tomography scan after selective angiography (A) shows a 1.5-cm enhancing nodule (arrow) at neck of gallbladder just above the head of the pancreas, which is also seen on somatostatin receptor scintigraphy (B). C: At surgical exploration, a discrete mass is seen within the wall of the common bile duct (arrow shows primary tumor; 1, gallbladder; 2, cystic duct; 3, common bile duct). The primary tumor after resection (D) was a primary intracholedochal gastrinoma (E), and the adjacent lumen of the bile duct (L) is lined by normal epithelium. The tumor showed typical aggregation of neuroendocrine cells and dense vasculature characteristic of neuroendocrine tumors (F). Immunoperoxidase stained positive for chromogranin, synaptophysin, and gastrin. (From ref. 29.)

At present, the cell of origin of gastrinomas and other PETs remains obscure. Recent studies have provided evidence that duodenal gastrinoma, which usually contains many well-differentiated gastrin-containing (G) cells (in contrast to pancreatic gastrinoma), originates from gastrin cells in the duodenal crypts and Brunner's glands.<sup>30,31</sup> Because pancreatic gastrinomas are pleomorphic with heterogeneous cell types, it has been proposed that they originate from a multipotential, endocrine-programmed stem cell that undergoes somewhat inappropriate and incomplete differentiation toward the G cell.<sup>30,31</sup> As G cells are not normally present in the adult pancreas, pancreatic gastrinomas are generally considered ectopic, whereas gastrinomas in areas that normally contain G cells (duodenum, stomach, jejunum) are considered entopic.<sup>14,32</sup>

In early studies in which patients presented late in the course of their disease, gastrinomas were found at surgery in most patients with ZES (81% to 94%).<sup>33</sup> In subsequent studies of patients undergoing potentially curative surgery, no gastrinomas were found in as many as 50% of patients.<sup>34</sup> Recent studies have shown that almost all the missed gastrinomas were in the duodenum.<sup>25</sup> Now that exploration of the duodenum is being performed routinely, gastrinomas are found in more than 90% of patients.<sup>35</sup>

In early studies, 60% to more than 90% of patients with ZES had a malignant gastrinoma,<sup>32,33,36,37</sup> whereas in recent studies only one-half of patients have a malignant gastrinoma at the time of diagnosis. Metastases usually are to peripancreatic lymph nodes and to the liver.<sup>14</sup> Bone metastases have been reported in approximately 30% of patients with metastatic gastrinoma in the liver.<sup>38,39</sup> and<sup>40</sup> The diagnosis of malignancy is complicated by the fact that no histologic criteria predict malignancy, which can be established only by the presence of metastases.<sup>2,14</sup> Even metastatic disease can be difficult to establish, because a number of cases of extrapancreatic gastrinoma localized in lymph nodes have been described with no evidence of primary tumor. Some of these cases have apparently been cured by excision of lymph nodes, which suggests that the gastrinoma was not metastatic but rather originated in the lymph node.<sup>41</sup>

Numerous studies have attempted to identify predictors of malignancy in gastrinomas as well as other PETs. Clinically, tumor size has been shown to be an important predictor of liver metastases but not lymph node metastases.<sup>26</sup> Liver metastases occurred in 4% of gastrinomas less than 1 cm in diameter, in 28% of tumors measuring 1.1 to 2.9 cm, and in 61% of tumors larger than 3 cm.<sup>26</sup> In several prospective studies, duodenal gastrinomas have been found to be malignant with metastatic spread in 48% to 75% of cases.<sup>25,26,42</sup> In one large study involving 90 patients with ZES with pancreatic or duodenal gastrinomas, an equal percentage had lymph node metastases (48% and 47%, respectively), showing that, as regards lymph node metastases, the malignant potential of ectopic and entopic gastrinomas does not differ.<sup>26</sup> However, in this same study, 5% of patients with duodenal gastrinomas had liver metastases, which was significantly less ( $P < .00001$ ) than the 52% incidence in patients with pancreatic gastrinomas. Because most duodenal gastrinomas are small (80% < 1 cm) and most pancreatic gastrinomas are large (70% > 3 cm), it remains unclear whether tumor size and location are independent predictors.

Recent studies have attempted to use assessments of nuclear DNA to differentiate benign from malignant gastrinomas and other PETs.<sup>2,43</sup> DNA ploidy analysis in some studies did not predict prognosis.<sup>2</sup> However, in a study of 59 patients with gastrinomas, 54% were diploid, 15% near-diploid, 0% pure tetraploid, and 25% nontetraploid aneuploid, while another 5% exhibited multiple stem line aneuploidy.<sup>44</sup> All patients with multiple stem line aneuploidy had widespread metastases, and the results of the DNA analysis correlated with disease extent.<sup>44</sup> Silver staining of nuclear organizer regions, expression of the proliferating nuclear antigen, and expression of the cell cycle-associated antigen Ki-67, have all been reported to be potentially useful in differentiating benign from malignant PETs.<sup>43</sup> Chromosomal abnormalities have recently been reported in PETs in five of nine patients, but such alterations were not associated with more aggressive tumor behavior.<sup>45</sup> The protooncogene HER-2/*neu* recently was reported to be overexpressed in gastrinomas from 11 patients, with no mutations in the *ras* gene and a mutation in the p53 gene in only 1 of 11 patients.<sup>46</sup> No correlation with malignancy and HER-2/*neu* was found, but a previous study by the same investigators on carcinoid tumors of the gastrointestinal tract found a trend toward increased HER-2/*neu* copy number and aggressiveness.<sup>47</sup> Similarly, no abnormal expression of p53 protein was found in PETs in another study.<sup>43</sup>

One study showed allelic loss on chromosome 11q13 in gastric carcinoids from patients with multiple endocrine neoplasia type 1 (MEN 1) and ZES, suggesting that the pathogenesis of these tumors is similar to that of the pancreatic and parathyroid tumors that develop in MEN 1 patients.<sup>48,49</sup> Using positional cloning, the gene for

MEN 1 has been located on chromosome 11q13,<sup>50</sup> and approximately 30% of gastrinomas occurring in the sporadic setting have mutations in the gene.<sup>51</sup>

Approximately 20% of patients with ZES have a familial form and demonstrate evidence of MEN 1 (Wermer's syndrome). MEN 1 is an autosomal dominant trait characterized by hyperplasia or tumors of multiple endocrine organs, hyperparathyroidism being the most common abnormality.<sup>52</sup> Islet cell tumors of the pancreas are the second most common abnormality, occurring in 82% of MEN 1 patients, with 57% having ZES and 25% insulinomas.<sup>52,53</sup> and<sup>54</sup> Pituitary and adrenal adenomas are less common. Patients with MEN 1 with ZES differ from sporadic cases in that they frequently present at a younger age; their tumors are almost always multiple and frequently small and, in some studies, patients with MEN 1 have an increased survival rate as compared with sporadic cases.<sup>7,26,54</sup>

Immunocytochemical studies of tumors from patients with ZES have demonstrated gastrin in 90% to 100% in some studies and in 56% to 78% in others.<sup>14</sup> This difference may be due to differences in tissue fixation or type of gastrin antibody used or to a low content of gastrin in small tumors. Recent studies have demonstrated that more than 50% of tumors also demonstrated other peptides, including PP in 17% to 50%, insulin in 20% to 33%, glucagon in 0% to 33%, somatostatin in 0% to 33%, and adrenocorticotrophic hormone–like immunoreactivity in 0% to 30%.<sup>14,54</sup> In one report that reviewed seven different immunocytochemical studies involving tumors from 75 patients with ZES, gastrin was found in 80%, insulin in 30%, human PP (HPP) in 35%, glucagon in 29%, and somatostatin in 21%.<sup>55</sup> Therefore, it has become increasingly difficult, if not impossible, to determine which of the hormones found in a tumor by immunocytochemistry are clinically important in a given patient.<sup>14</sup> The endocrine nature of the tumor is not always apparent and, at present, to obtain a precise classification, a combination of clinical and biochemical data and immunocytochemical studies for peptides as well as for chromogranins, neuron-specific enolase, and synaptophysin frequently are necessary.<sup>56,57</sup>

Plasma elevations of peptides other than gastrin frequently occur in ZES.<sup>14</sup> A prospective study in 45 consecutive cases of ZES demonstrated increased concentrations in plasma of another peptide besides gastrin in 62%.<sup>55</sup> Motilin was the peptide most often present at abnormally high levels (29%), and neurotensin and gastrin-releasing peptide were elevated in 20% and 10%, respectively. HPP was elevated in plasma in 27% of patients, which compares with plasma HPP elevations of 10% to 60% described previously.<sup>58,59</sup> Some investigators have proposed that plasma HPP elevations might be a useful marker for identifying patients with metastatic liver disease,<sup>60</sup> but other researchers do not agree.<sup>61</sup> Despite frequent reports of finding insulin, glucagon, or somatostatin by immunocytochemical study, as well as occasional ZES patients with a concomitant insulinoma<sup>62</sup> or glucagonoma, no patient had increased amounts of these peptides in plasma in the aforementioned prospective study of 45 patients.<sup>55</sup> The presence or absence of abnormal plasma levels of a particular peptide or the extent of elevation did not correlate with location of tumor, extent of tumor, or the presence or absence of a particular symptom.<sup>63</sup> Adrenocorticotrophic hormone (ACTH) production in PETs, particularly in ZES patients, is associated with a very aggressive tumor phenotype.<sup>40,64</sup>

Elevated concentrations of human chorionic gonadotropin (HCG) subunits (a or b chains) in sera or in the tumor by immunocytochemistry occur in some patients with gastrinoma and may be predictive of malignancy.<sup>57</sup> In a study of 30 patients with ZES, 57% of patients with malignant and 45% with benign disease had elevated concentrations of a-HCG in plasma.<sup>65</sup> Seven patients had elevated levels of b-HCG in plasma, with four having malignant disease. This study demonstrates that elevated plasma concentrations of a- or b-HCG are not useful in predicting malignancy.

Chromogranin A is a 48-kD protein that is co-stored and co-released with peptide hormones from gastrointestinal tract endocrine cells and tumors<sup>57</sup> and is not produced by nonendocrine cells. Immunocytochemical staining for chromogranin A has shown its presence in gastrinomas, carcinoids, antral G cells, and fundic enterochromaffin-like (ECL) cells of the stomach.<sup>57,66</sup> Elevated levels in the plasma are reported to be one of the best markers for PETs, although chromogranin levels also are elevated in carcinoid and other neuroendocrine tumors.<sup>57</sup> In a recent study of 72 patients with PETs or carcinoid tumors, 99% had elevated plasma chromogranin A levels, 88% chromogranin B levels, and 6% chromogranin C levels.<sup>67</sup> In another study, plasma chromogranin A levels were measured in 112 patients with ZES, and the value correlated significantly with fasting serum gastrin (FSG) levels.<sup>68</sup> However, there was no correlation between the plasma level of chromogranin A and the amount of tumor, presence or absence of metastatic disease, or presence or absence of MEN 1.<sup>68</sup>

Histologic studies have demonstrated the general similarity of PETs and carcinoid tumors.<sup>1,2</sup> Different histologic classifications have been proposed based on growth patterns, including a glandular pattern, solid nests of cells (solid pattern), a trabecular or ribbon-like structure (gyriform pattern), and unclassified pattern.<sup>1,2,14</sup> Similar patterns have been demonstrated in tumors from patients with other endocrine tumors, and the type of histologic pattern does not correlate with the type of hormone produced, clinical symptoms, or malignancy. Ultrastructural classifications have all been proposed on the basis of the type of granules seen, but this also does not correlate with malignancy or clinical features.<sup>2,14</sup>

## GENERALLY BENIGN NEOPLASMS: INSULINOMA

Insulinomas were first recognized by Whipple,<sup>69</sup> who described 30 patients with hypoglycemia and pancreatic adenomas. Whipple's triad consists of the characteristic symptoms of hypoglycemia associated with blood glucose levels of less than 50 mg/dL and immediate relief after ingestion of glucose and have, for many years, remained the major criteria for the diagnosis of insulinoma.<sup>69</sup> Insulinomas usually occur in patients between the ages of 20 and 75 years. The average age at presentation is between 44 and 46 years, and there is a preponderance of women in most series (60%).<sup>1,70,71</sup>

Insulinomas are the opposite of gastrinomas, in that whereas 60% to 90% of gastrinomas are malignant, only 5% to 11% of insulinomas are malignant.<sup>1,70,71,72</sup> and<sup>73</sup> Most insulinomas are found to be solitary benign pancreatic nodules, often encapsulated, with only 2% to 10% of patients having multiple tumors.<sup>1,70,71</sup> In a patient with multiple insulinomas, MEN 1 should be suspected.<sup>52</sup> Insulinomas are uniformly distributed throughout the entire pancreas and are usually less than 1.5 cm in maximum diameter.<sup>72,73</sup>

## CLINICAL PRESENTATION AND DIAGNOSIS

Resection is the only curative modality for patients with PETs, and the success of operation is contingent on establishing the correct diagnosis, determining whether a patient may belong to a MEN kindred, performing appropriate radiographic imaging studies to assess the location of the primary tumor and the extent of regional or distant metastatic spread, and ensuring adequate medical management of the functional sequelae of excess hormone production preoperatively.

## GASTRINOMA

Gastrinomas are slightly more common in men (60%) than in women (40%). The mean age at diagnosis is 45 to 50 years, and approximately 20% of patients have MEN 1. The most common presentation in patients with ZES is abdominal pain in 26% to 58%, which usually cannot be differentiated from pain caused by other common acid peptic disorders.<sup>8,9,74</sup> However, in some studies, a significant proportion of individuals (14% to 25%) have no peptic ulcer or abdominal pain at the time of diagnosis.<sup>74</sup> Diarrhea is the initial symptom in 37% to 73% of patients and, in 15% to 18%, it is the only symptom. In one study involving 122 patients with ZES, esophageal symptoms, endoscopic abnormalities, or both were present in 61% of patients.<sup>75</sup> In early studies, up to 93% of patients had a peptic ulcer and, in 36%, the ulcers were multiple or in unusual locations.<sup>8,9</sup> Although the decreased severity of peptic ulcer disease at diagnosis suggests that in patients with ZES diagnoses are being made earlier, in almost all series a delay of 3 to 6 years still exists between the onset of symptoms and diagnosis.<sup>76</sup> Intestinal perforation, especially of the jejunum, is a presenting event in up to 7% of patients with ZES.<sup>77</sup>

The diagnosis should be suspected on the basis of the clinical presentation and established in almost all patients by demonstrating elevated basal gastric acid secretion [basal acid output (BAO)] and fasting hypergastrinemia.<sup>7</sup> Between 38% and 68% of patients have a solitary peptic ulcer, and 14% to 25% have no peptic ulcer. ZES should be suspected in the clinical setting of peptic ulcer with diarrhea, familial peptic ulcer, peptic ulcer in unusual locations, and recurrent or resistant peptic ulcer. ZES should be particularly suspected in patients with peptic ulcers that persist or recur despite treatment for *Helicobacter pylori* infection or with H<sub>2</sub>-receptor antagonists, in patients with severe esophagitis, and in patients with duodenal ulcers without *H pylori* infection.<sup>74</sup> *H pylori* is present in 90% to 98% of patients with idiopathic duodenal ulcer disease, and 90% heal with *H pylori* eradication; in ZES, fewer than 50% of patients have *H pylori* infection. In all patients who have peptic ulcer disease severe enough to require gastric surgery, at least one preoperative FSG level should be obtained.

To make the diagnosis of ZES, it is necessary to demonstrate an FSG elevated above 200 pg/mL and an elevated BAO.<sup>8,74,76</sup> The FSG concentration usually is obtained first, and only rarely do normal values occur in patients with ZES.<sup>79,80</sup> Although nearly 32% of patients with ZES have an FSG of at least 1000 pg/mL, in the

remaining two-thirds the FSG is elevated but not to the level of 1000 pg/mL.<sup>81</sup> Two general types of disorders other than ZES are also known to cause elevation in FSG: those associated with gastric acid hypersecretion and those associated with hypochlorhydria or achlorhydria, including chronic gastritis, gastric cancer, and pernicious anemia and in postvagotomy patients.<sup>8,9</sup> One of the most common causes of FSG elevation is drug-induced hypergastrinemia due to inhibition of acid secretion with H<sup>+</sup>K<sup>+</sup>-ATPase inhibitors (omeprazole, lansoprazole).<sup>8</sup> Similarly, *H pylori* infection can, on occasion, cause elevations of FSG in the range seen in ZES.<sup>82</sup> No absolute level of elevation in FSG distinguishes patients with disorders of acid hypersecretion versus hyposecretion; they can be distinguished only by direct assessment of acid output. If facilities are not available to measure the BAO, then a simple determination of the pH of the gastric contents (while the patient is not taking antisecretory medications) should be performed. A pH of 2.5 or higher virtually excludes the diagnosis of ZES.<sup>78</sup>

The most commonly used secretory criteria for diagnosing ZES are a BAO of at least 15 mEq/h in patients who have not undergone previous acid-reducing operations and at least 5 mEq/h in patients who have had previous acid-reducing operations.<sup>8,74</sup> The mean BAO in various series ranged from 34 to 53 mEq/h for patients with a history of previous acid-reducing surgery.<sup>14</sup> A BAO of at least 15 mEq/h will include up to 99% of patients with ZES and exclude 90% of patients with routine duodenal ulcers. In patients who have undergone previous acid-reducing surgery, the mean BAO exceeds 5 mEq/h in most studies but, in 6% to 45% of ZES patients, is less than 5 mEq/h.<sup>78</sup> Patients with ZES also have an elevated maximum acid output (MAO) and an elevated BAO/MAO ratio that often exceeds 0.6.<sup>74,83</sup> However, diagnostic criteria based on the MAO or BAO/MAO ratio offer no advantage over an elevated BAO alone.<sup>8,9</sup>

If a patient has an FSG of at least 1000 pg/mL and a gastric pH of less than 2.5, then the diagnosis of ZES generally is established.<sup>1,74</sup> The only other disorder that can mimic ZES in this capacity is retained gastric antrum syndrome, an uncommon condition that occurs in patients who have undergone a Billroth II gastroenterostomy with a portion of antrum left attached to the excluded proximal duodenal stump. This diagnosis can be excluded in patients after gastric surgery by the secretin stimulation test and by gastric <sup>99m</sup>Tc pertechnetate scanning. In patients with only moderately elevated FSG levels and a gastric pH of less than 2.5, ZES must be differentiated from retained gastric antrum syndrome, *H pylori* infection, chronic gastric outlet obstruction, antral G-cell hyperplasia, massive small bowel resection and, rarely, chronic renal failure. These conditions are best distinguished from ZES by the use of various gastrin-provocative tests, including the secretin test,<sup>84,85</sup> calcium infusion test,<sup>53,85</sup> and meal test.<sup>86</sup> The sensitivity of the secretin stimulation test is superior to the calcium and meal-provocative tests and is the one most commonly used.<sup>87</sup> Gastrin levels after secretin increased by 110 pg/mL in 93%, by more than 200 pg/mL in 87%,<sup>81</sup> and by more than 50% in 85%<sup>87</sup> of patients with ZES. Because of its ease, lack of side effects, high sensitivity, and very low occurrence of false-positive outcomes, the secretin test is the diagnostic provocative test of choice; a rise in gastrin of 200 ng/mL is diagnostic. The calcium infusion test should be reserved for the rare patient in whom ZES is strongly suspected but the secretin test is negative.<sup>81</sup>

Antral G-cell hyperplasia is reported to mimic ZES clinically, with elevated FSG and BAO.<sup>88</sup> This syndrome frequently occurs in patients after vagotomy, is due to increased numbers of antral G cells, is curable by antrectomy, may be associated with *H pylori* infections, and is differentiated from ZES by a negative secretin test and an exaggerated (at least 100% increase) postmeal serum gastrin level. Antral G-cell hyperfunction is similar to antral G-cell hyperplasia except that there are normal numbers of G cells and the syndrome is frequently familial, with autosomal dominant inheritance, and is associated with hyperpepsinogenemia I.<sup>89</sup> This syndrome was reported to be distinguishable from ZES by its association with a negative secretin test and an exaggerated increase in postprandial serum gastrin.<sup>81,89</sup> In patients with ZES, only 30% had a greater than 100% increase and 10% had a greater than 150% increase in the postprandial serum gastrin level.<sup>86</sup> Therefore, the meal test actually is frequently positive in patients with ZES and does not reliably differentiate ZES from antral syndromes.

Chronic gastric outlet obstruction can be difficult to distinguish from ZES because the obstruction can be caused by ZES or it can mimic ZES and be secondary to other causes of duodenal obstruction.<sup>90</sup> ZES can be differentiated from the other causes of obstruction by a secretin test and prolonged gastric suction.<sup>91</sup> Massive small bowel resection can cause a transient hypergastrinemia and elevation of BAO and can be distinguished from ZES by history and the secretin test. Chronic renal failure and *H pylori* infections can cause hypergastrinemia, which is usually associated with acid hyposecretion, although occasionally it may be associated with acid hypersecretion<sup>82,92</sup> and can be differentiated from ZES by the secretin test.

## INSULINOMA

The clinical symptoms of insulinoma are due to hypoglycemia in almost all instances.<sup>4,70,71</sup> Most symptoms are neuroglycopenic in nature and include visual disturbances (59%), confusion (51%), altered consciousness (38%), and weakness (32%). Seizures occur but are uncommon (23%).<sup>4,70,71</sup> Symptoms also can occur due to excess catecholamine release (adrenergic symptoms), such as sweating (43%) and tremulousness (23%).<sup>71</sup> In one study, 49% of patients had both neuroglycopenic and adrenergic symptoms, 38% had neuroglycopenic symptoms only, and 12% had adrenergic symptoms only.<sup>4</sup> Symptoms are characteristically associated with fasting, a delayed meal, or exercise.

The diagnosis of insulinoma can be established only by documenting symptomatic hypoglycemia with inappropriately elevated serum insulin levels during a monitored fast (Table 38.5-3).<sup>4</sup> Hypoglycemia usually is defined as a blood glucose level of less than 50 mg/dL in the fasting state. In healthy individuals, the blood glucose value usually does not decrease to less than 70 mg/dL after an overnight fast. In more than 97% of individuals, a supervised fast of 48 hours or less will be sufficient to diagnose insulinoma by the development of clinical symptoms and a plasma glucose level of less than 50 mg/dL.<sup>4</sup> In addition, patients with the diagnosis will usually have serum insulin levels greater than 5 μU/mL, and 97% will have levels greater than 10 μU/mL. An insulin-glucose ratio greater than 0.3 is typical.<sup>93</sup> In some normal obese subjects, because of hyperinsulinemia due to insulin resistance, the fasting plasma insulin-glucose ratio may be elevated and may mimic the pattern in insulinoma.<sup>70,71</sup> In these patients, the fasting glucose is normal and, with prolonged fasting, the blood glucose level does not decrease to less than 55 mg/dL.

---

Symptoms of hypoglycemia (headache, lightheadedness, confusion, drowsiness, seizures)

Symptoms of catecholamine excess (tremors, palpitations)

Hypoglycemia during a monitored fast (<50 mg/dL)

Increased serum insulin (>5-10 μU/mL)

Increased proinsulin (≥25%)

Negative sulfonyleurea screen

Relief of symptoms after eating

---

**TABLE 38.5-3.** Common Diagnostic Criteria for Insulinoma

A number of other conditions can cause fasting hypoglycemia with increased plasma insulin levels, including causes of organic hyperinsulinism due to pancreatic islet cell disease aside from insulinoma, factitious use of excessive insulin or hypoglycemia agents, or autoantibodies against the insulin receptor.<sup>1,4,70,94,95</sup> To differentiate insulinoma from these other conditions, additional tests are useful, including plasma determination of proinsulin, C-peptide level, antibodies to insulin, and plasma sulfonyleurea levels. Because endogenous insulin is synthesized as a precursor, proinsulin, quantification of the higher-molecular-weight component, called the *proinsulin-like component*, is useful. In patients with surreptitious use of insulin or oral hypoglycemia agents, the proinsulin level is either normal or decreased.<sup>95</sup> The measurement of C peptide has proven useful in differentiating organic hypersecretion of insulin from patients surreptitiously using insulin because commercial insulin preparations contain no C peptide. In insulinoma, the characteristic finding is either an elevated or normal plasma C-peptide concentration, whereas in patients surreptitiously using insulin, the plasma insulin level is high and the C-peptide level low.<sup>70,71,95</sup>

## NONFUNCTIONING PANCREATIC ENDOCRINE TUMORS

Nonfunctioning PETs and PPomas present in the fourth and fifth decade of life.<sup>4,32,96</sup> PPomas release the hormone pancreatic polypeptide, which has no known functional sequelae.<sup>1</sup> Originally it was thought that nonfunctioning PETs did not release any hormone products, but these lesions have since been shown to secrete chromogranins, a-HCG or b-HCG subunits, or other peptides that do not cause symptoms.<sup>57</sup> Increasingly, what in the past were believed to be nonfunctioning PETs

now are appreciated to have elevated plasma PP levels. In one study, one-half to three-fourths of PETs not associated with any clinical syndrome and classified as nonfunctioning were found to be PPomas. Elevated plasma PP is specific for endocrine pancreatic tumors; of 53 patients with adenocarcinoma of the pancreas, none had elevated plasma PP levels.<sup>97</sup> Currently, no data are available to suggest that nonfunctioning PETs without elevated PP and PPomas differ in biologic behavior or presentation.<sup>1</sup> Immunohistochemically nonfunctioning PETs and PPomas can stain positively for numerous other gastrointestinal peptides. In one series of 30 nonfunctioning tumors, 50% displayed insulin-like immunoreactivity, 30% glucagon, 43% PP, and 13% somatostatin, and only 13% stained for no peptide.<sup>98</sup> With these tumors, symptoms arise largely from mechanical or mass effects of the neoplasm, and therefore the tumors are diagnosed late, when they are quite large and locally invasive.

They are usually solitary tumors except in patients with MEN 1, in whom multiple adenomas are seen.<sup>2,3</sup> The tumors are distributed throughout the pancreas at a pancreatic head-body-tail ratio of 7:1:1.5.<sup>4</sup> The malignancy rate varies from 64% to 92%.<sup>97</sup>

Chromogranin A and B levels are elevated in almost all patients with nonfunctioning PETs.<sup>67</sup> Elevated plasma levels of PP do not establish the diagnosis of a PPoma even when a pancreatic mass is present. Plasma PP levels are reported to be elevated in 22% to 71% of patients with functional PETs in various studies,<sup>1,99</sup> as well as in nonpancreatic carcinoid tumors. Furthermore, elevated plasma levels of PP can occur in other situations such as old age; after bowel resection; with alcohol abuse; during certain infections; in chronic noninfective inflammatory disorders, acute diarrhea, chronic renal failure, diabetes, chronic relapsing pancreatitis, and hypoglycemia; or after eating.<sup>99,100</sup> To increase the specificity of an elevated plasma level for a PPoma, an atropine suppression test may be used. In one study of 48 patients with elevated plasma PP levels, atropine (1 mg intramuscularly) did not suppress PP levels in any of the 18 patients with PETs but did suppress the level by 50% in all patients without tumors.<sup>59</sup>

Patients present with abdominal pain in 36% and jaundice in 28% of cases; in 16% of patients, the tumors are found incidentally at surgery and, in the remaining patients, a variety of symptoms due to the tumor mass are present.<sup>1,101</sup> The average delay from onset of symptoms until diagnosis varied from 5 months to 2 to 7 years.<sup>97</sup>

## OTHER RARE PANCREATIC ENDOCRINE TUMORS

The VIPoma syndrome, also commonly called the *Verner-Morrison syndrome*, was first described by Verner and Morrison in 1958.<sup>102</sup> Because of the resemblance of the diarrheal fluid to that seen in patients with cholera, the terms *pancreatic cholera* and *endocrine cholera*<sup>103</sup> and the abbreviation *WDHA*<sup>32</sup> (watery diarrhea, hypokalemia, and achlorhydria) have also been used for this condition. The tumors occur in a bimodal distribution. The mean age for adults at diagnosis is 50 years, with a range of 32 to 81 years. There is a female predominance. In children, the mean age at diagnosis is 2 to 4 years, with a range of 10 months to 9 years.<sup>104</sup>

In adults, more than 80% of VIPomas are located in the pancreas,<sup>1,4</sup> with rare cases caused by intestinal carcinoids or pheochromocytomas that produce vasoactive intestinal peptide (VIP).<sup>105</sup> VIPomas are usually large solitary tumors.<sup>1,106</sup> In one series, only 2% of tumors were multiple, with 50% to 75% reported to be in the pancreatic tail.<sup>105</sup> One- to two-thirds of patients with VIPomas have metastases at the time of diagnosis or surgery.<sup>103</sup> Characteristically in children younger than 10 years, and rarely in adults (5% of cases), VIPoma syndrome is due to a ganglioneuroma or ganglioneuroblastoma. These extrapancreatic tumors are less often malignant (10%) than are pancreatic VIPomas.<sup>105</sup>

Using immunocytochemical studies, 34% to 38% of VIPomas also stain for HPP, 19% for glucagon, 10% for somatostatin, 5% for insulin, and 0% for gastrin.<sup>98,107</sup> VIPomas also elaborate the peptide histidine methionine (PHM-27), a 27–amino acid peptide that shares with VIP a common precursor peptide, pre-pro-VIP/PHM-27.<sup>1,2,103</sup> The presence of immunoreactive VIP is strongly suggestive for VIPoma, as this peptide rarely is found in other pancreatic endocrine tumors (10 of 104 pancreatic endocrine tumors in one study).<sup>107</sup>

Plasma levels of VIP are consistently elevated in patients with the VIPoma syndrome and appear to be responsible for the functional syndrome ( [Table 38.5-4](#)).<sup>1,103,105</sup> A continuous infusion of VIP for 10 hours in normal human subjects to achieve plasma levels similar to those seen in patients with the VIPoma syndrome produced watery diarrhea in 6 to 7 hours.<sup>108</sup> The principal features of VIPoma syndrome are the presence of severe secretory diarrhea associated with hypokalemia and dehydration.<sup>1,103,104</sup> and <sup>105</sup> The diarrhea is copious, all patients with VIPoma producing more than 3 L/d.<sup>103,105</sup> A volume of less than 700 mL/d has been proposed to rule out the diagnosis of VIPoma.<sup>109</sup> Cramping pain or colic is reported in 35% to 63% of patients.<sup>103,105</sup> Gross steatorrhea usually is not present; in one study, none of 52 patients with VIPomas had 24-hour fecal fat greater than 15 g/d<sup>105</sup> and, in another study, 84% of the patients did not have steatorrhea.<sup>103</sup> Weight loss is almost universally present.<sup>105</sup> Erythematous flushing of the head or trunk area is characteristic and reported in 23% of patients. The clinical laboratory studies invariably demonstrate hypokalemia (83% to 100%) and, to a lesser degree, hypercalcemia (41%), hypochlorhydria (70%), and mild hyperglycemia (18%).<sup>1,103,104</sup> and <sup>105</sup> Hypokalemia is often severe, potassium levels being less than 2.5 mmol/L at some time in 93% of patients.<sup>105</sup>

VIPoma	Glucagonoma	Somatostatinoma
Diarrhea	Weight loss	Gallbladder disease
Dehydration	Migratory necrolytic erythema	Diabetes mellitus
Weight loss	Glucose intolerance	Weight loss
Crampy pain	Hypoaminoacidemia	Diarrhea
Hypokalemia	Thromboembolic disease	Steatorrhea
		Hypochlorhydria

**TABLE 38.5-4.** Symptoms Commonly Associated with Rare Pancreatic Endocrine Tumors

The diagnosis of VIPoma requires the documentation of an elevated plasma concentration of VIP and the presence of a large volume of secretory diarrhea.<sup>1,103,110</sup> A large number of possible causes for the diarrhea can be excluded by fasting the patient because, in patients with VIPomas, the diarrhea persists during fasting.<sup>1,103,109</sup> The diarrheal fluid should be characteristic of a secretory diarrhea,<sup>109</sup> wherein the stool electrolytes can account for all of the stool water osmolality [(sodium + potassium) × 2 = measured osmolality].<sup>109</sup> Other diseases can produce a chronic, large-volume secretory diarrhea and can be confused with VIPoma, one such syndrome being the *pseudo-VIPoma syndrome*.<sup>109</sup> Other causes of such diarrhea include ZES and chronic laxative abuse.<sup>111</sup> In addition, some cases of secretory diarrhea are of unknown origin.<sup>111,112</sup>

The range for normal fasting plasma VIP levels in most laboratories is 0 to 170 pg/mL.<sup>104,105</sup> In one series of patients with VIPomas, the mean value was 965 pg/mL, and the lowest value was 225 pg/mL.<sup>104</sup> In contrast, in another large study, the mean value in patients with VIPomas was 675 pg/mL, the highest value seen in a normal patient being 53 pg/mL and the lowest value seen in a VIPoma patient being 160 pg/mL.<sup>105</sup>

In 1942, the association of a pancreatic tumor with a skin rash was first described.<sup>113</sup> Then, in 1966, McGavran et al.<sup>114</sup> reported a patient with an elevated fasting glucagon level, dermatitis, diabetes, and a pancreatic endocrine tumor. Later, in 1973, Wilkinson<sup>115</sup> described the rash associated with this endocrine tumor as necrolytic migratory erythema. Mallinson et al.<sup>116</sup> specifically established the association of a cutaneous rash with glucagon-producing tumors of the pancreas when they reported nine cases in 1974.

Most glucagonomas are large at the time of diagnosis, the average size being between 5 and 10 cm. Glucagonomas have a predilection for arising in the pancreatic tail in 50% to 80% of patients.<sup>117</sup> In one study, 22% of these tumors were in the head, 14% in the body, and 51% in the pancreatic tail.<sup>118</sup> Most glucagonomas are malignant, and the most common site of metastatic spread is the liver. Less commonly, there is spread to lymph nodes, bone, and mesentery. In most cases,

glucagonomas are within the pancreas; however, a glucagonoma associated with the typical clinical syndrome was found in the proximal duodenum.<sup>117</sup> Glucagonomas usually occur as a single tumor, although in 10% of patients in one series, multiple tumors or diffuse involvement by a single mass was found.<sup>117</sup>

Glucagonomas usually occur in middle to late age, with only 16% of cases occurring in individuals younger than 40 years and most occurring at 50 to 70 years of age.<sup>117</sup> The typical dermatitis occurs in 64% to 90% of patients, diabetes mellitus or glucose intolerance in 83% to 90%, weight loss in 56% to 90%, diarrhea in 14% to 15%, abdominal pain in 12%, and thromboembolic disease with venous thrombosis in 24% and with pulmonary emboli in 11%; occasionally, psychiatric disturbances also are seen (see [Table 38.5-4](#)).<sup>1,117,118</sup> and <sup>119</sup> Laboratory abnormalities include anemia in 44% to 85% of patients, hypoaminoacidemia in 26% to 100%, hypocholesterolemia in 80%, and renal glycosuria.<sup>1,118</sup>

The pathophysiology of the glucagonoma syndrome is related to the known actions of glucagon. Glucagon stimulates glycogenolysis, gluconeogenesis, ketogenesis, lipolysis, and insulin secretion, as well as affecting gastrointestinal tract secretion, inhibiting pancreatic and gastric secretion, inhibiting intestinal motility, and increasing heart rate and contractility. Hyperglycemia in glucagonoma results from the increased hepatic glycogenolysis and gluconeogenesis. Weight loss has been attributed to the known catabolic effects of glucagon.<sup>119</sup> It has not been clearly established that the skin rash is due to the hyperglucagonemia *per se*, because in numerous patients given large doses of glucagon over extended periods of time, the skin rash did not develop.<sup>1,119</sup> Possibly, the glucagon-induced hypoaminoacidemia that develops in 80% to 95% of patients may be involved, because correction of the hypoaminoacidemia has been shown to correct the dermatitis without changing plasma glucagon concentrations in some patients.<sup>1,119,120</sup> The similarity of the lesions to those seen in patients with zinc deficiencies has resulted in trials of zinc therapy in some patients, with observed benefit<sup>119</sup>; however, plasma zinc levels are normal in most cases.

Glucagon is one of the most frequently recognized peptides in immunocytochemical studies of PETs, though in many cases it is not associated with any syndrome. In one series of 1366 autopsy cases, a frequency of 0.8% adenomas was reported, and all contained glucagon-producing cells.<sup>98,119</sup> The morphology of most glucagon-producing tumors demonstrates no general features that distinguish them from other PETs.<sup>1,98,117,119</sup>

The presence of cutaneous lesions often precedes the diagnosis of the syndrome for long periods, with a mean of 6 to 8 years and a maximum of 18 years. Typically, the rash starts as an erythematous patch, usually at periorofacial or intertriginous areas such as the groin, buttocks, thighs, or perineum, and then spreads laterally. The lesions later become raised, with superficial, central blistering. The top of the bullae frequently detach or rupture, leaving eroded areas that crust. The lesions tend to heal in the center, while the edges continue to spread with a crusting well-defined edge. Healing is associated with the development of hyperpigmentation. This entire sequence characteristically takes 1 to 2 weeks, so that while some new lesions are developing, others are healing; therefore, a mixed pattern of erythema, bullous formation with epidermal separation, crusting, and hyperpigmentation together with normal skin can occur. The histopathology can be as varied as the clinical presentation.<sup>117</sup> Glossitis or angular stomatitis is reported to occur in 34% to 68% of patients.

Once the diagnosis is suspected, it can be confirmed by establishing the presence of a marked elevation in plasma glucagon concentration. In most laboratories, the upper limit of normal for fasting glucagon concentration is 150 to 200 pg/mL. In one large review of glucagonomas, only two patients had a plasma glucagon level of 200 to 500 pg/mL, four patients had a level between 500 and 1000 pg/mL, and 52 patients had a level in excess of 1000 pg/mL.<sup>118</sup> These results are in agreement with another study,<sup>117</sup> in which the mean plasma glucagon concentration in 73 cases of glucagonoma was 2110 ± 334 pg/mL, with a range of 550 to 6600 pg/mL and no result of less than 500 pg/mL. Hyperglucagonemia (generally <500 pg/mL) is reported to occur in chronic renal insufficiency, diabetic ketoacidosis, prolonged starvation, acute pancreatitis, acromegaly, hypercortisolism, septicemia, severe burns, severe stress (trauma, exercise), familial hyperglucagonemia, and hepatic insufficiency.<sup>117,119</sup>

Somatostatinomas release somatostatin, a hormone that inhibits numerous endocrine and exocrine functions. Release of almost all gastrointestinal tract hormones, including insulin, glucagon, gastrin, secretin, cholecystokinin, and motilin, is inhibited by somatostatin. In addition to the inhibition of endocrine secretions, somatostatin has direct effects on a number of target organs, including inhibition of gastric acid secretion, increased intestinal motility, and reduced intestinal absorption of fat. In 1977, the first two cases of somatostatinoma were described by Ganda et al.<sup>121</sup> and Larsson et al.<sup>122</sup> Somatostatinomas are the least common PET, fewer than 50 cases having been described.<sup>123</sup> Patients characteristically have diabetes mellitus, gallbladder disease, diarrhea, weight loss, steatorrhea, and hypochlorhydria (see [Table 38.5-4](#)).<sup>1,97,103,124,125</sup>

Somatostatinomas occur in the pancreas in 56% to 75% of cases, and the remainder occur in the upper small intestine.<sup>97,125</sup> The tumors have a predilection for the pancreatic head and occur there two to three times as often as in the body or tail.<sup>97,125</sup> In 90% of patients, the tumors are solitary<sup>125</sup> and range from 1.5 to 10.0 cm in diameter. Tumors demonstrate evidence of metastatic spread at diagnosis or operation in 70% to 92% of patients.<sup>97,125</sup> Metastases usually occur in the liver (75% of patients with metastases) but also in the regional lymph nodes (31%) and, less frequently, in bone.<sup>97,125</sup>

Electron-microscopical studies show that the secretory granules are typical of those in D cells in 89% of the tumors examined.<sup>97,125</sup> Immunocytochemical analysis shows somatostatin-like immunoreactive material in tumors that, in addition, contained insulin (33%), calcitonin (27%), and gastrin (13%).

The mean age of patients is affected with somatostatinomas is 50 years.<sup>97,125</sup> For patients with intestinal somatostatinomas, 43% were women, as compared with 66% with pancreatic tumors.<sup>125</sup> Diabetes mellitus was present in 95% of patients with pancreatic tumors and in 21% of those with intestinal tumors.<sup>97</sup> Gallbladder disease was seen in 94% of pancreatic and 36% of intestinal tumor patients, and weight loss was noted in 90% of pancreatic and 44% of intestinal cases.<sup>97</sup> Steatorrhea and hypochlorhydria occurred in 83% to 86% of pancreatic tumor cases but in only 12% to 17% of intestinal tumor cases.<sup>1,97</sup> Symptoms attributable to excess somatostatin release are seen in no more than 45% of patients in some studies.<sup>123</sup>

GRFomas are the most recently described PET syndrome and feature excessive release of growth hormone–releasing factor (GRF).<sup>126,127</sup> and <sup>128</sup> In reviews of GRFomas, 29% to 30% originated in the pancreas, 53% in the lung, and 10% in small intestinal tumors, and there was a rare case in the adrenal gland.<sup>129,130</sup>

Multiple pancreatic tumors have been reported in 30% of patients with GRFomas in one series.<sup>129</sup> Approximately 40% of all GRFomas occur in patients with ZES and, in another 40%, Cushing's syndrome was present.<sup>1,129</sup> Tumors generally are large (>6 cm), varying from 1 to 25 cm in diameter.<sup>129</sup> In one series, tumor size, GRF levels, and the presence of metastases were not related.<sup>129</sup>

On light-microscopical studies, typical features of a PET are seen, the lesion being composed of trabecular or solid nests and sheets of uniform tumor cells.<sup>123,129</sup> In electron-microscopical studies, tumor cells containing 100- to 250-nm secretory granules are seen.<sup>129,131,132</sup> and <sup>133</sup> Immunochemical studies demonstrated GRF-immunoreactive material in all tumors examined, with 10% to 80% of cells possessing GRF.<sup>123,129,130</sup> GRF-immunoreactive materials were seen in 31% of all PETs in one study<sup>134</sup> but in 0% to 100% in other pathological studies,<sup>126,127,129,135</sup> although very few of these patients had acromegaly. The known actions of GRF as a stimulant of growth hormone release account for the clinical presentation with acromegaly.<sup>126,127,129,135</sup>

Patients are between 15 and 63 years old, the average age being 38.<sup>123,129,130</sup> Patients with intestinal GRFomas tend to be younger, with two of three patients in one study being younger than 20 years.<sup>129</sup> A female preponderance (73%) is seen for all GRFomas. Acromegalic features are indistinguishable from those of patients with classical acromegaly and include enlargement of hands and feet, facial changes, skin changes, headache, and peripheral nerve entrapment.<sup>123,129,130,135</sup> The diagnosis should be suspected in any patient with acromegaly who does not have a pituitary adenoma imaged by magnetic resonance modalities or with an abdominal mass<sup>123</sup> and is confirmed by measuring plasma GRF levels.

## IMAGING AND LOCALIZATION OF PANCREATIC ENDOCRINE TUMORS

Relatively precise localization of the gastrinoma has become an increasingly important factor in evaluating patients with ZES.<sup>83,136</sup> With the increased ability to control gastric acid hypersecretion with antisecretory drugs, emergency total gastrectomy rarely is necessary now, allowing the clinician time to determine the location and extent of the gastrinoma. The ability for long-term control of gastric acid hypersecretion has made tumor growth and possible metastatic spread an increasingly important determinant of long-term survival.<sup>14,15,26,37</sup> Preoperative imaging studies can identify patients with metastatic disease to the liver or other sites so that unnecessary surgery can be prevented. Gastrinomas frequently are multiple and extrapancreatic, and accurate imaging assists in determining the nature of the operative procedure. Imaging studies identify resectable metastatic disease to the liver in up to 15% of patients.<sup>137</sup> For insulinoma, the extent of preoperative imaging

necessary to ensure an operative cure has not been clearly defined. <sup>138,139,140</sup> and <sup>141</sup> It is generally agreed that some preoperative localization is essential, primarily because insulinomas are frequently small (90% <2 cm in diameter) and, to a lesser extent, because metastatic spread should be identified to prevent unnecessary surgery. However, the question of the extent of localization studies that should be performed in occult insulinomas has not yet been resolved. <sup>142,143</sup> and <sup>144</sup>

A number of different techniques, including abdominal ultrasonography, computed tomography (CT) scanning, magnetic resonance imaging (MRI), selective abdominal angiography, selective venous sampling for gastrin from portal venous tributaries (PVS), intraarterial secretin with hepatic venous gastrin sampling (IAS), somatostatin receptor scintigraphy (SRS), endoscopic ultrasonography (EUS) preoperatively, intraoperative ultrasonography (IOUS), and intraoperative endoscopy (IOE) with transillumination of the duodenum at surgery have all been reported as helpful in localizing gastrinomas.

Ultrasonography has a low sensitivity for localizing both primary and metastatic tumors, but, in a prospective study, <sup>145</sup> it was recommended that this imaging modality continue to be used because it has high specificity, is noninvasive and, on occasion, localizes gastrinomas not found by other modalities. <sup>145</sup> The CT scan detects nearly 50% of all primary and metastatic liver disease; however, its ability to detect primary tumors has been shown to be directly related to tumor size, <sup>136</sup> detecting 0% of tumors less than 1 cm in diameter, 30% of those between 1 and 3 cm, and 95% of tumors more than 3 cm in diameter. Frequently, small primary tumors, which are being increasingly found in the duodenum (<1 cm), usually are missed by CT. <sup>23,25,136,146</sup> Furthermore, CT scan is less sensitive for detecting extrahepatic, extrapancreatic gastrinomas than pancreatic gastrinomas. In a large, prospective study, selective angiography was found to detect 68% of primary tumors and 86% of hepatic metastases. <sup>147</sup> The ability to detect tumors was location-dependent: Of gastrinomas in the pancreatic head, 90% were found, as were 80% in the body, 45% in the tail, and 34% in the duodenum; 50% of extrapancreatic, extrahepatic, and extraduodenal tumors also were found. <sup>147</sup> In a comparative study, angiography detected 20% more hepatic metastases than did CT scanning (68%), and the combination detected 96% of all liver metastases. <sup>38</sup>

Improvements in the sensitivity of MRI have increased its usefulness in localizing gastrinomas and other PETs. A prospective study from the years 1986 to 1987 reported that MRI was less sensitive than either CT scanning or angiography, <sup>148</sup> but a recent study using current, improved MRI technology was more sensitive than either angiography or CT scanning for metastatic disease. <sup>149</sup> However, MRI remains less sensitive than angiography for primary tumor. <sup>149</sup> For insulinomas, ultrasonography localizes 33%, MRI 46%, CT scanning 35%, dynamic CT scanning 66%, selective arteriography 63%, and all imaging studies combined 80%. <sup>1,70,71,143,144</sup>

Pancreatic endocrine tumors frequently have a high density of somatostatin receptors, and scanning after injection of the radiolabeled long-acting somatostatin analog octreotide localizes pancreatic endocrine tumors. <sup>150,151,152,153</sup> and <sup>154</sup> This technique is one of the most sensitive methods for localizing primary gastrinomas <sup>38,39,152,153,155,156,157,158</sup> and <sup>159</sup>: 60% of primary gastrinomas and more than 90% of metastases to liver. <sup>38</sup> The sensitivity of SRS in identifying gastrinoma in patients prior to operation increases with tumor size: Only 30% of tumors less than 1.1 cm and 64% of those 1.1 to 2.0 cm are detected, as compared to 96% of tumors larger than 2 cm. <sup>146</sup> SRS appears to be the procedure of choice to screen ZES patients for the presence of bone metastases. In a study of 115 patients with ZES, 8 (7%) were determined to have bone metastases. <sup>160</sup> Bone scan was positive in 52 patients, resulting in a very low specificity. SRS and MRI were positive in 6 and 7 patients, respectively. Because it is noninvasive and highly sensitive and has the ability to image the entire body for metastatic foci, SRS is recommended as the initial procedure of choice in cases of gastrinoma and for all PETs except insulinomas ( Fig. 38.5-2). <sup>39</sup> SRS is reported to localize 53% of insulinomas but, because such lesions frequently have low densities of somatostatin receptors, this number may be higher than what can be routinely achieved. <sup>151</sup>

**FIGURE 38.5-2.** Example of somatostatin receptor scintigraphy sensitivity in detecting gastrinoma. A patient with biochemically confirmed Zollinger-Ellison syndrome underwent initial imaging studies. The magnetic resonance image (MRI) and computed tomography (CT) scan did not show any lesion. However, somatostatin receptor scintigraphy (SRS) showed a positive signal in the right upper quadrant, which was confirmed to be a 1.4-cm gastrinoma resected from the anterior lateral wall of the second part of the duodenum at surgical exploration. (From ref. <sup>39</sup>.)

EUS is being used increasingly to localize PETs. <sup>152,161,162</sup> and <sup>163</sup> It is reported to localize 75% of primary gastrinomas <sup>152,161,162</sup> and <sup>163</sup> and to be particularly useful for intrapancreatic tumors. Whether EUS can image small duodenal gastrinomas is unclear. <sup>164</sup> However, EUS is an invasive procedure, and the additional information obtained over SRS or current MRI techniques is unproven. Recently, EUS was reported to have a high sensitivity, localizing 80% of insulinomas, even though 15% were no more than 1 cm in diameter. <sup>162</sup>

PVS has been reported to be useful for functional localization of gastrinomas. <sup>136</sup> However, in a prospective study, a combination of PVS and standard CT and MRI imaging yielded results only marginally better than imaging alone in identifying gastrinomas. <sup>165</sup> In this study, neither the magnitude of the gastrin gradient nor its presence or absence correlated with whether a gastrinoma would be found at surgery. A gradient greater than 50% is reported to occur in 68% of all patients with ZES. PVS requires expertise, is time-consuming, and is associated with some morbidity, primarily abdominal pain at the catheter insertion site. <sup>165,166</sup> These drawbacks, combined with limited availability and the fact that 70% to 80% of gastrinomas are near the duodenum–pancreatic head, had led most <sup>165</sup> (but not all <sup>167</sup>) investigators to conclude that PVS has limited usefulness in ZES. This experience is in marked contrast to the use of PVS for insulinomas, where it has proven to be extremely valuable in localizing lesions throughout the pancreas. <sup>141,142</sup>

Most gastrinomas (91%) demonstrate a paradoxical release of gastrin with intravenous injection of secretin. <sup>81</sup> This characteristic has been used to localize gastrinomas selectively by injecting secretin intraarterially into various abdominal arteries and collecting venous samples from the hepatic veins for assays of gastrin. <sup>168</sup> Injection into the arterial supply of the tumor area causes a marked increase in gastrin. <sup>168</sup> In a recent comparative study, IAS was found to localize the gastrinoma as frequently as the much more technically difficult PVS. <sup>169</sup>

PVS for insulin can accurately localize an insulinoma to the exact region of the pancreas (head, body, tail) in nearly all patients. PVS, which requires considerable expertise and is highly invasive, is now being replaced by the intraarterial injection of calcium (IAC) during angiography, with hepatic venous insulin sampling. A recent preoperative study reported that 80% of insulinomas could be localized using this method. <sup>144</sup> In two studies, composed of 12 and 23 patients with insulinoma, PVS <sup>142</sup> and IAC <sup>144</sup> correctly localized the tumor in 75% and 88% of cases, respectively. In another study of 35 patients with insulinoma in whom radiologic studies imaged the tumors in 46%, PVS localized the tumor in 100%. <sup>170</sup> PVS localizes tumors to only a general area of the pancreas, and the insulinoma may be so small that it cannot be localized by palpation at surgery within this area. However, IOUS has been increasingly reported to be useful in localizing insulinomas at the time of surgery. <sup>142,171</sup> In one study of 12 patients with negative imaging studies in whom 75% had a PVS gradient localizing the insulinoma to the appropriate pancreatic area, at surgery insulinomas could be localized by palpation in only 41%. <sup>142</sup> IOUS identified insulinomas in five additional patients and was the single best modality in locating the insulinoma at surgery. <sup>142</sup>

The use of IOUS in a recent prospective study was demonstrated to change operative management in 10% of all ZES cases, either by localizing additional gastrinomas or by determining that a gastrinoma was malignant. <sup>172</sup> IOUS localized 22 of 23 pancreatic gastrinomas found at surgery but only 7 of 12 extrapancreatic gastrinomas. All five of the gastrinomas missed were in the duodenum. <sup>172</sup>

Even though gastrinomas frequently occur in the duodenum (see Table 38.5-2), they are rarely seen by routine upper gastrointestinal endoscopy because they are

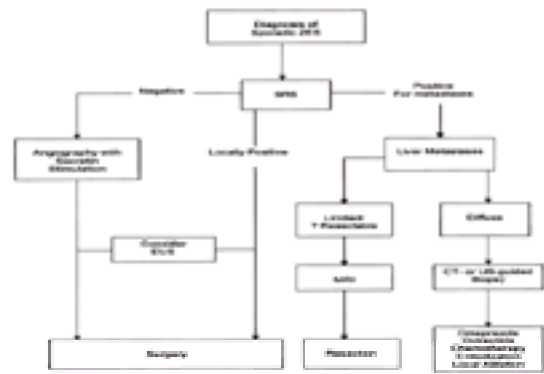

small and submucosal. IOE of the duodenum at surgery has been attempted and found useful in localizing small gastrinomas not found by other modalities.<sup>173</sup> In a recent prospective study, 12 duodenal gastrinomas were found at surgery in 10 patients.<sup>173</sup> IOE detected 10 of the 12 (83% sensitivity), which was significantly greater than either standard preoperative imaging, which detected 3 (25% sensitivity) or IOUS and palpation, which detected 5 (42% sensitivity). IOE with transillumination detects 20% more duodenal tumors than does palpation,<sup>174</sup> and duodenotomy detects an additional 15%. Endoscopic transillumination also is often helpful in establishing the placement of the duodenotomy incision.<sup>174</sup>

## TREATMENT OF RESECTABLE DISEASE

### GASTRINOMA

In ZES patients, gastric acid hypersecretion must be controlled because most patients will not be cured after surgical exploration.<sup>76,175</sup> If acid hypersecretion is controlled, patients have an excellent quality of life; however, long-term prognosis is being increasingly determined by the malignant nature of the gastrinoma.<sup>26</sup> As many as 90% of gastrinomas may be malignant; therefore, it is important to consider surgical therapy directed at the primary and metastatic disease, if feasible ( Fig. 38.5-3).

**FIGURE 38.5-3.** Flow diagram showing a proposed workup for patients with newly diagnosed sporadic Zollinger-Ellison syndrome (ZES). After biochemical confirmation of disease, an initial screening study with somatostatin receptor scintigraphy (SRS) should be performed. Patients who have results positive for metastases should undergo additional imaging studies. If disease is confined to the liver, then resection or other therapies, as shown, should be considered. For patients who have a locally positive result, endoscopic ultrasonography (EUS) should be considered, after which patients undergo exploration with curative intent. If somatostatin receptor scintigraphy is negative, then angiography with selective secretin stimulation should be performed. CT, computed tomography; MRI, magnetic resonance imaging; US, ultrasonography.

### Management of Gastric Acid Hypersecretion

Years ago, patients with ZES required total gastrectomy to control gastric acid hypersecretion. Before effective medical management, the operation was commonly done as an emergency procedure and carried a mortality rate of 15%.<sup>33</sup> Operative results were unsatisfactory for patients who had less than a total gastrectomy, with most patients developing recurrent ulcer disease, often with lethal complications, within days of surgery.<sup>33</sup> With the development of increasingly effective medical therapy, the mortality for patients with ZES undergoing total gastrectomy has decreased. Though an early study claimed that total gastrectomy could lead to regression of the gastrinoma in some patients,<sup>176</sup> subsequent studies have failed to substantiate this claim.<sup>37,176,177</sup> There is no evidence that either medical therapy of gastric hypersecretion or total gastrectomy affects the growth rate of the gastrinoma.<sup>14</sup>

Numerous studies have demonstrated that gastric acid hypersecretion can now be controlled medically over the long term in every patient who will reliably take oral medication—the H<sup>+</sup>K<sup>+</sup>-ATPase inhibitor omeprazole or lansoprazole.<sup>76,175,178,179</sup> The availability of these agents and their long duration of action have greatly simplified management because they can be taken once or twice per day. Therefore, most authorities recommend that total gastrectomy be reserved for patients who are unreliable, do not have access to routine medical follow-up, or cannot or will not take oral medication.<sup>14,76</sup> In all other patients, medical therapy is the treatment of choice. Although parietal cell vagotomy in patients with ZES in whom no tumor was found at surgery decreased the BAO by 66%, most patients still needed some antisecretory drug.<sup>34</sup> At present, routine performance of parietal cell vagotomy is not recommended.<sup>174</sup>

In patients with ZES and the MEN 1 syndrome, medical control of gastric hypersecretion can be greatly facilitated by correction of the hyperparathyroidism that is almost invariably present by the time ZES develops.<sup>52</sup> Correction of hyperparathyroidism may reduce the FSG concentration, increase the responsiveness to a given dose of antisecretory medication, or decrease the BAO.<sup>180</sup> Therefore, in patients with ZES and MEN 1 with hyperparathyroidism, parathyroidectomy should be performed before any contemplated surgical procedure to control acid hypersecretion.

The results of medical treatment of gastric acid hypersecretion have been reviewed extensively.<sup>3,14,76,175</sup> H<sub>2</sub>-receptor antagonists (cimetidine, ranitidine, famotidine) alone or in combination with anticholinergic agents (proprantheline, isopropamide) and, more recently, the substituted benzimidazole (omeprazole), which functions as an H<sup>+</sup>K<sup>+</sup>-ATPase inhibitor, have been used successfully in the long-term treatment of gastric hypersecretion in ZES. The number of patients in whom medical therapy fails varies greatly in different series.<sup>14,175</sup> For cimetidine, the reported failure rate varies from 0% to 65%,<sup>14,175,181</sup> for ranitidine from 0% to 40%,<sup>14,175,182</sup> and for omeprazole and lansoprazole from 0% to 7.5%.<sup>14,76,175,178,179</sup> The failure rate for famotidine has been reported as 0% in several series.<sup>14,175,183</sup> In general, studies have shown that relief of symptoms does not adequately reflect the effectiveness of antisecretory therapy. Most studies have demonstrated that in order to assess the adequacy of antisecretory therapy, gastric acid secretion must be measured while the patient is taking medication.<sup>14</sup>

The amount of antisecretory medication varies widely from patient to patient; thus, the optimal dose of medication must be determined for each patient initially and must periodically be reevaluated.<sup>14,175</sup> Recent studies have shown that if enough antisecretory drug is used to decrease gastric acid secretion to less than 10 mEq/h for the hour prior to the next dose of medications in patients with no history of gastric surgery and to less than 5 mEq/h in patients with a history of acid-reducing procedures or severe esophageal disease, peptic ulcers will heal and complications of peptic ulcer disease will be prevented.<sup>14,76,175</sup> To reduce acid output to these levels before the next dose of medication, patients frequently require more than twice the usual dose of H<sub>2</sub>-receptor antagonist or three times the usual dose of omeprazole recommended for idiopathic peptic ulcer disease.<sup>14,76,175</sup> In recent studies, the median doses were 3.6 g/d for cimetidine (range, 1.2 to 12.6 g/d), 1.2 g/d for ranitidine (range, 0.45 to 6.0 g/d), 0.25 g/d for famotidine (range, 0.05 to 0.8 g/d), 20 to 80 mg/d for omeprazole (range, 20 to 360 mg/d), and 30 to 120 mg/d for lansoprazole.<sup>14,76,175</sup> The long-term use of these doses of H<sub>2</sub> antagonists and omeprazole has proven to be both effective and safe.<sup>14,175</sup> Except for antiandrogen side effects (impotence, gynecomastia, and breast tenderness) with high-dose cimetidine in up to 60% of male patients, long-term treatment with cimetidine in women or with ranitidine, famotidine, or omeprazole in patients of either gender has been shown to be safe.<sup>14,175</sup> Omeprazole has been associated with the development of hepatitis that resolved after discontinuation of the drug.<sup>184</sup>

The long-term use of omeprazole has caused concern about toxicity, because female rats given long-term omeprazole (or other potent inhibitors of gastric acid secretion) have developed proliferation of gastric ECL cells and, in some cases, carcinoid tumors of the stomach.<sup>16,185</sup> Results from a number of studies have led most<sup>185</sup> (but not all<sup>186</sup>) investigators to conclude that the ECL hyperplasia and gastric carcinoid tumor formation in these animal models were most likely secondary to drug-induced achlorhydria and the resultant hypergastrinemia and not secondary directly to a toxic action of the antisecretory drug. Hyperplasia of gastric endocrine cells occurs in patients with ZES. Quantitative studies indicate that gastric ECL cells are increased approximately twofold, independent of administration of antisecretory agents.<sup>14,187,188</sup> and <sup>189</sup> In two studies in which omeprazole treatment was prolonged for up to 4 years, there was no statistical increase in gastric ECL cells owing to use of this drug.<sup>187</sup> In 15 of the 16 patients reported with gastric carcinoids and ZES in whom the presence or absence of MEN 1 could be determined, 14 had MEN 1.<sup>14</sup> These data suggest that the presence of MEN 1 may be an important predisposing factor to the development of gastric carcinoids in patients with ZES.<sup>188</sup> In patients with ZES without MEN 1, 0.6% had gastric carcinoid tumors in one study<sup>190</sup> and, in another study, 0% had gastric carcinoid tumors.<sup>191</sup> In contrast, in patients with MEN 1, 13% in a U.S. study<sup>190</sup> and 30% in a French study<sup>191</sup> had gastric carcinoids. These data demonstrate further the importance of the presence of MEN 1 in

determining the development of gastric carcinoids.

Most patients with ZES require H<sub>2</sub> antagonists every 4 to 8 hours to inhibit gastric secretion adequately, whereas omeprazole or lansoprazole has a very long duration of action (>48 hours), allowing most patients to require omeprazole only once or twice daily.<sup>14,175</sup> The usual starting dose for omeprazole is 60 mg/d, although a proportion of patients are better controlled with a twice-daily dose. Patients with ZES with complicated disease (previous gastric surgery, moderate to severe esophageal disease, or MEN 1), usually require a higher dose and are best treated by starting with 40 mg twice daily.<sup>14,175</sup> Recent studies show that in patients with uncomplicated ZES, the dose of omeprazole or lansoprazole can be reduced over time in more than 85% of patients.<sup>179,192</sup> It is recommended, though, that because of these drugs' acid lability, patients not be started on these low doses until they are proven safe and effective.<sup>179,192</sup>

For patients presenting with a complication who cannot take oral antisecretory medication and for patients undergoing surgery, it is important that acid secretion be adequately controlled parenterally. Studies have shown that continuous infusions of cimetidine (median dose, 3 mg/kg/h) or ranitidine (median dose, 1 mg/kg/h) or bolus doses of omeprazole (injectable, 60 mg every 12 hours; not yet available in the United States) are all effective.<sup>14,175</sup> Recently, a new parenteral proton pump inhibitor, pantoprazole, has been shown to produce a dose-dependent decrease in acid output in volunteers stimulated with pentagastrin.<sup>193</sup> These drugs should be continued until oral antisecretory agents can be restarted.

## SURGERY TO CURE GASTRINOMA

In a number of studies, the 5-year survival rate for all patients with ZES was 62% to 87%, and the 10-year survival was 47% to 77%.<sup>26,194,195,196,197,198</sup> and <sup>199</sup> A recent comprehensive report from the National Institutes of Health cited long-term outcome in 151 consecutive ZES patients who underwent operation with curative intent<sup>35</sup>. Among patients with sporadic gastrinoma, 34% were biochemically and radiographically free of disease at 10 years, as compared to no patients with MEN 1 and ZES. The overall 10-year survival was 94% (Fig. 38.5-4). In another study from the same institution, a multivariate analysis of factors associated with long-term (>5-year) cure was performed.<sup>200</sup> Age, gender, duration of symptoms or disease, and severity of disease (as reflected by the level of BAO, FSG, or secretin stimulation test) did not predict outcome. Only a diagnosis of MEN 1 was inversely correlated with cure. In addition, the status of preoperative imaging studies (either positive or negative), tumor size, and number of tumors resected did not correlate with cure. However, a normal postoperative FSG and secretin stimulation test did independently and significantly predict cure.

**FIGURE 38.5-4.** Disease-free (A) and disease-specific (B) survival in patients with the Zollinger-Ellison syndrome (ZES). **A:** Kaplan-Meier plot of disease-free survival after surgical exploration to resect and potentially cure gastrinoma. Twenty-eight patients with ZES and multiple endocrine neoplasia type 1 underwent 32 surgical explorations, and 123 patients with sporadic ZES underwent 144 surgical explorations. Data are presented based on number of operative procedures rather than number of patients. Results show the percentage of the total number of surgical patients in each group who are disease-free at the indicated time. **B:** Kaplan-Meier plot of survival specific for ZES. Four deaths occurred, secondary to progressive metastatic disease in three cases and a paradoxical cerebral embolus postoperatively through a patent foramen ovale valley in one case. MEN1, multiple endocrine neoplasia type 1; NIH, National Institutes of Health. (From ref. <sup>35</sup>.)

Though the growth of gastrinoma is generally slow, in long-term studies of patients originally treated by total gastrectomy, 57% of deaths were due to tumor progression.<sup>33,37</sup> Therefore, with the ability to control gastric acid hypersecretion, the malignant potential of the tumor is an increasingly important determinant of long-term prognosis. The extent of the tumor and whether MEN 1 is present or absent have been reported to determine survival rates.<sup>194,195,201</sup> In patients with no tumor found at laparotomy or in whom tumor is completely resected, 5- and 10-year survival rates are 90% to 100%, respectively.<sup>25,194</sup> Patients without liver metastases had a 5-year survival rate of 95%, and 10-year survival rates were 90%.<sup>26</sup> In contrast, patients with liver metastases had a 5-year survival rate of only 53% and a 10-year survival of 30% (Fig. 38.5-5).<sup>26</sup> In most studies in patients without liver metastases, a difference in survival is noted between patients whose tumors were resected completely and those in whom tumors were resected and recurred or in whom tumors were incompletely resected. There was, however, no difference in survival rate between patients with complete resection and those with no tumor found at surgery. In two studies, patients with MEN 1 are reported to have a better 5- and 10-year survival rate than patients without MEN 1,<sup>194</sup> whereas in other studies, the difference was not significant.<sup>26,195,201</sup> One study demonstrated a significant difference in the percentage of patients with ZES with MEN 1 (6%) who presented with liver metastases, as compared with non-MEN 1 patients (22%,  $P = .03$ ), with no difference in survival rate for the patients without liver metastases between MEN 1 and non-MEN 1 patients.<sup>26</sup> The presence of concurrent Cushing's syndrome may also be associated with a poor prognosis.<sup>202</sup>

**FIGURE 38.5-5.** Survival based on the presence or absence of liver metastases in patients with the Zollinger-Ellison syndrome (ZES). Survival rates were evaluated using death due to ZES-related causes. Six of 158 patients with no liver metastases died; 17 patients developed liver metastases during the follow-up period, of whom 4 died; and 23 of 37 patients who presented with liver metastases on initial evaluation have died. (Data from ref. <sup>40</sup>.)

Hence, because of the excellent prognosis for patients with gastrinomas that are resected and the evidence of increased importance of the malignancy in determining survival, surgical resection of gastrinoma should be considered in all patients with ZES.<sup>35</sup> After gastric acid hypersecretion is adequately controlled medically, it must be determined whether the patient has sporadic ZES (ZES without MEN 1) or whether ZES is present with MEN 1.<sup>14</sup> The role of surgery is controversial in patients with MEN 1.<sup>203,204</sup> and <sup>205</sup>

A recent study has addressed the question of whether surgical resection of the tumor alters its natural history.<sup>206</sup> In this study, only 3% of patients with ZES undergoing tumor resection developed liver metastases during follow-up, whereas significantly more patients treated medically developed liver metastases (26%,  $P < .003$ ) (Fig. 38.5-6). Two deaths occurred owing to metastatic disease in the nonoperated group, as compared with no disease-specific deaths in the surgical group ( $P = .085$ ). Although this was not a randomized study, the two groups did not differ in clinical or laboratory characteristics or time of follow-up ( $15.4 \pm 1.5$  years [no

surgery] vs.  $14.0 \pm 0.8$  years [surgery] from onset). This study strongly suggests that surgery alters the natural history of ZES and therefore should be recommended in patients without MEN 1. Additional studies reported after 1986 also indicate a higher cure rate, averaging approximately 40%, for patients with ZES who undergo operation; however, there was wide variation, from 17% to 100%.<sup>23,25,195,207,208,209,210 and 211</sup>

**FIGURE 38.5-6.** Incidence of liver metastases that developed in patients with the Zollinger-Ellison syndrome, some of whom had undergone surgery with curative intent while others were merely observed. Of 98 patients who underwent operation, 3 developed liver metastases at a mean follow-up of 6 years (range, 0.7 to 16.8 years), as compared to 6 of 26 patients who did not undergo operation, with a mean follow-up of 8.7 years (range, 1.5 to 19.0 years). (From ref. <sup>206</sup>.)

In most recent series, the improvement in outcome after surgical exploration and resection with curative intent is due to a number of factors. First, because gastric acid hypersecretion can be managed in all patients with antisecretory agents, surgical exploration can be done electively and safely.<sup>14,25,35,212</sup> Second, patients can be effectively screened to eliminate occult metastatic unresectable disease, thereby improving patient selection for potentially curative surgery.<sup>35,36,152</sup> Furthermore, the knowledge that small duodenal primary tumors are more frequent than previously was appreciated has resulted in increased detection and resection of these lesions than in earlier studies.<sup>35,42,79</sup> In a 10-year prospective analysis of surgical outcome in patients with ZES, the overall percentage of patients free of disease at 5 years was 30%,<sup>25</sup> consistent with the updated outcome from the same institution.<sup>35</sup> In addition, ectopic gastrinoma can occur in a variety of other locations, including small bowel mesentery, common bile duct, and ovary.<sup>29</sup>

At laparotomy, the entire pancreas as well as the duodenum should be dissected and exposed.<sup>23,25,171,213</sup> IOUS and transillumination of the duodenum should be performed.<sup>23,25</sup> Duodenotomy in the anterior wall of the second part of the duodenum also should be performed.<sup>23,25,171,213</sup> Palpation alone can identify 65% of duodenal gastrinomas, endoscopic transillumination an additional 20% of tumors, and duodenotomy an additional 15% of tumors not localized by any other modality.<sup>174</sup> For duodenal tumors, 71% are in the first part of the duodenum, 21% in the second part, and 8% in the third part.<sup>42</sup> Using this approach to carefully evaluate the duodenum, gastrinomas have been found in all patients undergoing operation,<sup>35</sup> 71% of such lesions being duodenal.<sup>76</sup> At laparotomy, if a gastrinoma is found as a solitary lesion in the liver, it should be removed, provided the resection can be performed safely. If gastrinoma is found in the pancreatic head, it should be enucleated.<sup>23,211</sup> If extensive gastrinoma not amenable to eradication is found in the pancreatic head area, performing a pancreaticoduodenectomy (Whipple's operation) for potential cure is controversial.<sup>214,215</sup> A Whipple procedure cured 11 of 12 patients with tumors localized by imaging studies and PVS to the peripancreatic head area.<sup>211</sup> However, no studies have demonstrated an increased survival rate overall in patients with ZES after pancreaticoduodenectomy. Because of the possible morbidity and mortality associated with this operation and the excellent long-term prognosis of these patients, it has not yet been established whether the adverse consequences of a pancreaticoduodenectomy might outweigh the adverse consequences of unresected occult gastrinoma. If no gastrinoma is found at surgery, as occurs in 7% to 30% of cases overall, a blind distal pancreatectomy should not be performed, because 65% to 90% of gastrinomas are now found in the pancreatic head or duodenum<sup>23,25,212</sup> and because such an approach has not improved cure rates.

At surgery, the use of IOUS is recommended to localize additional lesions, to confirm the significance of a palpated mass, and to establish the relationship between the tumor and the pancreatic duct.<sup>172,216,217,218 and 219</sup> For either pancreatic or duodenal primary tumors, any abnormal or suspicious lymph nodes in that area should be excised. In some patients undergoing exploration, disease may be limited to one or more lymph nodes.<sup>41</sup> Despite the inability to identify a primary site of disease in the duodenum or pancreas, long-term biochemical cures can be achieved. In one study of 13 patients who had disease limited to resected lymph nodes, 43% remained biochemically cured with a median follow-up of 5.3 years.<sup>41</sup>

At present, the role of surgery in the treatment of patients with ZES and MEN 1 is unclear.<sup>53,54,205,212</sup> A recent study reported that in eight patients (six surgical cases and two autopsy reports) with ZES and MEN 1, gastrinomas were found in the duodenum in all.<sup>220</sup> In all six patients whose tumors were surgically resected, the gastrin values were normal postoperatively, and this study raised the possibility that these patients could be cured. However, a number of limitations exist for this study; for example, cure cannot be established without a secretin provocative test, which was not reported in this study. A recent prospective study involving ten consecutive patients with ZES and MEN 1 demonstrated that no patients could be cured by simple tumor enucleation even after duodenotomy.<sup>221</sup> Cure was not possible short of pancreaticoduodenectomy, because 30% of patients had more than 20 duodenal tumors and 86% of patients had positive lymph nodes. This study also demonstrated that 20% of patients with MEN 1 and ZES had pancreatic gastrinomas.<sup>221</sup> Another recent study reported three patients with MEN 1 and ZES who were cured by a Whipple procedure.<sup>211</sup> In 77 patients with MEN 1 and ZES, the only independent factor associated with the development of liver metastases was a pancreatic primary tumor measuring greater than 3 cm.<sup>222</sup> Operation with curative intent in 118 patients did not influence survival. Currently, because of the excellent prognosis of these patients, the ability to control acid secretion medically, the presence of other pancreatic tumors, and the morbidity of this procedure, it is not routinely recommended. Our recommendation is to operate on patients with MEN 1 and ZES when a tumor of at least 2.5 cm is seen on imaging studies.<sup>8,9,203</sup> This policy is based on the recent observation that metastases to the liver correlated with tumor size.<sup>26</sup> If the tumor is in the pancreatic head, it is enucleated if possible, and, if in the pancreatic tail, it is resected and a duodenal exploration is performed.

Because most patients with sporadic ZES undergoing operation and resection will have persistent or recurrent disease, the role of reoperation in these patients warrants consideration. In a series of 17 patients who had previously undergone an operation with curative intent, reoperations were performed on the basis of biochemically documented recurrent disease and one or more positive imaging studies.<sup>18,223</sup> In those undergoing reoperation, it was possible to identify and resect disease in 17 of 18 cases, with biochemical cures in all, although median follow-up was short (34 months). Of note, the site of recurrent disease identified at reoperation was related to the initial operative findings. For example, in those in whom lymph node disease was resected initially, most patients had lesions identified in the duodenum at reoperation. In contrast, in those who had a primary duodenal or pancreatic lesion initially resected, recurrence was commonly identified in regional lymph nodes. Because of the increased potential risk of complications associated with reoperation in this setting, reoperation should be considered carefully.

## INSULINOMA

### Medical Therapy for Hypoglycemia of Insulinoma

The simplest form of nonsurgical treatment for insulinoma is dietary management.<sup>1,70,71 and 72</sup> Many insulinoma patients begin ingesting frequent small meals to alleviate symptoms prior to seeking medical evaluation, and a significant percentage report weight gain in the year prior to diagnosis. Slowly absorbed oral nutrients such as cornstarch, bread, potatoes, and rice are recommended.<sup>1,224</sup>

A number of drugs have been reported to control the hyperinsulinemia, with octreotide and diazoxide being the most effective.<sup>1,70,71 and 72</sup> Diazoxide, a benzthiazide analog, directly inhibits insulin release from  $\beta$  cells through stimulation of  $\alpha$ -adrenergic receptors and also has an extrapancreatic hyperglycemic effect, possibly by inhibiting cyclic adenosine monophosphate phosphodiesterase, which enhances glycogenolysis.<sup>1,70,71 and 72</sup> The major side effects of diazoxide are sodium retention, gastrointestinal symptoms such as nausea and, occasionally, hirsutism. Edema can result from the sodium retention, and the addition of a diuretic such as trichlormethiazide, a benzothiadiazine derivative, can correct the edema as well as augment the hyperglycemic effect.<sup>1,70,71 and 72</sup> Diazoxide should be initiated, with 150 to 200 mg given in two to three divided doses per day and, if not effective, increased to a maximum of 600 to 800 mg/d.<sup>1,70,71</sup> The calcium channel inhibitor verapamil has been used, either alone or in combination with other drugs, to help control hypoglycemia in a small number of patients,<sup>1</sup> as has propranolol.<sup>72,225</sup>

Phenytoin (Dilantin) inhibits the release of insulin from b cells and has been used successfully to treat a small number of patients with refractory hypoglycemia. <sup>72,226</sup> Maintenance doses of 300 to 600 mg/d are used, but it is reported that in only one-third or fewer patients is the hyperglycemic effect of phenytoin of any clinical significance. <sup>72</sup> Glucocorticoids (prednisone, 1 mg/kg) and glucagon, either alone or with diazoxide, have also been used in a few patients. <sup>72</sup>

Octreotide controls symptoms and hypoglycemia in 40% to 60% of patients. <sup>1,70,71,227,228</sup> This drug is generally well tolerated and usually is initiated at doses of 50 µg subcutaneously two or three times daily, which can be increased to 1500 µg/d. <sup>228</sup> The main side effects are gastrointestinal, such as bloating and abdominal cramping, and include long-term side effects such as malabsorption and cholelithiasis. <sup>1,70,71,228</sup> Besides improving symptoms, octreotide decreases plasma insulin levels in 65% of patients. <sup>228</sup> However, most patients were treated for less than 1 week preoperatively, so the long-term efficacy is not known in a significant number of patients. Octreotide also decreases plasma glucagon levels and growth hormone secretion; hence, it may worsen the hypoglycemia in some patients. <sup>70</sup>

### Surgical Therapy

All insulinomas without evidence of metastases should be surgically removed, regardless of the severity of symptoms. Of all insulinomas, 80% to 90% are benign isolated lesions that are cured by complete surgical removal. <sup>1,70,71</sup> and <sup>72,94,138,139</sup> and <sup>140</sup> The extent of preoperative imaging necessary for successful outcome of resection of presumed benign solitary pancreatic insulinoma is controversial. <sup>138,139</sup> and <sup>140</sup> Because insulinomas are exclusively located within the pancreatic parenchyma, thorough exploration and intraoperative evaluation with inspection, palpation, and IOUS can result in successful resection in the vast majority of patients undergoing operation. IOUS has been advocated as an important adjunct in operation for insulinoma, not only in identifying lesions at the time of surgery but as an aid in enucleating the lesion by identifying the relationship between the tumor in the pancreatic parenchyma and the adjacent pancreatic duct. This is particularly important in the case of lesions located in the head of the pancreas, where a resection other than enucleation would require pancreaticoduodenectomy. Selective arterial stimulation of the splanchnic vessels supplying the pancreas using the secretagogue calcium can produce a subsequent rise in insulin levels obtained from catheters positioned at the orifice of the hepatic veins. <sup>144</sup> The sensitivity of this test is almost 90% and allows one to direct attention to a particular region of the pancreas at the time of operation. Blind distal pancreatectomy has been used in the past in an attempt to cure insulinoma in patients in whom no lesion could be identified, based on the appreciation that insulinomas can be distributed anywhere in the pancreatic parenchyma and resection of a large portion of normal pancreatic tissue should therefore have a reasonable cure rate for occult disease. However, given the current status of available localization studies, this practice should be largely unnecessary. With careful inspection and the use of IOUS, the number of people with occult lesions that cannot be identified at the time of operation should be fewer than 5%. <sup>138,141</sup> In this setting, our recommendation would be to proceed with distal pancreatectomy only in the face of a position insulin step-up in the hepatic veins after selective intraarterial stimulation with calcium demonstrates a *bona fide* step-up in the splenic artery as compared to the gastroduodenal or hepatic arteries.

The liver must always be explored for evidence of metastatic disease, and the entire abdomen must be explored to rule out rare extrapancreatic tumors that primarily secrete insulinoma-related growth factors (IGFs). IGF-secreting tumors that cause hypoglycemia usually are of mesodermal origin and have considerable tumor bulk by the time hypoglycemia symptoms occur. <sup>71</sup> The entire pancreas must be explored for other tumors, since multifocal tumors occur in up to 10% of all cases. <sup>1,70,71</sup> Isolated lesions of the tail may be enucleated or removed *en bloc* by distal pancreatectomy. Body and head lesions require enucleation with careful dissection to avoid damage to the main pancreatic duct and its attendant morbidity. Even in cases of documented metastatic disease, refractory debilitating symptoms may be an indication for debulking the pancreatic lesions, as metastases are not always secretory. Removal of peripancreatic lymph nodes may be curative for malignant insulinoma if no liver metastases are present. <sup>93,224</sup>

The documentation of metastatic disease, either at the time of surgery or by imaging studies, is the only accurate means of diagnosing malignant insulinoma. Unlike all other PETs, malignant insulinomas are uncommon, occurring in only 5% to 11% of all cases of insulinoma. Malignant primary insulinomas usually are not occult and have a mean size of 6 cm, which is more than three times as large as benign insulinomas. <sup>1,70,71</sup> and <sup>72,229</sup> The median disease-free survival after curative resection of malignant insulinomas was 5 years in one series. <sup>229</sup> The recurrence rate was 63%, the median interval to recurrence was 2.8 years, and the median survival with recurrent tumor was 19 months. Palliative re-resection was associated with a median survival of 4 years, whereas median survival after biopsy was only 11 months. <sup>229</sup> Surgical resection of primary and metastatic insulinomas is desirable when possible. <sup>229</sup> Malignant insulinomas, like other PETs, may respond to chemotherapy and treatment with octreotide. <sup>1,71,228</sup> The use of these agents for all malignant PETs is described later in [Treatment of Metastatic Disease](#).

### OTHER PANCREATIC ENDOCRINE TUMORS

The remainder of the PETs are relatively infrequent and include VIP-producing tumors (VIPomas), glucagonomas, ACTHomas, somatostatinomas, and GRF pancreatic tumors (GRFomas). Each of these PETs is usually malignant.

The treatment is surgical, if possible, even in the more than 60% of cases in which metastases are present at the time of diagnosis ( [Fig. 38.5-7](#)).<sup>3</sup> Of 25 cases of nonfunctional PETS in one series, a Whipple procedure was performed in 20% of patients, partial or total pancreatectomy in 25%, and tumor excision in 10%. <sup>101</sup> The survival rates were 60% at 3 years and 44% at 5 years in this series. <sup>101</sup> The cure rate of these tumors at present is low because of their late recognition.

**FIGURE 38.5-7.** Flow diagram illustrating the general approach and management strategy for patients with pancreatic endocrine tumors (PET). Once the diagnosis has been established, initial staging studies are performed to determine the absence or presence of metastatic disease. A variety of palliative options are available to control the functional sequelae of hormone excess for increasing tumor burden. For those patients who have isolated liver metastases, resection should be performed when possible. Other regional therapies that may cause durable palliation of symptoms or disease control in the liver should be attempted. For those patients who have local regional disease, resection should be considered. MRI, magnetic resonance imaging.

The first treatment objective in patients with VIPomas, even before considering the diagnosis, is the replenishment of fluid and electrolyte losses to correct the profound hypokalemia, dehydration, and acidosis that usually are present. The patients may require 5 L/d or more of fluid and more than 350 mEq/d of potassium. <sup>104</sup> In the past, numerous drugs have been reported to control, to varying degrees, the diarrheal output in small numbers of VIPoma patients; among these agents are prednisone (60 to 100 mg/d), clonidine, indomethacin, phenothiazines, lithium carbonate, propranolol, metoclopramide, loperamide, lidamide, angiotensin II, and norepinephrine. <sup>1,103,104</sup>

Octreotide, a long-acting somatostatin analog, can control the diarrhea in both the short and long term in 87% of patients with VIPoma, and it is now the agent of choice. <sup>1,103,227,228</sup> In recent reviews of treatment of 20 and 25 patients with VIPomas with octreotide, the drug completely abolished diarrhea in 10% of patients in the first study and in 65% in the other and improved the diarrhea in 90% in the first study and in 95% in the other. <sup>1,227,228</sup> In some patients, responses have been reported to be short-lived, or a patient may respond initially to a low dose (50 to 100 µg three times daily) but subsequently may require a larger dose to control the diarrhea and may even become refractory to doses up to 1200 µg/d. <sup>228</sup> In nonresponsive patients or in patients whose symptoms recur, the administration of glucocorticoids concomitantly with octreotide has proven effective in a small number of cases. <sup>228</sup> With octreotide treatment, plasma VIP concentrations decreased in 80% to 88% of

patients.<sup>226,228</sup>

After imaging studies have been conducted to localize the primary VIPoma and determine the extent of the tumor, surgical excision for cure should be considered in all patients without metastatic disease. In one series, surgical resection of a pancreatic VIPoma relieved all symptoms in 17 patients (33%),<sup>105</sup> and 30% were cured in another series.<sup>230</sup> Surgical removal with complete control of all symptoms was possible in 78% of all patients with VIP-producing ganglioneuroblastomas.<sup>105</sup>

For patients with glucagonomas, medical therapy with octreotide improves dermatitis in 54% to 90% of patients, with complete disappearance of this symptom in up to 30%.<sup>1,227,228</sup> In one study, diarrhea improved in four of six patients and resolved in two of six patients. Diabetes mellitus was not improved with octreotide treatment.<sup>228</sup> The diabetes mellitus was severe enough to require oral hypoglycemia agents in 42% of patients and insulin in 27%. Plasma glucagon levels decreased in 80% to 90% of patients but only decreased to the normal range in 10% to 20% of patients on octreotide treatment.<sup>1,227,228</sup>

In 50% to 80% of patients, metastases are already present at the time of diagnosis.<sup>1,117,118</sup> and <sup>119</sup> Surgical resection has been successful in a number of patients with resectable disease,<sup>1,118,119</sup> but the exact percentage of cases that can be cured is not known. In one large review involving 92 cases of glucagonoma, only 16 of the malignant cases were treated by surgical resection alone. Seven cases exhibited normal plasma glucagon levels after resection and, in the five cases that had no evidence of metastatic spread, plasma glucagon levels postoperatively were normal in two. Even if a patient eventually develops a recurrence, an extended disease-free interval may be attained that is beneficial.<sup>119</sup> A number of studies have reported a benefit to patients even if surgical debulking only can be accomplished.<sup>117,118</sup> and <sup>119</sup> In patients with widely metastatic disease in whom surgical debulking is not possible, various chemotherapeutic agents are used and are discussed later in [Treatment of Metastatic Disease](#).

Most somatostatinomas are found at the time of laparotomy for cholecystectomy or during gastrointestinal imaging studies for various nonspecific complaints such as abdominal pain or diarrhea.<sup>97,125</sup> The symptoms produced by somatostatinomas are less pronounced and less specific than those seen with other PETs and probably do not reach a detectable level until patients develop high somatostatin blood levels late in the course of the disease. Though the plasma levels of somatostatin usually are elevated in pancreatic somatostatinomas, in duodenal or small-intestinal tumors these levels may fail to be conclusive.<sup>123,231</sup>

Duodenal somatostatinomas are increasingly associated with von Recklinghausen's disease.<sup>231</sup> In a recent review, 27 duodenal somatostatinomas with or without von Recklinghausen's disease were compared with pancreatic somatostatinomas without von Recklinghausen's disease.<sup>231</sup> The cases of somatostatinomas with von Recklinghausen's disease were similar to the sporadic duodenal cases in that they rarely were associated with the somatostatinoma syndrome, additional hormone production was infrequent, and they were less frequently malignant (30% vs. 71%).

The number of patients undergoing successful complete resection ranges from 60% to 80%.<sup>83,96</sup> In one series, 65% of patients were reported to have undergone successful resection, but the percentage actually cured was not stated.<sup>232</sup> In a number of patients, a combination of surgical resection and cytotoxic therapy was used,<sup>97,125,233</sup> and 60% of the patients were alive 6 months to 5 years after diagnosis. Because of the malignant nature of these tumors, if imaging studies demonstrate a possible resectable tumor, results suggest that patients with somatostatinomas will benefit from surgical resection.

In patients without metastatic disease, surgical resection of a GRFoma should be carried out. Surgical resection results in resolution of the GRFoma syndrome,<sup>126,129,234</sup> but the long-term cure rate is unknown. Before surgery and in those patients with nonresectable lesions, various agents may reduce plasma growth hormone levels. Even though dopamine agonists such as bromocriptine are successful and widely used in patients with classic acromegaly,<sup>135</sup> rarely is it possible to normalize plasma growth hormone levels in patients with GRFomas.<sup>123,128</sup> Octreotide is now the agent of choice.<sup>1,123,135</sup> In all cases thus far described, octreotide significantly suppressed or normalized growth hormone and IGF-1 levels.<sup>135,228,235,236</sup> and <sup>237</sup> and, in some cases, this was associated with pituitary shrinkage.<sup>235,237</sup> In 75% of cases, octreotide decreased plasma GRF levels by more than 50%.<sup>123</sup>

In a few studies in patients with PETs secreting the peptide neurotensin, a neurotensinoma syndrome has been proposed.<sup>1,3,55,97</sup> Clinical features of patients with possible neurotensinomas include hypokalemia, weight loss, diabetes mellitus, cyanosis, hypotension, and flushing in a patient with a PET.<sup>97</sup> In a review of six cases, one-half of the patients were cured by resection of the pancreatic endocrine tumor, and the remaining one-half improved with chemotherapy.<sup>97</sup> Elevated plasma neurotensin levels have been measured in patients with VIPomas, and their symptoms did not differ from those with normal levels; a similar result was found in patients with gastrinomas.<sup>55</sup>

Patients with PETs and Cushing's syndrome (ACTHoma) have been reported.<sup>64,202</sup> In recent studies, 4% to 16% of Cushing's syndrome cases attributable to an ectopic ACTH syndrome originated from a pancreatic tumor. Cushing's syndrome is reported in 19% of patients with the ZES syndrome and MEN 1. In these patients, the disease was of pituitary origin and was mild. Cushing's syndrome also occurs in sporadic cases of ZES and, in one prospective study, it was found in 5% of all cases.<sup>1,202</sup> In these patients, the Cushing's syndrome was severe due to the ectopic ACTH production and occurred with metastatic pancreatic endocrine tumors, which responded poorly to chemotherapy; hence, the disease was associated with a poor prognosis.<sup>202</sup> The occurrence of Cushing's syndrome as the only manifestation of a PET occurs in 37% to 60% of cases and may precede any other hormonal syndrome.

Hypercalcemia resulting from a PET secreting a parathyroid hormone-related protein or to an unknown hypercalcemia substance that mimics the action of parathyroid hormone and causes hyperparathyroidism has been reported.<sup>238,239</sup> and <sup>240</sup> The tumor is generally large and metastatic to the liver by the time of diagnosis,<sup>238,240</sup> although in one recent case, radical resection of a pancreatic tail tumor with subsequent treatment with chemotherapy resulted in a total remission for 5 years.<sup>239</sup>

## TREATMENT OF METASTATIC DISEASE

The treatment of all metastatic PETs is considered as a unit because, in most respects, cytotoxic protocols and surgical approaches are the same. The long-term natural history of most functional PETs (malignant insulinomas, VIPomas, glucagonomas, GRFomas, somatostatinomas) is not known because, until recently, effective treatment for the functional syndrome did not exist and therefore patients often died of complications of the hormonal excess rather than from the tumor *per se*.<sup>1,40</sup> In a study including 212 patients with ZES who had well-controlled gastric acid hypersecretion, 31% had died at a mean follow-up of almost 14 years.<sup>40</sup> One-half of these deaths were due to tumor progression, particularly in bone and liver, and to ectopic ACTH production. In a recent large study involving 185 patients with ZES in which no patient died from acid-related problems, the 10-year survival rate was not significantly different among patients in whom no tumor was found (only 8%), patients in whom tumor was completely resected, and patients in whom tumor was resected without biochemical cure (84%, 96%, and 93%, respectively).<sup>26</sup> However, in patients with unresectable disease, the 10-year survival rate was only 30%. This study demonstrates that the development of metastatic liver disease is the primary determinant of survival.<sup>26</sup> Currently, no data are available to suggest that survival for patients with other PETs will differ from that for patients with ZES and, in fact, limited data from PPomas, of which most were metastatic, reported mean survival of 4.3 years<sup>3</sup> and a 5-year survival rate of 44%,<sup>101</sup> which is similar to patients with metastatic gastrinomas. Most authorities would agree that treatment directed to metastatic unresectable liver disease is indicated. However, at present, there is no agreement about when therapy should be started or the efficacy of various therapeutic options, because of the small numbers of patients treated with various protocols. Chemotherapy either alone or combined with cytoreductive surgery, hepatic arterial embolization alone or with chemotherapy, hormonal therapy with the long-acting somatostatin analog octreotide, interferon, or hepatic transplantation have all been reported to be useful in small numbers of cases.<sup>241,242</sup>

## CHEMOTHERAPY

Almost all studies that include significant numbers of patients and investigate the effects of chemotherapeutic agents on PETs include all types of PETs, often combined with carcinoids. Whether these results can be extrapolated to each histologic type is unclear at present. Three studies have demonstrated no difference in response rates of various PETs to streptozotocin (STZ)<sup>243,244</sup> and <sup>245</sup>; however, only small numbers of patients with different type of PETs were included. Other studies have shown a variable response of gastrinomas, glucagonomas, and VIPomas to chemotherapeutic agents such as dacarbazine (DTIC) or STZ, suggesting that differences may exist. Finally, other studies suggest that functioning tumors respond better than nonfunctioning tumors<sup>243,246,247</sup> and, among functioning tumors, insulin and VIP-secreting PETs may be more sensitive to STZ-based therapies.<sup>246,247</sup> Therefore, it should not be considered established that each tumor responds equally to chemotherapy.

Except for STZ<sup>243,244,248,249</sup> or chlorozotocin,<sup>245,250</sup> single-agent chemotherapy with various other agents (doxorubicin,<sup>251</sup> etoposide,<sup>252</sup> carboplatin,<sup>253</sup> DTIC,<sup>254</sup> and tubercidin<sup>255</sup>) has had limited efficacy ([Table 38.5-5](#)). STZ, a glycosamine nitrosourea compound originally derived from a *Streptomyces* species, has been in clinical

use since 1967.<sup>256,257</sup> In preclinical studies, it was found to have cytotoxic effects on pancreatic islet cells<sup>258</sup> and has generally been used, usually in combination with other agents, for the treatment of metastatic PETs.<sup>13,218,243,245,249,259,260,261,262,263,264</sup> and<sup>265</sup> The current first-line regimen is the combination of STZ and doxorubicin.<sup>245</sup> This recommendation is based on a prospective study that demonstrated that STZ and doxorubicin were superior to STZ and 5-fluorouracil (5-FU) or chlorozotocin alone (response rates of 69%, 45%, and 30%, respectively).<sup>245</sup> Median durations of response were 18 months for the doxorubicin combination, 14 months for the 5-FU combination, and 17 months for the chlorozotocin group. Survival for patients treated with the doxorubicin combination was significantly longer. In a previous prospective study, STZ alone in 42 patients produced a response rate of 36%, with 12% showing a complete response, whereas STZ plus 5-FU had demonstrated a response rate of 63%, with 33% of patients having a complete response.<sup>243</sup>

**TABLE 38.5-5.** Drug Therapy for Pancreatic Endocrine Tumors and Gastrinomas

STZ combined with 5-FU or 5-FU plus doxorubicin causes an objective response in up to 80% of patients with metastatic gastrinoma. For all PETs, the combination of STZ plus 5-FU gave a response rate of 63%, which was significantly better than the 40% response rate with STZ alone.<sup>243</sup> However, in a prospective study of ten patients with progressive metastatic gastrinoma to the liver, chemotherapy with STZ, 5-FU, and doxorubicin resulted in only a 40% objective response rate, no complete remissions, and no statistical difference in survival in responders versus nonresponders.<sup>218</sup> In another study of a similar group of 22 patients, only 5% of patients demonstrated an objective decrease in tumor size.<sup>263</sup> Therefore, the precise role and efficacy of chemotherapy in patients with metastatic gastrinoma has not been established.

Also, when chemotherapy should be initiated in a given patient with metastatic disease has not been clearly determined.<sup>218</sup> Recently, it has become apparent that the time course of tumor progression in patients with metastatic untreated gastrinoma is highly variable.<sup>266</sup> Of 19 patients evaluated, 26% showed no tumor growth over a mean follow-up of 29 months, 32% had marginal progression (<50% increase in tumor volume), and 42% had rapid growth in less than 1 year. Some patients have been followed up for 20 years with stable metastatic disease,<sup>37</sup> although most die within 5 years, with the mean survival being 3 to 5 years.<sup>14,15,137,267</sup> Of the two research groups with considerable experience with metastatic gastrinoma, one group proposed that patients be treated with chemotherapy when they become symptomatic.<sup>243</sup> However, if gastric acid hypersecretion is controlled adequately, symptoms due to the tumor arise only very late in the course of the disease. Another group proposed that, after the initial evaluation, patients be reassessed in 3 to 6 months and those patients with evidence of increasing size of hepatic metastases be treated with chemotherapy.<sup>218</sup> No studies have recommended chemotherapy for patients with metastases only to regional lymph nodes.

STZ causes nausea and vomiting in almost all patients, dose-related renal dysfunction (including proteinuria) in 20% to 70%, decrease in creatinine clearance in 20% to 70%, abnormalities in hepatic function in 29%, and leukopenia and thrombocytopenia in 6% to 9%.<sup>218,268,269</sup> In one study, nine patients suffered from chronic renal failure, and seven required dialysis; thus, use of STZ must be carefully monitored.<sup>245</sup> The nausea and vomiting can now be controlled in almost all patients using 5-HT<sub>3</sub> antagonists such as ondansetron, so that the renal dysfunction is the major dose-limiting toxic effect. Chlorozotocin is structurally closely related to STZ,<sup>268,270</sup> but it causes less nausea and vomiting than does STZ. Patient response to chlorozotocin alone<sup>245,250</sup> or in combination with 5-FU<sup>270</sup> is, in general, similar to that of STZ (see [Table 38.5-5](#)).

Etoposide, dactinomycin, and cisplatin alone have been used in a few cases but are generally not effective.<sup>248</sup> The combination of etoposide and cisplatin was evaluated in 14 patients with metastatic PETs, and the results were compared with those in metastatic carcinoid tumors (13 patients) or anaplastic neuroendocrine tumors (18 patients: 6 pancreas; 8 stomach or intestine; 1 lung; 3 unknown).<sup>271</sup> This study was performed because recent work has demonstrated that these two agents are effective in small cell lung cancer, which has neuroendocrine features histologically similar to those seen in PETs. Sixty-seven percent of the anaplastic neuroendocrine tumors, 14% of the PETs, and 0% of the metastatic carcinoid tumors demonstrated partial to complete regression.<sup>271</sup>

Other etoposide combinations including doxorubicin, cisplatin, and 5-FU have been tried in a small number of patients with limited success (i.e., response rate of 20%).<sup>272</sup> Glucagonomas are reported to respond frequently to dacarbazine,<sup>1,118,273,274,275</sup> and<sup>276</sup> including some cases of complete remission, whereas in other PETs, the response rate is low.

### HORMONAL THERAPY WITH SOMATOSTATIN ANALOGS

Hormonal therapy with the long-acting somatostatin analog octreotide is effective in controlling the symptoms due to a number of different PETs or carcinoid-like tumors, including VIPomas, glucagonomas, GRFomas, insulinomas, gastrinomas, and carcinoids.<sup>277,278,279,280,281</sup> and<sup>282</sup> In animal studies, somatostatin analogs can inhibit tumor growth<sup>283</sup> and the growth of transplantable insulinomas and chondrosarcomas.<sup>284</sup> More than 90% of all PETs except insulinomas possess somatostatin receptors,<sup>1,151,154,277</sup> which may mediate the action of somatostatin on these tumors. Hormonal treatment with octreotide is reported to cause a decrease in tumor size in 8 of 66 patients with PETs in one review.<sup>228</sup> A decrease in hepatic metastases in 3 of 22 patients has been noted in different reports of gastrinoma treated with octreotide.<sup>228</sup> However, another study of nine patients with metastatic gastrinoma treated with octreotide for 1 to 11 months reported no benefit.<sup>285</sup> In subsequent studies, octreotide infrequently caused a decrease in PET tumor size,<sup>279,280,282</sup> but stabilization of disease was more commonly seen in 25% to 50% of patients, and increased survival was not demonstrated in these studies.<sup>278,279</sup> and<sup>280,282,286</sup> These results must be extended to a larger, multicenter study, but they suggest that octreotide may have a cytostatic effect and, by decreasing the tumor growth rate, may increase survival.

### INTERFERON-a

Interferon-a has been reported to be effective at controlling symptoms in patients with PETs.<sup>270,272,279,287</sup> In a review of numerous series involving 322 patients with various neuroendocrine tumors, 43% of the patients showed a biochemical response (>50% decrease in hormone levels) and 12% showed a decrease in tumor size with interferon-a treatment either alone or in combination with other agents.<sup>272</sup> Of 57 patients with PETs, 47% had a biochemical response and 12% experienced decreased tumor size. The mean duration of the response was 20 months (range, 2 to 96 months). Disease stabilization was seen in 25%. There was no difference in the response rate between patients with or without previous chemotherapy.<sup>272</sup>

In another study of 11 patients with metastatic gastrinoma to the liver that was increasing in size, interferon-a (5 million U/d) failed to decrease tumor size in any patients but slowed tumor growth in 3 patients.<sup>288</sup>

These results suggest that the effect of interferon-a on PETs is similar to that of octreotide in that it has minimal tumoricidal activity, with PETs rarely regressing with treatment. However, interferon-a may stabilize the disease in a significant percentage of patients and possibly extend survival, although with PETs this has not yet been proven. Interferon has been used with 5-FU,<sup>289</sup> octreotide,<sup>272</sup> and 5-FU plus STZ,<sup>272</sup> though in such small numbers of patients that clear assessment of any advantages of these combinations is not possible.

### HEPATIC ARTERY EMBOLIZATION

Hepatic artery embolization with or without postocclusion chemotherapy has been used successfully in small numbers of patients with metastatic PETs to the liver.<sup>110,247,290,291,292</sup> and <sup>293</sup> It is reported in some studies that 68% to 100% of patients demonstrated symptomatic improvement with this therapy.<sup>290,292,294</sup> In one study involving 111 patients, hepatic arterial occlusion was combined with chemotherapy in 64% of the patients, using doxorubicin plus dacarbazine or STZ plus 5-FU.<sup>247</sup> Objective remissions were observed in 60% of the patients treated with embolization alone and in 80% of patients treated with added chemotherapy.<sup>247</sup> With embolization alone, the median duration of the remission was 4 months and, with chemoembolization, it was 18 months. Chemoembolization using doxorubicin in iodized oil combined with either gelatin powder or sponge particles has recently been reported in two studies to improve symptoms in 68% to 100% of patients and to decrease tumor size or hormonal markers in 57% to 100% of patients.<sup>292,294</sup> Side effects include abdominal pain, nausea, vomiting, and fever usually lasting 3 to 10 days,<sup>290</sup> with severe complications (including hepatic failure, infection, acute renal failure, and death) occurring in 10% to 15%.<sup>290,295</sup> Until recently, it often was difficult to establish the true extent of the metastatic disease and, therefore, to decide which patients might be most helped by this procedure. With the availability of SRS, it should now be possible to accomplish this in most cases. In a patient with a symptomatic PET and diffusely metastatic disease to the liver but minimal or no bone metastases, in whom hormone symptoms cannot be controlled by octreotide, chemotherapy, or other medical treatment, hepatic artery embolization should be considered.

## SURGICAL TREATMENT

Systemic removal of all resectable tumor has been recommended in general for PETs<sup>110,296,297,299</sup> and <sup>300</sup> and, if possible, for VIPomas,<sup>103,301</sup> glucagonomas,<sup>118,119</sup> GRFomas,<sup>123</sup> and somatostatinomas.<sup>302</sup> The data of Zollinger et al.<sup>15</sup> suggest that removal of all resectable tumor, termed *debulking* or *cytoreductive surgery*, prolongs life expectancy. No studies to date have evaluated debulking surgery in a controlled, prospective manner. It is important to differentiate between the possible benefit of such surgery in patients with gastrinomas or nonfunctional tumors and the potential benefit in patients with functional PETs for whom poor medical therapy for the hormonal excess state might ensue. In the former group, the procedure must extend life or relieve tumor symptoms to be worthwhile, whereas in the latter group, improved ability to control the hormonal excess state in situations without effective medical therapy may be a major benefit.

A number of studies have provided data dealing with this approach.<sup>296,297,299,300</sup> One study involved 17 patients with potentially resectable metastatic PETs,<sup>296</sup> and the second evaluated 74 patients with metastatic neuroendocrine tumors (50 carcinoid, 23 islet cell, and 1 atypical tumor).<sup>297</sup> In the first study, in 80% of cases, the tumor was completely excised at surgery, and the survival rate was 79% at 5 years, with a mean follow-up of 3 years.<sup>296</sup> In this study, patients with extensive metastatic disease had a 5-year survival rate of 28%, equal to that in inoperable patients, whereas patients with limited resection had significantly prolonged survivals ( $P = .02$ ). In the second study, 36 hepatic lobectomies or extended hepatectomies and 38 nonanatomic liver resections were performed. Perioperative mortality was 2.7%, morbidity 24%, and 4-year survival 73%; 90% of patients experienced symptomatic improvement postoperatively.<sup>297</sup> Norton et al.<sup>137</sup> reported the successful resection of all metastatic disease in 5 of 20 patients with ZES with extensive disease, 2 of whom have maintained normal gastrin levels postoperatively. A series of 38 patients with PETs confined to liver who underwent resection was compared to 23 patients with comparable tumor burden but technically unresectable disease.<sup>299</sup> Survival was significantly longer in those who underwent resection, although other factors may also have influenced outcome. The conclusion of each of these studies was that resection of metastatic disease to liver should be considered in selected patients with neuroendocrine tumors.<sup>110,296,297,299</sup> It is important to remember that this may be possible in only a small proportion (9% in one study<sup>303</sup> and 5% in another<sup>296</sup>) of all patients with metastatic PETs in the liver. Furthermore, at present, whether such an approach actually increases survival is not clear (see Fig. 38.5-3, Fig. 38.5-7). This approach may be required in patients with symptomatic tumors in whom octreotide or the use of chemotherapy alone is not reducing plasma hormone levels sufficiently, so that symptoms remain poorly controlled.<sup>4</sup>

## LIVER TRANSPLANTATION

Liver transplantation has been attempted in small numbers of patients with metastatic PETs.<sup>304,305,306,307</sup> and <sup>308</sup> Each of the reported series involves small numbers of cases. All these studies recommend that liver transplantation be considered in selected cases, especially patients without extrahepatic disease. In the largest series of 31 patients who underwent liver transplantation for neuroendocrine tumors, 15 were for carcinoid and 16 were for PETs.<sup>309</sup> Survival rates were significantly higher for the carcinoid patients (69% alive at 5 years) than for the PET patients (8% alive at 4 years). It appears from this small number of cases that long-term cure is uncommon, with recurrence to liver being most common. Whether liver transplantation is more effective in PET cases than in other metastatic tumors and whether it appreciably prolongs survival remains undetermined.

#### PATHOLOGY AND TUMOR HISTOLOGY

Neuroendocrine tumors (NETs) are derived from the diffuse neuroendocrine system, which is made up of peptide- and amine-producing cells with different hormonal profiles depending on their site of origin.<sup>1</sup> Carcinoids are classified as NETs and share cytochemical features with melanomas, pheochromocytomas, medullary carcinoma of the thyroid, and pancreatic endocrine tumors (PETs).<sup>1,2,3,4</sup> and <sup>5</sup> Carcinoids are composed of monotonous sheets of small round cells with uniform nuclei and cytoplasm.<sup>4</sup> Mitotic figures are rare.<sup>1,2,4</sup> Oberndorfer<sup>6</sup> introduced the term *carcinoid* in 1907 to describe tumors that behaved more indolently than adenocarcinomas.<sup>6</sup> Pathologists cannot differentiate benign from malignant carcinoids based on histology, nor histologically can they differentiate PETs from carcinoids.<sup>3</sup> Malignancy can only be determined if invasion or distant metastases are found. Ultrastructurally, carcinoids possess electron-dense neurosecretory granules, and they contain small clear vesicles that correspond to the synaptic vesicles of neurons.<sup>1,4,7</sup> Carcinoids synthesize bioactive amines and peptides, including neuron-specific enolase; 5-hydroxytryptamine; 5-hydroxytryptophan; synaptophysin; chromogranin A and C; and other peptides, such as insulin, growth hormone, neurotensin, adrenocorticotrophic hormone (ACTH), melanocyte-stimulating hormone-b, gastrin, pancreatic polypeptide, calcitonin, substance P, other various tachykinins (e.g., neuropeptide K), growth hormone-releasing hormone, bombesin, and various growth factors such as transforming growth factor- $\beta$  (TGF- $\beta$ ), platelet-derived growth factor, and basic fibroblast growth factor.<sup>1,3,8</sup>

Most carcinoids are tentatively identified on routine histology.<sup>4,8</sup> However, these tumors are characterized by their histologic staining patterns due to their shared secreted products and certain cytoplasmic proteins.<sup>1,4</sup> Historically, one of the most important was their staining with silver.<sup>1,3,4</sup> Characteristically, carcinoids either take up and reduce silver (argentaffin reaction) or take it up but do not reduce it (argyrophilic).<sup>2,3</sup> Currently, the identification of chromogranin, synaptophysin, or neuron-specific enolase (NSE) is generally used.<sup>1,3,8</sup> The chromogranins (A, B, C) are acidic polypeptides that are the major component of the secretory granules of many neuroendocrine cells.<sup>8,9</sup> Generally, chromogranin A immunoreactivity is more specific than the argyrophil reaction because the latter also identifies other intracellular proteins such as melanin.<sup>8</sup> NSE, the gamma-gamma dimer of the glycolytic enzyme enolase, occurs in the cytoplasm of most neuroendocrine cells and is positive in most carcinoids as well as other APUD (amine precursor uptake and decarboxylation) tumors.<sup>1,8</sup> The advantage of NSE as a marker is that its reactivity is unrelated to secretory granule content. However, NSE can be occasionally misleading because some tumors not considered neuroendocrine, such as fibroadenomas of breast carcinoma and certain lymphomas, may contain a considerable amount of NSE activity.<sup>1</sup> Synaptophysin is a calcium-binding vesicle membrane glycoprotein that is expressed independently of other neuroendocrine proteins.<sup>1</sup>

In addition to the general histologic NET markers, specific markers for carcinoids may identify the tumor as a carcinoid.<sup>1</sup> Serotonin can be identified by various methods, including the use of the argentaffin reaction of Masson or using antibodies to serotonin.<sup>8,10</sup> In general, the argentaffin reaction of Masson is usually positive, and the serotonin antibody localization is frequently weak or negative in midgut carcinoids, whereas in foregut and hindgut carcinoids, serotonin immunoreactivity is detected more often than is the argentaffin reaction.<sup>8,10</sup>

Williams and Sanders<sup>11</sup> proposed classifying carcinoids according to their site of origin because carcinoids with similar sites of origin frequently share functional manifestations, histochemistry, and secretory products (Table 38.6-1). Foregut carcinoids generally have a low serotonin [5-hydroxytryptamine (5-HT)] content, are argentaffin-negative but argyrophilic, occasionally secrete 5-hydroxytryptophan (5-HTP) or ACTH, can be associated with an atypical carcinoid syndrome, are often multihormonal, and may metastasize to bone. Although many foregut carcinoids synthesize peptides, clinical syndromes are rarely produced and elevated plasma hormone levels are generally not detected. Midgut carcinoids are argentaffin-positive, have a high serotonin content, have smaller numbers of endocrine cells than foregut tumors, most frequently cause the classic carcinoid syndrome when they metastasize, release serotonin and tachykinins (substance P, neuropeptide K, substance K), rarely secrete 5-HTP or ACTH, and uncommonly metastasize to bone.<sup>12</sup> Hindgut carcinoid tumors are argentaffin-negative, often argyrophilic, rarely contain serotonin, rarely cause carcinoid syndrome, contain numerous gastrointestinal (GI) hormones, rarely secrete 5-HTP or ACTH, and may metastasize to bone.<sup>12</sup>

these tumors and provides better guidelines for tumors with similar behaviors in different tissues.

Carcinoids can be ubiquitous, but most take origin in four sites: bronchus, appendix, rectum, and jejunoleum.<sup>13,14</sup> In the past, carcinoids were most frequently reported in the appendix (approximately 40%); however, more recently the bronchus and lung are the most common site (32%) (Table 38.6-2). The distribution reported from analyses of two large National Cancer Institute databases from 1950 to 1971 and from 1973 to 1991 are contrasted in Table 38.6-2. A number of trends are apparent from comparison of the data from these two periods. The percentages of gastric carcinoids almost doubled, whereas the percentage of appendiceal carcinoids decreased more than fourfold from 38% to 7.6%. Small intestinal carcinoids remained a large group comprising approximately 20% of all carcinoids. Overall, GI carcinoids remain the most frequent, comprising 74% of all carcinoids in the 1973 to 1991 Surveillance, Epidemiology, and End Results (SEER) data,<sup>14</sup> with the respiratory tract being a distant second with 25%.<sup>14</sup>

TABLE 38.6-2. Carcinoid Tumor Location, Frequency of Metastases, and Association with Carcinoid Syndrome

The exact clinical incidence of carcinoids varies in different studies. An incidence of 7.1 per million for males is reported,<sup>15</sup> with 8.7 per million reported for females<sup>15</sup> in England and Scotland, and 13 cases per million population reported in Ireland. Carcinoids thus occur 11 times more frequently than insulinomas and 26 times more frequently than gastrinomas.<sup>16</sup> In other series, the incidence of clinically significant tumors was 7 per million population per year in Scandinavia, which was two times more frequent than all PETs, seven times more than gastrinomas, and eight times more than insulinomas.<sup>3,17,18</sup> The clinical presentation of carcinoids far underestimates their occurrence, because many are asymptomatic. This fact is demonstrated by SEER data, which report an annual incidence rate of 2.8 per million population for small intestinal carcinoids,<sup>19</sup> whereas in an autopsy study at the Mayo Clinic, 6500 cases per million were reported.<sup>20</sup> In another study, the annual incidence of malignant carcinoids at autopsy was 21 per million population per year,<sup>21</sup> whereas in a Swedish study calculated on autopsy and surgical results, the incidence was 84 cases per million population.<sup>21</sup> The distribution of carcinoid tumors found in various surgical or clinical series differs markedly from that found at autopsy.<sup>22</sup> As many as 76% of all carcinoids are found in the jejunoleum at autopsy, whereas they make up approximately one-fourth of cases in clinical and surgical series.

Approximately 1 in every 200 to 300 appendectomies result in discovery of a carcinoid.<sup>20</sup> Most occur in the tip of the appendix. The majority (i.e., 90%) are less than 1 cm in diameter and are without metastases.<sup>20,23,24</sup> In the SEER data of 1570 appendiceal carcinoids,<sup>25</sup> 62% were localized, 27% had regional lesions, and 8% had distant metastatic disease. Approximately 50% of the carcinoids between 1 and 2 cm in size metastasize to lymph nodes.<sup>26</sup>

Small intestinal carcinoids may be multiple; 70% to 87% are present within the ileum and 40% to 70% within 2 feet of the ileocecal valve.<sup>20,27,28</sup> Forty percent are less than 1 cm in diameter, 32% are 1 to 2 cm, and 29% are more than 2 cm.<sup>28</sup> In an analysis of 12 series, 47% (range, 0% to 100%) were associated with metastases,<sup>28</sup> whereas 35% to 70% were associated with metastases in the National Cancer Institute studies<sup>13,14</sup> (see Table 38.6-2). With the carcinoid, a marked fibrotic reaction can occur that can distort the gut or mesentery and can present clinically with small bowel obstruction or venous mesenteric infarction. Distant metastases occur to the liver (36% to 60%),<sup>27,28</sup> to bone (3%)<sup>28</sup> and, occasionally, to lung (4%).<sup>28</sup> Approximately 20% to 30% of patients with ileal carcinoid have one or more additional ileal primary carcinoids.<sup>27,29</sup> The incidence of metastases from small intestinal carcinoids is dependent on tumor size.<sup>27,29</sup> If the tumor is smaller than 1 cm, metastases occur in fewer than 15% to 25%.<sup>20,27,28</sup> If the tumor is between 1 and 2 cm in size, metastases occur in 58% to 80%.<sup>20,27,28</sup> If the tumor is larger than 2 cm, metastases occur in more than 70%.<sup>20,27,28</sup> In contrast to jejunoleal carcinoids, duodenal carcinoids are often discovered by endoscopy.<sup>30</sup> In two series<sup>13,30</sup> (see Table 38.6-2), 20% to 21% of duodenal carcinoids had metastases. Invasion into the muscularis propria, tumor size, and mitotic activity all correlated with metastatic spread, with invasion being the strongest predictor. No duodenal carcinoid smaller than 1 cm metastasized, whereas 33% of the tumors larger than 2 cm and 35% of tumors invading the muscularis mucosa metastasized.<sup>30</sup>

In approximately 1 in every 2500 proctoscopies, a small nodule is seen that is diagnosed as a carcinoid.<sup>20</sup> Nearly all rectal carcinoids occur submucosally on the anterior or lateral walls between 4 and 13 cm above the dentate line.<sup>20,31</sup> Sixty-six percent to 80% are less than 1 cm in diameter and rarely metastasize (5%).<sup>31</sup> Tumors 1 to 2 cm can metastasize (5% to 30%),<sup>31,32</sup> and tumors larger than 2 cm, which are uncommon, metastasize in more than 70%.<sup>20,26,31,32</sup> Colorectal carcinoids are almost entirely limited to the sigmoid colon and rectum, with the vast majority in the rectum. Metastases occurs in approximately 10% to 22%,<sup>31</sup> and in most cases, the tumor is larger than 2 cm in diameter and has invaded the muscularis propria. Invasiveness correlates with the presence of increased mitoses or atypical histology.<sup>33</sup> Colonic carcinoids uncommonly occur in the remainder of the colon, with almost 60% occurring in the cecum or ileocecal area. These tumors tend to be large (90% are larger than 2 cm; 50% are 5 cm or larger)<sup>34</sup> and are associated with metastases (61%).

Bronchial carcinoids resemble intestinal carcinoids and are not related to smoking.<sup>7</sup> Poor prognostic pathologic features include increased mitotic count, nuclear pleomorphism, vascular invasion, undifferentiated growth pattern, and lymphatic invasion.<sup>3</sup> The bronchus is the site of a primary carcinoid in approximately 2% of cases.<sup>35</sup> The classification of bronchial carcinoids has been a subject of debate.<sup>36</sup> Lung NETs have been classified into four categories: the typical carcinoid [also called *bronchial carcinoid* and *Kulchitsky cell carcinoma-I* (KCC-I)], atypical carcinoid (also called *well-differentiated neuroendocrine carcinoma* and *KCC-II*), intermediate small cell neuroendocrine carcinomas, and small cell neuroendocrine carcinomas (also called *KCC-III*).<sup>36,37</sup> and <sup>38</sup> Another proposed classification<sup>4</sup> includes these tumors under three general categories of lung NETs: benign or low-grade malignant (typical carcinoid); low-grade malignant (atypical carcinoid); and high-grade malignant (poorly differentiated carcinoma of the large cell or small cell type). The different categories of lung NETs have different prognosis, varying from excellent for typical carcinoids to poor for small cell neuroendocrine carcinomas.<sup>36,37,38</sup> and <sup>39</sup>

Gastric carcinoids account for three of every 1000 gastric neoplasms. Three subtypes of gastric carcinoids are proposed to occur,<sup>40</sup> and they originate from gastric enterochromaffin-like (ECL) cells.<sup>40</sup> Two subtypes are associated with hypergastrinemic states, either chronic atrophic gastritis (80%) (type I) or Zollinger-Ellison syndrome (6%) (type II), which is almost always as part of multiple endocrine neoplasia type 1 (MEN 1).<sup>40,41</sup> Gastric carcinoids types I and II generally pursue a benign course, with 9% to 30% developing metastases. They are usually multiple and small, with infiltration restricted to the mucosa and submucosa.<sup>40</sup> The third type of gastric carcinoids (type III) (sporadic ECL tumors) occur without hypergastrinemia, and they pursue a more aggressive course, with 54% to 66% developing metastases.<sup>40,41</sup> They are often large, single tumors; 50% have atypical histology, and some patients develop carcinoid syndrome.<sup>3,40</sup>

Carcinoids can be classified on their histologic growth patterns as insular, trabecular, glandular, undifferentiated, or mixed.<sup>3,8,42</sup> The midgut carcinoids frequently possess the most typical morphology,<sup>8</sup> with insular-like formation of regular tumor cells surrounded by fibrotic stroma. Most foregut carcinoids show a more mixed growth pattern, with a solid, ribbon-like, trabecular, or acinar pattern. Hindgut carcinoids are frequently solid or trabecular.<sup>8,42</sup> It has been demonstrated that the histologic types have prognostic significance.<sup>42,43</sup> and <sup>44</sup> In one classification of decreasing order of median survival time in years, the growth pattern ranked as follows:<sup>42</sup> mixed insular plus glandular (4.4 years), insular (2.9 years), trabecular (2.5 years), mixed insular plus trabecular (2.3 years), glandular (0.9 years), and undifferentiated (0.5 years). In other studies, carcinoids are divided histologically into typical (well-differentiated neuroendocrine tumors) and atypical (nuclear atypia, necrosis, increased mitotic activity),<sup>4</sup> and categorization has been shown to have prognostic significance.<sup>4,33,44</sup>

## MOLECULAR PATHOGENESIS

Little is known about the induction of malignant growth or the factors promoting the growth of carcinoids.<sup>3,45,46,47</sup> and<sup>48</sup> For some gastric carcinoids, studies show that gastrin is an important growth factor.<sup>3,40</sup> An increased occurrence of gastric carcinoids occurs in disease states (pernicious anemia, atrophic gastritis, Zollinger-Ellison syndrome) that result in hypergastrinemia.<sup>3,40</sup> The hyperplastic effect of hypergastrinemia is restricted to gastric ECL cells.<sup>49,50</sup> It has been proposed that, with prolonged hypergastrinemia, ECL hyperplasia (simple, linear, micronodular, adenomatoid), dysplasia, and carcinoid formation are increased.<sup>49,50</sup> In pernicious anemia and atrophic gastritis, up to 4% to 11% of patients develop gastric carcinoids.<sup>49,51</sup> Patients with Zollinger-Ellison syndrome also develop gastric carcinoids, although they are much more frequent in the subgroup with MEN 1.<sup>52,53</sup> In patients with Zollinger-Ellison syndrome with MEN 1 with gastric carcinoids, allelic loss occurs at the MEN 1 locus on chromosome 11q13, and thus fundic gastric carcinoids are now included in the spectrum of MEN 1 tumors. Studies suggest that other important growth factors in some carcinoid tumors are TGF- $\alpha$ <sup>50</sup> and TGF- $\beta$ ,<sup>54,55</sup> insulin-like growth factor-1 (IGF-1),<sup>47,50,55</sup> trefoil peptides (TFF1, TFF2, TFF3),<sup>50</sup> platelet-derived growth factor,<sup>47,54</sup> vascular endothelial growth factor,<sup>56</sup> acidic and basic fibroblast growth factor,<sup>47,54,55</sup> and epidermal growth factor.<sup>54,55</sup>

Limited studies have been performed on carcinoids examining the possible role of mutations of protooncogenes and alterations of tumor-suppressor genes in their pathogenesis.<sup>45,47,48</sup> Mutations in common oncogenes, such as K-ras, are uncommon in GI carcinoids.<sup>45,48</sup> Overamplification of HER2/NEU, c-myc, and c-jun have been described in some cell lines derived from GI endocrine tumors and some carcinoids.<sup>48,57</sup> In bronchial carcinoids, a high expression of c-fos, c-jun, and c-met occurs early, and a high expression of c-myc and L-myc occurs late. Alterations in the common tumor suppressor gene p53<sup>3,48,58,59</sup> are also uncommon in carcinoids,<sup>3,45,48,58,59</sup> as are alterations in the retinoblastoma gene in typical carcinoids, although they may occur in atypical carcinoids.<sup>24,45,60,61</sup> MEN 1 has been shown to be due to defects in a 10-exon gene on chromosome 11q13 that encodes for a 610–amino acid nuclear protein, MENIN.<sup>62,63</sup> Loss of heterozygosity at this locus has been reported in 26% to 78% of carcinoids,<sup>64,65</sup> and mutations in the MENIN gene were reported to be 18% in one study.<sup>64</sup> Microsatellite instability is rare in carcinoids<sup>67</sup>; however, by comparative genomic hybridization, both frequent gains (of chromosome 5, 14, 17q, 7) and losses (especially of chromosome 9p) are reported.<sup>68</sup>

## CLINICAL FEATURES

### GENERAL CHARACTERISTICS

The age of onset ranges from 10 to 93 years, with a mean onset of 36 years of age for tumors of the cervix, 63 years for tumors of the small intestine and respiratory tract, and 66 years for tumors of the rectum.<sup>14,22</sup>

### CARCINOID TUMORS WITHOUT SYSTEMIC FEATURES

The presentation of carcinoids that do not cause carcinoid syndrome is diverse and related to the site of origin of the tumor as well as the malignant spread of the tumor. In the appendix (see [Table 38.6-2](#)), carcinoids are usually found incidentally during surgery for suspected appendicitis.<sup>23</sup> Small intestinal carcinoids in the jejunioileum are the most common location for carcinoids of clinical significance.<sup>20,22,25</sup> Most small intestinal carcinoids found in autopsy studies do not cause symptoms, but these tumors can cause fibrosis of the mesentery, which results in kinking of the bowel, intestinal obstruction, and gut infarction or intussusception. The most common presenting symptoms due to the small intestinal carcinoids *per se* are periodic abdominal pain (51%),<sup>20,22,28,29</sup> intestinal obstruction with ileus and invagination (31%),<sup>28</sup> an abdominal tumor (17%),<sup>28</sup> or GI bleeding (11%).<sup>28</sup> Because of the vagueness of the symptoms, the diagnosis is frequently delayed, with a median time of onset from symptoms to diagnosis of approximately 2 years<sup>20,29</sup> and a range up to 20 years. Duodenal and gastric carcinoids are usually found incidentally during endoscopy.<sup>22,30,51</sup> Rectal carcinoids are frequently found incidentally during endoscopy but can be symptomatic.<sup>31,69</sup> The most common symptoms include melena and bleeding (39%), constipation (17%), and diarrhea (12%).<sup>31</sup> Bronchial carcinoids are frequently discovered on chest radiograph. In one large series,<sup>36</sup> 31% of patients were asymptomatic, and the carcinoid was incidentally discovered. The most common symptoms are pneumonia, hemoptysis, and cough.<sup>36</sup> Thymic carcinoids present as anterior mediastinal masses, usually on chest radiograph. Ovarian and testicular carcinoids may present as masses detected by physical examination or ultrasound. Most carcinoids present as an isolated disease, but associations exist between foregut carcinoids and MEN 1,<sup>40,52,53,70</sup> gastric carcinoids and diseases causing hypergastrinemia<sup>40,52,70</sup> ampullary somatostatin-rich carcinoids and von Recklinghausen's disease,<sup>45,71,72</sup> an intestinal carcinoid with myotonic dystrophy,<sup>73</sup> a gastric carcinoid in a patient with primary biliary cirrhosis,<sup>74</sup> and duodenal carcinoid tumors causing Zollinger-Ellison syndrome.<sup>75</sup> Metastatic carcinoids in the liver, presenting as hepatomegaly, may be the initial presentation in a patient who is fully active and productive with minimal symptoms and normal or near-normal liver function tests.<sup>20</sup>

### CARCINOID TUMORS WITH SYSTEMIC FEATURES

The most common systemic syndrome caused by carcinoids is the malignant carcinoid syndrome. As already mentioned, carcinoids may contain and secrete a number of biologically active substances. Immunocytochemical or radioimmunoassay studies show that carcinoids can contain ACTH, gastrin, somatostatin, insulin, motilin, growth hormone, gastrin-releasing peptide, serotonin, calcitonin, neurotensin, melanocyte-stimulating hormone-b, tachykinins (substance P, substance K, neuropeptide K), glucagon, pancreatic polypeptide (PP), vasoactive intestinal peptide (VIP), and prostaglandins.<sup>3,27,28,31,44,76,77</sup> These substances may not be released in sufficient amounts to cause symptoms. In various studies of patients with carcinoids, elevated serum concentrations of PP occur in 43%,<sup>17,76</sup> motilin in 14%,<sup>76</sup> and subunits of human chorionic gonadotropin (HCG) in 12%;<sup>17</sup> a slightly elevated level of gastrin was reported in 15%,<sup>17</sup> and none were reported with an elevated VIP<sup>76</sup> or plasma gastrin-releasing peptide level.<sup>76</sup> Even though these GI peptides were present in the serum, it is not apparent that any of these peptides contributed to any clinical symptoms.

Foregut carcinoids are more likely to produce various GI peptides than midgut carcinoids.<sup>78</sup> Ectopic ACTH production with Cushing's syndrome is increasingly seen with foregut carcinoids,<sup>22,78,79</sup> and in some studies, these tumors were the most common cause of the ectopic ACTH syndrome, accounting for 64% of all patients.<sup>79</sup> Acromegaly due to release of growth hormone–releasing factors can occur with a number of carcinoids.<sup>71</sup> The somatostatinoma syndrome due to somatostatin release can occur with duodenal carcinoids.<sup>71,72</sup>

## CARCINOID SYNDROME

### CLINICAL FEATURES

Flushing attacks occur in 23% to 65% of carcinoid syndrome patients initially and in 63% to 78% at some time during the disease course ( [Table 38.6-3](#)). The typical flush is the sudden appearance of a deep red erythema of the upper part of the body, primarily the face and neck. Flushes are often associated with an unpleasant feeling of warmth, occasionally with lacrimation, itching, palpitations, facial or conjunctival edema, and diarrhea. Flushes may be spontaneous or precipitated by stress; alcohol; certain foods, such as cheese; exercise; or pharmacologically by injections of agents such as catecholamines, calcium, or pentagastrin.<sup>22,80,81</sup> and<sup>82</sup> Flushes may be brief, lasting 2 to 5 minutes, especially initially, or may be prolonged for hours, especially later in the course. They are usually seen with carcinoids of midgut origin but can also occur in some patients with foregut tumors.<sup>22</sup> With bronchial carcinoids, the flushes can be frequently prolonged, lasting for hours to days, reddish in color, associated with salivation, lacrimation, diaphoresis, facial swelling, palpitations, deep furrowing of the forehead, diarrhea, and hypotension.<sup>22,81</sup> The flushing with bronchial carcinoids has a greater tendency to cause diffuse body involvement, and after repeated flushing of this type, patients may develop a constant red or cyanotic coloration.<sup>20</sup> The flush associated with gastric carcinoids is also reddish in color but patchy in distribution over the neck and face. It is frequently provoked by food intake or pentagastrin, with erythema associated with blotches and wheals with central clearing, frequently occurring around the root of the neck and on the arms, and the lesions are frequently associated with pruritus.<sup>20,22,81</sup>

**TABLE 38.6-3.** Clinical Characteristics in Patients with Malignant Carcinoid Syndrome

Diarrhea is commonly present in 32% to 73% of patients initially and in 67% to 84% at some time during the disease course (see [Table 38.6-3](#)). Diarrhea usually occurs with flushing (85% of cases), but it may occur alone (15% of cases).<sup>3,22,83</sup> The diarrhea is described as watery and, less commonly, as frothy or the pale bulky stool of steatorrhea, with the stool number ranging from 2 to 30 per day, and 60% of patients have output of less than 1 L/d.<sup>22,80,81,84</sup> Steatorrhea is present in 67% and in 46% is more than 15 g/d.<sup>84</sup> Abdominal pain may be present with the diarrhea or independently, and the frequency varies from 10% to 34% (see [Table 38.6-3](#)).

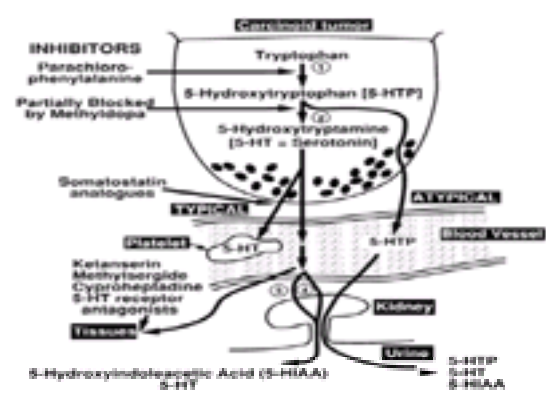

Cardiac manifestations occur in 11% to 66% of patients<sup>85,86</sup> and<sup>87</sup> (see [Table 38.6-3](#)). The cardiac disease is due to fibrosis involving the endocardium, primarily of the right side of the heart, although left side lesions can also occur.<sup>3,81,85,86,88</sup> The fibrous deposits are diffuse and are found most commonly on the ventricular aspect of the tricuspid valve and the associated chordae and less commonly on the pulmonary valve cusps. These fibrous deposits tend to cause constriction of both the tricuspid and pulmonic valves. At the pulmonic valve, stenosis is usually predominant, whereas at the tricuspid valve, the constriction results in the valve being fixed open, and tricuspid regurgitation is usually predominant.<sup>81,85,88</sup> In two series, 80% of the patients with cardiac lesions had evidence of heart failure.<sup>39,80</sup> Lesions on the left side occur in 30% of autopsy studies, are less extensive, and most frequently occur on the mitral valve.<sup>3</sup>

Other clinical manifestations of carcinoid syndrome are wheezing or asthma-like symptoms in 8% to 25% of patients and pellagra-like skin lesions with hyperkeratosis and pigmentation in 2% to 5% of cases (see [Table 38.6-3](#)).<sup>39</sup> arthralgias,<sup>39</sup> changes in mental state or confusion, and ophthalmic changes during flushing leading to vessel occlusion.<sup>3,39</sup> A variety of noncardiac problems secondary to increased fibrous tissue have been reported, including retroperitoneal fibrosis leading to ureteral obstruction, or Peyronie's disease of the penis; intraabdominal fibrosis; and occlusion of mesenteric arteries or veins.<sup>22,81</sup> Sexual dysfunction is a common complaint of men with carcinoid syndrome.<sup>22</sup> This may relate to the vascular effect of serotonin on pelvic blood vessels.<sup>22</sup>

## **PATHOBIOLOGY**

Carcinoid syndrome developed in 8% of 8876 patients with carcinoids,<sup>12</sup> with an incidence of 1.7% to 18.4% in six different series.<sup>12,80</sup> Carcinoid syndrome occurs only when sufficient concentrations of the hormonal products released by the tumor reach the systemic circulation. Its occurrence and severity are directly related to tumor size in an area that drains into the systemic circulation.<sup>26</sup> In 91% of cases, this only occurs after distant metastases (especially to the liver) develop.<sup>12,80,81</sup> Rarely, however, primary GI tumors with nodal metastases with extensive invasion retroperitoneally or drainage into the ovarian veins; pancreatic carcinoids with retroperitoneal lymph nodes; or carcinoids, such as those in the lung or ovary, with direct access to the systemic circulation can produce the carcinoid syndrome without hepatic metastases.<sup>12,80,89,90</sup> Rarely, medullary thyroid carcinoma, a duodenal adenoma, or small cell lung cancer also have been reported to cause carcinoid syndrome.<sup>81,91</sup> All carcinoids do not have the same propensity to metastasize and to produce the carcinoid syndrome (see [Table 38.6-2](#)). Because midgut tumors are the most common and frequently metastasize, midgut tumors account for 60% to 87% of the carcinoid syndrome, foregut tumors for 2% to 33%, hindgut for 1% to 8%, and an unknown primary location for 2% to 15% (see [Table 38.6-3](#)).

Symptoms of carcinoid syndrome were originally attributed to secretion of 5-HT (serotonin) by the tumor.<sup>92</sup> In one study<sup>22</sup> of 380 patients with carcinoid tumors, 56% had evidence of serotonin overproduction; 18% of 500 patients in a second study<sup>80</sup> and 88% of 103 patients with carcinoid tumors in a third study<sup>17</sup> had elevated urinary 5-hydroxyindoleacetic acid (5-HIAA), the major metabolite of serotonin ([Fig. 38.6-1](#)). When 44 consecutive cases were studied before any resection, 84% of the patients had serotonin overproduction.<sup>22</sup> In various studies, 12% to 26% of patients with evidence of serotonin overproduction did not have symptoms of carcinoid syndrome. In one study<sup>93</sup> of 44 consecutive patients with carcinoids, platelet and urinary serotonin, 5-HIAA, and seven catecholamine metabolites were measured. Platelet serotonin was elevated in 96%, 43%, and 0% of patients with midgut, foregut, and hindgut carcinoids, respectively. Urinary dopamine and catecholamine metabolites were elevated in 38% and 33% of midgut, 20% and 20% of foregut, and 7% and 14% of hindgut carcinoids, respectively. In a large review<sup>12</sup> of 748 cases of carcinoid syndrome, 92% had increased serotonin activity.

**FIGURE 38.6-1.** Synthesis, secretion, and metabolism of serotonin [5-hydroxytryptamine (5-HT)] and 5-hydroxytryptophan in patients with typical and atypical carcinoid syndrome, and site of drug action. (1) Tryptophan hydroxylase. (2) Aromatic L-amino acid decarboxylase (dopa decarboxylase). (3) Monoamine oxidase. (4) Aldehyde dehydrogenase. Arrows indicate the sites of action of therapeutic agents used in the treatment of carcinoid syndrome. Somatostatin analogues include octreotide and lanreotide. Serotonin receptor subtype 3 antagonists (5-HT<sub>3</sub>) include ondansetron, tropisetron, and alosetron.

Patients may develop either a typical or atypical type of carcinoid syndrome (see [Fig. 38.6-1](#)). In patients with the typical carcinoid syndrome, the conversion of tryptophan to 5-HTP is the rate-limiting step. Once formed, the 5-HTP is rapidly converted to 5-HT in the tumor by dopa decarboxylase, either stored in the neurosecretory tumor granules or released into vascular compartments, and most is taken up and stored in the granules of platelets. A small amount remains in the plasma. The majority in the circulation is converted by monoamine oxidase and aldehyde dehydrogenase to 5-HIAA, which appears in large amounts in the urine.<sup>3,83</sup> Characteristically, patients with carcinoid syndrome have expansion of the serotonin pool size, increase in blood and platelet concentrations of serotonin, and elevations of 5-HIAA in the urine.<sup>3,93,94</sup> This is the typical pattern in argentaffin- and argyrophil-positive tumors such as midgut carcinoids, which characteristically secrete large amounts of serotonin and which make up to 60% to 87% of all cases of carcinoid syndrome (see [Table 38.6-3](#)). Some carcinoids cause an atypical carcinoid syndrome<sup>22,95</sup> and are thought to be deficient in the enzyme dopa decarboxylase; thus, they cannot convert 5-HTP to 5-HT (serotonin), and 5-HTP is secreted into the bloodstream (see [Fig. 38.6-1](#)). Plasma serotonin levels are normal in these patients, but urinary levels are usually elevated because some of the 5-HTP is decarboxylated in the kidney and excreted as serotonin (5-HT). Patients with this type of carcinoid tumor may have a marked increase in urinary 5-HT and 5-HTP levels but normal or only slightly elevated 5-HIAA levels.<sup>22,83</sup> Foregut carcinoids are more likely to excrete high levels of 5-HT and 5-HTP in the urine and give the atypical carcinoid syndrome.<sup>22</sup>

The exact cause of flushing in carcinoid syndrome remains unclear.<sup>94,96</sup> Flushing is not thought to be due to serotonin overproduction, because serotonin antagonists generally have no effect on the flushing.<sup>94,97,98,99,100</sup> and <sup>101</sup> Using a specific radioenzymatic assay during spontaneous flushing in patients with midgut carcinoids, increased plasma serotonin and norepinephrine levels were found with higher levels in the external jugular than the antecubital veins.<sup>94</sup> This result suggests a possible role for these bioamines in the pathogenesis of flushing with midgut carcinoids. The exact etiology of the flushing in patients with carcinoid syndrome may differ depending on the different tumor types. In patients with gastric carcinoids, the red, patchy, pruritic flush is thought to be caused by histamine,<sup>82</sup> because this type of flushing can be prevented by the use of H<sub>1</sub>- and H<sub>2</sub>-receptor antagonists.<sup>3,82</sup> In addition to serotonin, other candidates for mediators of flushing include the tachykinins (substance P, neuropeptide K), various GI peptides, and prostaglandins.<sup>83,98,99</sup> However, other studies generally have concluded that prostaglandins are unlikely to be major mediators of the flushing or diarrhea.<sup>83,102</sup>

Studies demonstrate that numerous tachykinins are stored in carcinoids and are released during flushing.<sup>17,76,99,103,104,105</sup> and <sup>106</sup> In some studies, changes in plasma substance P or neuropeptide K levels did not correlate with the occurrence of flushing, leading the authors to conclude that circulating tachykinins have only a minor role, if any, in causing the flushing.<sup>83,98,107</sup> One study<sup>99</sup> demonstrated that all eight patients with midgut carcinoids had elevated plasma substance P levels; however, 88% of patients with PETs and 71% of patients with idiopathic flushing also had elevated levels. In one study,<sup>99</sup> octreotide relieved pentagastrin-induced flushing in all patients without necessarily altering the substance P response. Furthermore, pentagastrin caused flushing in some patients without rises in plasma substance P, suggesting that mediators other than substance P must be important in inducing the flushing.<sup>99</sup> Even though various GI peptides have been proposed to be involved in the flush, no changes in plasma levels of VIP, GIP, neurotensin, PP, motilin, insulin, glucagon, or enteroglucagon have been detected with provocation of the flush.<sup>108</sup>

Patients with carcinoid syndrome have been shown to have increased colonic motility with a shortened transit time and, possibly, a secretory or absorptive alteration.<sup>84,96,109,110</sup> Serotonin is thought to be predominantly responsible for the diarrhea in some patients by its effects on gut motility and intestinal electrolyte and fluid secretion.<sup>83,84</sup> Serotonin receptor antagonists (especially 5-HT<sub>3</sub>-receptor antagonists such as ondansetron<sup>101</sup>) relieve the diarrhea.<sup>97,98,100,101</sup> In one study,<sup>100</sup> diarrhea was improved by ondansetron in six of six patients with carcinoid syndrome (100%) and nausea in three of four patients (75%), whereas flushing was improved in none of five patients (0%). This finding suggests that 5-HT<sub>3</sub> receptors are mediating the diarrhea and nausea. This conclusion is further supported by the demonstration that alosetron, another 5-HT<sub>3</sub>-receptor antagonist, decreased proximal colonic emptying in patients with carcinoid syndrome.<sup>111</sup> One study<sup>110</sup> provides evidence that prostaglandin E<sub>2</sub> and tachykinins may also be important mediators of carcinoid diarrhea. Patients with carcinoid syndrome had decreased absorption of sodium, potassium, chloride, and water in the jejunum and increased intraluminal nonsubstance P tachykinin and prostaglandin E<sub>2</sub> concentrations compared with normal controls.<sup>96</sup> In combination with histamine, serotonin may be responsible for producing asthma<sup>112</sup> and may be involved in the fibrotic reactions causing heart disease, Peyronie's disease, and ureteral obstruction.<sup>81,98</sup> The pathogenetic link between the carcinoid and heart disease remains a subject of controversy.<sup>22</sup> No relationship between the severity of the heart disease and other common manifestations, such as flushing, diarrhea, or duration of disease, has been established.<sup>22,113</sup> It was reported<sup>85,113</sup> that patients with heart disease have higher urinary 5-HIAA excretion and higher plasma levels of neurokinin A<sup>113</sup> and substance P<sup>113,113</sup> than those without heart disease. A study<sup>114</sup> examining cardiac tissue specimens obtained at operation demonstrated, using immunocytochemistry, increased amounts of TGF-β1 and TGF-β3 but not TGF-β2. It was proposed<sup>114</sup> that TGF-βs may play an important role in proliferation in carcinoid heart disease.

## DIAGNOSIS

Diagnosis of carcinoid syndrome relies on the measurement of urinary or plasma serotonin or its metabolites (5-HIAA) in the urine, with the measurement of 5-HIAA in a 24-hour urine sample the most commonly used test (see Fig. 38.6-1). False-positives may occur if the patient is eating serotonin-rich foods, such as bananas, plantains, pineapple, kiwi fruit, walnuts, hickory nuts, pecans, and avocados, which falsely elevate urinary levels.<sup>115,116</sup> Medications, including cough medicine containing guaifenesin, acetaminophen, salicylates, and L-dopa, should also be avoided because they may affect urinary 5-HIAA levels.<sup>116,117</sup> If one properly controls dietary and medicinal intake, the normal range for urinary 5-HIAA excretion is between 2 and 8 mg per 24 hours,<sup>22</sup> although other researchers suggest that using a level of 15 mg/d may reduce false-positive results.<sup>116</sup> Many patients with serotonin-secreting carcinoids have urinary 5-HIAA excretion in the range of 8 to 30 mg per 24 hours.<sup>118</sup> The measurement of urinary 5-HIAA levels is the current method of choice to diagnose carcinoid syndrome.<sup>118</sup> In one study,<sup>83</sup> 5-HIAA determinations alone had a 73% sensitivity and a 100% specificity for carcinoid syndrome.<sup>83</sup>

Most physicians rely totally on the measurement of urinary 5-HIAA for diagnosis. However, urinary and platelet measurement of serotonin itself may give additional information; thus, it has been recommended that these should also be measured.<sup>22,83,93</sup> In two studies,<sup>119</sup> platelet serotonin levels not only were more sensitive than urinary 5-HIAA and urinary serotonin levels, they were not affected by the patient's diet, as are the 5-HIAA levels. In one comparative study of 44 consecutive carcinoid patients, the platelet serotonin levels,<sup>93</sup> urine 5-HIAA, and urinary serotonin levels were measured. In 14 foregut carcinoids, the sensitivities were 50%, 29%, and 55%, respectively; for 25 midgut carcinoids, the sensitivities were 100%, 92%, and 82%, respectively; and for hindgut carcinoids, the sensitivities were 20%, 0%, and 60%, respectively. The data demonstrate the increased sensitivity of measuring platelet serotonin levels. Elevations of 5-HIAA can occur in malabsorption states and a number of other conditions.<sup>81,116</sup> It is important to remember that foregut carcinoids tend to produce an atypical carcinoid syndrome with increased plasma 5-HTP but not serotonin, because they lack the appropriate decarboxylase (see Fig. 38.6-1), with the result that urinary 5-HIAA may not be markedly increased.<sup>22</sup> In such patients with a normal or minimally elevated 5-HIAA and for whom there is a strong suspicion of carcinoid syndrome, they should be screened for other urinary metabolites of tryptophan,<sup>118</sup> and platelet serotonin levels should be measured. However, this screening is usually not necessary because some of the 5-HTP is decarboxylated in the intestine and other tissues, and many of these patients have elevated urinary 5-HT or 5-HIAA levels.<sup>118</sup>

Diagnostic difficulties may arise in patients who flush for reasons other than carcinoid syndrome,<sup>22,120</sup> in patients with carcinoid syndrome in whom flushing is not apparent, in patients with certain carcinoids (especially foregut tumors in whom 5-HIAA may be normal or minimally elevated),<sup>118</sup> or in the rare patient without metastatic disease who presents with flushing.<sup>89</sup> The differential diagnosis of flushing includes menopausal flushing; reactions to alcohol and glutamate; side effects due to drugs such as chlorpropamide, calcium channel blockers, and nicotinic acid; and other neoplastic disorders, such as chronic myelogenous leukemia and systemic mastocytosis.<sup>120,121</sup> None of these conditions causes increased urinary 5-HIAA, and these disorders can be distinguished pathologically.

The diagnosis of a carcinoid may be suspected by clinical symptoms suggestive of carcinoid syndrome or by the presence of the other clinical symptoms, such as abdominal pain or diarrhea, or it can be made in relatively asymptomatic patients from the pathology report at surgery or after liver biopsy for hepatomegaly. Ileal carcinoids, which make up more than 25% of all clinically detected carcinoids, should be suspected if a patient presents with bowel obstruction, abdominal pain, flushing, or diarrhea.<sup>22</sup> In one study<sup>26</sup> involving 154 consecutive patients with GI carcinoids, 60% found at surgery were asymptomatic. In patients with symptomatic tumors, the time from onset of symptoms until diagnosis is frequently delayed, varying from 1 to 2 years.<sup>17,20</sup> Attempts are being made to identify more specific and sensitive serum markers for carcinoids, which may allow earlier diagnosis.<sup>17,22,76,83</sup> In one study,<sup>76</sup> urinary 5-HIAA had a sensitivity of 73% and a specificity of 100%; plasma substance P a sensitivity of 32% and a specificity of 85%; and plasma neurotensin a sensitivity of 41% and a specificity of 60%. In another study,<sup>17</sup> 88% of patients with carcinoid tumors (93% with hepatic metastases) had an elevated 5-HIAA; 66% an elevated plasma neuropeptide K; and 43% an elevated plasma PP concentration. A number of studies<sup>122,123</sup> and <sup>124</sup> demonstrate that serum chromogranin A levels are elevated in 56% to 100% of patients with carcinoids, and the level correlates with tumor bulk. Serum chromogranin A elevations are not specific for carcinoids because increased levels occur with high frequency in patients with PETs,<sup>9,122,123,125</sup> and certain other NETs.<sup>123,125</sup> The a (a-HCG) or b (b-HCG) subunits of HCG are detected frequently by immunocytochemistry in carcinoids, and elevated plasma levels of HCG are reported in 28% of carcinoids<sup>126</sup> and 13% of patients with carcinoid syndrome.<sup>127</sup> NSE also is used as a plasma marker of carcinoid tumors,<sup>126</sup> but it is less sensitive than chromogranin A, being positive in only 17% to 47% of patients.<sup>122,123</sup>

## LOCALIZATION

A number of techniques, including GI endoscopy, barium radiographs, chest radiographs, imaging studies [ultrasound, computed tomographic (CT) scan, magnetic resonance imaging, angiography], endoscopic ultrasound, selective venous sampling for various hormones, positron emission tomography scanning, and various forms of radionuclide scanning [radiolabeled somatostatin receptor scintigraphy (SRS), iodinated metaiodobenzylguanidine (MIBG)], all have been used to determine the location of the primary tumor as well as tumor extent.<sup>3,22,128,129,130</sup> and <sup>131</sup>

Bronchial carcinoids are usually detected by chest radiography, CT or, occasionally, by bronchoscopy.<sup>22,36,38</sup> They appear frequently (37%) as opacities with sharp or often notched margins.<sup>132</sup> They are slow growing and often induce airway compression with resultant atelectasis. Enlarged hilar lymph nodes from metastasis are

rare.<sup>132</sup> Rectal, duodenal, colonic, and gastric carcinoids are almost always detected by GI endoscopy, with barium radiographs being generally negative.<sup>26,68</sup> When positive, barium radiographs show dilated loops of small bowel or extrinsic filling defects but rarely detect a mucosal lesion,<sup>26</sup> whereas ileal, cecal, and right colon tumors are often diagnosed on radiographic studies.<sup>133</sup>

The main problem is localizing small bowel carcinoids, which may be very small and frequently missed by barium studies, and small carcinoids in other GI tissues.<sup>3</sup> Some of these tumors can be localized by angiography, SRS, or CT,<sup>3</sup> but many are not seen with these modalities. Liver metastases usually are detected by CT or, more recently, SRS. Angiography is more sensitive than CT for detecting liver metastases.<sup>3,22</sup> At present, CT and SRS are the primary diagnostic modality for tumor staging. CT frequently misses the primary tumor, especially if it is small (less than 1.5 cm).<sup>134</sup> However, CT is generally helpful in evaluating the presence of liver metastases and retroperitoneal lymphadenopathy.<sup>3,134</sup>

Carcinoids possess high-affinity receptors for somatostatin in 88% to 100% of cases.<sup>55,128,135</sup> The somatostatin receptors are present in both the primary tumor and metastases. Five subtypes (numbered sst<sub>1</sub> to sst<sub>5</sub>) of somatostatin receptors have been described.<sup>135</sup> Octreotide binds with high affinity to sst<sub>2</sub> and with a lower affinity to sst<sub>3</sub> and sst<sub>5</sub> and has a very low affinity for sst<sub>1</sub> and sst<sub>4</sub>.<sup>135</sup> Studies show almost all carcinoids (90% to 100%) possess sst<sub>2</sub>; 50% to 60% sst<sub>5</sub>; 10% to 100% sst<sub>3</sub>; 70% to 100% sst<sub>1</sub>; and 20% to 100% sst<sub>4</sub>.<sup>55</sup> [<sup>111</sup>In-DTPA-DPhe] octreotide has been approved for localizing carcinoids using radionuclide scanning.<sup>135</sup> SRS images tumor in 73% to 89% of patients with carcinoids.<sup>128,134,135</sup> In one comparative study of 40 patients,<sup>129</sup> SRS localized tumors in 78% and CT in 82%. SRS detected primary tumors in two patients missed on CT, and in 16% of cases it detected lesions not previously seen.<sup>129</sup> Numerous other studies<sup>134,135</sup> have demonstrated that SRS has greater sensitivity for localizing carcinoids, especially the extent of metastatic spread, than conventional imaging studies ( Fig. 38.6-2). More recent studies demonstrate that it has a higher specificity than bone scanning and equal or greater sensitivity.<sup>136,137</sup> In general, SRS has excellent specificity, but it is important to remember that high densities of somatostatin receptors exist on a number of other normal and abnormal cells that can lead to increased uptake and a false-positive response.<sup>138</sup> These include granulomas (e.g., sarcoid, tuberculosis), activated lymphocytes (wound infections, lymphomas), thyroid diseases (goiter, thyroiditis), PETs, and other endocrine tumors. In one study,<sup>138</sup> 12% of SRS localizations were false-positives; however, by considering the clinical context the number of false-positives was reduced to less than 4%. Because of its sensitivity and ability to image all body areas, SRS should be the initial imaging procedure to localize and establish the extent of carcinoids.

**FIGURE 38.6-2.** Comparison of the ability of magnetic resonance imaging (MRI) and somatostatin receptor scintigraphy (SRS) to localize hepatic metastases in a patient with carcinoid syndrome and metastatic gastric carcinoid to the liver. MRI was negative for tumor, whereas SRS demonstrated liver metastases (labeled *tumor*) in the left and right hepatic lobes. The imaging results in this patient demonstrate the greater sensitivity of SRS for localizing hepatic metastases from a carcinoid tumor over conventional imaging studies.

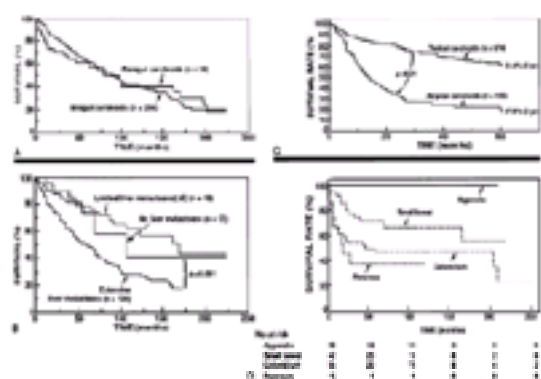

Bone metastases are increasingly being recognized in patients with metastatic carcinoid and other PETs.<sup>3,136</sup> In one study<sup>137</sup> of 30 patients with carcinoid tumors, bone metastases were found in four (13%) using SRS and bone scanning. In general, technetium 99m bone scanning and SRS have been found to be more sensitive than conventional radiographs for detecting bone metastases.<sup>3,22,139</sup>

Positron emission tomography scanning with 5-hydroxytryptophan [<sup>111</sup>C-labeled 5-HTP] has been compared with CT in 16 patients with carcinoids.<sup>131</sup> Positron emission tomography was more sensitive in ten of the patients than CT and was equally sensitive to CT in the others.<sup>131</sup> During treatment, a close correlation ( $r = 0.91$ ) was found between changes in the positron emission tomography scan transport rate constant and changes in urinary 5-HIAA, suggesting that positron emission tomography scanning may be useful for monitoring the results of therapy.<sup>131</sup>

## PROGNOSIS

Clinically, carcinoid syndrome is generally a manifestation of advanced disease.<sup>3,12,20,80</sup> Two in every three patients with carcinoid syndrome have physical signs of cancer, such as an abdominal mass or hepatomegaly.<sup>20</sup> A clear positive correlation exists between tumor mass and urinary 5-HIAA levels therefore, the laboratory test measuring 5-HIAA levels is a good marker for extent of disease.<sup>20,43,80;</sup>

Carcinoids from different locations not only differ in the percentage that are malignant and the percentage that develop carcinoid syndrome (see Table 38.6-2), but also in their aggressiveness. The percentage of carcinoids in different locations having localized disease, regional metastases, or distant metastases varies widely. The highest percentage of nonlocalized disease is with pancreatic (91%), colonic (77%), and small intestinal carcinoids (75%), whereas the highest percentage with localized disease is the larynx (100%), followed by the ovary, appendix, and rectum (62% to 95%). Overall metastases are present at the time of diagnosis in 45% of patients in the SEER group data.<sup>14</sup> In one study,<sup>140</sup> no difference was found in the overall 5-year survival rate of patients with foregut (60%) or midgut carcinoids (63%) (Fig. 38.6-3A).

**FIGURE 38.6-3.** Effect of carcinoid tumor type, extent of metastases, histologic pattern, or localization of primary tumor on survival. **A:** No significant difference was noted in 5-year survival rates for patients with foregut or midgut carcinoid tumors (60% vs. 63%).<sup>140</sup> **B:** The 5-year survival rate of patients with no liver metastases was not significantly different from patients with a few hepatic metastases (fewer than 5) (73% vs. 79%), but was significantly ( $P < .001$ ) greater than those patients with extensive hepatic metastases (more than 5) (47%).<sup>140</sup> **C:** Effect of the histologic pattern of the carcinoid tumor in 833 patients, with the 5-year survival rates for both patterns, is shown.<sup>44</sup> **D:** The number of patients at risk at different times are shown. Patients with an appendiceal primary tumor had a significantly ( $P < .01$ ) better prognosis than those with pancreatic or colorectal carcinoids.

Survival rates with different carcinoids depend on both the site and the extent of tumor <sup>13,14,141</sup> (Table 38.6-4 and Table 38.6-5; see Fig. 38.6-3D). For all 8305 patients in the SEER data<sup>14</sup> with local disease only, the 5-year survival rate was 80%, varying from 0% for liver and 65% for small intestine and ileum to 94% for appendix. In patients with regional involvement, the 5-year survival rate was 51% overall, varying from 0% for the pancreas and gallbladder to 85% for the appendix. For patients with distant metastases, the overall 5-year survival rate was 22%, varying from 0% for the liver to 36% for the small intestine. In different studies for the common carcinoids, the 5-year survival rate was the highest for carcinoids of the appendix (86% to 100%), <sup>13,20,25,142,143</sup> followed by lung (77% to 87%), <sup>13,14</sup> rectum (62% to 72%), <sup>13,14,26,31,143</sup> small intestine (42% to 73%), <sup>3,13,14,20,27,28</sup> and <sup>29,142,143</sup> and colon and stomach (42% to 75%). <sup>13,14,34,142,143</sup>

**TABLE 38.6-4.** Five-Year Survival Rates of Carcinoid Tumors by Site and Stage

*[The content of this table is illegible due to extreme blurriness in the provided image.]*

**TABLE 38.6-5.** Prognostic Factors in Carcinoid Tumors

One of the main determinants of survival is the presence of liver metastases (see Table 38.6-4 and Table 38.6-5 and Fig. 38.6-3).<sup>3,14,28,31,141,143</sup> In a multivariate analysis of 188 cases of patients with carcinoids,<sup>142</sup> the one factor independently predictive of death was the presence of metastases. Additional prognostic factors are summarized in Table 38.6-5. The extent of hepatic metastases is also an important prognostic factor (see Fig. 38.6-3B; Table 38.6-5). In one study,<sup>140</sup> the survival rate was similar in patients with limited hepatic metastases (fewer than five) or no metastases, and it was significantly greater ( $P < .001$ ) than for patients with extensive metastases. Female gender is associated with a better prognosis,<sup>142,143</sup> as is younger age.<sup>140,143,144</sup> and <sup>145</sup> The level of tissue invasion is an important predictor of the probability of developing liver metastases.<sup>28,31,142</sup> The likelihood of finding regional invasion, metastatic disease, and decreasing survival rates is directly proportional to the size of the primary tumor.<sup>3,20,27,32,33,142</sup> With carcinoids of less than 1 cm in diameter, fewer than 15% to 30% in the small bowel have metastatic disease; in the rectum, fewer than 0% to 20%; and in the appendix, fewer than 0% to 2%.<sup>17,20,23,31,32</sup> In contrast, for those tumors more than 2 cm in diameter, 33% to 95% in the small bowel have metastases; in the rectum, more than 70% have metastatic disease; and in the appendix, 33% have metastatic disease.<sup>20,27,28,29,31,32</sup> For all patients with carcinoids the 5-year survival rate varies from 11% to 86% in different studies <sup>13,14,17</sup> (see Table 38.6-4).

The histologic features as well as the stage of the carcinoid have been shown to correlate with disease-specific survival and the risk of metastases <sup>26,28,30,33,34,44,142</sup> (see Table 38.6-5 and Fig. 38.6-3C). In one study,<sup>142</sup> for patients with bowel tumors invading only the submucosa (T1), the 5-year survival rate was 100%; with tumors invading the muscularis propria (T2), it was 81%; with tumors invading to the subserosa (T3), it was 70%; and with tumors involving the visceral peritoneum or directly invading other structures (T4), it was 52%. These results are consistent with numerous studies that have demonstrated that, for carcinoids, the probability of developing liver metastases is closely related to the level of tissue invasion.<sup>3,27,28,31,32,34,44</sup> With bronchial carcinoids,<sup>38</sup> the most important variables affecting prognosis are increasing age, tumor diameter larger than 3 cm, T stage, N stage, lymph node involvement, and number of lymph nodes involved. For all pulmonary NETs, which include typical and atypical carcinoids, and for large cell and small cell neuroendocrine carcinomas,<sup>146</sup> the histologic features, number of mitoses, degree of necrosis, vascular invasion, and extent of nuclear pleomorphism all had a significant effect on survival.<sup>146</sup> Histologic features such as necrosis, increased mitotic count, nuclear pleomorphism, vascular or lymphatic invasion, and undifferentiated growth pattern are used to classify carcinoids histologically as typical or atypical,<sup>4,38</sup> and this variable can have a marked effect on survival (see Fig. 38.6-3C and Table 38.6-5).<sup>27,33,34,38,44,146</sup> Measures of proliferation, such as Ki-67 activity or proliferative cell nuclear antigen expression, correlate with tumor aggressiveness or survival in some studies,<sup>147,148</sup> and <sup>149</sup> but not in others.<sup>150</sup> Flow cytometry has been used to attempt to define the malignant potential for both GI and bronchial carcinoids.<sup>38,149,151,152,153,154,155</sup> and <sup>156</sup> In two studies<sup>3,151</sup> of GI carcinoids, the presence of metastases or decreased survival correlated with the presence of aneuploidy,<sup>152,153</sup> whereas in other studies,<sup>149,154,157</sup> no correlation was found. In bronchial carcinoids, aneuploidy was reported to occur in 50% to 79%,<sup>3</sup> and in some studies,<sup>156,158,159</sup> but not others,<sup>157,160</sup> the flow cytometric result was predictive of the presence of metastases or decreased survival. In one study,<sup>158</sup> aneuploidy was seen significantly more frequently in atypical (74% of cases) than in typical (18%) bronchial carcinoids.

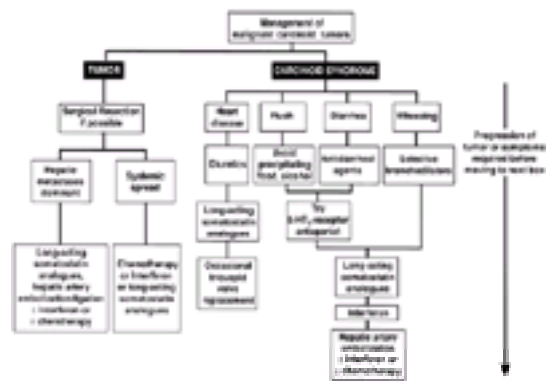

In various studies in the before-octreotide era,<sup>17,80</sup> the median survival of patients with carcinoid syndrome from the time of onset of symptoms varied from 3.5 to 8.5 years, and the presence of carcinoid syndrome was associated with decreased survival. The mean survival after recognition of abnormal excretion of 5-HIAA was 23 months,<sup>80</sup> and the 5-year survival rates after onset of symptoms in two studies were 30% and 67%.<sup>17,80</sup> In a number of studies,<sup>140,161</sup> the level of 5-HIAA excretion has been correlated with survival (see Table 38.6-5). In one study, patients excreting 10 to 49 mg/d had a median survival of 29 months; those with 50 to 149 mg/d had a survival rate of 24 months, and those with more than 150 mg/d had a mean survival rate of 13 months.<sup>80</sup> Octreotide treatment has been proposed to extend survival. Studies show the level of plasma chromogranin A elevation is predictive of survival,<sup>140</sup> as is the plasma level of the tachykinin neuropeptide K.<sup>140,161</sup> In one study,<sup>140</sup> patients with a plasma chromogranin A level of less than 5000 µg/L had significantly ( $P < .001$ ) longer survival than those with higher values (56 months vs. 33 months, respectively). A number of studies<sup>28,31</sup> have provided evidence that patients with carcinoids are at increased risk of developing a synchronous adenocarcinoma (7% to 10%), with the most common site being the large intestine. The development of a second malignancy is associated with a worse prognosis.<sup>144</sup>

The most immediate life-threatening complication of carcinoid syndrome, the carcinoid crisis, is observed more frequently in patients who have intense symptoms from foregut carcinoids or who have greatly elevated urinary 5-HIAA levels (more than 200 mg per 24 hours).<sup>162</sup> The carcinoid crisis may occur spontaneously, or it may be associated with stress, anesthesia, chemotherapy, or even biopsy of hepatic metastases.<sup>3,20,135,163,164</sup> Patients usually develop flushing, diarrhea, and abdominal pain. Mentation is altered, ranging from light-headedness to coma. Cardiac abnormalities also occur, including tachycardia, hypertension, or profound hypotension.<sup>3</sup> The carcinoid crisis may be successfully treated, but in some patients it may also be a terminal event.<sup>20,162</sup> In one study<sup>165</sup> of 21 patients with abdominal carcinoids, of whom 90% had an elevated urinary 5-HIAA level, 80% had evidence of cardiovascular instability during surgery, primarily hypotension. In five cases pretreated with octreotide, the changes in blood pressure were less and responded easily to additional octreotide.<sup>165</sup> Other investigators also have described the value of octreotide in the treatment and prevention of carcinoid crises.<sup>3,135,163,164,165</sup> and <sup>166</sup>

## TREATMENT

Many patients with hepatic metastases from carcinoid tumors remain active and well except for occasional episodes of flushing or diarrhea. Treatment of these patients includes avoiding stress and conditions or substances that precipitate flushing, and dietary supplementation with nicotinamide ( Fig. 38.6-4). Heart failure may require diuretics; wheezing may require oral bronchodilators such as salbutamol, a bronchodilator that interacts with b-adrenergic receptors and does not induce flushing, or aminophylline; and mild diarrhea may respond to antidiarrheal agents such as loperamide or diphenoxylate. If patients still have carcinoid syndrome symptoms, serotonin receptor antagonists or somatostatin analogues are the drugs of choice, although a number of other drugs also have been shown to be effective in small numbers of patients<sup>3,77</sup> (see Fig. 38.6-1 and Fig. 38.6-4).

**FIGURE 38.6-4.** Algorithm for the treatment of malignant carcinoid tumors. *Somatostatin analogues* refers to the use of octreotide, lanreotide, or their long-acting depot formulations (long-acting–release octreotide or sustained-release lanreotide). 5-HT<sub>3</sub>, 5-hydroxytryptamine subtype 3.

These various agents act in a variety of ways, including by inhibiting the synthesis of serotonin (parachlorophenylalanine, a-methyl dopa), by functioning as serotonin receptor antagonists and blocking the action of 5-HT on target tissues, or by inhibiting the release of various vasoactive substances (octreotide, interferon- $\alpha$ ) (see Fig. 38.6-1 and Fig. 38.6-4). Parachlorophenylalanine, which blocks the hydroxylase enzyme that converts tryptophan to 5-HTP, relieves diarrhea and improves flushing in some patients and reduces urinary 5-HIAA.<sup>162,167</sup> However, its side effects include hypersensitivity reactions and psychiatric disturbances, making it intolerable for long-term clinical use.<sup>162,167</sup> a-Methyl dopa blocks the conversion of 5-HTP to serotonin; however, its effect is partial. It occasionally relieves flushing, which may be secondary to inhibiting catecholamine-stimulated release of vasoactive substances, and has little effect on GI symptoms.<sup>78,81</sup> Phenoxybenzamine, an  $\alpha$ -adrenergic antagonist, as well as phenothiazines, possibly acting as  $\alpha$ -adrenergic receptor antagonists, may block flushing provoked by alcohol or other agents, although patients frequently become refractory.<sup>78,81,97</sup> Fourteen subclasses of serotonin (5-HT) receptors have been described.<sup>168</sup> The 5-HT<sub>1</sub> and 5-HT<sub>2</sub> receptor antagonists methylsergide,<sup>93,97,169</sup> cyproheptadine,<sup>169,170</sup> and ketanserin<sup>169,171,172</sup> frequently decrease the GI symptoms but usually do not decrease the flushing. In one study,<sup>20</sup> cyproheptadine used at a dose of 3 to 8 mg three times per day reduced diarrhea in 50% of patients, with minimal, if any, effect on flushing or excretion of 5-HIAA. Cyproheptadine also is reported to have antitumor activity.<sup>3,173</sup> The use of methylsergide is limited because it can cause or enhance retroperitoneal fibrosis. In various studies,<sup>166,171,172,174</sup> ketanserin diminished frequency and severity of flushing in 6% to 100% and diarrhea in 30% to 100% of patients. 5-HT<sub>3</sub>-receptor antagonists (ondansetron, tropisetron, alosetron) usually control diarrhea and nausea and, occasionally, flushing.<sup>93,100,101,111,169</sup> A combination of histamine H<sub>1</sub>- and H<sub>2</sub>-receptor antagonists are effective in carcinoid syndrome that is caused by gastric carcinoids.<sup>82</sup> Prednisone in doses of 20 mg/d gives occasional relief in some cases with severe flushing; however, it is ineffective in controlling the GI symptoms.<sup>78,81</sup> Tamoxifen was reported to cause symptomatic improvement in two patients with carcinoid syndrome<sup>3</sup>; however, in a study involving 16 patients with malignant carcinoids, no improvement or sustained reduction in 5-HIAA occurred with tamoxifen administration.<sup>175</sup>

Native somatostatin reduces symptoms in patients with carcinoid syndrome.<sup>176</sup> However, its use is limited by its short half-life (2.5 to 3.0 minutes). With the availability of synthetic, long-acting somatostatin analogues, octreotide (half-life, 90 minutes),<sup>177</sup> and lanreotide, treatment can be given subcutaneously every 6 to 12 hours.<sup>178</sup> These drugs are now the drugs of choice to control the symptoms of patients with carcinoid syndrome.<sup>110,135,164,179,180,181,182,183,184,185,186,187,188,189</sup> and <sup>190</sup> These somatostatin analogues are effective at relieving symptoms and decreasing hormone levels when self-administered every 6 to 12 hours subcutaneously in patients with carcinoid syndrome.<sup>20,110,135,164,179,180,181,182,183,184,185,186,187,188</sup> and <sup>189,189,190</sup> and <sup>191</sup> Octreotide<sup>192</sup> decreases 5-HT and neuropeptide K release and synthesis from midgut carcinoids by a direct action on tumor cells. In an analysis of 62 published studies,<sup>164</sup> octreotide controlled symptoms in more than 80% of patients. When doses in excess of 375  $\mu$ g/day were used, diarrhea improved in more than 80%.<sup>135,164,179</sup> If more than 400  $\mu$ g/d of octreotide were used, flushing was controlled in more than 80%.<sup>135,164,179</sup> At least 70% of patients had a higher than 50% decrease in 5-HIAA.<sup>164,179</sup> It was recommended<sup>164</sup> that, in patients with carcinoid syndrome with mild to moderate symptoms, treatment should be initiated with 100  $\mu$ g subcutaneously every 8 hours. Individual responses vary and some patients require higher doses, with doses increased as high as 3000  $\mu$ g/d.<sup>164</sup> Forty percent of patients escaped from control after a median time of 4 months, with the remaining patients having sustained control for up to 2.5 years; all responded for more than 1 year, and one-third responded for more than 2 years.<sup>20</sup>

Results similar to octreotide have been described with lanreotide.<sup>181,183,185</sup> In patients with life-threatening features of carcinoid syndrome or the carcinoid crises, somatostatin analogues are effective at both treating these as well as preventing their possible development during known precipitating events, such as surgery, anesthesia, chemotherapy, or stress.<sup>135,163,165,193</sup> It has been recommended<sup>179</sup> that patients with carcinoids scheduled for surgery should be given 150 to 250  $\mu$ g of octreotide subcutaneously every 6 to 8 hours beginning 24 to 48 hours before anesthesia. In patients receiving chemotherapy, 250 to 300  $\mu$ g subcutaneously 1 to 2 hours before chemotherapy is recommended.<sup>179</sup>

Sustained-release preparations of somatostatin have been developed that facilitate treatment. These include monthly octreotide-LAR (long-acting release) or biweekly lanreotide-SR (sustained release) formulations.<sup>84,181,182,194</sup> With octreotide-LAR (30 mg/month) a plasma level of 1 ng/mL or more is maintained for 25 days, whereas this requires three to six injections per day of the non-sustained-release form.<sup>84,195</sup> Similar to the nondepot forms, the sustained-release preparations are highly effective at controlling symptoms of carcinoid syndrome.<sup>181,182</sup> and <sup>183,194</sup>

Short-term side effects of somatostatin analogues have been minimal, occurring in 40% to 50% of patients.<sup>3,135,181,196</sup> Pain at the injection site and effects related to the GI tract (discomfort in 59% and nausea/diarrhea in 15%) are most common. Most are short-lived and therapy is not interrupted.<sup>135</sup> Important long-term side effects include gallstone formation, steatorrhea, and deterioration in glucose tolerance.<sup>3,135,181,197,198</sup> In various studies,<sup>135</sup> the incidence of gallstones in patients treated long term with octreotide has varied from 5% to 80%, and in a review<sup>135,199</sup> of 13 studies involving 213 acromegalic patients, 29% developed gallstones.<sup>135,199</sup> In a study<sup>197</sup> of 45 patients with metastatic carcinoid or PETs treated long term with octreotide, the overall incidence of gallstones, biliary sludge, or both was 52%, with 7% having symptomatic disease requiring surgical treatment.

Interferon- $\alpha$  is effective in carcinoid syndrome, either alone<sup>200,201,202,203</sup> and <sup>204</sup> or combined with hepatic artery embolization.<sup>203,205</sup> In more than 300 patients with carcinoids and carcinoid syndrome treated with interferon,<sup>204</sup> the overall biochemical response rate was 42%. In 111 patients<sup>201,204</sup> from one center given interferon- $\alpha$  (1.5 to 7.0 mU three to seven times per week), 42% had a biochemical response (a more than 50% decrease in tumor marker) with a median duration of 32 months. In 70% of patients, an improvement in flushing or diarrhea was seen. In another study,<sup>206</sup> high doses of interferon- $\alpha$  were used (24 mU/m<sup>2</sup>/d); 39% of patients had a decrease in 5-HIAA secretion, flushing improved in 65%, and diarrhea improved in 33%. However, these responses were transient, lasting a median of only 7 weeks. Interferon- $\alpha$  has been combined with hepatic embolization<sup>205</sup> in seven patients and compared with interferon given alone in 12 patients (5 mU/d) for the treatment of carcinoid syndrome. Evaluation after 1 year of treatment showed that, with interferon alone, 50% of patients had decreased urinary levels of 5-HIAA, and when combined with embolization, 71% of patients had a decrease. With interferon alone,<sup>205</sup> 58% had decreased flushing and 67% had decreased diarrhea, whereas with the addition of embolization, 86% had decreased flushing and 43% had decreased diarrhea.

Patients with carcinoid syndrome who have no response to octreotide or interferon- $\alpha$  alone have been treated with a combination of both agents.<sup>184,204</sup> In one study<sup>204</sup>

involving 24 patients, all demonstrating increased urinary 5-HIAA levels and 19 having classic carcinoid syndrome, complete biochemical remission occurred in 18% and partial biochemical remission occurred in 59%. For a patient with severe carcinoid syndrome not responsive to other measures, hepatic artery embolization or ligation either alone or combined with interferon or chemotherapy may be effective <sup>20,203,205,207,208,209,210,211,212 and 213</sup> (see Fig. 38.6-4). In two studies<sup>214,215</sup> involving 32 patients with metastatic liver disease with carcinoid syndrome, embolization or ligation resulted in at least a 50% decrease in urinary 5-HIAA levels in 63% of patients. In the largest study,<sup>215</sup> 100% of patients had disappearance of diarrhea and flushing immediately after the procedure, and at 1 year postprocedure, 61% were free of symptoms. Chemoembolization,<sup>20,207,208,210,211 and 212</sup> which is embolization with Gelfoam and simultaneous chemotherapy (doxorubicin, mitomycin C, cisplatin, 5-fluorouracil) or interferon,<sup>213</sup> was reported to result in symptomatic improvement in a significant number of patients with carcinoid syndrome. In one large study<sup>212</sup> involving 42 patients with carcinoid tumors, 83% had a decrease in 5-HIAA with chemoembolization followed by treatment with doxorubicin plus dacarbazine [(dimethyltriazeno)imidazole carboxamide; DTIC] and streptozotocin plus 5-fluorouracil, and the mean decrease was 87%. Among patients responding, 98% had improvement in flushing and 88% had improvement in diarrhea.<sup>212</sup> In another study<sup>207</sup> of 15 patients who were unsuccessfully treated with chemotherapy and somatostatin analogue, hepatic artery chemoembolization with 5-fluorouracil, adriamycin, cisplatin, and mitomycin C controlled diarrhea in 75%, flushing in 58%, and pain in 75%. Hepatic artery occlusion or embolization can have significant side effects, with nausea, vomiting, liver pain, and fever.<sup>208,209,212</sup> Major complications occurred in 12% to 17% of patients,<sup>208,212</sup> including hepatorenal syndrome, sepsis, gallbladder perforation or necrosis, upper GI bleeding, and abscess formation. In two studies,<sup>209,216</sup> 5% to 7% of patients died of a complication of hepatic artery occlusion. In the literature, the mortality rate is reported as less than 3%, pain occurs in 100%, and pyrexia and leukocytosis are reported in 50%, as well as occasional acute gangrenous cholecystitis from obstruction of the cystic artery, hepatic abscess, paralytic ileus, and renal failure.<sup>214</sup>

The approach to treatment of carcinoid syndrome at present is summarized in Figure 38.6-4. After symptomatic treatment, patients should avoid precipitating food and alcohol and use oral antidiarrheal agents for mild diarrhea and oral selective bronchodilators for wheezing. Serotonin receptor antagonists, particularly the new 5-HT<sub>3</sub> antagonists (ondansetron, tropisetron), may be effective, particularly for diarrhea and nausea. Octreotide or lanreotide are the drugs of choice, self-administered by the patient. If tachyphylaxis develops, the dose can be increased. If symptoms recur, are severe, and do not respond to an increased octreotide dose, other serotonin receptor antagonists, such as cyproheptadine or ketanserin, should be considered. If this strategy is ineffective, then interferon alone or subsequently combined with somatostatin analogues should be considered (see Fig. 38.6-4).

## TREATMENT OF THE CARCINOID TUMOR

Resection of local or regional nodal metastatic disease can result in cure in some patients.<sup>217,218 and 219</sup> Because in the case of most carcinoids the possibility of metastatic disease is directly related to primary size, the extent of surgical resection for possible cure should be determined accordingly. In the case of appendiceal tumors smaller than 1 cm without gross metastases, which pertains to the majority,<sup>20,25,217,219</sup> a simple appendectomy is sufficient.<sup>20,217,219</sup> Of 103 such patients treated with a simple appendectomy, of whom 103 were followed for 5 years and 83 for 10 to 35 years, no patient developed a local recurrence or metastatic disease.<sup>20,23</sup> With rectal carcinoids smaller than 1 cm, local resection usually is adequate and results in cure.<sup>3,20,32,65,220,221</sup> The depth of invasion is also an important prognostic factor<sup>32</sup> and should also be assessed in all tumors.<sup>32</sup> If no invasion of the muscularis propria is present for rectal carcinoids smaller than 2 cm, local resection is adequate.<sup>32</sup> With small intestinal carcinoids smaller than 1 cm, complete agreement about treatment has not been reached. In most series, 15% to 20% of tumors smaller than 1 cm have metastases. In another series, however, 69% of tumors smaller than 0.5 cm were associated with metastases,<sup>222</sup> and in another series,<sup>28</sup> 32% of tumors 0.6 to 1.0 cm in size had metastases, leading one group<sup>222</sup> to conclude that, with midgut carcinoids, malignancy is independent of size. This has led some to recommend a wide *en bloc* resection of the adjacent lymph node-bearing mesentery for all small intestinal carcinoids.<sup>26</sup> If the carcinoid is 2 cm or larger, which is uncommon in the case of carcinoids of the rectum or appendix and occurs in 40% of small bowel carcinoids,<sup>20</sup> a full-scale cancer operation should be done.<sup>20</sup> In the case of carcinoids of the appendix that are 2 cm or larger, a right hemicolectomy is the operation of choice.<sup>20,23,26,217,219</sup> In a tumor larger than 2 cm in the rectum or a smaller tumor with invasion through the muscularis propria, an abdominoperineal resection or a low anterior resection with primary anastomosis is recommended by some<sup>3,26,32,223</sup> but not by others.<sup>33</sup> In two studies<sup>33,221</sup> in patients with rectal carcinoids larger than 2 cm, all patients died from or developed metastatic disease to the liver despite abdominoperineal or low anterior resection, and the authors concluded that radical surgery is inappropriate if anorectal carcinoids can be removed by local excision. In the case of a small intestinal carcinoid of 2 cm or more, a wide resection is recommended with *en bloc* resection of the adjacent lymph node-bearing mesentery.<sup>26</sup> For carcinoids of the appendix 1 to 2 cm in size, simple appendectomy is recommended by some,<sup>20,23,217</sup> whereas others favor more aggressive surgery, such as a partial cecectomy or formal right hemicolectomy for those lesions located at the base of the appendix to ensure clear margins<sup>26</sup> or in patients with invasion of the mesoappendix or vascular invasion.<sup>217</sup> For carcinoids of the rectum 1 to 2 cm in size, it is estimated that 11% to 47% have metastases,<sup>31,32 and 33</sup> and thus it is recommended by some that these tumors be locally resected with a wide, local, full-thickness excision<sup>221</sup> and that those tumors found to invade the muscularis propria undergo abdominoperineal or low anterior resection.<sup>20,26,217,223</sup> In another study,<sup>33</sup> however, 47% of these patients had metastases and 50% without metastatic disease developed metastases on follow-up, leading the authors to conclude that extensive surgery is not routinely warranted in these patients. With gastric carcinoids, treatment is generally stratified by whether hypergastrinemia is present (type I or II) or not (type III).<sup>40,224,225,226,227 and 228</sup> Most recommend that, in patients with type I or II with small lesions of less than 1 cm, the carcinoids should be removed endoscopically.<sup>226,228,229</sup> In patients with type I or II gastric carcinoids, if the tumor is larger than 2 cm or if there is local invasion, some recommend total gastrectomy,<sup>26,230</sup> whereas others recommend it be removed surgically with resection, with antrectomy performed for type 1 (pernicious anemia) lesions.<sup>40,228</sup> For type I or II lesions of 1 to 2 cm, no general agreement has been reached on treatment; some recommend that these lesions should be treated surgically,<sup>224</sup> whereas others recommend endoscopic treatment.<sup>228</sup>
