Epidural local anesthetics are used to manage patients with localized pain syndromes, usually below the waist. Intermittent and continuous epidural infusions of local anesthetics have been used to manage the difficult chronic pain associated with metastatic disease below the waist, often involving the sacrum and lumbosacral plexus.<sup>157</sup> This method consists of infusing a local anesthetic via a subcutaneous infusion pump or Ommaya reservoir to a catheter, temporarily or permanently placed in the epidural space. If the amount and concentration of the anesthetic are varied, effective pain relief can be achieved without interrupting significant motor or autonomic function. The risk of infection is minimized because local anesthetics have antimicrobial effects. The use of continuous low-dose infusions of local anesthetics is associated with minimal systemic side effects. Further studies on the use of this technique in comparison with standard therapies are needed to define its place in the management of the cancer patient. Its major advantages are that the resultant analgesia is not cross-tolerant with the analgesic produced by the opioid analgesic, and that temporary use of this technique allows for reduction in the amount of systemic opiate drugs, therefore partially reversing tolerance. This has been a useful preliminary approach in patients for whom the use of spinal opiate analgesia is considered, but who have developed tolerance from large doses of systemic opiates. Because tolerance develops to these analgesic effects, this approach is temporary (days to weeks) rather than long-term. This approach is most useful in patients who experience an acute pain crisis, such as the patient with a pathologic hip fracture who is not a surgical candidate; this approach would allow the patient to move about in bed. In patients with chronic cancer neuropathic pain, local anesthetics combined with opioids are used.

## PERIPHERAL NERVE BLOCKS

Peripheral nerve blocks are used both diagnostically to localize the nerve distribution and therapeutically to interrupt pain transmission within a determined nerve distribution. This technique is limited to areas of the body in which the interruption of both motor and sensory function will not interfere with the patient's functional status. This approach is most commonly used with patients who have pain in the head, chest, or abdomen.<sup>158,159</sup> This technique is also limited by the fact that each peripheral nerve subserves sensory function over many levels, and usually several nerves must be blocked to provide adequate analgesia. These techniques are most useful in patients with somatic pain; neuropathic pain is rarely controlled by peripheral nerve blocks alone. Examples of successful blocks include gasserian ganglion block for craniofacial pain, intercostal blocks for chest wall infiltration from tumor, and paravertebral blocks for radicular pain.

In patients with somatic pain who respond to a local anesthetic block, neurolytic blockade with either alcohol or phenol may provide more prolonged relief. A block produced by phenol tends to be less profound and of shorter duration than that produced by alcohol. Phenol has local anesthetic as well as neurolytic effects.

The most common peripheral neurolytic block is a paravertebral block for localized intercostal pain. From our experience in treating patients with chest wall pain, we advise that this procedure be done under fluoroscopic control or computed tomographic localization to accurately interrupt the individual intercostal nerve.

Epidural and intrathecal neurolytic blocks have been used primarily to manage patients with far-advanced disease whose pain is either unilateral in the chest or abdomen or midline in the perineum. These approaches are less useful in managing upper and lower limb pain associated with brachial and lumbosacral plexopathy because of the high risk of motor weakness associated with effective neurolytic blockade by this route. Epidural phenol blocks are useful in chest wall pain over several dermatomes. Such an approach obviates the need for multiple paravertebral injections. Phenol is injected in small increments (1 to 2 mL per segment) over 2 or 3 days by an epidural catheter, and preliminary data demonstrate 80% pain relief in patients with documented somatic pain. Epidural and intrathecal phenol blocks have been used to manage perineal pain, but no studies have delineated the superiority of one approach over the other.<sup>159</sup>

A review of a large number of alcohol subarachnoid blocks reports an average of 60% good relief, 21% fair relief, and 18% poor relief.<sup>7c</sup> Because the duration of pain relief has seldom been documented with careful follow-up studies, the overall estimate for relief of pain with both subarachnoid alcohol and phenol blocks suggests a mean duration of pain relief of between 2 weeks and 3 months.

Complications are of two kinds. With intrathecal injection, a self-limiting spinal headache may occur. Complications that result from the action of neurolytic substances on nerve fibers include motor paresis, loss of sphincter function, impairment of touch and proprioception, and troublesome dysesthesias. Injection in the thoracic region has a low complication rate. In our experience, many cancer patients already have both motor and autonomic dysfunction before the use of neurolytic blockade; these often remain the same or may worsen. Patients should be informed of the risk of these procedures, with particular attention to the fact that they may develop motor paresis and bladder dysfunction, specifically incontinence, after the blockade.

The selection of patients for management with epidural or intrathecal neurolytic agents should be based on the following criteria: exhaustion of appropriate antitumor approaches; clear clinical and radiologic definition of the pain; poor candidacy for percutaneous cordotomy; failure of nonopioid, opioid, and adjuvant analgesics to produce adequate analgesia without significant side effects; a favorable response to diagnostic or epidural or intrathecal blocks, producing at least 75% pain relief; and MRI of the spine or myelography done before the procedure to rule out tumor infiltration of the subarachnoid space.

## AUTONOMIC NERVE BLOCK

Sympathetic block is effective in conditions with vasomotor or visceromotor hyperactivity. This hyperactivity accompanies many of the cancer-related pain syndromes such as visceral pain or plexopathies. The most commonly used sympathetic block is that of the celiac ganglion for pain due to abdominal malignancy, including cancer of the pancreas, stomach, duodenum, liver, gallbladder, adrenal gland, and colon. Nociceptive fibers of the splanchnic, sympathetic, vagal, phrenic, and somatic nerves converge on the celiac ganglion, which is amenable to a regional block that is successful in from 70% to 85% of patients treated.<sup>158</sup>

Standardized approaches for the use of this technique have been described using computed tomography monitoring or fluoroscopic control. After placement of the needle, 25 mg of absolute alcohol mixed with local anesthetic and contrast is injected. Bilateral needle placement has been reported to provide the best results, but anecdotal reports suggest that unilateral needle placement on the right provides comparable analgesia. The major side effect of the procedure is transient hypotension, and patients must be well hydrated and monitored carefully during the procedure and for 4 to 6 hours afterward. Significant neurologic complications occur in less than 1% of patients if proper technique is used. Complications include paraparesis, postural hypotension, and urinary difficulties.

Although there has been debate about the usefulness of this procedure in patients with pancreatic cancer, it should be considered as one of the approaches, together with pharmacologic approaches, in managing these patients.

Lumbar sympathetic block may provide significant relief of intractable urogenital pain or pain due to carcinomatous invasion of local nerves and plexus in the perineum and lower extremity.<sup>159</sup> This ganglion conveys visceral nociceptive afferents from the pelvic viscera. Pain caused by cancer of the sigmoid colon or rectum

may be relieved by bilateral lumbar sympathetic block if the disease is confined to those viscera. Pain caused by cancer of the seminal vesicles or prostate may sometimes be relieved by bilateral lumbar sympathetic block. Similarly, pain caused by uterine cancer may be relieved if the disease is confined to the body of the uterus. In many instances, however, the block must be extended to the T-12 ganglion. Good evidence suggests that lumbar sympathetic block alone is not useful in patients with lumbosacral plexopathy; therefore, the role of this procedure is limited to specific anatomic sites of pain.

Stellate ganglion block may sometimes be useful for pain in the face, upper neck, ear, and hemicranium. However, the potential complications of stellate ganglion block limit the use of this technique with neurolytic solution, as there is a high risk of spillage of the neurolytic material into the brachial plexus, with secondary nerve injury and focal pain.

## NEUROADENOLYSIS OF THE PITUITARY

Chemical hypophysectomy is a special use of a neurolytic method. Several early studies suggest that 35% to 95% of patients undergoing this approach report pain relief, with a median duration of 6 to 7 weeks and a maximum duration of 20 weeks.<sup>160</sup> The mechanism by which analgesia is produced may result from alcohol tracking up the pituitary stalk into the hypothalamus, with consequent disruption of the hypothalamic-thalamic endorphinergic pain pathways. Side effects include diabetes insipidus, cranial nerve palsies, cerebrospinal fluid leakage, and rarely meningitis. The lack of detailed clinical data limits critical assessment of these studies. This technique is rarely if ever used in patients with diffuse pain.

## NEUROSURGICAL APPROACHES

Neurosurgical approaches for cancer pain can be divided into two major categories, antitumor and antinociceptive. These approaches are often used alone or in combination by neurosurgeons to provide improved pain relief.<sup>161,162</sup>

### ANTITUMOR APPROACHES

Antitumor approaches are often more acceptable to patients because they focus on cancer treatment, offering the hope of prolonged survival. The major procedures are listed in [Table 56.1-8](#) and include tumor removal from the spine, epidural space, or adjacent plexus; stabilization procedures for spinal fracture, instability, and subluxation; and implantation of regional delivery devices for epidural, intrathecal, and intraventricular opioid drugs.

Tumor removal through resection of spinal metastases is associated with dramatic improvements in pain in 70% to 90% of patients.<sup>163,164</sup> With the use of improved methods of internal fixation with methyl methacrylate and improved stabilizing procedures, the use of this approach has increased in patients with intractable continuous or incidental back and neck pain. Patients may also have an associated segmental instability associated with a pathologic fracture of the vertebral body or subluxation, syndromes that place patients at significant risk for neurologic dysfunction. Careful radiologic workup is necessary to define the specific anatomic basis for the spinal pain, but aggressive surgical approaches have improved the quality of life for many patients bedridden by uncontrolled pain. In patients with epidural cord compression, the indications for surgery include uncontrolled pain in a patient with a pathologic fracture or a solitary relapse in the epidural space or vertebral body from a radioresistant tumor. In patients with radiosensitive tumors who relapse after radiation therapy, spinal surgery should be considered as a reasonable approach and is specifically indicated in the patient with an acute neurologic deterioration during radiation therapy. When percutaneous or open vertebral body biopsy is impossible, surgical resection should be strongly considered to define the primary tumor type in patients with undiagnosed lesions; this serves as both a diagnostic and therapeutic procedure.

In patients with paraspinal tumor or tumor infiltration of the plexus, *en bloc* resection of tumor has successfully provided pain relief and has served as a debulking antitumor procedure. In patients with Pancoast's syndrome, invasion of the spine or epidural extension is present in 20% at initial presentation and is associated with a significant morbidity in up to 50% of patients when local treatment is ineffective. In the good-risk patient with plexopathy and spinal invasion, Sundaresan et al. recommend surgery in which tumor is removed from the lower plexus, C-8 to T-1, and the vertebral body is resected, with brachytherapy to provide further tumor control.<sup>164</sup>

In patients with tumor invasion of the paraspinal area (specifically the psoas and iliacus), radical resection of these tumor masses concurrent with spinal surgery, followed by brachytherapy, combines antitumor and antinociceptive therapies.

When considering the use of these neurosurgical procedures to provide palliative surgery with an antinociceptive component, the patient's extent of disease, performance score, prognosis, and ability to tolerate the surgery must be weighed.

### ANTINOCICEPTIVE PROCEDURES

Antinociceptive procedures include neuroablative, neurostimulatory, and neuropharmacologic approaches.

#### **Neuroablative Procedures**

Neuroablative procedures involve the production of a surgical or radiofrequency lesion along the nociceptive neural pathway. Sectioning on the posterior roots (rhizotomy), lesioning the lateral dorsal horn (dorsal root entry zone lesion), and interrupting the ascending spinothalamic pathway (cordotomy) or the crossing interneuronal fibers (myelotomy) in the spinal cord are examples of neuroablative procedures performed for pain relief.

Cordotomy, either percutaneous or open, is the most common neuroablative procedure used to manage cancer pain.<sup>162,163,164,165,166</sup> and <sup>167</sup> It is the neurosurgical procedure of choice for patients with unilateral pain below the waist and with a relatively short life expectancy. Cordotomy is usually effective for 1 to 3 years, with dysesthesias substituting for analgesia in patients living longer than 3 years. Pain in the chest wall or upper extremity may be successfully treated initially with cordotomy, but extensive data demonstrate that, with time, the level of analgesia drops, limiting the effectiveness of this approach. Somatic pain appears to be the most responsive to cordotomy; visceral and neuropathic pain are less responsive for reasons that are not fully understood.

Percutaneous cordotomy is performed in a supine, awake patient through a lateral C-1 to C-2 approach.<sup>162,165</sup> A needle is advanced under fluoroscopic control until cerebrospinal fluid is obtained. A minimyelogram is done to identify the dentate ligament. A cordotomy electrode is passed through the spinal needle and the spinal cord is punctured with the aid of impedance monitoring. Electrophysiologic stimulation is done to identify the spinothalamic tract and then a radiofrequency lesion is made in the appropriate painful site. Such a lesion interrupts pain and temperature on the contralateral side of the lesioned site. Patients typically report spontaneous relief of pain in this lesioned area.

The anatomic area at the lesion site includes fibers mediating respiration and autonomic function. These fibers are adjacent to the anterior horn and the cervical spinothalamic fibers. Near the lumbar spinothalamic tract are the fibers governing the intercostal muscles. This quadrant of the spinal cord also contains the sacral fibers to and from the bladder, which are closer to the spinothalamic fibers. These anatomic relations explain some of the complications associated with cordotomy: bladder dysfunction, respiratory compromise, and ipsilateral motor weakness.

From the literature that does not provide comparative studies in cancer patients with pain, pain relief can be obtained in 60% to 80% of patients immediately after cordotomy; results at 6 to 12 months are 40% to 50%.<sup>162,163,164,165,166</sup> and <sup>165</sup> In a retrospective survey of 40 percutaneous cordotomies in patients with predominant unilateral pain below the waist, 70% of patients obtained complete relief with continued use of some supplemental analgesics, 16% had moderate relief, and 13% did not benefit from this procedure.<sup>167</sup> In another study, Arbit reported that 16% of patients referred for percutaneous cordotomy could not undergo the procedure because of difficulty in positioning or with participating in the procedure, even with the use of increased analgesic drug doses and anesthetic assistance.<sup>162</sup> Careful patient selection is necessary for this procedure.

Open cordotomy is usually done below the cervicothoracic junction through a hemilaminectomy or full laminectomy. Open cordotomy should be reserved for the patient who cannot tolerate a percutaneous approach or for the patient with limited motor or sensory dysfunction from tumor infiltration below the waist in whom bilateral cordotomy is to be done for bilateral or midline pain.

The complications of cordotomy vary with the type of procedure (percutaneous or open) and are also strongly influenced by the patient's premonitory neurologic condition. Many patients have borderline bladder function and mild paresis from tumor infiltration that is transiently or permanently exacerbated by these procedures. In our series at Memorial Sloan-Kettering Cancer Center, 45% of patients had transient or permanent urinary retention.<sup>167</sup> After cordotomy there is often an unmasking of pain ipsilateral to the cordotomy site. This pain was reported in 22% of patients in our series.<sup>162</sup> In some patients it was difficult to clarify if this nerve pain was caused by unidentified tumor and really represented mirror pain or was caused by the unmasking of tumor-related pain. In 60% of patients in the Arbit series, unmasking of pain on the contralateral side occurred because of bilateral lumbosacral plexopathy. Dysesthesias characterized by burning pain in the area of sensory loss are reported in 1% to 2% of patients after a delay of several months to 2 years after the procedure. Ipsilateral motor weakness results from an inadvertent anterior extension of the lesion to involve the corticospinal tract. In our series, 7% of patients had transient paresis and 22% had permanent paresis. Most series report motor paresis in 10% to 20% of patients.

Respiratory complications occur in patients with a dysfunctional lung contralateral to the site of the cordotomy. This is a predictable risk when patients undergo cordotomy on the same side as their only functioning lung: Interruption of the reticulospinal fibers controlling the intercostal muscles and of the phrenic nerve may occur because of their proximity to the lateral spinothalamic tract in this spinal cord quadrant.

Several other complications, including headache, fever, and meningismus, are associated with the percutaneous procedure, as well as a Horner's syndrome because of interruption of the sympathetic tract.

In our series, 30% of patients demonstrated a profound depressive syndrome associated with significant pain relief.<sup>167</sup> Patients should be warned about this complication, but the factors contributing to its development have not been fully clarified. Rapid reduction in opioids, realization that with pain relief they must face their terminal illness, and other factors, including exhaustion, depression, and preexisting psychopathology, may all play a role in the appearance of this problematic complication. Psychological intervention and the use of tricyclic antidepressants have been effective in managing these patients.

Dorsal rhizotomy is the next most common neuroablative procedure used for cancer pain. It is performed by sectioning the posterior sensory rootlets, and a specific localized dermatomal pain level can be identified. It can be performed by an operative section of the nerve, or as previously discussed, by a neurolytic block. In patients with chest wall pain from tumor invasion, improved analgesia in 50% to 80% has been reported with dorsal rhizotomy.<sup>168</sup> Arbit et al. have adapted this procedure to manage patients with significant chest wall pain.<sup>169</sup>

Rhizotomies of the trigeminal nerve, nervus intermedius, glossopharyngeal nerve, and portions of the vagus nerve are effective in controlling pain from head and neck tumors that invade the base of the skull.<sup>170</sup> Bilateral sacral rhizotomy has been reported to treat sacral or perineal pain involving the sacral plexus at the S-2 and S-3 levels. However, these patients have often had extensive radiation therapy, and wound closure in the irradiated skin over the sacrum may complicate recovery and increase the risk-to-benefit ratio. A neurolytic, epidural, or subarachnoid block is usually considered before surgical sacral rhizotomy.

The use of a dorsal root entry zone lesion is based on the recognition that nociceptive fibers enter laminae I and II at the dorsal horn; interruption of this anterior lateral site has been associated with reduction in neuropathic pain in experimental animals. This approach has been used most commonly in avulsion of the brachial plexus, postherpetic neuralgia, and postradiation plexopathy. Because this approach has not been widely used in cancer pain, its usefulness for brachial and lumbosacral plexopathy is not established, but it is an interesting approach for such patients.<sup>171</sup> The procedure requires a laminectomy of several levels to provide an adequate approach to this anatomic site, and this may be too extensive a procedure for the cancer patient with advanced disease. Further studies are necessary to determine its usefulness.

The midline commissural myelotomy approach has been used in patients with midline perineal or coccygeal pain or bilateral pain in the lower extremities. Using a limited midline myelotomy, Gildenberg and Hirschberg reported satisfactory pain relief in 10 to 14 patients with midline pain below the waist from cancer.<sup>172</sup> This procedure is based on the fact that nociceptive fibers cross in the anterior commissure from the dorsal horn to the contralateral spinothalamic pathway. This approach is used rarely, if ever, in patients with bilateral pain.

Cingulotomy has received attention in the treatment of some patients with cancer pain, using a stereotactic procedure with MRI to permit a radiofrequency lesion. Four patients with pain from widely metastatic, diffuse bone disease who were receiving opioid analgesics reported immediate pain relief with bilateral cingulate lesions.<sup>173</sup> The pain relief persisted until death in 2 to 6 weeks. This procedure was previously used to treat psychiatric illness and has a long history of use in severe chronic pain from a variety of neuropathic syndromes. The literature suggests that up to 50% of cancer patients have had moderate, marked, or complete relief for 3 months after the procedure. The extent to which the development of this improved method will alter the use of this technique needs to be clarified.

### **Neurostimulatory Procedures**

Neurostimulatory procedures involving the peripheral nerve and spinal cord are generally based on the gate theory of pain. The original theory suggests that there is a neurophysiologic gating mechanism in the spinal cord, probably within the substantia gelatinosa. Noxious sensation is conducted via small-diameter peripheral nerve fibers and nonnoxious sensation via large-diameter fibers, and both send collaterals to the substantia gelatinosa and up the spinal dorsal columns. Stimulation of the small fibers tends to promote pain, or *open the gate*, whereas stimulation of the large fibers tends to inhibit pain or *close the gate*. Because the large nerve fibers ascend in a compact bundle through the dorsal columns, they are accessible to selected electric stimulation. Retrograde firing of the large fibers ensues, and pain sensation is inhibited at multiple levels of the spinal cord below that being stimulated.

Based on reports that high-frequency (50 to 100 Hz) percutaneous electrical nerve stimulation relieved chronic neurogenic pain, the use of transcutaneous electrical nerve stimulation (TENS) was reported effective in treating neuropathic pain. Although control studies are lacking, numerous clinical surveys suggest that this approach is useful for nociceptive and neuropathic pain. With the advent of sophisticated electronic devices, various patterns of electric stimulation are currently in use transcutaneously, including pulsed (burst), modulation (ramped), random, and complex wave forms, all designed to improve efficacy. Patients are instructed on proper electrode placement in a dermatomal pattern and are instructed to try both intermittent and continuous stimulation. By trial and error, analgesic effects should be observed either immediately or, in some cases, after the stimulation is discontinued.

TENS is used for a wide variety of pains and serves as a safe, noninvasive approach. Clinical experience suggests its usefulness in some patients with peripheral nerve pain. Several investigators have reported that it is useful in cancer pain for a wide variety of tumor-related and neuropathic pain syndromes.<sup>174</sup> Further studies are necessary to define the usefulness of TENS in the cancer patient with pain.

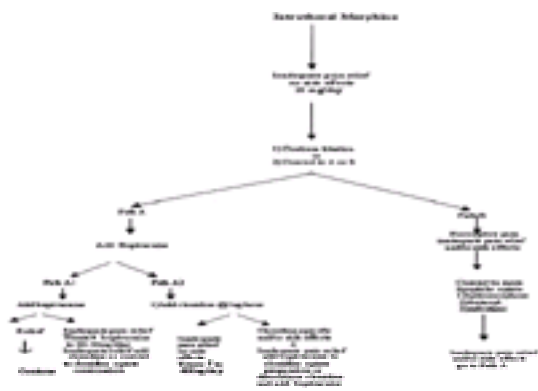

The dorsal column stimulation technique involves the introduction of an electrode into the epidural or intrathecal space and advancing it to the appropriate level overlying the dorsal columns. The main indications for placement of a dorsal column stimulator are intractable dysesthetic or deafferentation pain of the limbs or trunk, such as radiation-induced brachial or lumbosacral plexopathy. This procedure is effective in 43% to 75% of patients and carries a low morbidity. The most common complication is failure of the device itself, which occurs in approximately 10% of patients annually. Other complications include infection, cerebrospinal fluid fistula, allergic or rejection response to the device material, and changes in stimulation over time, which may be related to cellular changes around the electrode or shifts in its position.

Thalamic stimulation involves the placement of electrodes in the medial thalamus and has been reported to be most useful for managing neuropathic pain from lesions in the central and peripheral nervous system. There are a series of reports on the usefulness of this technique in patients with head and neck cancer and prominent cranial neuropathic pain, but the limited use of this technique in these patients makes it difficult to define its specific role.<sup>175,176</sup>

### **Neuropharmacologic Approaches**

Epidural and intraspinal analgesia using opioids alone or in combination with local anesthetics, clonidine, or both or experimental agents are used to manage chronic cancer pain in patients with a reasonable (1 year) prognosis. In all instances, patients should have a trial of an epidural or intraspinal drug combination before permanent implementation is considered. It is advised that patients have as continuous intrathecal trial lasting as long as possible before permanent implementation, and [Figure 56.1-3](#) provides an algorithm for the use of opioid intrathecal alone or with clonidine in a patient with a mixed somatic-neuropathic pain syndrome inadequately managed by systemic opioids.<sup>177</sup> A wide array of external and implantable catheters and pumps are available with specific indicators and uses. Both computer-controlled battery-operated pumps and continuous fixed infusion pumps are used. Cost of the pumps and the patient's psychosocial status and social

support systems and ability to care for the pump and port are important considerations in selecting the use of such devices. No studies have clearly defined the efficacy of this approach as compared with systemic treatment, and longitudinal surveys have identified complication rates that vary from 10% to 50%, with meningitis as a serious complication. With long-term epidural catheter use, 5% to 15% infection rates have been reported.

**FIGURE 56.1-3.** In intrathecal analgesic titration, doses are usually increased to about 20 mg/day of morphine and sometimes higher. Alternative therapies for when intraspinal morphine is failing are shown.

## TRIGGER POINT INJECTION

The use of trigger point injections is within the scope of the practicing physician.<sup>178</sup> Patients with significant musculoskeletal pain often describe specific, tender trigger point areas that, when injected with either saline or local anesthetic, are associated with significant pain relief. Effective relief of pain from trigger point injections, however, is not diagnostic of musculoskeletal pain alone, and an evaluation of the cause of the pain is still necessary to rule out the specific etiology.

Acupuncture has been used to treat both acute and chronic pain. The selected acupuncture points are manually or electrically stimulated with a needle until the patient feels the sensation. A wide variety of acupuncture techniques are available, ranging from a traditional Chinese approach to a Western adaptation. Laser acupuncture with external laser probes has also been used. The studies in cancer patients with pain represent large, uncontrolled, retrospective surveys. Minimal stimulation in manual acupuncture was used in all cases, and three acupuncture treatments represented an adequate trial. Fifty-two percent and 56% of patients reported some pain improvement for at least 7 days; an additional 30% and 22% had pain relief for 2 days or less or reported increased mobility alone.<sup>179</sup> A lack of detailed pain assessment in specific acupuncture techniques or a critical review of the patient population make it difficult to interpret these observations. Based on its current empiric use, this approach is relatively safe, but its benefit in cancer patients with pain remains undefined.

## PHYSIATRIC APPROACHES

Rehabilitation medicine plays an important role in the multidisciplinary approach to the patient with cancer pain. Physiatrists are concerned with a patient's physical functioning and provide expertise in assessing how impairment in a patient's physical capacity affects his or her ability to function. A wide variety of interventions are available, including TENS, diathermy (heating pads, ultrasound, hydrotherapy), and cryotherapy (ice and vapo-coolants). Assistive device and braces, as well as therapeutic exercise and massage, are important. Trigger point injections and acupuncture have also been used. These interventions are commonly used in combination with other pain-therapy approaches, particularly behavioral and pharmacologic approaches. Rehabilitation approaches are discussed throughout the text specific to cancer patients' needs.

A large body of data supports the use of rehabilitative interventions in acute and chronic nonmalignant pain, but similar studies have not addressed the rehabilitation needs of the cancer pain patient. From our experiences, neurologic dysfunction is one of the common components in patients with cancer pain, and aggressive neurorehabilitation is necessary to ambulate these patients and provide them with functional independence.

## SEDATION IN THE IMMINENTLY DYING

### NITROUS OXIDE

Nitrous oxide has analgesic properties and has been used in the management of patients with far-advanced disease to provide added analgesia. It is administered with oxygen through a nonbreathing face mask in concentrations from 25% to 75%. Its use in combination with systemic opioid analgesics is associated with improvement of symptoms of pain and anxiety and a demonstrable improvement in alertness.<sup>180</sup> This anesthetic approach should be considered in patients with breakthrough pain or incident pain to provide adequate analgesia to facilitate their care.

### INTRAVENOUS BARBITURATES

This approach has been advocated to manage dying patients who have inadequate analgesia or uncontrolled symptoms, who ask to be maintained in a sedated state. Intravenous thiopental titrated to a level of sedation was the approach advocated in a series of 17 terminally ill patients.<sup>181</sup> The authors suggested that the value of this approach is based on the use of one agent to treat both physical and psychological symptoms. This approach may be seen as a more generalized one to palliative care and should be considered only if the standard approaches with opioid analgesics and adjuvant drugs fail to provide adequate analgesia with minimum side effects. However, because it is the physician's responsibility to manage not only pain but also suffering, this may be a reasonable approach, particularly in the dying patient with profound dyspnea, myoclonus, or agitation. Further studies are needed to clarify the usefulness of this approach. In the published study, 13 of 17 patients developed somnolence and died; the somnolence lasted from 2 hours to 4 days, with an average of 23 hours. Four patients died without being somnolent.

Several problematic symptoms often arise in the management of the dying patient, including intractable vomiting, profound dyspnea, extreme agitation and anxiety, and uncontrolled pain. Several authors have reported that most cancer patients have crescendo symptoms before death, requiring somnolence.<sup>182,183 and 184</sup> This approach offers one method to manage these difficult patients.

Whatever pain management techniques are used, the physician is responsible for providing continuing care, constantly reassessing both the diagnosis and the treatment to achieve optimal relief of pain and suffering for both patient and family.

The care of patients with cancer and chronic pain strains the resources of a single physician, especially after the patient's discharge from the hospital. Various supportive care and continuing care programs have been developed to manage dying patients, both in the hospital and at home. In these patients the focus of treatment shifts to symptom control and palliative comfort care. Palliative care services, home- and hospital-based hospices, and high-technology home care programs are some of the approaches to care for patients with terminal illness.

The program at Memorial Sloan-Kettering Cancer Center centers on the patient and family and is coordinated by a nurse, physician, and social worker.<sup>185</sup> The nurse is responsible for day-to-day management of the patient's pain and works with the patient, family, and community physicians and nurses on symptom control and supportive care. Community health professionals work with the patient at home, and the team is available to the patient, family, and community health workers on a 24-hour-a-day basis.

## ALGORITHM FOR CANCER PAIN MANAGEMENT

An algorithm has been developed that integrates all of these management approaches for cancer pain. It attempts to integrate assessment techniques, drug therapy, behavioral approaches, and anesthetic and neurosurgical approaches and stresses continuity of care. Treatment begins with a diagnostic evaluation that addresses the medical, psychological, and social components of pain. A plan is developed to treat the cancer and pain. If the anticancer treatment is effective, pain relief usually

occurs and the drugs used for analgesia can be discontinued without difficulty. Pain treatment begins with the use of analgesic drugs, starting with nonopioid drugs alone or in combination. If they are successful, no further therapy is necessary. If severe persistent pain does not respond to analgesic drugs or if the side effects of the drugs are not tolerated, the physician should consider switching analgesics (e.g., from oral morphine to methadone), changing the route of administration (e.g., from oral to subcutaneous), or performing a cordotomy for localized pain. A trial of an adjuvant drug together with the opioid and nonopioid drug would also be appropriate. In patients with excessive sedation or confusion, the use of a neurostimulant or haloperidol provides adequate treatment of the side effects of the opioid drugs and maintains the patient's analgesia while markedly reducing concurrent side effects. Alternatively, epidural or intrathecal opioids may be considered if systemic analgesics produce excessive side effects such as confusion or sedation. If the pain is localized (e.g., intercostal pain from tumor infiltration of the chest wall), neurolytic blocks are indicated. If the pain is unilateral and below the waist, cordotomy should be considered. For diffuse pain, nitrous oxide inhalation may be tried. Cognitive-behavioral approaches must be integrated from the onset of treatment and should be used along with the medical and surgical approaches.

## FUTURE DIRECTIONS

The study of pain in cancer patients offers a unique opportunity to use clinical observations to advance our biologic knowledge. There is a critical need to expand both the research and educational efforts in cancer pain to improve the control of pain in these patients. Information on the basic mechanisms of pain modulation can be culled only from a careful study of these clinical pain problems. These patients can teach us the physiologic and psychological differences between acute and chronic pain problems, the importance of the evolution of psychological factors, the difference between pain and suffering, the clinical pharmacology of analgesic drugs, and the behavioral mechanisms humans use to suppress pain. The use of innovative approaches based on sound scientific principles and advanced on research technology offers the opportunity to understand the complex phenomenon of pain.

## INTRODUCTION

Malnutrition is common in cancer patients and is frequently referred to as *cancer cachexia*. Although this is a true malnutrition syndrome, it differs from the protein-calorie malnutrition seen in starvation. Further, the etiology of this clinically obvious problem is not entirely clear, but investigations delineating the role of cytokines and other substances responsible for mediating the cachexia of cancer have increased our knowledge of the causes of malnutrition in these patients with advanced malignant disease. Studies have also provided insight into why it is difficult or impossible to gain lean body mass in cachectic cancer patients even when aggressive feeding regimens are implemented. Now and in the future, nutritional therapy may be most effective in cancer patients when used in combination with other forms of metabolic intervention.

While cancer patients can develop deficiencies in vitamins and trace minerals, the most common form of nutritional depletion is that of protein-calorie malnutrition, manifested as a loss of body cell mass. Severe protein-calorie malnutrition is associated with increases in postoperative complications in cancer patients, and it has been shown to have adverse effects on immune function and treatment tolerance to anticancer treatments. Since intuition would indicate the well-nourished patient should tolerate aggressive antineoplastic therapy better than the malnourished individual, numerous studies have tried to define the role of nutritional support in patients with malignant disease. Moreover, the observation that this commonly occurring weight loss is a predictor of therapeutic response and survival has led to aggressive attempts to restore nutritional integrity. The rationale for providing nutritional support to selected patients is to prevent or reverse host tissue wasting, broaden the spectrum of therapeutic options, improve the clinical course, and ultimately prolong patient survival.

More recent developments have increased our understanding of the relationship between nutrition and metabolism in cancer patients, and it is clear that limited weight loss in cancer patients is acceptable because short-term undernutrition does not appear to adversely affect treatment tolerance. However, many cancer patients do develop significant malnutrition such that some form of nutritional support or metabolic intervention appears to be indicated. Cancer patients often require chemotherapy, radiation therapy, or both in combination with surgery, and these treatments can further compromise an already fragile nutritional status and further reduce treatment tolerance. Not only may the anticancer treatments directly affect nutrition and reduce the urge to eat, but they may affect the ability to chew, swallow, or absorb food. Accordingly, oncologists need to become familiar with the changes in body metabolism developing during malignancy and with the indications and delivery of nutritional or metabolic support to the cancer patient. Although the need for well-designed prospective randomized trials examining the role of nutritional support as adjunctive therapy in cancer patients continues to exist, it is clear that patients with a functioning gut deserve enteral nutrition as the route of preference for feeding. Parenteral nutrition should be reserved for patients who have unusable gastrointestinal tracts.

The purpose of this chapter is to examine the etiologies and metabolic alterations in cancer cachexia, to establish a rationale for metabolic treatment and support in the malnourished cancer patient, and to define the indications for and the effect of nutritional support in patients with malignant disease. Portions of this review have been previously published.<sup>1,2,3 and 4</sup>

## CLINICAL MANIFESTATIONS OF CANCER CACHEXIA

### WEIGHT LOSS

The most obvious clinical manifestation of cancer cachexia is the depletion of host tissues that becomes quite apparent to the casual observer as weight loss. Most patients lose weight at some point during the course of their disease and nearly one-half of all cancer patients have weight loss at the time of initial diagnosis. Warren and colleagues in 1932 reported that 22% of deaths were due to inanition, and two-thirds of all tumor-bearing patients in their series developed some degree of cachexia.<sup>5</sup> A large study from the Eastern Cooperative Oncology Group showed significantly shorter survival if weight loss was present. Further, the amount of weight loss was dependent on the type and site of the tumor. Non-Hodgkin's lymphomas, breast cancers, acute nonlymphocytic leukemias, and sarcomas had the least weight loss. Colon, prostate, and lung cancers had a moderate weight loss, whereas pancreatic and gastric cancers had the most.<sup>6</sup>

DeWys and colleagues<sup>6</sup> reported that patients who presented without weight loss had a significantly prolonged survival following therapy than similarly treated patients who had weight loss at presentation. These findings suggest that weight loss adversely affects survival following antineoplastic therapy and imply that appropriate nutritional therapy may be beneficial to certain patient groups ( [Table 56.2-1](#)). In both animals and patients with cancer, it is apparent that weight loss is dependent on the presence of the tumor since curative surgical resection (or nonsurgical ablation) of the malignancy is almost invariably associated with a return of normal food intake and normal body weight, whereas palliative resection is not. In fact, in patients not regaining their weight following supposedly curative surgical resection, the presence of metastatic or recurrent disease should be suspected. As a general rule, cancer patients with significant weight loss do not tolerate treatment regimens as well as well-nourished patients.

Type of Cancer (Diagnosis)	No. of Patients	Percentage of Patients with Weight Loss at Diagnosis	Survival of Patients with Weight Loss (yr)	Survival of Patients without Weight Loss (yr)
Breast	29	36	6	27
Colon	37	34	5	10
Esophagus	3	33	3	10
Liver	18	39	5	10
Lung	38	42	3	20
Head and Neck	45	49	2	16
Stomach	17	47	2	14

P, 0.05 versus patients with weight loss.  
(From ref. 4, with permission.)

**TABLE 56.2-1.** Extent of Weight Loss in Cancer Patients at the Time of Initial Diagnosis and Its Effect on Survival after Antineoplastic Therapy

Nutritional support therapy has attempted to reverse this cachexia and, although some weight loss has been halted, restoration of the protein and caloric intake has not reversed the abnormalities of energy, protein, carbohydrate, and fat metabolism, showing that something else must be added.<sup>7,8</sup>

### LOSS OF APPETITE

Loss of appetite resulting in a reduction in voluntary food intake is a central component of the syndrome of cancer cachexia. Careful studies in numerous animal models of cancer cachexia have documented a decline in food intake.

Appetite is strongly controlled by various neurotransmitters such as serotonin, catecholamines, and opiates.<sup>9</sup> Any serotonergic agonist decreases appetite. In animal studies, there is evidence of increased brain tryptophan and serotonin turnover in the tumor-bearing host.<sup>10,11</sup> Inhibition of serotonin synthesis increases food intake. However, serotonin antagonists demonstrate no effect on tumor anorexia. Further, there may be a serum factor responsible since rats receiving serum from tumor-bearing rats become anorectic.<sup>12</sup>

At some point during the course of their disease, most patients report a loss of appetite including alterations in taste and smell plus the loss of the appeal of most foods. Moreover, some patients exhibit an increase in resting energy expenditure (REE) that is seldom accompanied by a compensatory increase in caloric intake. The combination of a decrease in voluntary food intake with an increase in energy expenditure further contributes to weight loss and negative caloric and nitrogen balance.

There may also be anatomic factors including the location of the tumor affecting the ability to eat. Sometimes the malignant process may even involve the digestive tract, leading to pain, early satiety, mechanical obstruction, or nausea. Head and neck cancers and the treatments used for them may cause dysphagia, mucositis, and stomatitis, with the resultant inability to take oral feeds. Gastric and pancreatic cancers cause obstruction, early satiety, or pain with eating and notoriously present late with marked metabolic changes and weight loss. Early provision of enteral routes for feeding need to be considered along with any other types of treatment and should be performed with the primary surgery or early in the course of radiation therapy. With today's minimally invasive procedures for tube placements, there is no excuse for delay in provision of enteral feeds.

### WEAKNESS

Secondary to loss of body cell mass and treatment regimens, cancer patients almost invariably develop a reduction in strength and a diminished physical capacity for work. Evidence for a central role of the tumor in the etiology of this weakness is derived from the clinical observation that cure of the cancer almost always results in a return to preillness strength and work capacity.

### CAUSES AND CONSEQUENCES OF CANCER CACHEXIA

Many of the physiologic changes seen in cancer cachexia resemble those of simple starvation, but it is clear that more derangement is involved since few studies have documented that aggressive feeding of cachectic cancer patients completely restores lean body mass<sup>7</sup> (Table 56.2-2). Rather, such patients tend to primarily gain water and fat. Although the substrate demand of the tumor may account for the tumor behaving as a nitrogen trap, the actual energy and nitrogen demands of human tumors cannot account for the profound weight loss generally observed. It is unusual for the total mass of the tumor to exceed 1% or 2% of total body weight, yet patients with much smaller tumors are often markedly cachectic. Studies in the last decade suggest that circulating factors are the major cause of cancer cachexia and that appropriate therapy for this detrimental syndrome of weight loss and wasting will require a better understanding of these mediators.

	Simple Starvation	Advanced Malignant Disease
Basal metabolic rate	- or decreased	-, increased, or decreased
Presence of mediators	-	+++
Hepatic ureagenesis	+	+++
Negative nitrogen balance	+	+++
Gluconeogenesis	+	+++
Muscle proteolysis	+	+++
Hepatic protein synthesis	+	+++
Lipolysis	+	+++

-, indicates normal; +, indicates slightly increased; +++, indicates a substantial increase.

**TABLE 56.2-2.** Metabolic Differences between the Response to Simple Starvation and Advanced Malignant Disease

The term *cancer cachexia* is used to describe a complex metabolic syndrome composed of weight loss, anorexia, and wasting of host lean body mass secondary to the growing malignancy. No consistent or clear-cut association with duration of illness, stage of disease, or tumor histology has been demonstrated. Although the exact prevalence of cancer cachexia is unknown, many studies have shown a high frequency of nutritional derangements in cancer patients. These studies have focused on findings such as weight loss or hypoproteinemia as indicators of cancer cachexia. Consequently, the prevalence of cancer cachexia may be underestimated, since it is likely that subtle metabolic alterations precede these clinically apparent changes manifested by the weight and lean tissue loss.

Since many cancer-related deaths are a consequence of malnutrition and host depletion, understanding the mechanism of cancer cachexia is imperative, as the syndrome always results in death if oncologic therapy is not administered. Many etiologies for the cancer cachexia syndrome have been proposed, but no clear explanation exists. Therefore, the etiology seems to be multifactorial. Causes can be broadly categorized into anorexia of malignancy, anorexia of therapy, and abnormalities in host intermediary metabolism.

### ANOREXIA OF MALIGNANCY

As mentioned previously, the *anorexia of malignancy* refers to the decrease in voluntary food intake that occurs in cancer patients. Although this anorexia comes eventually in all patients with advanced cancer, it may sometimes develop early in the course of the disease when the tumor is quite small. Weight loss is common in patients with gastrointestinal tumors, but dysfunction of the digestive tract cannot solely explain this phenomenon, since significant cachexia is also noted in patients with cancers that originate outside the abdominal cavity. Proposed mechanisms include local effects of the tumor, alterations in taste or palatability, hypothalamic

dysfunction, modification of satiety mechanisms, and learned food aversion. Many of these effects seem to be mediated by circulating factors.

## ANOREXIA OF THERAPY

Oncologic therapies may often initiate or worsen anorexia. Many chemotherapeutic agents can cause nausea, vomiting, mucositis, gastrointestinal dysfunction, or all of these symptoms for varying periods of time that may result in anorexia and weight loss. Radiation therapy is often associated with similar acute side effects and may lead to stricture formation in the bowel. After surgery, causes of weight loss range from routine postoperative ileus to the hypermetabolism associated with sepsis. An important consideration for the clinician to remember is that, in the midst of a diagnostic workup, hospitalized cancer patients are often restricted from taking adequate nutrition. As a result, the patient may become iatrogenically malnourished before even the initiation of oncologic treatment.

## CACHEXIA SECONDARY TO ALTERATIONS OF HOST INTERMEDIARY METABOLISM

A number of metabolic abnormalities are characteristic of the tumor-bearing host (Table 56.2-3). REE is variably affected by the presence of a tumor. Knox and coworkers studied 200 malnourished cancer patients using indirect calorimetry and found that 41% had normal basal metabolic rates, 33% had decreased expenditures, and 25% had increased expenditures.<sup>13</sup> Even patients with no increase in metabolic rate can develop weight loss and negative nitrogen balance despite a normal food intake and a small tumor burden. Fearon and coworkers demonstrated that whole body protein turnover was increased 50% in solid tumor-bearing patients, despite having no change in REE.<sup>14</sup> Other studies have shown that, unlike simple starvation, REE remains elevated even in the face of reduced intake.<sup>15</sup> But, even for tumors with elevated REE, the increased energy expenditure is not enough to explain the weight loss. Curative resections return the REE to normal, but palliation does not.<sup>16,17</sup> and <sup>18</sup> Further, rebound in the REE indicates a recurrence of the tumor.

Substrate	Clinical Parameter	Observation
Water	Total body water	Increased
Energy	Energy balance	Negative
	Energy stores	Diminished
Lipid	Body fat mass	Decreased
	Lipoprotein lipase activity	Decreased
	Fat breakdown	Increased
	Serum lipid levels	Increased
Carbohydrate	Gluconeogenesis	Increased
	Insulin resistance	Present
	Body glucose consumption	Increased
	Hepatic glucose production	Increased
Protein	Muscle mass	Diminished
	Muscle proteolysis	Increased
	Muscle amino acid release	Increased
	Hepatic protein synthesis	Increased
	Hepatic amino acid transport	Increased
	Nitrogen balance	Negative

TABLE 56.2-3. Metabolic Abnormalities in Animal and Human Cancer Cachexia

Glucose metabolism is also abnormal in cancer patients secondary to increased whole body glucose turnover. There is decreased glucose use by skeletal muscle, increased hepatic glucose production, and increased production of glucose from lactate through Cori's cycle.<sup>19,20</sup> There is also increased glucose use by the tumor as the tumor switches to glucose as its primary fuel source. Shaw and Wolfe demonstrated that hepatic gluconeogenesis in patients with gastrointestinal malignancies was elevated proportional to tumor burden.<sup>20</sup> Patients with the largest tumors even failed to suppress endogenous glucose production during glucose infusion, a response attributed to insulin resistance.<sup>26,21</sup> and <sup>22</sup> This glucose intolerance and hyperglycemia in cancer patients has been recognized for a long time.<sup>23</sup> Lundholm et al. showed that the beta cell receptor in the pancreas may have diminished sensitivity to glucose loading,<sup>24</sup> indicating that the tumor-bearing host may be in a type II diabetic-like state. However, this insulin resistance also shares elements similar to the stress state. Overall, there is a combination of a significant decrease in metabolized and cleared glucose in both the weight-stable and weight-losing cancer patients. Since the insulin resistance may decrease after complete tumor resection, it appears to be related to the tumor itself, rather than the associated malnutrition.<sup>25</sup> This could contribute significantly to tissue wasting, since insulin is important for tissue anabolism.

Protein and amino acid metabolism are also altered in the tumor-bearing host. Jeevanandam et al. compared tumor-bearing patients with both malnourished non-tumor-bearing patients and healthy controls to find elevated levels of protein turnover in the cancer group.<sup>26,27</sup> and <sup>28</sup> Patients with non-small cell lung cancer have increased whole body protein turnover, elevated 3-methylhistidine excretion, and increased muscle proteolysis.<sup>29</sup> In tumor-bearing rats, whole body nitrogen turnover and liver protein fractional synthetic rates increase, and the animal cannot adapt to starvation by diminishing the rate of muscle amino acid release. Further, skeletal muscle synthesis of new protein decreases. Norton et al. measured arteriovenous differences of amino acids across a sarcoma-bearing limb in patients using the non-tumor-bearing limb as a control.<sup>30</sup> Compared with the non-tumor-bearing extremity, the tumor-bearing limb released lesser amounts of every amino acid, consistent with the tumor's requirement for amino acids to support neoplastic growth. Further work by Fischer et al. has shown the primary amino acid for tumor protein synthesis is glutamine.<sup>34</sup>

Lipid metabolism is also altered in the host with cancer. Shaw and Wolfe studied glycerol and fatty acid kinetics using radioisotopes and found cancer patients with weight loss have increased glycerol and fatty acid turnover compared with weight-stable patients.<sup>20</sup> These weight-losing patients may be incapable of oxidizing endogenous fatty acids or intravenous lipids at normal rates and fail to suppress lipolysis during glucose infusion. In fact, there is increased lipid mobilization from peripheral fat stores and decreased serum lipid clearance, leading to depletion of body fatty tissue. There have now been a number of studies suggesting a transmissible fat-mobilizing substance [lipid-mobilizing proteoglycan (LMF), *azafitig*] in the serum of cancer patients that increases lipid breakdown and decreases fat synthesis.<sup>31,32</sup> and <sup>33</sup> This lipid-mobilizing factor is a 24-kD zinc  $\alpha_2$ -glycoprotein that has been isolated from the urine of tumor-bearing animals and patients. It has been found in the urine of pancreas, lung, breast, and ovarian cancer patients. The N-terminal amino acid sequence is different from that of any of the known cytokines. Administration of this material shows significant reduction in body weight and decrease in both fat and lean body mass and can be neutralized by administration of monoclonal or polyclonal antibodies.

## GLUTAMINE AND CANCER CACHEXIA

Glutamine metabolism in the tumor-bearing host has been extensively studied for four principal reasons: (1) glutamine is the principal amino acid used by many cancers,<sup>36</sup> (2) it is the most abundant amino acid in the body, (3) its stores are quite labile, and (4) studies indicate that glutamine is a conditionally essential amino acid. Glutamine appears to be an unusually good substrate for use by the tumor. In fibrosarcoma cells, glutamine oxidation is decreased and the glutamine is shunted into protein synthesis while the tumor switches to glucose for energy.<sup>34</sup> Circulating glutamine extraction by the tumor is 50% greater than the rate of glutamine extraction for any normal healthy organ. Because tumors must compete with host tissues for plasma amino acids and are often poorly vascularized, they must possess efficient mechanisms for their extraction, especially in an environment (e.g., intratumoral space) in which levels of these nutrients may be diminished compared with plasma levels. Studies<sup>35</sup> in a variety of different solid tumor cell lines, regardless of tissue origin, indicate a single efficient high-affinity carrier-mediated  $\text{Na}^+$ -dependent glutamine transport. There was a range of kinetic parameters for the glutamine transporter in each cell type, but the amino acid inhibition profiles were nearly identical, consistent with uptake by the system ASC family of transporters. Rates of cell growth, DNA and protein synthesis, and thymidine transport correlated with the glutamine concentration in the culture media, indicating the central role of this amino acid in regulating cellular proliferation.

The methylcholanthrene-induced sarcoma (MCA tumor) rat model has been used by several investigators to study glutamine metabolism.<sup>35</sup> One of the most reproducible observations in rats bearing the MCA tumor is a progressive decrease in plasma glutamine concentrations that correlates with tumor size. With time, blood glutamine levels decrease to less than 50% of normal, indicating an imbalance between rates of glutamine production and consumption expressed by the various organs of the body. This reduction in circulating levels occurs despite an increase in the rate of muscle glutamine release because the accelerated glutamine consumption by tumor and other tissues exceeds the net rate of glutamine uptake into the blood stream. Concomitant temporally with the tumor-induced alterations in muscle glutamine metabolism are marked increases in tumor and hepatic glutamine uptake. Thus, with progressive tumor growth, glutamine depletion gradually becomes more severe. This low glutamine level may serve as a signal to induce net proteolysis.

Since glutamine uptake by the tumor is increased, the assumption might be made that providing exogenous glutamine would promote tumor growth. However,

glutamine-enriched total parenteral nutrition (TPN) seems to be more beneficial to the host than the tumor.<sup>36</sup> In fact, dietary glutamine improves the immune status of rats recovering from chemotherapy in a dose-dependent manner and becomes more pronounced after a longer duration of intake.<sup>37</sup>

### CYTOKINES: MEDIATORS OF CANCER CACHEXIA

Cytokines, polypeptide signalers produced by the host's cells in response to a growing tumor, regulate many of the nutritional and metabolic derangements that occur in the host with cancer (Table 56.2-4). The recognition that cytokines are important mediators of the body's response to the growing tumor has allowed investigators to focus research efforts on finding common mechanisms responsible for the development of the cancer cachexia. These studies will likely lead to the incorporation of nutritional strategies designed to optimize the metabolic and immunologic integrity of the host while simultaneously allowing tumor-directed therapies to be maximally effective.

---

Reduce appetite
Stimulate basal metabolic rate
Stimulate glucose uptake
Stimulate mobilization of fat and protein stores
Reduce adipocyte lipoprotein lipase activity
Enhance muscle amino acid release
Stimulate hepatic amino acid transport activity

---

**TABLE 56.2-4.** Some Effects of Cytokines on Nutrition and Metabolism in the Tumor-Bearing Host

Elevated concentrations of tissue and circulating cytokines have been demonstrated in the host with cancer,<sup>38</sup> and enhanced hepatic cytokine gene expression has been demonstrated in tumor-bearing animals. Cytokines can regulate both energy intake (appetite) and energy expenditure (metabolic rate). Administration of tumor necrosis factor (TNF) to rodents and humans decreases food intake, but the effect appears to be short lived. In rats treated with chronic injections of TNF, voluntary food intake was markedly reduced for 2 days but had normalized by the sixth day of TNF administration.<sup>39</sup> In patients receiving TNF, food intake was also diminished, but nitrogen losses were not accelerated, indicating that the resultant negative nitrogen balance was due to something other than TNF alone. Interleukin-1 (IL-1) also suppresses food intake, and its effect, like that of TNF, appears to be directly on the central nervous system. Darling and associates<sup>40</sup> suggest that when TNF is given via a constant infusion, the anorexic effects are sustained as opposed to the tolerance that develops when the cytokine is given by bolus injection. Further evidence for a role for TNF and IL-1 in mediating appetite suppression during critical illness comes from additional studies that demonstrate that treatment of tumor-bearing mice with anticytokine antibodies improves food intake and attenuates weight loss.<sup>41</sup> Even mice whose tumors were injected with inhibitors to TNF and IL-1 resulted in the attenuation of weight loss, an increase in food intake, a decrease in serum triglyceride and glucose, and an increase in total protein.<sup>42</sup> Mice implanted with tumors that secreted TNF showed marked reductions in weight compared with animals with non-TNF-secreting tumors.<sup>43</sup> Therefore, the effects of TNF on food intake and body composition are unlikely to be due to partial starvation alone, but rather may be due to the ability of TNF to stimulate basal metabolic rate (oxygen consumption). In patients receiving injections of TNF, metabolic rates were noted to increase by 30%.<sup>44</sup>

In addition to stimulating anorexia and thermogenesis, cytokines can also stimulate mobilization of fat and protein stores *in vivo*. Accordingly, TNF was first identified as a mediator of cachexia and was termed *cachectin*. Although few clinical studies demonstrate weight loss in subjects receiving TNF, it is likely that these cytokines cause fluid retention. It is clear that TNF can alter the vascular endothelium and lead to an increase in capillary permeability.

Other cytokines have been shown to have effects as well, particularly IL-6. IL-6 is increased in lung cancer patients and is correlated with poor nutritional status and shorter survival.<sup>45</sup> Further, IL-6 levels decrease in treatment responders and do not change or may even increase in nonresponders. IL-12 may also increase secretion of interferon- $\gamma$ , which may enhance TNF production and subsequent cytokine-induced cachexia.<sup>46</sup> Serum levels of soluble TNF receptors have also been measured and found to correlate with the extent of disease, degree of cachexia, and inversely with nutritional parameters.<sup>47</sup> But the cachexia of cancer does not depend on cytokines alone. Other mediators that have been investigated include corticosteroids,  $\beta$ -agonists, and insulin-like growth factors. Glucocorticoids appear to have additive effects to cytokines in the development of cachexia and may be the missing factor for the cachectic effects of cytokines.<sup>48</sup> In the presence of dexamethasone, there is an up-regulation of IL-6 receptors that seems to prime liver cells for subsequent stimulation by cytokines.<sup>49</sup> There may also be an effect from the autonomic nervous system. One study has shown increased renal sympathetic nerve activity in cachexia, and another has shown improvement in dietary intake with the use of propranolol to block the elevation of REE from this autonomic dysfunction.<sup>50,51</sup> Insulin-like growth factor and insulin have also been studied in an attempt to attenuate cancer cachexia and although they induced weight gain in other mice, they could not do so in those with colon tumors.<sup>52</sup> Some of the most promising effects on cachexia may come from eicosanoids and progestogens (see [Nutritional Support of the Cancer Patient](#), later in this chapter).

#### Effects on Glucose Metabolism

Studies evaluating the effects of cytokine administration on the circulating glucose concentration indicate that the plasma glucose level rises or falls depending on the dose of cytokine administered, the temporal nature of the measurement, and the specific cytokine given. In rats, sublethal doses of TNF that do not produce hemodynamic changes result in the development of hyperglycemia within 1 hour of administration.<sup>53</sup> The increase in plasma glucose was only mild, however (20%), and was associated with an increase in the circulating concentration of glucagon, adrenocorticotrophic hormone, corticosterone, and epinephrine, all of which can cause hyperglycemia. Further, incubation of adrenocortical cells with TNF stimulated cortisol secretion to the same extent, as did adrenocorticotrophic hormone. Blood glucose was unchanged when a lower dose of TNF was used.<sup>54</sup> Similar changes in blood glucose levels are observed after IL-1 administration. At higher IL-1 doses, Fischer and colleagues<sup>55</sup> reported a rapid increase in blood glucose from 100 to 140 mg/dL within 1 hour. However, this increase was transient, with a return to baseline levels by 2 hours. Simultaneously, there was a several-fold increase in hindquarter (most likely skeletal muscle) glucose consumption that was also transient. In cultured muscle cells (L6 cell line), TNF- $\alpha$  stimulates glucose transport via a mechanism that involves *de novo* synthesis of glucose transporters that are inserted into the plasma membrane.<sup>56</sup> Simultaneously, there is depletion of cellular glycogen stores and an increase in lactate efflux, all of which are consistent with stimulation of anaerobic glycolysis.

Meszaros and colleagues<sup>57</sup> have studied tissue glucose utilization *in vivo* using the 2-deoxyglucose tracer technique in rats following infusion of a nonlethal dose of TNF. Glucose uptake was increased by 80% to 100% in liver, kidney, and spleen, skin (60%), lung (30% to 40%), and ileum (30% to 40%). The largest increase was observed in diaphragm (150%). No significant increase was observed in skeletal muscle, testis, or brain. These data indicate a marked increase in whole body glucose use following TNF administration. Acute exposure of pancreatic islets to IL-1b results in no change in glucose uptake but diminishes the rate of mitochondrial glucose oxidation, a response that is potentiated by TNF.<sup>58</sup> In response to IL-1b, islets exhibit an increase in insulin release in the presence of high glucose concentrations.

#### Effect on Fat Metabolism

Altered fat metabolism is apparent clinically in catabolic patients from the observation that fat stores are diminished in association with weight loss. It is likely that the loss of fat stores in cancer patients is due to the ability of TNF, IL-1, and LMF to mobilize fat stores. Bolus administration of TNF to rats causes an increase in serum triglyceride levels within 2 hours.<sup>59</sup> Greenberg and colleagues investigated the possible role of IL-6 and TNF in mediating the depleted fat stores that occur with malignancy-associated cachexia.<sup>59</sup> Injection of IL-6 and TNF each reduced adipose tissue lipoprotein lipase activity by more than 50%. Similarly, both IL-6 and TNF reduced heparin-releasable lipoprotein lipase activity in 3T3-L1 adipocytes in a dose-dependent manner by 50% to 70%. In addition to a reduction in adipocyte lipoprotein lipase activity, the increase in serum triglyceride levels that is observed after TNF administration is also due to stimulation of hepatic lipid secretion.<sup>60 and 61</sup>

The discovery of the LMF may either add to the lipid-mobilizing effects or be stimulated by the cytokines. Further study of this factor is needed to elucidate its full

effects in cancer cachexia.

### **Regulation of Protein and Amino Acid Metabolism**

Marked changes in protein and amino acid metabolism are characteristic of cancer patients, and a number of published studies have evaluated the effects of cytokines on muscle protein metabolism with conflicting results. When recombinant TNF was infused into cancer patients, forearm amino acid efflux was accelerated, consistent with net skeletal muscle proteolysis, although this accelerated nitrogen release could have been due to starvation effects.<sup>58</sup> Similarly, when Flores and colleagues infused radiolabeled leucine into rats receiving TNF, IL-1, or both using tracer methodology techniques, they found an increase in muscle protein degradation in cytokine-treated animals.<sup>62</sup> However, when the IL-1 activity in activated monocyte supernatants was blocked with specific anti-IL-1 antibodies, the accelerated protein breakdown was not attenuated, indicating a major role for other mediators.<sup>63,64</sup> Thus, although it is generally agreed that cytokine administration *in vivo* (at sufficient doses) stimulates net muscle proteolysis, it is unclear which distal mediators in the cytokine cascade are the key players (IL-6, LMF).

In contrast to whole animal studies, the majority of which indicate that *in vivo* administration of TNF or IL-1 results in net muscle proteolysis, *in vitro* studies have yielded negative results. In studies evaluating the effects of corticosterone on muscle protein breakdown, this glucocorticoid was noted to accelerate protein degradation and diminish protein synthesis. In combination with TNF, these steroid-mediated effects were augmented, but TNF alone did not alter protein turnover, indicating a helping role for the corticosteroid.<sup>65</sup>

*In vitro* and *in vivo* studies demonstrate that cytokines occupy an important role in mediating the hepatic metabolic response to malignant disease. Tumor-bearing rats display a global increase in Na<sup>+</sup>-dependent amino acid transport, a response that can be attenuated by treatment with anti-TNF antibody.<sup>66</sup> Similar observations were made in animals treated with a single dose of TNF: Stimulation of hepatic amino acid transport systems A, ASC, and N were noted within 4 hours of TNF administration.<sup>67,68</sup> The increase in transport activity was due to an increase in carrier maximal transport velocity, consistent with the appearance of increased numbers of transport protein molecules in the plasma membrane. IL-6 and glucocorticoids have also been shown to work in a coordinated fashion to stimulate hepatic amino acid transport *in vivo*.<sup>69</sup> Moreover, these cytokines stimulate amino acid transport activity in cultured hepatocytes.<sup>70</sup>

## **NUTRITIONAL SUPPORT OF THE CANCER PATIENT**

### **RATIONALE**

Malnutrition is defined as any nutritional deficit that is associated with an increased risk of morbidity and mortality. There is a diminished risk of such events when the nutritional deficiency is corrected. Although it seems apparent that the provision of nutritional support to the malnourished patient with cancer is essential and would be beneficial, evidence indicating that currently available nutritional formulae *alone* can maintain or reverse malnutrition in the patient with advanced malignant disease is lacking. This observation suggests that many patients with cancer exhibit ongoing catabolism of body cell mass that persists and is refractory to nutritional repletion. Despite diminished food intake, the tumor-bearing host does not adapt to partial starvation by conserving lean body mass. Instead, the host continues to deplete its own muscle mass to provide amino acids taken up by the tumor to support growth and by the liver to support gluconeogenesis and biosynthesis of important defense proteins. The rationale behind the provision of specialized nutritional support, whether it be enteral or parenteral, is the belief that such support will preferentially benefit the patient rather than stimulate tumor growth. From a more practical standpoint, nutritional support would not be indicated if it clearly demonstrated no favorable effect on the response to antineoplastic therapies, no lengthening of the disease-free survival, or no improvement in the quality of life. Interestingly, a consensus of opinion regarding the role and efficacy of nutritional support in patients with cancer is lacking. Nonetheless, several well-designed clinical studies have allowed us to generate guidelines for the use of enteral and parenteral nutrition in patients with cancer, and most physicians and surgeons who care for patients with cancer continue to use nutritional support aggressively under specific circumstances.

Several studies have suggested additional therapies can be used along with nutritional support to alleviate the tumor cachexia. The synthetic progestogens, megestrol acetate (MA) and medroxyprogesterone acetate, may be helpful in high doses in the non-hormone-sensitive cancer with associated cachexia syndrome to decrease production of cytokines, particularly TNF and IL-6, as well as serotonin. These agents have been able to improve appetite, well-being, and quality of life as well as decreasing nausea and vomiting. MA has also been shown to increase body nonfluid weight gain although primarily with fat. Patients have been reported to respond with only 15 days of therapy with MA, and it may be discontinued after just 2 weeks of therapy. However, MA may be associated with more thromboembolic complications and there may have been less response to chemotherapeutic regimens.<sup>71,72,73,74,75,76,77,78,79 and 80</sup>

Other agents associated with a beneficial effect on the cachexia syndrome include eicosanoids and melatonin. Tisdale reported eicosapentaenoic acid, a component of fish oil, attenuated the action of cachectic factors and stabilized the weight loss and energy expenditure in patients with pancreatic cancer.<sup>81</sup> Reports from Japan show that maintained body weight was significantly greater in groups of mice treated with two different eicosanoids, docosahexanoic acid and eicosapentaenoic acid.<sup>82</sup> McMillan et al. reported that patients with advanced gastrointestinal cancers given ibuprofen, 1200 mg/d, in addition to MA, 480 mg/d, had an increase in body weight and no change in body water.<sup>83</sup> Lissoni et al. reported that melatonin has also been shown to decrease levels of TNF and lead to decreased weight loss in untreatable metastatic tumor patients and may therefore be helpful in treating cancer cachexia.<sup>84</sup> Gagnon and Bruera reviewed other treatment modalities for cancer cachexia and suggested drugs such as thalidomide and melatonin may be useful because of their effects on TNF. They also suggested b-adrenergic agonists might help as well because of their effect on muscle metabolism.<sup>85</sup>

### **NUTRITIONAL ASSESSMENT OF THE CANCER PATIENT**

In order to determine the best strategies for treatment of the cancer patient, the nutritional status must first be determined. This is done by a careful history and physical examination followed by additional tests to confirm the clinical impression. The history should include inquiries about appetite, preferred foods, and weight loss. The physical examination can establish the diagnosis of muscle wasting and specific nutrient deficiencies. Anthropometric measurements should be done including measurement of body weight and height, skinfold thickness, and a 24-hour urine collection for the measurement of nitrogen. Peripheral blood lymphocyte count and skin testing to common antigens for assessment of delayed hypersensitivity have been used as indicators of immunocompetence in the cancer patient. Altered immunologic responses are not specific for nutritional deficiencies and are often observed even in patients with advanced malignant disease who are well nourished. Serum albumin and transferrin are the most common serum proteins measured. Other laboratory studies useful in nutritional assessment include red blood cell indices to determine iron and micronutrient deficiencies, plasma glucose to assess insulin resistance, blood urea nitrogen to determine renal status, and liver function tests to evaluate hepatic function.

### **NUTRITION AND TUMOR GROWTH**

With the introduction of specialized enteral and parenteral feeding regimens into clinical medicine, aggressive nutritional support can be provided to cancer patients who previously could not or would not eat. However, concerns over the stimulation of tumor growth have existed for many years. While animal studies indicate that tumor growth can be enhanced with a high-protein diet and diminished by protein-depleted diets, studies in cancer patients are less clear. Baron and coworkers studied 14 malnourished patients with untreated head and neck squamous cell carcinoma who underwent biopsies of both normal and malignant tissues.<sup>86</sup> The patients were then randomized to either a control or TPN group. Cell-cycle kinetics were analyzed using flow cytometry after 3 to 17 days of TPN. After TPN, the percentage of hyperdiploid cells in malignant tissue was significantly increased over controls. It is likely that species differences exist and that different tumors respond dissimilarly to nutrient manipulation. If tumor growth is stimulated by nutritional or metabolic support, this could potentially be exploited with cycle-specific chemotherapeutic agents.

### **ENTERAL NUTRITION IN CANCER PATIENTS**

Numerous clinical trials have evaluated the use of aggressive enteral nutritional support as adjunctive therapy during the administration of antineoplastic regimens to cancer patients, but well-designed studies make up a small fraction of these. Although these trials do not demonstrate any consistent benefits of enteral nutrition, most authorities would agree that enteral nutrition is always the preferred route of feeding cancer patients when the gastrointestinal tract is functional ( [Table 56.2-5](#)). This can be accomplished by using in-between meal supplements, inserting soft comfortable nasogastric feeding tubes, or inserting gastrostomy or jejunostomy feeding catheters. Some of the better enteral clinical trials in cancer patients<sup>87,88,89,90,91,92,93,94,95,96,97 and 98</sup> are listed in [Table 56.2-6](#), [Table 56.2-7](#), and [Table 56.2-8](#). Commonly used enteral formulas are listed in [Table 56.2-9](#). A physician order form for enteral nutrition is presented in [Figure 56.2-1](#).

**FIGURE 56.2-1.** Enteral order sheet. KUB, kidney, ureter, bladder; LCT, long-chain triglyceride.

## TOTAL PARENTERAL NUTRITION IN THE CANCER PATIENT: GENERAL RECOMMENDATIONS

Although the initial enthusiasm for the use of TPN in cancer patients was considerable, it is now clear that TPN should only be provided to selected patients. Because of the failure of numerous clinical trials to yield a consensus with regard to the efficacy of TPN in cancer patients<sup>89,99,100,101,102,103,104,105,106,107,108,109,110,111,112,113,114,115,116,117,118,119,120,121,122</sup> and <sup>123</sup> (see [Table 56.2-6](#), [Table 56.2-7](#), and [Table 56.2-8](#)), more recently published articles have used metaanalysis to review these studies collectively and generate feeding guidelines. The general conclusion has been that parenteral nutrition appears to be of little benefit in most cancer populations. In some patients, the use of TPN was associated with an increase in complications. However, the most important factor to consider when making decisions about the use of TPN in patients with cancer is the response of the tumor to antineoplastic therapy. It is anticipated that the guidelines listed in [Table 56.2-10](#) will undergo future revision, as more effective antitumor regimens become clinically available.

TPN, total parenteral nutrition.

**TABLE 56.2-10.** Indications for the Use of Total Parenteral Nutrition in the Cancer Patient

## SPECIFIC INDICATIONS FOR THE USE OF TOTAL PARENTERAL NUTRITION IN THE CANCER PATIENT

### **Patients with Enterocutaneous Fistulas**

Patients with cancer who undergo major gastrointestinal surgery occasionally develop enterocutaneous fistulas that preclude the use of the gastrointestinal tract for nutritional support. In such patients, enteral nutrition often stimulates fistula output and can result in metabolic disturbances and dehydration. TPN can affect the course of disease in cancer patients with gastrointestinal fistulas. Studies indicate that TPN increases the spontaneous closure rate of enterocutaneous fistulas, although fistulas that originate from radiated or neoplastic bowel have a much lower rate of spontaneous closure. In such patients, aggressive early surgical treatment is generally indicated. Provision of TPN maintains the nutritional status of the cancer patient who develops an enterocutaneous fistula such that he or she better tolerates operative intervention if closure does not occur. Perhaps insulin-like growth factor or a progestogen may help in this situation.

### **Patients with Hepatic or Renal Failure**

Patients with cancer occasionally develop liver failure after major surgery or from cytotoxic chemotherapy. Because of liver damage and portasystemic shunting, these patients develop derangements in their circulating levels of amino acids. The plasma aromatic to branched chain amino acid ratio is increased. Transport of amino acids across the blood–brain barrier favors the aromatic amino acids such as tryptophan, precursors for *false neurotransmitters* such as serotonin, which contribute to lethargy and encephalopathy. Treatment of individuals with liver failure with solutions enriched in branched chain amino acids and deficient in aromatic amino acids may result in improved tolerance to the administered protein and clinical improvement in the encephalopathic state.

TPN with amino acids of high biologic value may also be of value in patients with acute renal failure. Presumably, provision of only essential amino acids allows the body to maximally reuse nitrogen for the synthesis of nonessential amino acids and thereby helps prevent rapid increases in blood urea nitrogen. If the hypermetabolic cancer patient is receiving dialysis, there appears to be no advantage to using an essential amino acid solution and therefore a balanced standard amino acid formulation is recommended. Solutions containing branched chain amino acids or just essential amino acids are expensive and probably not worth the cost except in specific patients in whom adjusted standard formulas are not tolerated.

### **Acute Radiation and Chemotherapy Enteritis**

Cancer patients who receive abdominal or pelvic irradiation or chemotherapy may develop severe and prolonged mucositis and enterocolitis, precluding use of the gastrointestinal tract for nutritional support. Under these circumstances, TPN should be provided to malnourished patients until the enteritis resolves and oral feeding can be resumed. Moreover, under circumstances in which chemotherapy has been contraindicated secondary to severe malnutrition, TPN may be beneficial in optimizing nutritional status and allowing the initiation of the chemotherapeutic regimen. When enteral nutrition is feasible in such patients, TPN has not demonstrated a treatment advantage. When studies have been performed using well-nourished patients, the effects of TPN predictably have not been beneficial.

Patients undergoing radiation treatment may also develop malnutrition secondary to inadequate nutritional intake from an inability to eat. The potential side effects from radiotherapy are broad and include nausea, vomiting, malnutrition, mucositis, xerostomia, dysphagia, diarrhea, and anorexia. Whenever possible, the enteral route is preferable for nutritional support. However, in cases involving severe dysfunction of the gastrointestinal tract, TPN is indicated. TPN can be useful in allowing the malnourished, poor-risk patient to complete radiotherapy with less morbidity. Patients undergoing irradiation of the head, neck, or chest need to be considered for early tube placement so enteral nutrition can be used.

### **Use of Perioperative Total Parenteral Nutrition in Cancer Patients**

One of the best studies to date evaluating the effects of preoperative TPN was published by the Veterans Affairs Total Parenteral Nutrition Cooperative Study Group.<sup>107</sup> More than 3500 patients, many of whom had cancer, were entered into this prospective randomized trial. The patients were divided into one of four groups: well-nourished, borderline malnourished, moderately malnourished, or severely malnourished. Patients in each malnourished category were randomized to at least 7 days of preoperative TPN or immediate operation. Patients randomized to receive TPN received 1000 kcal/d in excess of calculated caloric requirements. Lipid was provided on a daily basis. One criticism of this study was that patients were allowed to eat in addition to receiving parenteral feedings. Analysis of the data from this study indicated that there was no difference in short-term or long-term survival among groups. Infectious complications including pneumonia, abscess, and line sepsis were statistically significantly higher in patients receiving TPN. Noninfectious complications (impaired wound healing) were significantly lower only in those patients receiving TPN who were in the severely malnourished group (greater than 15% weight loss and serum albumin less than 2.8 mg%). This study strongly suggests that preoperative TPN should be limited to the severely malnourished patient. Therefore, contraindications to the use of preoperative TPN should include patients requiring emergency operation and those who are only mildly or moderately malnourished.

In the few patients who are candidates for preoperative nutritional support, we recommend instituting TPN only if the gastrointestinal tract cannot be used for tube feedings. In most patients undergoing major abdominal surgery, feeding tubes may be placed intraoperatively if resumption of oral feedings is not anticipated for relatively lengthy periods of time (7 to 10 days) after surgery. TPN may also be required in the well-nourished cancer patient who develops a postoperative complication that precludes enteral support. For example, some cancer patients develop a prolonged ileus after an abdominal procedure that precludes the use of the intestinal tract as a route of feeding. Such an occurrence is generally unpredictable and the cause of the ileus is often not demonstrated. If the patient is unable to eat

by postoperative day 7, TPN should be considered. The ileus may persist for several weeks, especially in gastric or pancreatic cancer patients. Although provision of TPN does not influence the disease process per se, it is beneficial because it prevents further erosion of lean body mass.

Two prospective studies have helped to further clarify both the indications and contraindications for the use of TPN in the surgical patient with cancer. Brennan and colleagues<sup>124</sup> examined the use of routine postoperative TPN following major pancreatic resection. In patients randomized to receive TPN starting on postoperative day 1, the investigators found a statistically significant increase in the incidence of intraabdominal abscesses as well as a tendency toward an increased incidence of peritonitis and bowel obstruction. The control group received a peripheral infusion of dextrose rather than luminal nutrition, suggesting that the increase in complications was not due to the absence of luminal nutrients but rather to some toxic effect of the TPN. The authors concluded that routine use of postoperative TPN was not indicated and may in fact have harmful side effects. It should be noted that many surgeons would elect to place a feeding jejunostomy in such patients.

In contrast to the Brennan study, Fan and colleagues<sup>125</sup> studied the use of perioperative (starting 7 days before the planned procedure) TPN for patients undergoing hepatectomy for hepatocellular carcinoma. They found that patients randomized to receive perioperative TPN had a statistically significant reduction in infectious complications and a decreased diuretic requirement compared with similar patients who did not receive TPN. The significance of this study is that it is only one of two studies that show a benefit to the use of routine perioperative TPN in patients not suffering from severe malnutrition. In addition, it establishes a distinct group of patients in whom routine perioperative TPN may be of benefit. The mechanism by which TPN is of value in these patients is not known.

### Patients with Short Bowel Syndrome

Cancer patients may develop short bowel syndrome secondary to multiple bowel resections or massive resection of infarcted bowel. Most of these patients, if cured of their cancer, can now survive for long periods on home TPN. Due to the duration of therapy involved, these patients are at risk for developing long-term problems such as micronutrient deficiency, bone demineralization, or line sepsis. Studies by Wilmore and colleagues<sup>126</sup> have demonstrated that the requirement for TPN could be decreased or even eliminated in patients with short gut syndrome by providing a nutritional regimen consisting of supplemental glutamine, growth hormone, and a modified oral high-carbohydrate, low-fat diet. There was a marked improvement in the absorption of nutrients with this combination therapy and a decrease in stool output. In addition, TPN requirements were reduced by 50%, as were the costs associated with care of these individuals. Discontinuation of the growth hormone did not increase TPN needs in these patients once they had undergone successful gut rehabilitation.

### COMPOSITION OF TOTAL PARENTERAL NUTRITION FORMULATIONS

TPN solutions are administered through a central venous catheter that is generally inserted into the subclavian vein. TPN solutions are hyperosmolar and calorie dense (1 kcal/mL), and the infusion of 2.0 to 2.5 L/d provides 2000 to 2500 kcal/d. The addition of minerals, vitamins, and electrolytes completes the basic composition of the solution (Table 56.2-11). Solutions must be prepared under sterile conditions. Because of the hyperosmolarity of such solutions, they must be delivered into a high flow system to prevent venous sclerosis. As a general rule, 65% of total nonprotein calories should be provided as dextrose and 35% in the form of an intravenous fat emulsion. Patients receiving TPN should be monitored regularly by measuring blood sugar, serum electrolytes, triglycerides, and liver function test results. The amounts of the various electrolytes provided to cancer patients receiving TPN may vary depending on factors such as previous nutritional and hydration status. Careful monitoring is critical because severe hypokalemia or hypophosphatemia can develop with aggressive feedings. Hypophosphatemia may develop in the chronically malnourished cachectic cancer patient given dextrose infusion who uses the phosphate to make adenosine triphosphate. This is referred to as the *refeeding syndrome*. These electrolyte disturbances can develop rapidly and are much more life-threatening than hyponatremia. Critical drops in serum phosphate levels below 1.5 mmol/dL can lead to an irreversible cardiac arrest.

<b>Volume</b>	
Amino acids	5000 mL
Dextrose	3000 mL (30%)
Fat emulsion (10%)	1000 mL (10%)
Electrolytes + vitamins + minerals	Approximately 500 mL
<b>Total volume</b>	Approximately 10000 mL
<b>Composition</b>	
Amino acids	50 g
Dextrose	6000 kcal (1500 g)
Fat	2000 kcal
<b>Total nitrogen and Ca, P</b>	Approximately 10000
<b>Standard electrolytes</b>	
Na	50 mEq
K	50 mEq
Ca	5 mEq
Mg	5 mEq
Cl	50 mEq
Acetate	50 mEq
Phosphate	5 mEq
<b>General rules</b>	
Protein	1.0-1.5 g/kg/d
Volume	10 mL/kg
Nonprotein calories	25 kcal/kg/d
Minimum volume	10 mL/kg/d
Dextrose	60% of calories (never less than 30%)
Fat	35% of calories

### POTENTIAL COMPLICATIONS OF TOTAL PARENTERAL NUTRITION

Advances in technology, monitoring, and catheter care have greatly reduced the incidence of complications associated with the use of TPN. The establishment of a nutritional support team (physician, dietitian, nurse, and pharmacist) and the recognition of such a team as an important part of overall patient care have also been key factors in reducing complications. Complications of TPN that occur in cancer patients can be divided into three types: (1) mechanical (i.e., pneumothorax, laceration of the subclavian artery, air embolism, catheter embolism); (2) metabolic (hyperglycemia, electrolyte abnormalities, abnormalities in liver enzymes); and (3) infectious (catheter sepsis). These complications are listed in Table 56.2-12. The management of the patient who develops signs and symptoms of catheter sepsis is shown in Figure 56.2-2.

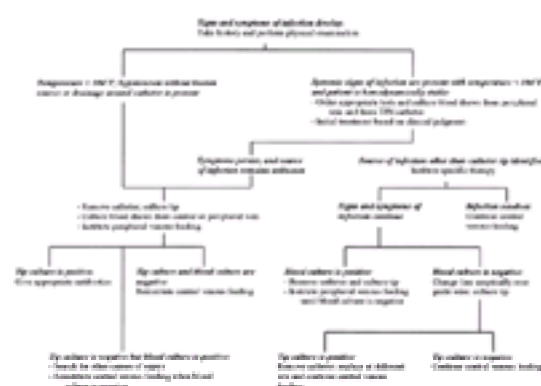

FIGURE 56.2-2. Algorithm for the evaluation of a cancer patient on total parenteral nutrition (TPN) who develops signs and symptoms of sepsis.

Complication	Cause	Remedy
<b>HEMATOLOGIC</b>		
Prothrombin	Protein deficiency of fibrinogen	Serial coagulograms; check ratio of redoxant
Reduction serum lipids	Protein deficiency of albumin serum being metabolized	Rediography; serial monitoring of serum lipids
Acidosis	Impairment of the bicarbonate and respiratory system	Flux pattern in the bicarbonate system; pH
Calcium metabolism	Retention of the lipids with increasing calcium	Monitor calcium; supplement with bone origin phosphate
Uremia	Overhydration to great extent; retention of urea	Hypernatremia if clinically significant
Calcium metabolism	High calcium content in parenteral solution	Regulate order of administration
<b>NEURALGIC</b>		
Hypoglycemia	Excessive glucose solution or glucose metabolism	Decrease glucose solution; administer insulin
Hypophosphatemia	Excessive phosphate solution	Reduce phosphate solution; monitor blood phosphate
Calcium chloride retention	Excessive calcium solution in excess of energy needs	Decrease glucose solution and replace with the
Hypophosphatemia, hypomagnesemia, hypocalcemia	Excessive phosphate solution, excess of the	Decrease phosphate solution; monitor blood phosphate
Hypomagnesemia, hypocalcemia	Excessive phosphate solution	Decrease phosphate solution; monitor blood phosphate
Acidosis	Excessive phosphate solution with metabolic acidosis	Decrease phosphate solution; monitor blood phosphate
Excess fat and deficiency	Excessive essential fatty acid administration	Reduce fat solution
Hypoglycemia	Excessive glucose solution	Decrease glucose solution
Hypophosphatemia, hypomagnesemia	Excessive phosphate solution	Decrease phosphate solution
Metabolic	Excessive phosphate solution	Decrease phosphate solution
<b>OTHER</b>		
Low serum	Calcium deficiency	Monitor calcium; administer
Infection in the site	Retention of calcium in the site	Monitor calcium; local treatment

## EFFECTS OF TOTAL PARENTERAL NUTRITION ON THE GASTROINTESTINAL TRACT

Although the intestinal tract had long been considered an organ of inactivity in critically ill patients, this concept has clearly been shown to be invalid. Disuse of the gastrointestinal tract, either via starvation or nutritional support by TPN, may lead to numerous physiologic derangements as well as changes in gut microflora, impaired gut immune function, and disruption of the integrity of the mucosal barrier. Thus, maintaining gut function in the cancer patient who is receiving vigorous therapy may be essential in order to minimize septic complications and organ failure.

The majority of studies that have examined the effects of TPN on intestinal function and immunity have been done in animals. These studies clearly demonstrate that TPN is detrimental and related to intestinal disuse. In rats receiving TPN, villous atrophy develops and there appears to be a breakdown in the gut mucosal barrier. TPN results in significant disruption of the intestinal microflora and bacterial translocation from the gut lumen to the mesenteric lymph nodes. In addition, when insults such as chemotherapy or radiation are introduced into these models, animals on TPN have a much higher mortality. This body of literature suggests that under certain circumstances, TPN may predispose patients to an increase in gut-derived infectious complications. Whether these are related to bacterial translocation or just absorption of endotoxin or cytokines is still debated.

## IMPROVING THE EFFICACY OF CURRENT FEEDING REGIMENS

### Role of Ambulation

Patients with cancer may be bedridden, but should be encouraged to ambulate as much as is feasible. Exercise can increase functional aerobic capacity, stimulate skeletal muscle amino acid uptake, and reduce proteolysis in normal individuals receiving TPN. It is unclear whether higher exercise thresholds are necessary to induce anabolism in nutritionally depleted cancer patients, although a higher threshold does seem to reduce fatigue.

### Pharmacologic and Hormonal Therapy

The potential beneficial effects of the administration of insulin, the primary anabolic hormone in the body, to the tumor-bearing host has been studied because of its role in stimulating muscle amino acid uptake and protein synthesis. Studies indicate that treatment with insulin stimulates food intake and nitrogen retention without stimulating tumor growth. Likewise, administration of insulin in combination with the glutamine antimetabolite acivicin to tumor-bearing rats on TPN preserved lean body mass and retarded tumor growth. Whether these observations can be extrapolated to the clinical arena is unknown.

The availability of recombinant human growth hormone has led investigators to examine the role of this anabolic agent in patients. The present data indicate that growth hormone is capable of promoting accrual of lean body mass in healthy individuals. It is unclear whether this anabolism will be observed in cachectic cancer patients. A potential downside to the use of growth hormone in patients is its association with the development of lymphoid malignancies. In tumor-bearing rats, treatment with exogenous growth hormone has been shown to increase carcass weight and improve the host immune response. Additional studies that examine the effects of growth hormone on tumor growth parameters are necessary before clinical use of this drug is justifiable.

Additional research using the progestogens MA and medroxyprogesterone acetate, as well as melatonin, is needed to assess the value of their use in treating or preventing cancer cachexia. Current recommendations for MA are 480 mg/d in addition to nutritional support.

### Use of Glutamine and Arginine

The classification of glutamine as a nonessential or nutritionally dispensable amino acid implies that, in its absence from the diet, it can be synthesized in adequate quantities from other amino acids and precursors. For this reason, and because of the relative instability and short shelf life of glutamine compared with other amino acids, it has not been considered necessary to include glutamine in nutritional formulas. Glutamine has been eliminated from TPN solutions and with few exceptions, glutamine is present in oral and enteral diets only at the relatively low levels characteristic of its concentration in most dietary proteins. Based on our knowledge of the changes in glutamine metabolism that are characteristic of the host with cancer, this categorization of glutamine as a nonessential amino acid may be misleading. Several studies in the tumor-bearing host suggest that supplemental glutamine may benefit the cancer patient ( [Table 56.2-13](#) ). One of the best studies to date evaluating the effects of glutamine-enriched TPN in cancer patients is a randomized, double-blind controlled trial in adults receiving allogeneic bone marrow transplants for hematologic malignancies.<sup>127</sup> Patients received a standard, glutamine-free TPN solution or an experimental isonitrogenous, isocaloric solution supplemented with L-glutamine (0.57 g/kg body weight per day). Patients received the diets for approximately 4 weeks after transplantation. Patients receiving glutamine-supplemented parenteral nutrition after bone marrow transplant had improved nitrogen balance, a diminished incidence of clinical infections, less fluid accumulation, and a shortened hospital stay (see [Table 56.2-13](#) ). In a more recent study, glutamine-enriched TPN was shown to prevent the increase in gut mucosal permeability that develops with the administration of commercially available glutamine-free TPN. Van der Hulst and associates<sup>128</sup> randomized surgical patients requiring parenteral feedings to either receive standard TPN or glutamine-enriched TPN for 10 to 14 days. Duodenal mucosal biopsies and gut permeability studies were performed at the start and completion of TPN. The investigators found no change in either villous height or gut permeability in the group receiving glutamine-enriched TPN, whereas the control group showed both loss of villous height and increased gut permeability. This study provides strong evidence in favor of a gut-protective effect of glutamine. Similarly, arginine, because of its immunomodulatory properties may be useful as a dietary supplement in cancer patients, but further work is necessary to more clearly define the potential role of these two amino acids in the nutritional care of the cancer patient.

Group	No. of Patients Studied	Nitrogen Balance (g/d)	% of Patients with Clinical Infections	% of Patients with Fluid Retention	Percent Excess Water (L)	Hospital Day (d)
Standard total parenteral nutrition	25	-42 ± 12	9 (36%)	1 (4%)	32 ± 19	36 ± 2
Glutamine-enriched total parenteral nutrition	25	-11 ± 13	3 (12%)	0 (0%)	6 ± 10	28 ± 2

Data analysis by unpaired t-test or Fisher's exact test.

## TECHNIQUES OF PROVIDING NUTRITIONAL SUPPORT

### TRANSNASAL (NASOGASTRIC AND NASODUODENAL) FEEDING CATHETERS

The use of transnasal feeding catheters for intragastric feeding or for duodenal intubation is a popular adjunct for providing nutritional support by the enteral route. The stomach is easily accessed by the passage of a soft flexible (8 Fr.) feeding tube. Intragastric feedings provide several advantages for the patient. The stomach has the capacity and reservoir for bolus feedings. Feeding into the stomach results in the stimulation of biliary-pancreatic axis, which is probably trophic for the small bowel, and gastric secretions have a dilutional effect on the osmolarity of the feedings, reducing the risk of diarrhea. The major risk of intragastric feeding is the regurgitation of gastric contents resulting in aspiration into the tracheobronchial tree. This risk is highest in patients who have an altered mental sensorium or who are paralyzed.

The placement of the feeding tube through the pylorus into the fourth portion of the duodenum reduces the risk of regurgitation and aspiration of feeding formulas. To place a transnasal intraduodenal feeding catheter, the patient should be in the sitting position with the neck slightly flexed. This allows for the passage of a lubricated 8-Fr. polyurethane feeding catheter (with a stylette in place) through the patient's nose in a posterior and inferior direction, bringing the catheter to the level of the pharynx. The head is brought back to a neutral position and the patient is instructed to swallow while the feeding catheter is simultaneously passed down into the esophageal lumen. The advancement of the catheter is continued for a distance of about 45 to 50 cm. Once the catheter is confirmed to be in the stomach by injecting air while listening over the epigastrium, the patient is laid on the right side and the tube is advanced another 15 to 20 cm. This should position the tube into the duodenum and can be confirmed by listening over the right upper quadrant while advancing the tube. The stylette is removed and the position of the catheter is confirmed radiographically before the initiation of feedings. Tubes can be positioned fluoroscopically if necessary.

Gastric feedings are initiated by a bolus test volume of saline, representing the hourly feeding volume infused over 1 hour, into the stomach. The tube is clamped for 30 minutes and then checked for residual volume. If less than 50% of the volume load returns, then the selected volume is appropriate. In general, duodenal feedings can be started at 25 mL/hr at full-strength concentration unless the patient has been at bowel rest for several days, in which case the formula should be diluted to one-fourth strength. In such patients, we generally increase the rate of infusion before increasing the concentration. Despite these precautions, approximately 10% to 20% of patients receiving enteral feedings develop some degree of diarrhea secondary to malabsorption and the osmotic load of the feedings. When this occurs, decrease the rate of feeding by 50% rather than stopping the feedings altogether. The rate of feedings is then increased as tolerated over the next 3 to 4 days.

### GASTROSTOMY TUBE FEEDINGS

A feeding gastrostomy should be considered in patients requiring long-term enteral nutrition and in patients with unresectable carcinomas of the head and neck or esophagus. In patients with an unresectable esophageal carcinoma who are not surgical candidates or in individuals who are unable to maintain caloric needs, a permanent gastrostomy should be considered. A temporary Stamm gastrostomy is a popular method for access to the gastric lumen that can be performed at the time of any major abdominal procedure. The surgical technique is relatively simple and straightforward.<sup>4</sup> After placement, the gastrostomy tube is placed to gravity drainage for 3 days and then is elevated. If the patient tolerates catheter elevation, we advance enteral feedings as described previously.

Percutaneous endoscopic gastrostomy to provide access for gastric feedings can be performed without a laparotomy or general anesthesia. This technique involves the safe passage of an endoscope into the stomach. The stomach is then dilated by the insufflation of air via the endoscope. Transabdominal illumination with the endoscopic light source selects an area on the anterior abdominal wall, usually halfway between the costal margin and the umbilicus. Local anesthesia is injected over the site followed by the insertion of an Angiocath percutaneously into the stomach. A wire is passed through the Angiocath, grabbed by a snare that has been passed through the endoscope, and pulled back with the endoscope out of the mouth. A standard percutaneous gastrostomy tube with a wire loop is attached to the guidewire and pulled back down the esophagus and out through the abdominal wall. The endoscope is passed back with the tube and the catheter is pulled under direct visualization until taut and then sutured to the abdominal wall. Inability to pass the endoscope safely or to identify the transabdominal illumination of the endoscope tip within the dilated stomach are contraindications to the procedure. Ascites, coagulopathies, and intraabdominal infections are relative contraindications as well.

### FEEDING CATHETER JEJUNOSTOMY PLACEMENT AND WITZEL JEJUNOSTOMY

A feeding catheter jejunostomy should be placed following any major upper abdominal oncologic procedure if prolonged enteral nutrition support is anticipated, especially after gastric or pancreatic cancer surgery. The simplest method is a needle catheter jejunostomy, which can be performed fairly quickly at the end of the definitive operation. The entire length of a 14-gauge needle is used to create a subserosal tunnel approximately 30 to 40 cm distal to the ligament of Treitz and then the needle tip is introduced into the jejunal lumen. A 16-gauge feeding catheter is inserted through the needle and advanced 30 to 40 cm distally into the bowel lumen and the needle is withdrawn. The catheter is secured to the jejunal wall with sutures and then the loop of jejunum is anchored to the parietal peritoneum. The catheter is then secured to the skin with nylon sutures. The needle catheter jejunostomy is generally removed 2 to 4 weeks postoperatively when no longer needed.

A more permanent form of feeding jejunostomy employs the use of a 14-Fr. red rubber catheter for feeding. The placement technique is simple Witzel tunnel<sup>128</sup> and takes only 10 to 15 minutes. Jejunal feeding catheters can be used immediately for feeding purposes following the operation. Catheter care is essential to maintain patency, and the nursing staff need to flush the catheter with saline every 8 hours to ensure adequate patency. The catheter can be removed at the patient's bedside at the desired time by simple traction and the resulting fistula should close quickly.

### PERIPHERAL INTRAVENOUS FEEDINGS

Peripheral veins may be used for infusion of glucose, amino acid solutions, and fat emulsions. However, these solutions must be nearly isotonic to avoid peripheral vein sclerosis. Ten percent glucose solutions may be used to increase the efficacy of amino acid use. Fat emulsions can be administered simultaneously with glucose and amino acid solutions, because they provide an efficient fuel source and isotonic. The major disadvantage of these peripherally administered mixtures is limited caloric delivery to meet catabolic demands within tolerated fluid volumes. Patients with renal and cardiac diseases may not tolerate the additional fluid load. Indications for peripheral vein feeding include the following: (1) as a supplement when enteral feedings can only be partially tolerated because of gastrointestinal dysfunction; (2) as a method of nutritional support when the gastrointestinal tract must be kept relatively empty for short periods during diagnostic workup; and (3) as preliminary feedings before subclavian catheter insertion in patients requiring TPN.

### CENTRAL VENOUS TOTAL PARENTERAL NUTRITION

The preferred method of access to the superior vena cava is by percutaneous cannulation of the subclavian vein. Alternate sites include the internal and external jugular vein, but with the catheter exiting in the neck region this makes it more difficult to secure and maintain a sterile dressing site. Thus, long-term indwelling catheters should not be placed in this location because of an increased risk of catheter infections.

An individual who is experienced in the technique should perform the placement of a central venous catheter. To reduce the risk of hemostatic complications, patients with a platelet count below 50,000 should receive fresh platelets before catheter insertion. The procedure is performed using aseptic technique; the surgeon should wear a hat, mask, gown, and gloves. The patient is placed in Trendelenburg's position with both arms at the sides and the head turned away from the site of insertion. The chest is shaved, prepped, and draped in a sterile fashion. Local anesthesia is infiltrated near the insertion site and the underlying tissues along the inferior border of the clavicle. A standard subclavian insertion tray is used for catheter insertion via the Seldinger technique. The tip of the needle is inserted into the skin and subcutaneous tissues at the midpoint of the clavicle aiming for the suprasternal notch. The needle is directed parallel to the patient's bed, inserting beneath the clavicle with negative pressure applied at all times to the syringe. The prompt inflow of blood into the syringe indicates entrance into the subclavian vein, and the needle is advanced a few millimeters to ensure the bevel is within the lumen of the vessel. The patient is instructed to perform a gentle Valsalva maneuver to prevent an air embolism, the syringe is disconnected from the needle and the guidewire is passed through the needle lumen, and the needle is then withdrawn over the guidewire. The passage of the wire through the needle should be met with minimal resistance and the needle should be removed only after 15 cm of the wire has been passed into the vessel. A small incision is made at the guidewire exit site and a dilator is passed over the wire. The dilator is then removed over the wire and is replaced by the catheter that is fully advanced. The wire is withdrawn and the catheter is flushed with sterile saline. The catheter is then sutured into position, the insertion site cleaned, and a sterile dressing placed. A portable chest radiograph is taken to confirm placement of the catheter. Chest films are inspected for location of the catheter tip and to search for evidence of pneumothorax and hemothorax.

Complications from long-term central venous catheterization in the cancer patient population include venous thrombosis and catheter-related infections. Thrombosis of the central vessels is a complication that may be often overlooked. The clinical suspicion of subclavian vein thrombosis is only approximately 3%, whereas studies that use phlebography or radionuclide venography indicate that the incidence is as high as 35%. Febrile episodes are not uncommon in the cancer patient population, particularly in the neutropenic individual. If primary catheter sepsis is confirmed, the catheter must be removed immediately. The tip of the catheter is sent to the laboratory for culture and compared with the blood cultures drawn from the patient. Appropriate antibiotics are administered and a new catheter is inserted when the patient's repeat blood culture results are negative.

## NUTRITION SUPPORT FOR CANCER PATIENTS AND HEALTH CARE REFORM

The effect of corporate medicine on nutrition support has been addressed.<sup>129</sup> With the introduction of health care reform, nutrition support teams and the services they provide are now considered a cost center rather than a revenue center and both the role and existence of the traditional team is being threatened. Formal nutrition support teams began to form in the 1970s when TPN gained widespread clinical acceptance in the cancer. Although the indications for TPN in the cancer patient are few, the risk to these patients is that issues of cost may override those of access to and quality of nutritional support.

The challenge to nutrition support professionals is to coordinate efficient and early intervention and to document its efficacy and outcome. In the absence of any documented efficacy, many people argue, there is no need for formal nutrition support or the team in charge of that service. Therefore, it becomes imperative that the team justifies its importance to the hospital and convinces the administration that a formal nutrition support team provides quality control and polices the administration of nutritional support. To do this, nutrition support units must (1) identify specific patient populations who will benefit from nutrition support, (2) establish clinical pathways (guidelines), and (3) develop and implement measurements of efficacy (outcomes). In capitated models of health care, it is in the best interest of all caregivers to provide cost-effective care.

In the past, the costs required to pay the members of the nutrition support team have been more than offset by the reimbursements for the services provided, particularly for the delivery of TPN. The danger of this approach in the nutritional support of hospitalized patients, particularly patients with complicated problems and complex diseases, is that the withholding of nutritional and metabolic support from certain patients may result in serious consequences. Aggressive early feeding may be the best approach if it reduces complications in the long run. Methods of ensuring that nutrition support is cost effective have been suggested.<sup>129</sup>

sexual stimulation. The HSRC consists of four, somewhat arbitrary, phases—*excitement*, *plateau*, *orgasm*, and *resolution*. In [Table 56.3-2](#) we have listed some of the key responses in each phase, with a focus on those that might be affected by cancer and its treatments. The disease and treatment can disrupt the response cycle entirely or can lead to changes in sensation and experience during the response cycle. The response cycle is similar for women and men, with parallel processes for homologous tissues.

Although Masters and Johnson's research advanced our knowledge of the psychophysiology of human sexual response, the four-phase model of the HSRC has been criticized on both conceptual and methodologic grounds.<sup>2,3</sup> In a triphasic model of human sexuality, Kaplan<sup>4</sup> addressed two of the primary concerns—the characterization of the phases of sexual responding as sequential and interdependent and the inattention to motivational aspects of sexuality. The triphasic model is characterized by separate *desire*, *excitement*, and *orgasm* phases. Kaplan proposed that these are discrete phases controlled by distinct neurophysiologic mechanisms. Thus, she suggests that different etiologic factors and treatment approaches should be considered, depending on the phase in which difficulties occur.<sup>5</sup> However, the extent to which responses in each of these phases is mediated through different pathways has not been documented empirically.<sup>2</sup> The fact that individuals often report dysfunction in more than one phase argues against assuming unrelated etiologies.<sup>6</sup>

## SEXUAL DYSFUNCTIONS AND PROBLEMS

The nomenclature for diagnosing sexual dysfunctions<sup>7</sup> uses the triphasic model of sexuality—involving disturbances in desire, excitement, or orgasm—or by pain associated with sexual intercourse. For patients to be diagnosed with a sexual dysfunction, their disturbance or pain must cause marked distress or interpersonal difficulties, must be persistent or recurrent, and cannot be due to another psychiatric disorder (such as mood or personality disorders). The diagnosis also includes reference to etiologic factors. If the dysfunction is due exclusively to one set of factors (psychological causes, general medical conditions, or substance use), the diagnosis so indicates. In the case of many cancer patients, sexual dysfunctions may be diagnosed as “due to combined factors,” indicating a more complex etiology in which multiple causes contribute to the dysfunction. [Table 56.3-3](#) provides a list of the diagnostic categories given in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*.<sup>7</sup>

<b>Desire disorders</b>	
Hyposexual sexual desire disorder	Deficiency or absence of sexual fantasies and desire
Sexual aversion disorder	Aversion to and avoidance of genital sexual contact with a partner
<b>Arousal disorders</b>	
Female sexual arousal disorder	Inability to attain or maintain adequate lubrication-swelling response of sexual excitement until completion of sexual activity
Male erectile disorder	Inability to attain or maintain adequate erection until completion of sexual activity
<b>Orgasmic disorders</b>	
Female orgasmic disorder	Delay in or absence of orgasm after a normal sexual excitement phase
Male orgasmic disorder	Delay in or absence of orgasm after a normal sexual excitement phase
Premature ejaculation	Orgasm and ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it
<b>Pain disorders</b>	
Dyspareunia	Genital pain associated with sexual intercourse
Sexual pain disorder in females (vaginismus)	Involuntary contractions of the genital muscles with vaginal penetration

**TABLE 56.3-3.** Diagnostic Categories for Sexual Dysfunctions

In addition to these diagnosable disorders, many patients experience disruptions that are less intense in nature but that, nonetheless, cause decreases in previously enjoyable sexual activities and reduce global satisfaction with sexuality. The subjective experience that one has a satisfying sex life may or may not be associated with the ability to progress through the phases of the HSRC. Some individuals with no diagnosable dysfunction can be dissatisfied with factors such as the frequency or variety of sexual behavior, whereas some individuals with organically based dysfunctions can enjoy other forms of sexual and intimate contact. Also, as indicated in [Table 56.3-1](#), cancer can have an indirect influence on sexuality through disruptions in partnership factors, body image, and overall psychological well-being.

## SEXUAL PROBLEMS AND THEIR PREVALENCE AMONG THE GENERAL POPULATION

### PREVALENCE OF SEXUAL DYSFUNCTIONS AND PROBLEMS

Sexual problems are common, even among community samples of happily married couples.<sup>8,9</sup> In a large and extensive national survey of sexuality of 18 to 59 year olds in the United States, 43% of women and 31% of men reported dysfunction in one of the diagnostic categories during the previous year.<sup>10</sup> Among men, premature ejaculation was the most common complaint (28.5%), followed by anxiety about performance (17.0%), lack of interest in sex (15.8%), and inability to keep an erection (10.4%).<sup>8</sup> Women most frequently reported lack of interest in sex (33.4%), inability to reach orgasm (24.1%), not finding sex pleasurable (21.2%), difficulty becoming lubricated (18.8%), and pain during intercourse (14.4%). Individuals who experienced emotional or stress-related problems or who were victims of adult-child sexual contact were significantly more likely to report sexual dysfunction. Other predictors varied somewhat between men and women, with poor health being particularly salient for men and falling household income and low sexual activity being important for women. Despite these difficulties, most respondents indicated that sex was emotionally satisfying and was associated with very positive feelings.

Although specific prevalence rates vary somewhat in other studies,<sup>11,12,13,14,15,16</sup> and <sup>17</sup> depending on study sample and methodology, the general conclusions are similar. Sexual dysfunction is a common experience, with most individuals experiencing difficulty at some points in their lives. However, sexual dysfunction need not result in dissatisfaction with sexuality or loss of intimacy. Sexuality after cancer should be viewed within this larger context.

### SEXUALITY AND AGING

Normal aging is associated with decreases in both physiologic functioning and behavioral aspects of sexuality. With regard to the phases of the HSRC, response slows and decreases in intensity with age for both men and women.<sup>1</sup> For example, vasocongestion during arousal occurs more slowly, extending the time required for penile erection and vaginal lubrication. More intense and direct tactile stimulation typically is required for arousal and orgasm than is needed in younger men and women. As most men age, erections are less rigid, ejaculation is less forceful, and the refractory period lasts longer (often for many hours). In addition to the anatomic changes associated with menopause, women experience decreased lubrication and, in some cases, reduced intensity of orgasm. Chronic medical conditions and general ill-health can exacerbate the natural slowing of sexual response.<sup>18</sup>

The prevalence of some diagnosable sexual disorders varies with age, although little research has been done on very old populations to provide specific information. Sexual desire and the frequency of sexual thoughts appear to decline with age, particularly for men, although sexual interest does remain present.<sup>2,10,19,20</sup> Researchers consistently have found that erectile functioning also worsens with age, with increases in dysfunction beginning in middle age and increasing gradually over the rest of the lifespan.<sup>10,21,22</sup> For example, the Massachusetts Male Aging Study<sup>22</sup> demonstrated that rates of complete erectile dysfunction triple from 5% to 15% between the ages of 40 and 70. For women, the prevalence of arousal disorders, as indicated by difficulty lubricating, increases with age.<sup>2,10</sup> Findings regarding the rates of other disorders in women are inconsistent, with different studies reporting that problems can increase, decrease, or remain stable.<sup>10,14,15,16,21</sup>

Sexual activity decreases with age for both women and men.<sup>8,14,15,21,23</sup> In some cases, this decrease results from the absence of a partner, coupled with an unwillingness to engage in self-pleasuring activities, especially among very old women.<sup>10,13,23</sup> Even among older married couples, rates of intercourse decrease.<sup>8,21</sup> Nonetheless, many older individuals do consider sex an important part of their lives and have satisfying sex lives.<sup>8,24</sup> Age alone should not be viewed as an adequate explanation for serious sexual dysfunction or inactivity among interested older adults.

### MENOPAUSE AND SEXUAL FUNCTIONING

Menopause is clinically diagnosed when a previously menstruating woman with an intact uterus has amenorrhea for at least 12 months. The average age of menopause in North American women is 51 years.<sup>25</sup> Secondary forms of amenorrhea may be related to endocrine disorders or conditions such as anorexia nervosa; however, cancer treatment–induced secondary amenorrhea is the most relevant for our purposes. Hysterectomy can complicate the evaluation of woman's

menopausal status, because menstrual bleeding can no longer be used to classify her status. If a woman's ovaries are removed as a result of surgery, she experiences a surgically induced menopause.

The menopausal transition is characterized by a decreased responsiveness of the ovaries to luteinizing hormone and follicle-stimulating hormone. Gradually, over time, the estradiol levels fall as the ovarian follicles are depleted and there is no further response to the pituitary gonadotropins luteinizing hormone and follicle-stimulating hormone. It is with these changes that the clinical symptoms of estrogen deficiency begin to occur. Lowered levels of estradiol affect various target tissues, including the vagina, skin, bone, vascular endothelium, and smooth muscle, as well as the hypothalamic temperature-regulating centers.<sup>26</sup> The ovaries are the primary source of androgens in women, even into postmenopause, and decreased production of ovarian androgens may account for changes in libido during this time. Many women who become menopausal experience symptoms associated with estrogen deficiency, including vasomotor symptoms (hot flashes, sweats, palpitations), urinary incontinence, and vaginal dryness. Vasomotor symptoms are most frequent (up to 75% of menopausal women experience these at some point) and are among the earliest symptoms of menopause, with urinary incontinence and vaginal dryness increasing slowly during the later postmenopausal years.<sup>26</sup>

The impact of menopause on sexual health is controversial, because many women remain sexually active into old age. Several population-based studies of perimenopausal and menopausal women have documented that most women who have partners are sexually active<sup>13</sup>; however, changes can occur in sexual functioning (desire, arousal, orgasm) that are age related<sup>23,27</sup> and to which menopause may contribute. The relation between menopause, sex steroids, and sexual motivation (“libido”) remain controversial.<sup>26</sup> Research suggests that, in postmenopausal women, a variety of factors are potential moderators of the components of sexual functioning (e.g., psychological distress, quality of the partner relationship, physical activity, body mass index).<sup>13</sup> Without sufficient levels of endogenous estrogen, the vaginal epithelium may become atrophic, leading to clinical symptoms of vaginal dryness and dyspareunia. With chronic or untreated symptoms of vaginal dryness, postmenopausal women may choose to avoid sexual intercourse completely. However, this may not preclude other forms of sexual activity. In a volunteer sample of healthy postmenopausal women who were not on hormone replacement therapy, vaginal dryness was reported by 37% of women 45 to 64 years of age.<sup>13</sup> Hormone replacement therapy is effective in managing menopausal symptoms, such as hot flashes and vaginal dryness, but does not appear to improve sexual functioning.<sup>28,29</sup>

Premature menopause and vaginal dryness that cannot be treated with estrogen after cancer can contribute to dyspareunia, thus affecting both desire and arousal in women with cancer (see [Chemotherapy](#), later in this chapter). If one adds to this the variety of physical, psychosocial, and treatment-related factors associated with cancer treatment, a menopausal woman may certainly experience sexual dysfunction. Nevertheless, the menopause per se may not be the culprit.

## ERECTILE DYSFUNCTION IN HEALTHY AGING MEN

Erectile function may be impaired by a number of conditions, both physical and psychological, and it declines with advancing age. As healthy men age, androgen levels begin to decline. Although these changes do not occur as precipitously as in menopause, a steady, age-related diminution is noted in most men. This can result in declining libido, which in turn tends to decrease erectile function. A notable variation in this pattern exists, and it is not uncommon for men to remain libidinous and potent well into advanced years. Peripheral circulatory problems and degenerative neuromuscular conditions also become more common, both increasing the incidence of vasculogenic and neurogenic erectile dysfunction (see [Table 56.3-1](#)).<sup>30</sup>

## IMPACT OF CANCER AND ITS TREATMENT ON SEXUAL HEALTH

### PSYCHOLOGICAL DISTRESS

Symptoms of anxiety or depression are frequent, and often appropriate, among cancer patients.<sup>31,32 and 33</sup> Psychological distress affects sexual functioning in healthy individuals, and this can be an important problem for patients with cancer. The literature suggests that patients with higher levels of psychological distress experience more sexual dysfunction.<sup>31,32,33,34 and 35</sup> For example, in a study of 227 newly diagnosed breast cancer patients, Schag et al.<sup>31</sup> found that patients who were classified by a social worker at 1 month after surgery as being “at-risk” for psychosocial distress were found to have more sexual difficulties than a comparison “low-risk” group, both at 1 month after surgery and 1 year later. Sexual problems that were increased included not being interested in having sex, difficulty in being sexually aroused, and difficulty reaching orgasm.<sup>31</sup> In a comprehensive follow-up study of advanced Hodgkin's disease and acute leukemia survivors, Kornblith et al.<sup>33</sup> found higher levels of distress in the Hodgkin's disease survivors, which was associated with significantly poorer sexual functioning than in the acute leukemia survivors. In a study of patients with early-stage cervical cancer, psychological as well as physical problems were highly correlated with sexual outcome.<sup>34</sup> In a study of long-term survivors of acute leukemia, no difference was found in psychosexual outcomes for patients treated with bone marrow transplantation compared to conventional therapy; however, those survivors who reported decreased sexual frequency and satisfaction and poorer body image were more likely to demonstrate greater psychological distress and decreased energy.<sup>44</sup> Thus, psychological distress, often manifested as increased symptoms of anxiety or depression, is an important variable that influences sexual outcomes, both acutely and chronically, in cancer patients.

### BODY IMAGE CHANGES

One prominent cause of distress among cancer patients is change in body image. The changes associated with cancer and its treatment are often dramatic, ranging from surgical defects and deformities (e.g., limb amputation, loss of a breast, radical neck dissection) to total body alopecia from chemotherapy (e.g., loss of scalp hair, eyebrows, eyelashes, pubic and axillary hair) to more subtle changes (e.g., weight loss secondary to disease or treatment, weight gain from corticosteroids). All of these alterations can influence the patient's sense of sexual attractiveness and self-esteem.<sup>36</sup>

For women with breast cancer, the major advantage of breast-conserving surgery is the preservation of body image.<sup>37,38,39 and 40</sup> Patients with head and neck cancer often experience a range of physical and psychosocial problems related to disfiguring surgery, with consequent effects on sexual functioning.<sup>41</sup> Patients with colorectal cancer and stomas experience more body image problems than nonstoma patients and have poorer sexual functioning.<sup>42</sup> Thus, contemporary treatments that set organ preservation as a goal or provide immediate reconstructive surgery may well spare cancer patients the added burden of poorer body image. In one study, more favorable body image was a significant predictor of sexual interest in breast cancer survivors.<sup>43</sup> Nevertheless, the complexity of contemporary combined modality treatment (surgery, radiation therapy, and chemotherapy) aimed at organ preservation may also contribute to poorer body image through weight loss and hair loss, which may have a temporary or long-term adverse effect on body image.<sup>35,44,45</sup> In a study of long-term survivors of Hodgkin's disease (median time since treatment, 9 years), Fobair et al.<sup>45</sup> found that 26% of these survivors felt that their physical attractiveness had decreased, which was attributed to the diagnosis or treatment of the disease. More research is needed to determine the mechanisms through which body image disruption affects sexual functioning.

For some patients, weight gain is an important consequence of treatment that can interfere with body image. This effect has been particularly noted for women receiving adjuvant chemotherapy for breast cancer.<sup>46,47,48 and 49</sup> Goodwin et al.<sup>49</sup> followed an inception cohort of 535 women with newly diagnosed locoregional breast cancer and performed anthropometric measurements at baseline and 1 year later. Mean weight gain overall was 1.6 kg, with an average 2.5 kg gain in women receiving chemotherapy, 1.3 kg in those receiving tamoxifen, and 0.6 kg in those receiving no adjuvant treatment. In a multivariate analysis, onset of menopause and chemotherapy administration were each independent predictors of weight gain. Weight gain was not explained by increased caloric intake or decreased physical activity.<sup>49</sup> Thus, in addition to the effects of chemotherapy on energy, nausea, vomiting, and alopecia, weight gain must be added to the list, potentially decreasing self-esteem and sexual attractiveness.

### DETERIORATING PHYSICAL FUNCTION, FATIGUE, AND PAIN

Declining physical functioning and the symptoms of fatigue and pain negatively influence sexual functioning. In a cross-sectional evaluation of 779 patients with colorectal, lung, and prostate cancers at all phases of disease (i.e., no evidence of disease, localized, and metastatic), sexual functioning was poorest for patients with advanced metastatic disease, who concomitantly experienced more frequent and severe physical problems associated with the cancer.<sup>50</sup> This finding was most significant for the patients with colorectal and lung cancer, whereas sexual problems were important for prostate cancer patients independent of stage and physical symptoms, likely due to the local effects of treatment on sexual functioning for all stages of the disease.<sup>50</sup>

Fatigue has begun to emerge as an important symptomatic problem for cancer patients and survivors.<sup>51,52 and 53</sup> Although this may be the result of clinical problems, such as anemia, which can be managed medically with transfusions or growth factors, chronic fatigue after cancer treatment may be multifactorial and represent late effects of chemotherapy and radiation, as well as be manifestations of both pain and depression. Fatigue has been most dramatically noted in patients treated for Hodgkin's disease,<sup>45,53</sup> in which the impact of fatigue on quality of life is multifaceted but includes sexual dysfunction as well. Treatment of the underlying causes of

the fatigue, whether medically or psychologically, may have important benefits in terms of psychological functioning.

Other studies have begun to examine fatigue in breast cancer survivors.<sup>51,52,54</sup> In an analysis reported by Bower et al.<sup>54</sup> in almost 2000 breast cancer survivors, the strongest predictors of fatigue were pain and depression—both treatable problems. In that study sample, fatigue was significantly correlated with poorer sexual functioning ( $r = -0.265$ ,  $P = .0001$ ); when fatigue scores were used to classify the patients as either high or low energy, a significant difference was found in sexual functioning scores ( $P = .0001$ ).<sup>55</sup> Interestingly, specific treatments (chemotherapy, radiation, tamoxifen) were not significantly associated with fatigue in the predictive model.<sup>54</sup>

Similarly, uncontrolled pain can be an important contributor to sexual dysfunction in cancer patients and survivors. Uncontrolled pain is associated with psychological distress, poor appetite, and lack of sleep, all of which can decrease sexual interest. Surprisingly, little empiric research has been conducted in this area. However, one study demonstrated the association of pain with decreased sexual functioning after high dose chemotherapy and autologous bone marrow support.<sup>56</sup> Another study that examined breast cancer patients with upper extremity lymphedema found that the presence of associated pain predicted psychological distress, but it did not independently predict sexual dysfunction.<sup>57</sup>

## PARTNER RELATIONSHIPS

The literature suggests that the presence of a partner plays an important role in the maintenance of an active sex life for both men and women.<sup>8,10,13,23</sup> Problems in the marital relationship after cancer most often reflect preexisting stresses and strains, such that marital dissolution as a result of cancer is probably less common than once thought.<sup>58</sup> Often, cancer patients cite improvement in their love relationships rather than deterioration.<sup>59</sup> In a study of prostate cancer survivors compared with aged matched health controls, marital function did not differ between treatment groups and controls.<sup>60</sup>

The presence of a spouse or partner is invaluable for patients facing the possibility of sexual dysfunction from cancer or its treatments. Not only can spouses provide much needed emotional support, but they may also contribute to the clinical decision-making process. Physicians must be aware that the spouse often does not agree with the patient when assessing the relative value of sexual function versus survival. In fact, studies comparing husbands and wives suggest that the latter are much more willing to give up sexual function for a chance at longer survival.<sup>61,62</sup> Ultimately, the right choice of treatment must emanate from the patients themselves, but involvement of spouses can facilitate this process.

In addressing the partner relationship, it is also important never to assume that the patient is heterosexual, especially when the patient is alone for tests, consultations, and follow-up visits. The astute clinician should probe in a nonjudgmental way about the patient's partnership status and ensure that a same-gender partner is included, as appropriate, in medical decision making. Gay and lesbian couples enjoy long-term relationships that are emotionally equivalent to heterosexual marriage, yet given the degree of societal homophobia, they may fear being honest, even with their physicians. A few words of candid support may go a long way in allowing patients to feel better about involving their same-gender partner.

The literature does suggest that survivors of childhood and adolescent cancers are at increased risk for marital difficulties. In a large study of long-term survivors of childhood cancers compared with sibling controls, Byrne and colleagues<sup>63</sup> noted that both male and female survivors were less likely to marry than sibling controls and that the marriage deficit was particularly pronounced for survivors of brain and central nervous system tumors. In addition, the average length of first marriages was shorter for survivors than controls.<sup>63</sup> Men who had survived central nervous system tumors before the age of 10 years and male survivors of retinoblastoma had substantially higher divorce rates than controls (relative risk, 2.9 and 1.9, respectively). As noted by this study's authors, the treatment intensity for the patients studied in this cohort was much less intense than contemporary therapies, thus making altered marriage practices an important concern among adult survivors of pediatric brain tumors.<sup>63</sup> These findings have largely been confirmed in a preliminary report from a successor cohort study, the Childhood Cancer Survivor Study, in which rates of marriage have been compared to U.S. population census data and are found to be reduced.<sup>64</sup> Survivors were less likely to have married, particularly women and whites, but once married, they were less likely to divorce or separate. As in the study of Byrne et al.,<sup>63</sup> pediatric brain tumor survivors, particularly men, were less likely to have married and more likely to divorce or separate compared to those with other cancer diagnoses and the general population.<sup>64</sup> Other single-institution, detailed investigations of childhood survivors support these findings,<sup>65</sup> with the observation that many former patients indicate their diagnosis and treatment for childhood cancer influenced their own personal decision to have children and that this decision may play a role in the marital relationship. These findings may have important long-term implications for the sexual functioning of these long-term survivors, warranting more detailed inquiry.

## SPECIFIC TREATMENTS

### *Surgery in General and Pelvic Surgery*

Surgical treatment usually involves hospitalization, general or local anesthetic, and exploration of body cavities (thoracic, abdominal, pelvic), with adjacent organ dysfunction and the need to recover from the treatment insult. Postoperative pain and fatigue are important factors that limit recovery of sexual functioning for several weeks after surgery. Surgical treatments with the most significant impact on sexual functioning are those involving the pelvis, such as radical prostatectomy, radical cystectomy, abdominal-perineal resection for rectal cancer, and radical hysterectomy for gynecologic cancers. When radiation is added to surgical treatments, additional nerve and tissue injury may occur, with fibrosis and occasional pelvic pain syndromes. Changes in body image may occur as a result of surgery, especially when it is disfiguring and visible to others, but even hidden body scars may present a difficulty for some patients.

In men, pelvic surgery for prostate, bladder, or rectal cancer can easily damage the parasympathetic sacral fibers that are responsible for penile erection. These nerves course posterolateral to the prostate and anterolateral to the rectum and are intimately associated with both structures, especially at the apex of the prostate just anterior to the rectal wall. Although techniques have been developed for identification and preservation of these neurovascular bundles during radical prostatectomy,<sup>66</sup> such preservation is much more difficult during abdominal-perineal resection of the rectum.<sup>67,68</sup> These nerves do not need to be cut to disrupt their function. The mere trauma of dissection to separate them from the prostate or rectum may also lead to their permanent failure. The effect is immediate, and neuronal recovery is slow, often lasting months or years. Pelvic surgery for bladder or rectal cancer may also result in female sexual dysfunction, largely due to scarring, shortening, and stenosis of the vagina.<sup>69,70</sup> Despite initial dyspareunia, many women who are treated for bladder cancer with surgery and radiation ultimately do enjoy a return of sexual function.<sup>71</sup>

Retroperitoneal lymphadenectomy in men with testis cancer does not interfere with erections, but it may cause retrograde ejaculation. The primary landing site for lymphatic spread from the testes is located in the interaortocaval region for right-sided tumors and in the paraaortic region for left-sided tumors. From here, metastatic deposits can extend cephalad or caudad alongside the great vessels. Intertwined with these lymphatic channels are the lumbar sympathetic fibers that are responsible for normal antegrade ejaculation. If these are damaged during surgery, patients may experience a failure of both seminal emission and bladder neck closure. This in turn results in retrograde ejaculation. Although the patient is able to enjoy the pleasure of orgasm, it is dry and fluidless. Techniques to preserve these nerve fibers by using template dissections have been popularized and are largely successful at maintaining antegrade ejaculation in most men undergoing retroperitoneal lymphadenectomy.<sup>72,73,74</sup> and <sup>75</sup>

The effects of pelvic and genital surgery on sexual response in men and women vary depending on the organs involved and are summarized in [Table 56.3-4](#) and [Table 56.3-5](#). Schover and Fife<sup>76</sup> provide an excellent overview of the components of the sexual response that are affected by these various surgical procedures. The amount of dysfunction depends on the extent of injury to the sacral plexus (especially for erectile functioning in men), and for women, vaginal lubrication may be strongly influenced by oophorectomy and the loss of estrogen, as well as the prohibition against estrogen replacement therapy. Dry orgasms occur in men after radical prostatectomy and radical cystectomy through surgical removal of the prostate and seminal vesicles. For women, vaginal shortening and anatomic changes that result from several of the surgical procedures leads to dyspareunia and the need to use lubricants and vaginal dilators.

Procedure	Sex	Pain on Touch	Ability to Have Erection	Ejaculation	Pain with Intercourse
Radical prostatectomy	No change	No change	Decreased (increasing the degree of impotence)	No change or some decreased intensity	No change
Radical hysterectomy	No change	No change	Decreased (increasing the degree of impotence)	No change or some decreased intensity	None, but some men may have some pain with intercourse
Abdominal-perineal resection	No change	No change	Some improvement (but less than radical prostatectomy)	No change or some decreased intensity	None, but some perineal pain or discomfort with intercourse
Total pelvic exenteration	No change	No change	None (obvious atrophy required)	No change or some decreased intensity	None, possible groin or pelvic pain with intercourse
Partial prostatectomy	No change	Some increase in sensitivity genital area	No change	No change	None, possible groin or pelvic pain with intercourse
Total gynecectomy	No change	Some increase in sensitivity genital area	No possible	No change (and to change with some)	Occasional, groin or pelvic pain with intercourse

(Adapted from ref. 91, with permission.)

**TABLE 56.3-4.** Effects of Surgery for Pelvic or Genital Cancer on Male Sexual Physiology

Procedure	Sex	Pain on Touch	Orgasm/Lubrication	Erection of Vagina	Pain with Intercourse
Radical hysterectomy	No change	No change	None (not IET)	No change	None, some vaginitis
Radical oophorectomy	No change	No change	Reduced (not IET)	No change	None, but can be treated
Abdomino-perineal resection	No change	No change	None (not IET)	Probably no change	None, but can be treated
Total pelvic exenteration and sigmoid resection	No change	Some loss of rectal area	Less	Need to relax less to reach orgasm	Occasional
Radical vulvectomy	No change	Some loss of rectal area	No change	Need to relax less to reach orgasm	None, but can be treated

(IET, estrogen replacement therapy; Adapted from ref. 91, with permission.)

**TABLE 56.3-5.** Effects of Surgery for Pelvic or Genital Cancer on Female Sexual Physiology

The goals of contemporary multimodal therapies for cancer have focused on limiting the extent of surgery, with the addition of chemotherapy and radiation to control local and distant disease. Excellent examples of this trend are primary radiation therapy for prostate cancer, bladder-conserving surgery with radiation and chemotherapy, and sphincter preservation treatment of anal and rectal cancer. These approaches still have associated sexual dysfunctions, but the time course and specific problems may differ from surgery alone. In addition, patients may have to deal with the morbidity of the additional therapies. Other procedures, such as bladder replacement with a continent reservoir, may avoid the embarrassment of external stomas and appliances, but this may not necessarily have a positive impact on sexual functioning.<sup>77</sup>

### Chemotherapy

The effects of systemic chemotherapy on sexual functioning can be conceptualized as acute and chronic, with somewhat different risks for men and women. Acutely, and dependent on the type of chemotherapeutic agent, many patients experience nausea, vomiting, fatigue, hair loss, and mucositis. All of these factors contribute to a decrease in well-being and less interest in sexual activity. Women may experience vaginal and perineal mucositis from some agents, with some data suggesting decreased vaginal lubrication as a late effect of chemotherapy.<sup>78,79</sup> Loss of body hair decreases sexual attractiveness for most individuals, and extra effort may be required to maintain this aspect of sexuality. All of these effects are intensified in those receiving high-dose chemotherapy regimens.<sup>80</sup> Protracted fatigue may be a significant contributor to sexual dysfunction in bone marrow transplantation survivors.<sup>56</sup>

For women, one of the most dramatic consequences of chemotherapy treatment is the cessation of menses and the onset of menopause, with the consequent loss of fertility. This effect also has been reviewed for breast cancer treatments.<sup>81,82</sup> In a prospective study of a cohort of 183 early-stage breast cancer patients receiving no adjuvant therapy, either chemotherapy or tamoxifen adjuvant therapy, or both chemotherapy and tamoxifen,<sup>83</sup> age and systemic chemotherapy (in this case cyclophosphamide, methotrexate, or epirubicin, plus 5-fluorouracil) were the strongest predictors of menopause in women with locoregional disease, with tamoxifen making a small contribution (Fig. 56.3-1). As Figure 56.3-1 demonstrates, the probability of menopause with chemotherapy begins to rise at approximately 35 years of age, with more than 40% of women at age 40 predicted to become amenorrheic. The closer a woman was to the age of natural menopause (age 51), the greater her risk of amenorrhea.<sup>83</sup> Because this study only followed women for 1 year after treatment, however, some small proportion of women may have resumed menses after that time. Because some evidence suggests that amenorrhea may be beneficial in preventing breast cancer recurrence, it may be an acceptable consequence of treatment for some women. Nevertheless, the effects of menopause on sexual functioning, especially vaginal dryness, may contribute to sexual dysfunction in breast cancer survivors.<sup>43</sup>

**FIGURE 56.3-1.** Probability of menopause during the first year after the diagnosis and adjuvant treatment of breast cancer. Horm, hormone; Chem, chemotherapy. (From ref. 90, with permission.)

Preservation of fertility is very important for younger patients treated for leukemia, testicular cancer, lymphoma, and Hodgkin's disease. Although current regimens for Hodgkin's disease that avoid alkylating agent therapy [e.g., Adriamycin, bleomycin, vinblastine, and dacarbazine (ABVD)] may spare ovarian and testicular function in terms of fertility and premature menopause, their value in preservation of sexual functioning may be more limited.<sup>84</sup> In Kornblith et al.'s study<sup>84</sup> examining the late effects of ABVD in comparison to Mustargen, Oncovin, procarbazine, and prednisone (MOPP) or MOPP/ABVD, no difference was found in sexual functioning by treatment arm. However, the small sample size of this study (93 disease-free survivors) across three treatment arm comparisons may have made it difficult to detect significant differences in outcomes. In another study comparing survivors of advanced-stage Hodgkin's disease and acute leukemia survivors treated on a variety of chemotherapy protocols, Kornblith et al.<sup>33</sup> found that Hodgkin's disease survivors experienced significantly poorer sexual relationships than the leukemia survivors. Thus, the specific type of chemotherapy regimen and its duration can have differing effects on sexual functioning.

### Radiation Therapy

The acute effects of radiation include fatigue, nausea, skin changes, and hair loss, with local changes limited to the area of the radiation port. As already discussed, fatigue can interfere with sexual functioning, and hair loss and skin changes can affect sexual functioning through changes in body image. Long-lasting effects on skin

and hair may occasionally occur, especially when combined modality therapies are used. Radiation injury to the pelvis can lead to fibrosis of soft tissue, as well as nerve damage, with loss of sexual functioning attributable to treatment. This is especially an issue when high-dose primary therapy is given, as for prostate cancer, bladder-conservation treatment, cervical cancer, and rectal cancers. In addition, injury to adjacent normal tissues (rectum, bladder, vagina) can lead to symptomatic problems (proctitis, cystitis, vaginal stenosis) that can detract from sexual activities.

Primary pelvic irradiation for prostate or bladder cancer may be as damaging to the erectile nerves as surgery. Radiation also damages the small blood vessels that supply and drain the corpora cavernosa.<sup>85</sup> The primary difference is the time course over which the effect is seen. Whereas surgical nerve injury reveals itself immediately, radiation injury to the nerves and vessels often does not manifest itself for many months. Because the mechanism of radiation tissue damage is to induce scarring over time, the pelvic vessels and erectile nerves may retain normal function initially and then decline fairly rapidly as long as 18 to 36 months after the completion of treatment.<sup>86</sup> The advent of three-dimensional conformal therapy has improved the radiation oncologist's ability to focus the beam at the center of the prostate and decrease the dose delivered to its periphery, where the nerves are located.<sup>87</sup> To treat prostate cancer effectively, however, an adequate dose must be administered to the entire gland, and this can certainly cause subsequent nerve damage. Proton-beam therapy, a variation of external-beam radiotherapy, is heavily marketed as causing fewer erectile complications in prostate cancer patients; however, no published evidence supports this claim.

Brachytherapy, the implantation of radioactive seeds into the prostate, has gained national prominence because it, too, is reputed to cause fewer complications than external-beam therapy. However, no reliable and valid longitudinal measurements of erectile function have yet been reported in patients who undergo this form of treatment. More information is needed before it can be established whether brachytherapy preserves erectile function in men treated for prostate cancer.

### **Hormonal Treatments**

Hormonal treatments used in the management of endocrine-sensitive cancers may have important effects on sexual functioning. Tamoxifen, an antiestrogen, increases the rate of vaginal discharge and vasomotor symptoms in a proportion of breast cancer patients<sup>79</sup> and in those women taking this therapy for breast cancer prevention.<sup>88</sup> Although rates of sexual activity did not appear to differ between the women taking tamoxifen and those taking a placebo in the now completed Breast Cancer Prevention Trial, subtle differences in sexual functioning for women taking tamoxifen were noted (see [Breast Cancer](#), later in this chapter).<sup>86</sup> In a small study that examined the effect of tamoxifen and sexual functioning in patients with breast cancer, Mortimer et al.<sup>89</sup> found that the desire, arousal, and orgasmic problems were not increased in their patient sample, but that more than one-half of patients complained of pain, burning, or discomfort with intercourse and that the majority of those with these symptoms routinely used a vaginal lubricant with intercourse. Vaginal cytology was examined in these women, and the presence of an estrogen effect was associated with negative reactions during sex ( $P = .02$ ) and vaginal dryness or tightness ( $P = .046$ ), but it was not associated with other aspects of sexual functioning.<sup>89</sup>

Weight gain is an important side effect with megestrol acetate, which is often used in the treatment of metastatic breast and endometrial cancers. This weight gain may contribute to a poorer body image in these patients and potentially affect sexual functioning.<sup>90</sup> Since the 1990s, interest has been renewed in ovarian ablation for women with breast cancer, either with surgical oophorectomy or with use of gonadotropin-releasing hormone analogues. As already mentioned, the precipitation of premature menopause in these women may cause substantial disruption in sexual functioning.

For men with advanced prostate cancer, the mainstay of therapy is androgen ablation,<sup>91</sup> which can be accomplished by either surgical or medical castration. Historically, the medical approach involved an oral estrogen, such as diethylstilbestrol, which inhibits the release of luteinizing hormone from the anterior pituitary and, in turn, decreases testicular androgen production. More recently, chemical castration is achieved with gonadotropin-releasing hormone blockers with or without the addition of antiandrogens to eliminate the effect of adrenal androgens. Other agents, such as aminoglutethimide or ketoconazole, may also be used for the same effect. Men who participate actively in the selection of their androgen ablation option tend to be happier with their decisions.<sup>92</sup>

The primary sexual side effect of androgen ablation is loss of libido. Many men report the ability to have erections and ejaculations despite the absence of testosterone, although decline in libido is universal. As a result, men who are sexually active and asymptomatic from the cancer (e.g., those who have a rising prostate-specific antigen level without documented metastatic disease) often choose to delay hormone therapy. For men who are experiencing clinical progression of metastatic prostate cancer, sexual function may already have declined or disappeared as their constitutional symptoms have advanced. For these individuals, androgen ablation may not have a great impact on erectile function, which is already greatly reduced.<sup>93</sup>

### **CONCERNS ABOUT FERTILITY**

Preservation of fertility is an important aspect of treatment, especially for those individuals who have not had children. This issue pertains in particular to children and young adults with cancers who are treated with curative intent. As noted by Laufer,<sup>94</sup> it is increasingly useful to know the reproductive health outcomes for specific types of cancer treatments and "to differentiate between sex steroid production and fertility or reproductive function." In one of the largest studies of the effects of treatment on fertility in long-term survivors of childhood or adolescent cancer, Byrne and colleagues<sup>95</sup> estimated the risk of infertility after treatment in a retrospective cohort study of survivors of cancer and controls. The cancer patients, who were diagnosed before the age of 20 years, were treated between 1945 and 1975 at five cancer centers in the United States. Cancer survivors who married were less likely than their sibling controls to have ever begun a pregnancy [relative fertility, 0.85; 95% confidence interval (CI), 0.78 to 0.92]. With regard to therapy, radiation directed below the diaphragm decreased fertility in both sexes by approximately 25%, and chemotherapy with alkylating agents, with or without subdiaphragmatic radiation, was associated with a fertility deficit of approximately 60% in men. Among women, no effect of alkylating agents alone was found in this young group of patients; however, a moderate fertility deficit was noted when alkylating agents were combined with subdiaphragmatic radiation (relative fertility, 0.81).<sup>95</sup> Adjusted relative fertility varied widely by cancer site, with a rate of 0.45 (95% CI, 0.26 to 0.78) for male genital cancer and 1.47 (95% CI, 0.81 to 2.65) for Wilms' tumor. For many of the cancer sites, the 95% confidence intervals overlapped by 1.0.<sup>95</sup>

More detailed studies of gonadal function tend to confirm these general observations, with evidence of preserved Leydig cell function in young boys receiving treatment but also of increased germ cell dysfunction and decreased spermatogenesis.<sup>96,97</sup> Female childhood cancer survivors do not exhibit significant changes in gonadal function with contemporary treatments<sup>97</sup>; however, in the earlier era of extensive craniospinal and abdominal radiation used in the treatment of childhood acute lymphoblastic leukemia, lack of pubertal development and delayed onset of menses was common.<sup>98</sup> Even in young women treated for ovarian dysgerminoma, reproductive function can be preserved with conservative surgery and contemporary chemotherapy treatment regimens.<sup>99</sup>

For young adults with cancer, strategies to conserve fertility are often used and are highly dependent on the type of cancer and available treatments.<sup>100</sup> ABVD has largely replaced MOPP chemotherapy for Hodgkin's disease because of a more limited risk of infertility.<sup>101</sup> In general, however, diseases that require treatment with alkylating agents are likely to put both men and women at risk for infertility.<sup>100</sup> The risk for women begins to rise after 30 years of age, and for men the risk increases at any age. Cryopreservation of sperm is a strategy used to preserve fertility in men. Newer approaches to ovarian tissue preservation and subsequent reimplantation are on the horizon for women.<sup>102,103</sup>

A past history of cancer, uncertainty related to reproductive potential, and changes in sense of self-esteem and attractiveness may impair dating and sexual function in young adults with a history of cancer. Often, young adults who were treated for cancer as a child may have limited awareness of their past treatment, and they may be confronting this aspect of their health for the first time as they marry and attempt to start a family. Importantly, these individuals can be reassured that their offspring are unlikely to experience adverse consequences as a result of past parental treatments for cancer.<sup>104,105</sup>

## **SEXUAL PROBLEMS ASSOCIATED WITH SPECIFIC CANCERS**

### **BREAST CANCER**

Among specific cancer sites, breast cancer has been one of the most frequently studied regarding sexual functioning because of the surgical trauma to the breast and the severe disruption in body image associated with mastectomy. The important role of the breast in terms of femininity and sexual identity, and as an organ involved in sexual activity, has made sexual health after breast cancer an important issue. All of these concerns point to the potential impact of the type of surgical treatment on sexual functioning. However, as adjuvant treatment for breast cancer has expanded to earlier stages of disease, including noninvasive cancer, the impact of chemotherapy and hormonal therapy (e.g., tamoxifen, oophorectomy, gonadotropin-releasing hormone analogues) must also be considered. As already noted, each of these adjuvant therapies may induce premature menopause, lead to vaginal dryness, and may have other specific effects that can influence sexual health. These issues take on increasing importance in treatment decision making, because women with very early-stage breast cancer can expect survival that is equivalent to

women without a cancer diagnosis.

One of the most investigated questions in breast cancer patients has been the impact of type of surgery on sexual health and quality of life. [40,106,107](#) and [108](#) Several large reviews of this topic [37,38](#) and [39,109](#) address the potential differences in outcomes for women treated with modified radical mastectomy compared to breast-conserving surgery with radiation. In only a few studies were women randomly assigned to the type of surgical treatment; most have been observational cohort studies in which patient choice or preference for treatment likely occurred. Thus, some bias could be influencing the results. Nevertheless, the consistency of findings across so many studies and countries suggests that the findings are real. There is consensus that breast-conserving surgery offers a better sense of body image to women after breast cancer but only limited differences in other dimensions of quality of life (physical, emotional, or social functioning). In studies that have specifically addressed sexual functioning, [40,107,109,110](#) little difference was found between the two types of surgery, although in the one randomized treatment trial, [110](#) some evidence suggested better sexual functioning in women with conservation surgery.

In a study comparing women with breast conservation treatment to those receiving mastectomy with reconstruction, Schover et al. [111](#) found that the two groups did not differ in body image, satisfaction with relationships, or sexual life. However, the authors did find that women with breast reconstruction experienced less caressing of the breast in lovemaking than women with partial mastectomy. [111](#) In a study of sexual health and functioning in breast cancer survivors, [43](#) body image influenced sexual interest, but the type of surgery did not predict any aspect of sexual health after breast cancer. Thus, although total loss of the breast may negatively influence a woman's body image, it does not necessarily impact her sexual health and functioning. As has been shown in healthy women without breast cancer [13](#) and in breast cancer survivors, [43](#) other factors may play a more important role in influencing sexual health in middle-age women (e.g., presence of a partner, vaginal dryness, emotional well-being, quality of the partnered relationship).

The etiology of sexual dysfunction in breast cancer survivors has not been well studied. As with other patients, multiple predisposing factors are involved, including preexisting sexual problems, negative sexual self-schemas, and normal age-related changes in sexual functioning. [14,15,112,113](#) In addition, induction of premature menopause by chemotherapy can result in an estrogen deficiency state that increases the likelihood of hot flashes and poor vaginal lubrication that may contribute to sexual dysfunction. [81,114,115](#) and [116](#) These symptoms are also a potential problem for older patients for whom hormone replacement therapy is discontinued at the time of a breast cancer diagnosis. Furthermore, these symptoms may be exacerbated by tamoxifen adjuvant therapy. [117](#) The results from the newly completed Breast Cancer Prevention Trial [86](#) suggest that, overall, tamoxifen has minimal effects on sexual functioning in healthy high-risk women. Comparing women taking tamoxifen to those taking placebo, [86](#) over the course of 3 years of follow-up, no difference was found in the number of women who were sexually active, although both groups showed a subtle decline in sexual activity over time. There was an increase in vaginal discharge, genital itching, and pain with intercourse in women taking tamoxifen, as well as very subtle changes in some aspects of sexual functioning (sexual interest, sexual arousal, orgasm). [88](#)

Multiple studies suggest an important role for chemotherapy in increasing sexual dysfunction in women with breast cancer. [78,79,115,118,119](#) This effect may be working through the precipitation of premature menopause and loss of both estrogens and androgens from the ovary. [119](#) However, chemotherapy may also have a direct effect on the vaginal epithelium, causing vaginal dryness, because postmenopausal women also experience poorer sexual functioning after chemotherapy. [78](#)

An increasing body of literature has examined sexual functioning in long-term survivors of breast cancer, with comparative information on women without a cancer diagnosis. [78,120,121](#) and [122](#) In a cross-sectional study of more than 800 breast cancer survivors between 1 and 5 years after diagnosis, Ganz et al. [78](#) found that approximately 60% of the study sample had been sexually active with a partner in the past 6 months, with the most common reason for inactivity being lack of a partner, lack of interest, her partner's lack of interest, or the partner's physical health problems. [78](#) Sexual functioning data from two standardized instruments showed a decline in sexual functioning with age, especially in the areas of arousal and orgasm. Overall, the responses of the breast cancer survivors were comparable to an age- and menopause-matched sample of healthy women who participated in the Postmenopausal Estrogen Progestins Intervention Trial and were not on hormone replacement therapy. [13](#) Overall, the breast cancer survivors reported fairly high levels of satisfaction with their sexual relationships. [78,121](#) Nevertheless, in a more detailed analysis, this study's authors found that one-third of women reported that breast cancer had had a negative impact on their sex life, and most reported negative changes in at least some areas (e.g., frequency of sexual activity, awareness of decreased lubrication in vagina with sexual activity, pain in genital area during sexual activity, discomfort when touching breast cancer surgery area). [121](#) Women who were most likely to report a negative impact were significantly more likely to report relationship difficulties, to have experienced changes in hormonal levels because of breast cancer (premature menopause or discontinuation of hormone replacement), and to be bothered by vaginal dryness. [121](#) These findings are similar to those obtained in smaller samples of breast cancer survivors. [120,122](#)

## PROSTATE CANCER

The effect of erectile dysfunction on sexual functioning after treatment for prostate cancer has been studied extensively with a variety of experimental designs. All studies have shown that men undergoing radical prostatectomy or pelvic irradiation have more sexual impairment than age-matched controls. [123,124](#) Despite consistent reports of better outcomes with nerve-sparing techniques in centers of excellence, rates of sexual dysfunction in random, national, population-based samples reveal that erectile dysfunction remains common after surgery [125,126](#) or radiation [127](#) for early-stage prostate cancer.

Talcott [128](#) examined a group of men who underwent nerve-sparing radical prostatectomy and compared them with men who underwent non-nerve-sparing radical prostatectomy. Talcott found that patients who underwent nerve-sparing surgery had low levels of sexual function that were not significantly different from men who underwent non-nerve-sparing procedures. However, when the nerve-sparing population was broken down into one or both nerves spared, the bilateral nerve-sparing group reported significantly better potency at 1 year when compared to those who underwent non-nerve-sparing surgery. In a longitudinal follow-up study, Talcott et al. [129](#) confirmed that nerve-sparing appears to improve postoperative sexual function to a lesser extent than previously reported. Talcott et al. [86](#) also published the first prospective cohort study of patients treated with either surgery or radiotherapy, in which 279 patients were assessed with validated quality-of-life instruments before treatment and at 3 and 12 months afterward. Initially, surgery patients had more impotence; however, over time, sexual function declined in the radiotherapy group and improved in the surgery group. Hence, with longer follow-up, treatment group differences in sexual function continued to narrow. Other studies also have shown that the incidence of impotence increases to at least 35% to 40% during the 2 to 3 years after radiation therapy for localized prostate cancer. [130,131](#)

In a more recent longitudinal study of 438 men treated with surgery or radiation for early-stage prostate cancer, [132](#) sexual function after treatment for prostate cancer appeared to improve over time. Although sexual function was significantly better in radiation than surgery patients immediately after treatment, both groups improved at comparable rates during the first year. In the second year, radiation patients began to show a modest but statistically significant decline in sexual function, whereas surgery patients continued to improve. Both nerve-sparing and postsurgical erectile aids improved sexual function after prostatectomy. Given the decline in sexual function during the second year after radiation, these factors ultimately serve to equalize sexual function in the postsurgical and postradiation settings. The most elderly men experienced a posttreatment sexual function course that differed greatly from the youngest men. This finding validates the clinical observation that older men are much less likely than younger men to regain sexual function after treatment. In particular, octogenarians who choose radiotherapy can expect significant declines in sexual function without apparent recovery.

## TESTIS CANCER

Therapy for testicular cancer, including orchiectomy, retroperitoneal lymphadenectomy, and radiation therapy, can cause a variety of physical and psychological sequelae. [133](#) Rieker et al. [134,135](#) showed that these patients express distress over poor sexual performance and infertility, although not with decreased libido. Those with ejaculatory dysfunction note more strained intimate relationships and more psychological problems. Compared with healthy controls, testis cancer patients as a group do not reveal any more difficulty with relationships, employment, divorce, or overall mental outlook. Bloom et al. [136](#) compared a sample of men treated for testis cancer with an age-matched sample treated for Hodgkin's disease. Those with testicular cancer were significantly more likely to report decreased sexual enjoyment; however, they were also more likely to report their health as excellent when compared to the lymphoma group, leading the authors to conclude that the response to testicular cancer is more site-specific.

After radiation therapy for seminoma, most men marry within a few years; however, a significant proportion of patients continue to report ejaculatory dysfunction and anxiety about fertility. [137](#) Gritz et al. [44,138](#) compared the outlooks of patients and their wives several years after testicular cancer treatment. Compared to their wives, patients reported higher levels of anxiety over sexual performance. Long-term psychosocial adjustment was good in both groups, however.

## BLADDER CANCER

The overwhelming majority of men who undergo cystectomy for bladder cancer either report difficulties before treatment or develop erectile dysfunction after treatment. Despite this observation, at least 50% of these patients continue to enjoy some form of sexual stimulation other than coitus after recuperation from surgery,<sup>139</sup> and at least 75% maintain their libido.<sup>140</sup> For women, changes may occur that are associated with decreased vaginal lubrication if women are estrogen deficient,<sup>76</sup> and similar issues face both men and women if a stoma is created. Mansson and colleagues<sup>77</sup> administered a quality-of-life instrument to patients undergoing cystectomy and compared those reconstructed by continent cutaneous ileocecal diversion with those undergoing simple conduit diversion. Patients in both groups experienced equivalent declines in quality of life related to sexual problems, disturbed partner relationships, and emotional dysfunction.<sup>77</sup> In a similar study, Boyd and colleagues<sup>141</sup> demonstrated that, postoperatively, ileal conduit patients had the poorest self-image, as defined by a decrease in sexual desire and in all forms of physical contact (sexual and nonsexual). Those who later underwent conversion from ileal conduit diversions to continent cutaneous Kock pouches were the most physically and sexually active. Gerharz et al.<sup>142</sup> found that, after cystectomy, patients receiving an ileal conduit had worse scores than continent reservoir patients in sexual activity and general quality-of-life domains. Hart et al.<sup>143</sup> reported more optimistic findings, showing that general quality of life was not differentially affected by the choice of urinary diversion method after cystectomy in either women or men.

## GYNECOLOGIC CANCERS

Cancer involving the female genital organs immediately evokes concerns about sexual dysfunction related to cancer-related symptoms that predate the diagnosis,<sup>144</sup> as well as treatments that may be required to extirpate the cancer. Cancers of the uterine corpus and cervix make up the majority of gynecologic cancers (roughly 70%), and these primarily localized cancers are treated with surgery or radiotherapeutic approaches, or both. Rarer cancers, such as vulvar cancer, may be treated with a variety of local or extensive surgical modalities, with some use of topical therapies. Nevertheless, the visible and disfiguring aspects of perineal surgery has its own serious sexual consequences. Other gynecologic cancers (ovarian cancer, trophoblastic disease, uterine sarcomas) are treated with combinations of chemotherapy, surgery and, sometimes, radiotherapy. The more disseminated nature of these cancers and the severity of the disease lead to different patterns of sexual dysfunction. For all gynecologic cancers, the age, partnership status, menopausal status, and preexisting sexual functioning of a woman play an important role in her sexual rehabilitation after cancer treatment (see [Table 56.3-1](#) and review by Andersen<sup>145</sup>).

Because of the involvement of the genital organs with gynecologic cancers, changes in sexual functioning may often take place before the diagnosis of cancer. In a comparison of healthy control subjects and women with early-stage cervical and uterine cancer, Andersen et al.<sup>144</sup> found few differences in aspects of the sexual response cycle reported before the onset of signs or symptoms of the cancer. However, a substantial number of the gynecologic cancer patients reported a disruption in sexual responsiveness with the onset of symptoms, including changes in desire, excitement, orgasm, and resolution and a global deterioration in sexual functioning.<sup>144</sup> These changes were most often associated with symptoms of fatigue, postcoital bleeding, and multiple other signs and symptoms.

Sexual functioning outcomes in patients with gynecologic cancers often have been reported in small case series. Andersen and colleagues<sup>146</sup> prospectively studied 47 women with early-stage gynecologic cancers (cervix, n = 33; endometrium, n = 9; ovary, n = 5) and benign gynecologic disease before treatment, and then interviewed them again at 4, 8, and 12 months posttreatment. Women treated for disease, whether benign or malignant, reported similar declines in frequency of intercourse, decreased sexual excitement, and a less positive global evaluation of their sexual life. In addition, a three- to sixfold increase in the incidence of sexual dysfunction diagnoses was found in comparison to the rates in healthy women.<sup>146</sup> Pain with intercourse, prominent early in the recovery period in treated women, improved with time but remained more frequent in the cancer patients. Although both treated groups experienced increased sexual dysfunctions posttreatment, the cancer patients experienced a higher incidence of inhibited excitement. As discussed by Andersen et al.,<sup>146</sup> these particular changes can be a manifestation of increased anxiety associated with the cancer diagnosis.

Looking more specifically at the impact of cervical cancer and its treatment on sexual functioning, several other small, descriptive studies are relevant. Schover et al.<sup>147</sup> examined sexual frequency, function, and behavior in 61 women with early-stage invasive carcinoma of the cervix. The impact of treatment (radical hysterectomy alone, radiotherapy with or without surgery) was examined in this study. Sexual satisfaction, capacity for orgasm, and frequency of masturbation remained stable over 12 months of observation posttreatment; however, frequency of sexual activity with a partner and the range of sexual practices decreased significantly over the course of the year of follow-up. Although at 6 months few differences were noted between those who had received irradiation and those who had not, at the 12-month assessment, the women receiving radiotherapy had more dyspareunia (as well as an abnormal vaginal examination) and had more problems with sexual desire and arousal.<sup>147</sup> Treatment modality had no effect on marital happiness or stability.

These findings suggest an additional complication from irradiation of the pelvis, which is vaginal stenosis or foreshortening. Several other studies have documented this problem,<sup>148,149</sup> with level of sexual activity being lowest at the completion of radiotherapy. The finding of progressive dyspareunia and vaginal shortening<sup>147</sup> suggests the need for active intervention in these women, with the need for early use of vaginal lubricants, resumption of sexual activity, or use of dilators to maintain vaginal length and elasticity. In one small study,<sup>150</sup> women who did not follow advice regarding use of vaginal dilators and did not resume the same level of sexual intercourse as before their illness were more likely to develop physical and sexual changes.

These small descriptive studies shed some light on the mechanisms of sexual dysfunction and the range of sexual problems in the first year after treatment for cervical cancer. However, the late sexual effects of treatment for cervical cancer are important, because this is a group of women who are likely to be cured of their disease and be long-term cancer survivors. A report by Bergmark et al.<sup>151</sup> provides important new information on vaginal changes and sexuality in a large sample of Swedish cervical cancer survivors (n = 256) and a concurrent control sample (n = 350). The cancer survivors had been treated, on average, approximately 5 years earlier and were a mean age of 51 years at the time they responded to the study questionnaire. Significant differences were found between the two groups in problems with vaginal lubrication (26% of the women with cancer vs. 11% of the controls), reporting of a short vagina (26% of the women with cancer vs. 3% of the controls), and decreased vaginal elasticity (23% of the women with cancer vs. 4% of the controls). In spite of these significant changes associated with the treatment of cervical cancer, no differences were noted in sexual interest, desire, frequency of vaginal intercourse, or orgasm; however, there was much distress related to the frequency of vaginal intercourse and problems during vaginal intercourse (dyspareunia, vaginal bleeding) among the women with a history of cervical cancer.<sup>151</sup>

Treatment with surgery alone was associated with decreased vaginal lubrication, vaginal shortness, and decreased vaginal elasticity.<sup>151</sup> When surgery was combined with radiotherapy or when radiotherapy was given alone, no apparent differences in these vaginal outcomes were found when compared to surgery alone, except for some decreased sexual interest among those treated with radiotherapy alone. Interestingly, treatment for cervical cancer negatively influenced feelings of femininity and attractiveness among the cervical cancer survivors but did not seem to influence sexual satisfaction. Importantly, the authors observed no age above which sexual function was not important to women, and they suggest that efforts to prevent vaginal changes or relieve them after therapy should be considered in all women who are treated for cervical cancer.<sup>151</sup> Finally, it should be noted that the use of a healthy control group in this study was important, in that 41% of both patients and controls reported little or no interest in sex in the previous 6 months, with more than 50% reporting reduced sexual desire in the previous 5 years. Without such a control group, these findings might have been attributed to the history of cancer.

Although rare, other gynecologic cancers can have profound effects on sexual functioning. In spite of being the third most common gynecologic cancer, ovarian cancer patients have been less frequently studied.<sup>152</sup> Most experience all of the physical changes associated with the treatment of uterine and cervical cancer due to surgical removal of the uterus and ovaries. However, treatment of these patients is often dominated by the use of systemic or intraperitoneal chemotherapy and the side effects of this treatment, especially decreased physical functioning, fatigue, pain, and abdominal discomfort. Symptoms of advanced cancer significantly impact sexual functioning in these women.

Sexual functioning after vulvar cancer has been examined in two series.<sup>153,154</sup> In Andersen et al.'s study,<sup>153</sup> women with *in situ* vulvar cancer were compared with a matched sample of gynecologically healthy women. They found a higher rate of inhibited sexual excitement and inhibited orgasm among the women with cancer, as well as an increasing rate of sexual inactivity over time, compared with the healthy women. As might be predicted, the wider the surgical excision, the greater the magnitude of sexual disruption.<sup>153</sup> In a prospective study of ten couples, with the women being treated for vulvar cancer with radical vulvectomy, Weijmar Schultz et al.<sup>154</sup> found a postoperative decline in functioning with gradual recovery over 2 years. However, genital symptoms of sexual arousal and satisfaction were diminished in the cancer group and did not return to levels of those found in the control group.<sup>154</sup> Importantly, general satisfaction with sexual interaction with the partner hardly changed over a 2-year period of observation.<sup>154</sup>

## HODGKIN'S DISEASE

As a group, patients with Hodgkin's disease can anticipate long-term survival and cure. Therefore, the impact of disease and treatment on sexual functioning is an

important consideration. Several groups have studied the long-term psychosocial outcomes for this group of patients. <sup>32,45</sup> Hodgkin's disease survivors in one study <sup>32</sup> (n = 273) were found to have elevated levels of psychological distress, on average, compared to healthy controls, and those survivors in greater distress reported more problems in other areas of functioning, including sexual problems. When survivors rated their overall current sexual satisfaction, the median scores were similar to healthy subjects. However, when asked to consider the effect of cancer on their sexual life, 37% reported one or more sexual problems, primarily because of decreased sexual satisfaction (31%), interest (21%), and activity (18%). Of these survivors, 26% had been tested and were told they were infertile, and an additional 27% believed that they were infertile. <sup>32</sup> In addition, all survivors who were not currently married experienced higher distress than those who were married, and 56% of those who were separated or divorced attributed their marital status to having had cancer. <sup>32</sup> Although these data are not controlled, from the patient perspective, the disease and its treatment has had a substantial effect on sexual functioning. However, in a comparative study of survivors of acute leukemia, <sup>33</sup> the same investigators found substantially more psychological distress and poorer sexual functioning among the Hodgkin's disease survivors than those with leukemia. These authors suggest that the risk of second malignancies, relapse, and infertility are likely contributors to the greater problems in adjustment among the Hodgkin's disease survivors. <sup>33</sup>

In another comparative study, Bloom et al. <sup>136</sup> examined the psychosocial outcomes of testicular cancer and Hodgkin's disease to test the hypothesis that more specific dysfunction and less hiding of symptoms would be found among the testicular cancer patients. The main differences were in physical activity, fatigue, and vigor (worse for Hodgkin's disease) and decrease in quality of orgasm (worse for testicular cancer), with no difference in psychological distress between the two groups of patients. In addition, no differences between the two sites were found in terms of body image. <sup>136</sup> As noted by these authors, <sup>136</sup> without concurrent data on healthy controls, it is uncertain how much sexual dysfunction may be specifically related to the disease, its treatment, age, or other unmeasured variables.

## COLORECTAL CANCER

Colorectal cancer is a disease of older individuals, with most cancers occurring in persons older than 60 years of age. There is a paucity of specific literature on sexual dysfunction in this population, but the information that is available focuses on the consequences of abdominoperineal resection and ostomies. In a review of sexual functioning in women after radical surgery for rectal cancer, <sup>155</sup> prospective studies of small samples suggest a decline in sexual activity postoperatively, with declines in interest, lubrication, and orgasmic activity. In a study comparing abdominoperineal resection with colostomy and low anterior resection, sexual functioning was preserved at a higher rate with low anterior resection. Overall, the prognostic variables most influencing posttreatment sexual functioning include the woman's age at surgery, the magnitude of the surgical intervention, handmade versus stapled anastomoses, and the number of autonomic nerves present in the surgical specimen. <sup>155</sup>

For men, similar issues pertain; however, erectile dysfunction is a more salient issue. <sup>156</sup> In a study of 60 sexually active men surgically treated for colorectal cancer, Koukouras et al. <sup>156</sup> found that sexual activity was decreased in 32% of patients. The distribution of difficulties among those affected were dry ejaculate (25%), erection not firm enough for penetration (45%), and complete absence of erection (25%). The decreases in sexual functioning occurred in all groups of patients, from high anterior resection to low anterior resection to abdominoperineal resection, but were most frequent in those with abdominoperineal resection. <sup>156</sup>

In another report, Sprangers et al. <sup>42</sup> reviewed the quality of life in colorectal cancer according to whether a sphincter-preserving procedure was performed. They found that stoma patients reported higher levels of psychological distress than nonstoma patients and that sexual functioning of male and female stoma patients is consistently more impaired than that of patients with intact sphincters. Both groups, however, are troubled by frequent and irregular bowel function that can increase psychological distress and affect sexual functioning. <sup>42</sup>

## STRATEGIES FOR ASSESSMENT AND INTERVENTION

### ASSESSMENT

A comprehensive assessment of sexual difficulties requires an interdisciplinary and multifaceted approach that is often beyond the scope of the oncology team. Depending on the particular problem(s), it can be important to consider hormonal, physiologic, anatomic, psychological, cognitive, behavioral, relational, and cultural factors in a biopsychosocial model <sup>6</sup> (see [Table 56.3-1](#)). To provide a differential diagnosis, it also is necessary to assess for psychopathology, medical conditions, substance abuse, and relationship difficulties as primary etiologic factors. Modes of assessment include open-ended conversations, structured diagnostic interviews, standardized self-report questionnaires, medical examination, and laboratory studies. Several volumes are available for readers who wish to learn about specific assessment procedures. <sup>2,4,17,157</sup>

Although a comprehensive assessment is unrealistic within the constraints of an oncology practice, a preliminary review of sexual difficulties *is essential* to providing optimal care to the cancer patient. Patients regularly report that they would like to discuss sexual issues with their physicians but feel reluctant to do so. <sup>24,114</sup> Therefore, it is up to the medical team to broach the issue and open lines of communication. Straightforward questions about each of the four categories of sexual dysfunction—desire, arousal, orgasm, and pain—and questions about sexual activity and satisfaction generally provide sufficient information to determine the need for further testing or referral. <sup>11,158</sup> One member of the team could be identified as a primary resource for assessment and referral.

### COUNSELING, INTERVENTION, AND REFERRAL

After a member of the oncology team has raised the issue of sexuality and made a preliminary assessment of reported problems, a decision must be made regarding the level and type of intervention that is needed. <sup>159</sup> In some cases, the specific concerns that arise can be addressed directly by a member of the team who has developed expertise in sexuality and cancer. Providing patients and (when appropriate) their partners with information about sexual functioning, aging, and sexual problems related to the cancer experience can help to normalize the concerns that arise for some patients. Patients also can benefit from receiving written materials, such as those available from the National Cancer Institute and the American Cancer Society or produced by other experts. <sup>160</sup> They may also benefit from learning about local resources for cancer patients and survivors. For limited problems, specific suggestions or a brief course of sexual counseling may be sufficient. For example, for a woman with vaginal dryness who cannot use estrogen, a vaginal lubricant or moisturizer might be extremely effective. Schover and colleagues <sup>16</sup> found that 63.5% of cancer patients who received brief sexual counseling within a cancer center reported improvement. Patients who were depressed or in conflicted marriages were least likely to benefit.

When the patient has more complex problems, it may be necessary to provide a referral to a mental health professional with special training in sex therapy, marital therapy, or individual psychotherapy with cancer patients. The oncologist can play a pivotal role in ensuring successful treatment by making appropriate referrals that normalize the need for therapy. In addition, specific medical interventions such as those detailed in the next two sections may be helpful.

### MEDICAL INTERVENTIONS FOR WOMEN

One of the most important targets for intervention in women is vaginal dryness. This problem is common for women as they age, independent of cancer treatment, and is usually managed with some form of estrogen therapy. In women who can receive estrogen therapy after cancer, this treatment is the most effective therapeutic remedy, and it can be used topically or systemically. The role of hormone replacement in addressing sexual functioning after intensive chemotherapy should not be underestimated. In a study of the prevalence and predictors of sexual dysfunction in long-term survivors of bone marrow transplantation, Syrjala et al. <sup>161</sup> found that women reported significantly more sexual dysfunction than men. The number of women with lubrication problems increased from 30% before transplantation to 49% at 1 year posttransplantation and 52% at 3 years posttransplantation. <sup>161</sup> This finding was associated with a doubling in the rate of women reporting pain with intercourse, from 14% at pretransplantation to approximately 34% posttransplantation. In addition, this study's authors found a significant difference in sexual satisfaction at 3 years for those who had received hormone replacement therapy by 1 year compared to the 15% of women who had not. Changing hormone replacement therapy after 1 year, either by starting therapy or electing to stop hormone therapy, did not show a measurable influence on reported sexual satisfaction at 3 years. <sup>161</sup> This finding suggests that once sexual problems are established early after cancer treatment (vaginal dryness, dyspareunia), it may be more difficult to restore satisfactory sexual activity. Thus, early intervention with hormonal therapy should be considered for patients receiving chemotherapy if it is not otherwise contraindicated.

In breast cancer patients and survivors, the use of hormone replacement therapy is much more controversial (see discussion of menopause earlier in [Menopause and Sexual Functioning](#)). As a result, nonestrogen alternatives are often considered first in the management of vaginal dryness. One randomized controlled trial comparing estrogen to the vaginal moisturizer Replens has demonstrated improvement in vaginal cytology with this preparation in healthy women. <sup>162</sup> The North Central Cancer Treatment Group has tested the efficacy of Replens for the management of vaginal dryness and dyspareunia in a placebo-controlled trial. <sup>163</sup> They

found this product to be effective in relieving symptoms; however, similar results were seen with the placebo (K-Y Jelly), which was apparently not an inert substance. A discussion of these nonestrogen alternatives is reviewed elsewhere.<sup>164,165 and 166</sup> If these therapies do not work, the use of the estrogen-impregnated product Estring can be considered for topical relief of symptoms without significant systemic absorption.<sup>167</sup>

In a study addressing menopausal symptoms in breast cancer survivors, Ganz et al.<sup>168</sup> found that most of the women who wanted some form of treatment were highly symptomatic, with more than 80% having two of three symptoms (hot flashes, vaginal dryness, urinary incontinence). Using education, counseling, lifestyle modifications, and several pharmacologic agents (Bellergal-S, clonidine patch, megestrol acetate, Replens), after a 4-month period of intervention, a significant improvement in the target menopausal symptoms and sexual functioning in the women assigned to treatment was demonstrated, compared to a no-treatment control group. Unlike the single-agent pharmacologic trials, this study tried to address all three symptoms simultaneously, as well as tailor the treatment strategies to the individual's needs and her willingness or unwillingness to take a medication.

Other important strategies to consider are the treatment of psychological distress and marital or partner difficulties. In both healthy women and women with breast cancer,<sup>13,43</sup> distress in these domains has been shown to influence sexual functioning and satisfaction. Control of pain and other symptoms may also be critical for assuring sufficient relaxation to allow women to engage in meaningful sexual activities.

## MEDICAL AND SURGICAL INTERVENTIONS FOR MEN

The clinical management of cancer patients with erectile dysfunction should follow the same algorithms used in men presenting primarily for evaluation of impotence. Even when other interventions are prescribed, brief sexual counseling in the primary oncology setting can play a critical role in the care of the patient.<sup>169</sup> The model currently used in the management of patients with erectile dysfunction involves a stepwise approach.<sup>169</sup> First-line therapies are selected based on their ease of administration, reversibility, and noninvasiveness. Oral erectogenic agents, such as sildenafil, yohimbine, trazodone, and phentolamine, have gained widespread popularity, largely because of the convenience and effectiveness of sildenafil.<sup>170</sup> Sildenafil works in most forms of erectile dysfunction and has few side effects. It is a selective type 5 phosphodiesterase inhibitor, which increases penile cyclic guanosine monophosphate, thus enhancing the effect of nitric oxide in response to sexual stimulation. In the penis, the effect of sildenafil is to increase cavernosal smooth muscle dilation, a requisite component of erection. At doses of 25, 50, or 100 mg taken 30 to 60 minutes before sex, it is successful in approximately 70% of impotent men. Side effects are minor and may include mild headache, facial flushing, rhinitis, dyspepsia, or blue-hued vision.<sup>171</sup> Sildenafil is thought to have been partially responsible for mortality in a very small percentage of cases by interacting with medicinal or recreational nitrates or by allowing sexual overexertion in men with severe cardiac disease. It should never be used concomitantly with nitrates. Apomorphine, another oral erectogenic whose U.S. Food and Drug Administration approval is reportedly imminent, is thought to work by interacting with central and peripheral dopaminergic pathways in impotent men.<sup>172</sup>

Another noninvasive technique is the penile vacuum erection device (VED).<sup>173,174 and 175</sup> Although it is somewhat more cumbersome and requires training, a substantial minority of patients prefer the VED for its simplicity, safety, and effectiveness. A clear, plastic, hollow cylinder is placed around the penis and sealed at the skin with lubricant. A small handheld pump, attached by a rubber tube to the tip of the cylinder, is activated, creating a vacuum around the penis within the cylinder. This draws blood into the erectile bodies and creates an erection. Once the penis becomes tumescent, a rubber constriction band is placed around the base of the penis to retain the erection, and the cylinder is removed. After sex, the band is removed, allowing the penile blood to drain. Few risks are associated with use of the VED.

Second-line therapies involve the administration of pharmacologic vasodilators, either by direct intracavernosal needle injection<sup>176</sup> or by intraurethral suppository.<sup>177</sup> Injections typically include prostaglandin E<sub>1</sub> alone (marketed as Caverject or Edex) or in combination with papaverine or phentolamine. The intraurethral suppository (marketed as Muse) contains prostaglandin E<sub>1</sub> alone in doses of 5, 10, or 20 µg. Both methods function by producing dilation of the cavernosal smooth muscle, enhancing the vascular component of penile erection. Intracavernosal injection is much more effective than intraurethral administration, but it also carries a greater short-term risk of priapism or pain and the long-term risk of corporal scarring at the injection sites. With intracavernosal medication, the patient is trained to draw up the drug in a tuberculin syringe and inject it into the penis. The patient must take care to place the needle perpendicular to the long axis of the penis and advance it all the way through the subcutaneous fat into the corpus cavernosum. Because of intercavernosal connections, only one corpus needs to be injected to induce erection. The patient must be careful to avoid the nerve bundle dorsally and the urethra ventrally. He must also rotate injection sites and apply 2 to 3 minutes of pressure after injection to avoid bruising. The intraurethral medication is sold as a suppository of 250, 500, or 1000 µg loaded into a small applicator that the patients inserts into his urethral meatus. Once in position, he pushes the medicated pellet out by advancing a small probe. The medication is packaged with pictorial instructions that facilitate patient teaching. With either penile vasodilator, the dose must be individually titrated.

Third-line therapies include the surgical implantation of semirigid or inflatable penile prostheses.<sup>178</sup> The operation is usually performed on an outpatient basis and involves a single, small dorsal or ventral incision at the base of the penis. After dissecting and entering the corpora cavernosa, their internal spongy tissue is compressed with dilators and their size calibrated. The appropriate length prostheses are inserted into both corpora. Semirigid prostheses may contain malleable metal rods encased in silicone, or they may be made of solid silicone. After recovery from surgery, the semirigid penile prosthesis requires no training and is ready for use approximately 8 to 12 weeks postoperatively. Inflatable prostheses contain pliable hollow tubes that are filled with saline from a nearby reservoir by activating a pump. In the three-piece versions, the reservoir is implanted through the groin in the perivesical space, and the pump is implanted subcutaneously in the scrotum. These components are connected to each other and to the cylinders with silicone tubing. A two-piece version is also available, in which the pump and reservoir are combined into one scrotal component. Self-contained inflatable prostheses have the cylinders, reservoir, and pump all located in one structure. These have become the preferred choice because of easier surgical implantation. After recovery, the inflatable prosthesis requires detailed training before the patient becomes comfortable with its use. The primary advantage of the inflatable version is that it appears flaccid when not in use; however, it is also associated with a greater chance of mechanical problems, which may require further surgery. Both semirigid and inflatable prostheses carry some risk of infection, but this complication is uncommon. Placement of a penile prosthesis is an invasive maneuver, in which any residual existing erectile capacity is lost. This option is reserved for the most severe and refractory cases of erectile dysfunction. If the devices ever require removal, natural erections are unlikely to return.

## CONCLUSIONS

It is important to recognize that sexual problems are prevalent in the general population and that age-related changes in sexual interest and responsiveness occur naturally. When one adds a cancer diagnosis and its treatments to this background environment, existing sexual problems can be exacerbated, and an active sex life may cease for some cancer patients. Understanding the natural history of sexual problems associated with specific treatments and cancers can enhance the ability of clinicians to detect sexual problems in the patients under their care. Because patients seldom directly express sexual concerns to their health care provider either before or after cancer treatment, it is essential that these issues be brought up with patients in a routine and matter-of-fact way. The treating oncologist should find a comfortable way to ask, "How is your sex life going?" Often, a good time to ask this question is somewhere in the middle or toward the end of a treatment course. This can serve as a "check-in" to let the patient know the oncologist is willing to talk about these issues. If the patient has no problems or is not interested in talking, the conversation ends there. However, patients know that they can bring up the topic in the future if they wish. Similarly, patients who are anxious to share concerns about sexual functioning appreciate the opportunity to discuss the specific problems. The health care professional can often provide information, reassurance, referrals, and specific remedies (e.g., treatment for vaginal dryness, medication of erectile dysfunction, treatment of pain).

Another perspective that is often overlooked is that of the young adult with cancer. Even more challenging than when a spouse is present is the young man with testis cancer, the young woman with breast cancer, or the teenager with lymphoma. With less experience and self-confidence, these individuals may be even shyer about bringing up the topic of sexuality with their oncologists. For the young adult with cancer, it is especially incumbent upon the clinician to talk about sex during and after treatment. In these situations, the difficult questions may be, for example, "Should I tell a new romantic interest about the cancer on the first date, or should I wait?" Of course, these problems are relevant for the single patient at any age.

With the increasing media attention given to sexual health in the general population, patients now expect their physicians to be well informed and receptive to discussing these issues. The very privileged relationship that oncologists have with their patients with cancer, guiding them through treatment decisions for a life-threatening condition, should permit the physician to assist the patient with this aspect of health and recovery. We are fortunate that a growing body of research on sexual health after cancer now exists, which can inform and guide those discussions.

#### INTRODUCTION

The availability of clinically based genetic testing has brought with it a growing demand for accurate risk assessment and cancer genetic counseling. Extensive coverage of this topic by the media and widespread advertising by commercial testing laboratories has further fueled the demand for counseling and testing.

The field of cancer genetic counseling is evolving rapidly to meet the newfound needs of patients and the medical community. Cancer genetic counseling is a communication process between health care professionals and individuals concerning cancer occurrence and risk in their family. <sup>1</sup> The process, which may include the entire family through a blend of genetic, medical, and psychosocial assessment and intervention, has been described as a bridge between the fields of traditional oncology and genetic counseling.<sup>1</sup>

The goals of this process include providing clients with an assessment of individual cancer risk while offering the emotional support needed to understand and cope with this information.<sup>2</sup> The process also involves deciphering whether the cancers in a family are likely to be caused by a mutation in a cancer gene and, if so, which one. To achieve the informed consent crucial to the testing process, each patient is thoroughly counseled about the associated risks, benefits, and limitations of testing. If the patient is interested in pursuing testing, the counselor will identify a laboratory that offers appropriate genetic testing and will facilitate sample collection and shipping and result interpretation. The result session will include detailed counseling about medical management options for early detection and risk reduction counseling and may include referrals to prevention trials, surveillance programs, and medical specialists.

Counselors find that this process differs from traditional genetic counseling in several ways. Clients seeking cancer genetic counseling are rarely concerned with reproductive decisions and risks that are often the primary focus in traditional genetic counseling but are instead seeking information about their own and other relatives' chances of developing cancer.<sup>3,4</sup> Additionally, the risks given are not absolute but change over time as the family and personal history changes and the patient ages. Perhaps the greatest divergence from traditional genetic counseling is the departure from nondirectiveness. *Nondirectiveness*, one of the cornerstones of traditional genetic counseling, can be loosely defined as the tenet of presenting clients with accurate genetic and medical information, providing them with their options, helping them to choose the option that best fits their needs (free of coercion from the counselor regarding which choices are "right" or "wrong"), and then supporting their decision. Nondirectiveness is not always appropriate in cancer genetic counseling. Standard screening guidelines and prevention strategies are presented as recommendations,<sup>5</sup> and the counselor is often proactive in promoting behavioral changes that could reduce the risk of developing cancer.<sup>3</sup> Counseling for susceptibility testing is based on the nondirective framework, although some data indicate that patients desire more assistance in decision making than their health care providers offer.<sup>6</sup> Helping patients reach the decision that is most consistent with their personal values and goals and that is best suited to their personal situation is the ultimate goal of genetic counseling.

Why is cancer genetic counseling necessary? The advances in cancer genetics bring with them new issues involving the medical, psychological, discriminatory, and ethical side effects of genetic testing for cancer predisposition.<sup>7</sup> Potential clients must be made aware of these risks before testing and, when possible, assisted in avoiding pitfalls. Additionally, the public demands this resource.<sup>8</sup> Several studies have documented a high level of interest in genetic testing among people who have one first-degree relative with diagnosed cancer.<sup>9,10,11,12</sup> and <sup>13</sup> Although anticipated interest in testing generally overestimates actual uptake,<sup>14,15,16</sup> and <sup>17</sup> the need for cancer genetic counseling is great and is bound to grow as more genes are cloned.

At present, a limited number of referral centers across the country specialize in cancer genetic counseling. Graduate programs in genetic counseling are actively integrating this new body of knowledge into their curricula and are producing more counselors who can provide cancer services. However, some experts insist that the only way to keep up with the overwhelming demand for counseling will be to educate more physicians and nurses in cancer genetics.<sup>18,19</sup> The feasibility of adding another time- and energy-consuming task to the clinical burden of these professionals is questionable. A more practical goal may be to educate primary care providers better in the area of generalized risk assessment so that they can screen their patient populations for individuals at high risk for hereditary cancer and refer them to comprehensive counseling and testing programs.

#### WHO IS A CANDIDATE FOR CANCER GENETIC COUNSELING?

Only 5% to 10% of most cancers are due to mutations within inherited cancer susceptibility genes.<sup>20</sup> The key for the clinician is to determine which patients are at greatest risk to carry one of these mutations. Six risk factors that are common among hereditary cancer families have been identified ( [Table 56.4-1](#) ). The first is early age of cancer onset. This risk factor, even in the absence of a family history, has been shown to be associated with an increased frequency of germline mutations in many types of cancers.<sup>21,22,23,24,25</sup> and <sup>26</sup> The second risk factor is the presence of the same cancer in multiple affected relatives on the same side of the pedigree that are consistent with autosomal dominant inheritance. These cancers do not necessarily have to be of similar histologic type to be caused by a single mutation. The third risk factor is the clustering of cancers known to be caused by a single gene mutation in one family. Examples include breast-ovarian cancer, pancreatic cancer–melanoma, and colon-ovarian-uterine cancers. The fourth risk factor is the occurrence of multiple primary cancers in one individual. This includes multiple primary breast cancers, colon cancers, and melanomas and a single individual with separate cancers known to be caused by a single gene mutation (e.g., breast and ovarian cancer in a single individual). Ethnicity also plays a role in determining who is at greatest risk to carry a hereditary cancer mutation. Individuals of Jewish ancestry are at increased risk to carry three specific BRCA1/2 mutations<sup>27</sup> and the I1307K APC allele.<sup>28</sup> Founder BRCA1/2 mutations have also been discovered in families of French Canadian descent, and mutations in cancer susceptibility genes are likely to be identified in other ethnicities as more subpopulations are studied.<sup>29,30,31</sup> and <sup>32</sup> The final risk factor for a hereditary cancer syndrome is the presence of a cancer that presents unusually, the prime example of which is breast cancer in a man. These risk factors should be viewed in the context of the entire family history and must be weighed in proportion to the number of individuals who have not developed cancer.

---

Early age of onset
Presence of the same cancer in multiple family members on the same side of the pedigree
Clustering of cancers known to be caused by a single gene mutation (e.g., breast-ovarian cancers, colon-uterine-ovarian cancers)
Multiple primary cancers in one individual
Ethnicity (e.g., Jewish ancestry for breast-ovarian cancer syndrome)
Unusual presentation of cancer (e.g., breast cancer in a man)

---

**TABLE 56.4-1.** Risks Factors for Hereditary Cancer Syndromes

A less common but extremely important finding is the presence of birth defects or unusual medical findings that are known to be associated with rare hereditary cancer syndromes. Examples include benign skin findings and thyroid disorders in Cowden syndrome, sebaceous skin tumors in Muir-Torre syndrome, and supernumerary teeth in familial adenomatous polyposis (FAP).<sup>33</sup>

Another class of candidates for genetic counseling are those patients who are very concerned about their risks for cancer, even in the absence of a strong family history. Many patients overestimate their risks to develop cancer. This inaccurate perception of risk may have a profound effect on a patient's anxiety level and quality of life and may have a negative impact on his or her surveillance patterns.<sup>34</sup> Such patients may gain reassurance and empowerment from learning their actual—as compared to their anticipated—risks for developing cancer and their options to reduce those risks.

At present, breast-ovarian cancer syndrome referrals account for the majority of patients seen in the average cancer genetic counseling clinic. In this chapter, the breast-ovarian cancer counseling session will serve as a paradigm that all other sessions may follow broadly.

## COMPONENTS OF THE CANCER GENETIC COUNSELING SESSION

### PRECOUNSELING INFORMATION

Before coming in for genetic counseling, the counselee should be given some basic information about the process. This information, which can be imparted by telephone or in the form of written material, should outline what the counselee can expect at each session and what information he or she should collect before the first visit. The counselee can then begin to collect medical and family history information that will be essential for the genetic counseling session.

### FAMILY HISTORY

An accurate family history is undoubtedly one of the most essential components of the cancer genetic counseling session. Despite its importance, the thorough family cancer history has been called “the most severely neglected portion of the patient's medical evaluation,”<sup>35</sup> possibly reflecting a lack of emphasis placed on the family history during the primary and postgraduate education of physicians.<sup>36</sup> It may also be due, in part, to the lack of knowledge about what to do with the information once it has been collected.

A thorough family history should include at least two, optimally three, generations.<sup>37</sup> For each individual affected with cancer, it is important to document the exact diagnosis, age at diagnosis, treatment strategies, and environmental exposures (i.e., occupational exposures, cigarettes, other agents).<sup>5</sup> The current age of the individual and laterality and occurrence of any other cancers must also be documented.<sup>3</sup> Individuals should be asked whether there are any consanguineous (inbred) relationships in the family, whether any relatives were born with birth defects or mental retardation, and whether other genetic diseases run in the family, as these pieces of information could prove important in reaching a diagnosis and in counseling.

It is advised that cancer diagnoses be documented with pathology reports, hospital summaries, or other medical records to maintain accuracy.<sup>3</sup> A study by Love et al.<sup>38</sup> revealed that individuals accurately reported the primary site of cancer only 83% of the time in their first-degree relatives with cancer and 67% and 60% of the time in second- and third-degree relatives, respectively. It is common for patients to report a uterine cancer as an ovarian cancer or a colon polyp as an invasive colorectal cancer. These differences, although seemingly subtle to the patient, can make a tremendous difference in risk assessment.

The most common misconception in family history taking is that somehow a maternal family history of breast, ovarian, or uterine cancer is more significant than a paternal history. Conversely, many still believe that a paternal history of prostate cancer is more significant than a maternal history. Few of the cancer genes discovered thus far are located on the sex chromosomes; therefore, both maternal and paternal history are significant and must be explored thoroughly.

### DYSMORPHOLOGY SCREENING

Congenital anomalies, benign tumors, and unusual dermatologic features occur in a large number of hereditary cancer predisposition syndromes. Examples include osteomas of the jaw in FAP, palmar pits in Gorlin syndrome, and papillomas of the lips and mucous membranes in Cowden syndrome. Obtaining an accurate medical history of benign lesions and birth defects and screening for such dysmorphology can have a great impact on diagnosis and counseling. For example, BRCA1/2 testing is unnecessary in a patient with breast cancer who has a family history of thyroid cancer and the orcutaneous manifestations of Cowden syndrome.

### RISK ASSESSMENT

Risk assessment is one of the most complicated components of the genetic counseling session. It is crucial to remember that risk assessment changes over time as the person ages and as the health status of family members changes.<sup>3</sup> Risk assessment can be broken down into three separate components: What is the chance that the counselee will develop the cancer observed in his or her family (or a genetically related cancer)? What is the chance that the cancers in this family are caused by a single gene mutation? What is the chance that we can identify the gene mutation in this family with our current knowledge and laboratory techniques?

Cancer clustering in a family may be due to genetic or environmental factors (or both) or may be coincidental because some cancers are common in the general population. Although inherited factors may be the primary cause of cancers in some families, in others cancer may develop because an inherited factor increases the individual's susceptibility to environmental carcinogens.<sup>39</sup> It is also possible that members of the same family may be exposed to similar environmental exposures, owing to shared geography or patterns in behavior and diet that may increase the risk of cancer.<sup>40</sup> Therefore, it is important to distinguish the difference between a familial pattern of cancer (due to environmental factors or chance) and a hereditary pattern of cancer (due to a shared genetic mutation).

Several models are available to calculate the chance that a woman will develop breast cancer. Each model has its strengths and weaknesses, and the counselor must decide which model is most appropriate for each individual family. The Gail model for calculating risk takes into account current age, age of first menses, age at first live birth, and number of previous biopsies.<sup>41</sup> This model may be problematic for women who cannot recall their exact age at menses and who are followed more aggressively than women without a positive family history and, therefore, may be subjected to biopsy more frequently. Biopsy results are not considered in this model, so a normal biopsy is weighed equally with a result of atypical hyperplasia. It has also been suggested that the importance of general risk factors for breast cancer, such as age at first menses and first live birth, may vary in hereditary cancer families.<sup>42</sup> A modified form of the Gail model was used to determine entry into the National Surgical Adjuvant Breast and Bowel Project (NSABP) Breast Cancer Prevention Trial and will also be used for entry into the NSABP P-2 STAR trial.<sup>43</sup> Although this model has utility in determining entry for trials and may be of use for women in the general population who receive frequent breast screening, it is not appropriate in families in which there is a question of a hereditary cancer syndrome. The Gail model considers only first-degree relatives in its calculations and, therefore, does not take into account paternal family history and extended family members. It does not weigh ovarian cancer, Jewish ancestry, male breast cancer,

and other factors essential in hereditary risk assessment and is, therefore, not the appropriate tool when hereditary cancer is in question.

Claus et al.<sup>44</sup> created a model that considers limited paternal and maternal family history as well as age of onset of affected relatives in determining empiric cancer risk. This model allows calculation of individual risk by decade and by lifetime, which is useful in helping women understand that their risk accumulates over time and is not clumped at their current age. This model does not take ancestry, ovarian cancer, or extended family history into account and is, therefore, not useful in families in which there appears to be a genetic mutation. Of course, all empiric risks are superseded in families in which DNA testing has revealed a mutation for cancer predisposition.

When the BRCA1 gene was mapped, risk tables were created based on linkage data from high-risk breast and ovarian cancer families. These tables estimated the chance that the cancers found in hereditary breast-ovarian cancer families were due to mutations in BRCA1, and these estimates were fairly high.<sup>45</sup> When direct mutation analysis for BRCA1 became available, the number of families found to carry a mutation was significantly smaller than predicted by linkage studies. This finding suggests that current techniques do not detect all mutations within the gene. More recent tables reflect the chance of actually finding a mutation within BRCA1.<sup>46</sup> Parmigiani et al.<sup>47</sup> have developed a more sophisticated computer model that calculates the probability of finding a BRCA1 or 2 mutation in a family using a variety of risk factors. This model is being validated.

## DNA TESTING

DNA testing is available for a variety of hereditary cancer syndromes [e.g., breast-ovarian cancer syndrome, hereditary nonpolyposis colon cancer (HNPCC), and hereditary melanoma]. However, despite misrepresentation by the media,<sup>48</sup> testing is feasible for only a small percentage of individuals with cancer. DNA testing offers the obvious and important advantage of presenting clients with actual risks instead of the empiric risks derived from risk calculation models.

The results of DNA testing are generally provided in person in a result disclosure session. It is recommended that patients bring a close friend or relative with them to this session who can provide them with emotional support and who can help them to listen to and process the information provided.

One of most crucial aspects of DNA testing is accurate result interpretation. One study found that test results for the hereditary colon cancer syndrome FAP were misinterpreted more than 30% of the time by those ordering the testing.<sup>49</sup> The potential impact of test results on the patient and his or her family is great; therefore, accurate interpretation of the results is paramount.

Results of genetic testing fall into three categories: true positive, whereby an individual is found to carry a mutation that is known to be deleterious; true negative, whereby an individual does not carry the deleterious mutation found in their family and, therefore, the cancer risks are reduced to the population risks; and indeterminate, whereby a mutation cannot be identified in the affected family members or a genetic change is identified with unknown significance. This result category is currently the most common outcome.

To pinpoint the mutation in a family, an affected individual likely to carry a mutation should be tested first. This is most often a person affected with the cancer in question (i.e., the proband). Test subjects should be selected with care, as it is possible for a person to develop sporadic cancer in a hereditary cancer family. If a mutation is detected in an affected relative, other unaffected family members can be tested for the same mutation with a great degree of accuracy. Family members who do not carry the mutation found in their family are deemed to be true negative. Those who are found to carry the mutation in their family will have more definitive information about their risks to develop cancer. This information can be crucial in assisting patients in decision making regarding surveillance and risk reduction.

If a mutation is not identified in the affected relative, it usually means either that the cancers in the family are not caused by a single genetic mutation or that the mutation in the family is undetectable by current methods. Such results are indeterminate, and other family members cannot be offered accurate predisposition testing. In some such cases, DNA banking should be offered to the proband for a time in the future when improved testing may become available. A notarized letter indicating exactly who in the family has access to the DNA should accompany the banked sample.

The result stated as "genetic variant of uncertain significance" must be interpreted with caution. Sometimes, other affected family members can be tested to see whether the variant segregates with disease in the family. Most of the time, the significance of the variant remains unknown until functional studies are conclusive or further data are available.

The penetrance of mutations in cancer susceptibility genes is also difficult to interpret. Initial estimates derived from high-risk families provided very high cancer risks for BRCA1 and BRCA2 mutation carriers.<sup>45</sup> More recent studies of populations that were not selected for family history have revealed lower penetrances.<sup>27</sup> Some have interpreted these population-based data as being "more accurate" and have suggested that they apply to all families. In fact, the higher range of risk may be more accurate for families who present with strong histories of breast and ovarian cancer. Because exact penetrance rates cannot be determined for individual families at this time, it is prudent to provide patients with a range of cancer risk and to explain that their risk probably falls somewhere within this spectrum.<sup>50,51</sup>

Female carriers of BRCA1 and BRCA2 mutations have a 50% to 85% lifetime risk of developing breast cancer and between a 15% to 60% lifetime risk of developing ovarian cancer.<sup>27,45,52,53,54,55,56</sup> and <sup>57</sup> Carriers of HNPCC mutations have a 65% to 85% lifetime risk of developing colon cancer, and female carriers have a 30% to 40% lifetime risk of uterine cancer and as great as a 10% risk of ovarian cancer.<sup>58,59</sup>

## OPTIONS FOR SURVEILLANCE AND RISK REDUCTION

The cancer risk counseling session is a forum to provide counselees with choices, options, and hope ( [Table 56.4-2](#)). Mutation carriers can be offered earlier and aggressive surveillance, chemoprevention plus surveillance, or prophylactic surgery.

Cancer Type	Genetic Testing	Surveillance	Risk Reduction
Breast	BRCA1, BRCA2	Biopsy of examination, clinical breast examination, mammography	Prophylactic bilateral mastectomy, tamoxifen <sup>60</sup>
Ovary	BRCA1, BRCA2, MLH1, MSH2	CA-125, transvaginal ultrasonography	Prophylactic oophorectomy and salpingectomy
Colon	MLH1, MSH2, APC	Colonoscopy	Prophylactic colectomy, colectomy with ileostomy <sup>61</sup>
Melanoma	CNN1, CDH1	Skin examination, clinical skin examination	Avoidance of ultraviolet light exposure, use of sun screen and protective clothing

Investigate.  
Note: Best of likely recommendations for cancer prevention are available through national cancer organizations.

**TABLE 56.4-2.** Methods for Surveillance and Risk Reduction for Selected Hereditary Cancers

It is recommended that individuals at increased risk for breast cancer have annual mammograms beginning between ages 25 and 35 years and annual or semiannual clinical breast examinations, and that they perform monthly breast self-examinations.<sup>60</sup> BRCA1/2 carriers may take tamoxifen in hopes of reducing their risks of developing breast cancer. However, although tamoxifen has proven effective in women at risk due to a positive family history of breast cancer, the efficacy of this intervention in BRCA1/2 carriers is still unknown.<sup>61</sup> The results of preliminary studies indicate that a second chemopreventive agent, raloxifene (EVISTA), may also be effective in reducing the risk of breast cancer in healthy postmenopausal women.<sup>62</sup> However, this medication is approved by the U.S. Food and Drug Administration only for the prevention of osteoporosis and has not been studied in BRCA1/2-positive women. A current study, the NSABP P-2 STAR trial, is examining the role of this drug in women at high risk for breast cancer. Data should be available by 2006. Prophylactic bilateral mastectomy is believed to reduce the risk of breast cancer by more than 90% in women at high risk for the disease<sup>63</sup>; however, the efficacy of this procedure specifically in BRCA mutation carriers is unknown. Before genetic testing was available, it was not uncommon for entire generations of cancer families to have their at-risk organs removed without knowing whether they were personally at increased risk for their familial cancer. Fifty percent of individuals in hereditary cancer families do not carry the inherited predisposition gene and can be

spared prophylactic surgery or invasive high-risk surveillance regimens. Therefore, it is no longer appropriate to offer prophylactic surgery until a patient is referred for genetic counseling and, if possible, testing ( [Table 56.4-3](#)).<sup>64</sup>

**TABLE 56.4-3.** Cancer Genetic Counseling and Testing Resources

Women who carry BRCA1/2 mutations are also at increased risk for developing second contralateral and ipsilateral primary tumors of the breast.<sup>65</sup> These data bring into question the option of breast-conserving surgery in women at high risk to develop a second primary tumor within the same breast. For this reason, BRCA1/2 carrier status may have a profound impact on surgical decision making in the future.<sup>64</sup>

Women who carry BRCA1/2 mutations are also at increased risk for developing ovarian cancer, even if no one in their family has developed this cancer. Surveillance for ovarian cancer is complex, with the recommended interventions being annual transvaginal ultrasonography and tests of CA-125 levels beginning between the ages of 25 and 35 years.<sup>66</sup> The effectiveness of such surveillance in detecting ovarian cancers at early and more treatable stages has not been proven in any population. Oral contraceptives have been shown to reduce the risk of ovarian cancer in women carrying BRCA mutations.<sup>66</sup> The impact of this intervention on breast cancer risk is not known. However, it is possible that, given the likelihood of mortality from breast versus ovarian cancer, a risk-benefit analysis would favor the use of oral contraceptives in carriers of BRCA1/2 mutations.<sup>40</sup> Prophylactic oophorectomy is the most effective means to reduce the risk of ovarian cancer,<sup>67</sup> but even women who have had this procedure may develop primary peritoneal carcinoma.<sup>68,69</sup> This condition is clinically and histologically similar to ovarian cancer but appears to arise from the cells lining the peritoneal cavity. Some data indicate that BRCA1 carriers who opt for prophylactic oophorectomy also have a reduced chance of developing a subsequent breast cancer, particularly if they have this surgery before menopause.<sup>70</sup> Premenopausal women who opt for oophorectomy and, therefore, experience premature surgical menopause may be candidates for hormone replacement therapy (HRT) with the lowest dose of estrogen possible.<sup>4c</sup> This may provide some of the benefits of HRT while minimizing the potential breast cancer-related risks. Preliminary data suggest that premenopausal BRCA1 carriers who have oophorectomies followed by HRT still have a reduced risk of future breast cancers.<sup>70</sup>

The standard surveillance method in carriers of HNPCC mutations is full colonoscopy to the cecum every 1 to 3 years beginning between the ages of 20 and 25 years.<sup>71</sup> Although several studies are investigating chemopreventive options for colorectal cancer, no agents are currently approved for clinical use. Prophylactic subtotal colectomy with ileorectal anastomosis is an option for HNPCC carriers, and a decision analysis revealed that this procedure may offer slightly greater gains in life expectancy for young HNPCC carriers than surveillance alone.<sup>72,73</sup>

Options for endometrial cancer surveillance include endometrial aspirate and transvaginal ultrasonography beginning between the ages of 25 and 35 years. The efficacy of such surveillance in HNPCC carriers is unknown. Oral contraceptives are known to reduce the risk of endometrial cancer in the general population,<sup>74</sup> but the impact of this intervention in HNPCC carriers is currently unknown. Prophylactic transabdominal hysterectomy is also an option. Although this option is likely to reduce risk of uterine cancer significantly, long-term prospective studies of the impact of this intervention on HNPCC carriers have not been performed. Women who carry HNPCC mutations are also at risk for ovarian cancer and should, therefore, be offered the aforementioned surveillance and risk reduction options for ovarian cancer.

Management of hereditary melanoma patients involves frequent full-body examination by a dermatologist familiar with pigmented lesions. Semiannual appointments typically include photography of the entire body, to allow for objective determination of differences in size or appearance of moles, and subsequent excision of any suspicious lesions. Avoidance of sunlight exposure is recommended. Melanoma is often curable when diagnosed and treated in an early stage.

Genetic counseling and testing are also available for many rare cancer syndromes, including von Hippel-Lindau syndrome, multiple endocrine neoplasia, and FAP. Surveillance and risk reduction for patients who are known mutation carriers for such conditions may decrease the associated morbidity and mortality of these syndromes.

## **FOLLOW-UP**

A follow-up letter to the patient is a concrete means of documenting the information conveyed in the sessions so that the patient and his or her family members can review it over time. (It is crucial that this letter be sent only to the patient and health care professionals to whom the patient has granted access to this information; in most cases, it should not be placed in the patient's general medical records.) A follow-up phone call is also helpful, particularly in the case of a positive test result. Some programs provide patients with an annual or biannual newsletter updating them on new information in the field of cancer genetics. A small proportion of patients may return for a follow-up counseling session months, or even years, after their initial consult to discuss the emergence of new family history data and new clinical issues or because they are now ready to move forward with genetic testing.

## **ISSUES IN CANCER GENETIC COUNSELING**

### **PSYCHOSOCIAL ISSUES**

The psychosocial impact of cancer genetic counseling cannot be underestimated. Just the process of scheduling a cancer risk counseling session may be fairly difficult for some individuals with a family history who are not only frightened about their own cancer risk but are reliving painful experiences associated with the cancer of their loved ones.<sup>2</sup> Counselees may be faced with an onslaught of emotions, including anger, fear of developing cancer, fear of disfigurement and dying, grief, lack of control, negative body image, and a sense of isolation.<sup>5</sup> Their feelings about cancer will also vary depending on how close they have been to affected individuals, both emotionally and in geographic proximity, and how often they saw these relatives. Some counselees are wrestling with the fear that insurance companies, employers, family members, and even future partners will react negatively to their cancer risks. For many, it is a double-edged sword as they balance their fears and apprehensions about dredging up these issues with the possibility of obtaining reassuring news and much-needed information.

A person's perceived cancer risk is often dependent on many "nonmedical" variables. They may estimate that their risk is higher if they resemble an affected individual or share some of that individual's personality traits.<sup>5</sup> Their perceived risks will vary depending on whether their relatives were cancer survivors or died painful deaths from the disease. Many people wonder not *whether* they are going to get cancer but *when*. Some first-degree relatives of women with breast cancer said they felt as though they were living with a sword over their heads or that they were walking time bombs.<sup>75</sup>

In their study of women with a first-degree relative who had breast cancer, Lerman et al.<sup>76</sup> found that more than one-half of their respondents reported having intrusive thoughts and waves of feelings about breast cancer. More than one-third of these nonaffected women reported breast cancer images and associations that intruded on their awareness, and 20% had difficulty in sleeping because of their breast cancer concerns. Importantly, these authors found that genetic counseling was significantly less effective among women with higher baseline levels of breast cancer preoccupation. Therefore, they concluded that efforts to provide individuals with cancer genetic counseling are not likely to be effective unless their cancer anxieties and feelings are also addressed.<sup>76</sup>

It might be assumed that fear of cancer motivates individuals to increase their cancer awareness and prevention strategies. On the contrary, Kash et al. <sup>34</sup> found that women who perceived their breast cancer risks as high were engaged in *fewer* general preventive health care behaviors (including breast self-examinations and regular clinical breast examinations) than those women who perceived their risks as only moderate. It is theorized that perhaps these individuals believe that they will definitely develop breast cancer and are helpless in decreasing their risks, or perhaps they are completely immobilized by their fear or denial. Whatever the reason for these behaviors, it is obvious that psychological and educational interventions should be a component of cancer genetic counseling.

The counseling session is an opportunity for individuals to express why they believe that they have developed cancer or why their family members have cancer. Some explanations may revolve around family folklore, and it is important to listen to and address these explanations rather than to dismiss them. <sup>5</sup> In doing this, the counselor will allow the clients to alleviate their greatest fears and to give more credibility to the "medical" theory. For patients who are moving forward with DNA testing, a referral to a mental health care professional who can help to facilitate the process is often very helpful.

To date, studies conducted in the setting of pre- and post-genetic counseling have revealed that, at least in the short term, most patients do not experience adverse psychological outcomes after receiving their test results. <sup>77,78</sup> In fact, preliminary data have revealed that individuals in families with known mutations who seek testing seem to fare better psychologically at 6 months than those who avoid testing. <sup>79</sup> Although these data are reassuring, it is important to recognize that genetic testing is an individual decision and will not be right for every patient or every family.

## **PRESYMPTOMATIC TESTING OF CHILDREN**

Presymptomatic testing of children has been widely discussed, and most concur that it is appropriate only when the onset of the condition regularly occurs in childhood or there are useful interventions that can be applied. <sup>80</sup> For example, DNA-based diagnosis of children and young adults at risk for hereditary medullary thyroid carcinoma has improved the management of these patients. <sup>81,82</sup> and <sup>83</sup> DNA-based testing for RET mutations is virtually 100% accurate and allows at-risk family members to make informed decisions about prophylactic thyroidectomy. FAP is a disorder that occurs in childhood and in which mortality can be reduced if detection is presymptomatic. <sup>84,85</sup> Testing is clearly indicated in these instances.

Predisposition testing may also be appropriate if it will be useful to the minor child in making reproductive decisions now or in the near future. <sup>86</sup> Early observations by Malkin et al. <sup>87</sup> indicated an interest among parents in cancer-predictive testing for their children. Their willingness to have their children undergo testing appeared to be dependent on the accuracy of the test and the availability of preventive or curative options. Questions have been raised about parents' right to demand testing for adult-onset diseases. Parents may have a constitutionally protected right to demand that unwilling physicians order this test, but there is little risk for liability for damages unless the child experiences physical harm as a direct result of this refusal. <sup>80</sup> The child's right not to be tested must be considered. Whenever childhood testing is not medically indicated, it is preferable that testing decisions be postponed until the children are adults and can decide for themselves whether to be tested. However, the argument has been made that if a child younger than 18 years is able to appreciate not only the genetic facts but also the emotional and social consequences, he or she should be allowed to have genetic testing. <sup>88</sup> This subject is highly controversial and will likely continue to be debated.

## **CONFIDENTIALITY**

The level of confidentiality surrounding cancer genetic testing is paramount, owing to concerns of genetic discrimination. Many programs are opting to keep shadow files separate from the general hospital charts. Patient-identifying data are generally not entered into computer databases that are accessible by modem or a network of users. Some counseling programs are submitting DNA samples to laboratories by coded number only in an attempt to increase the level of confidentiality. Special precautions to protect confidentiality should be taken when leaving voice mail messages, at home and at work, regarding patient appointments. Conversations with patients or other colleagues via E-mail that include patient names are discouraged, as the Internet is not secure. Additionally, genetic counseling summary letters are sent directly to patients and are copied to the referring physicians only with the explicit permission of the patient. These measures are taken because confidentiality and genetic discrimination are a grave concern for many of the patients seen in the cancer genetic counseling clinic. <sup>15,74,89</sup>

Confidentiality of test results within a family can also be an issue, as genetic counseling and testing often reveal the risk status of family members other than the patient. Under confidentiality codes, the patient should grant permission before at-risk family members can be contacted. It has been questioned whether family members could sue a health care professional for negligence if they were identified as at high risk yet not informed. <sup>90</sup> Most recommendations have stated that the burden of confidentiality lies between the provider and the patient. However, more recent recommendations state that confidentiality should be violated if the potential harm of not notifying other family members outweighs the harm of breaking a confidence to the patient. <sup>91</sup> There is no patent solution for this difficult dilemma, and situations must be considered on a case-by-case basis with the assistance of the in-house legal department and ethics committee.

Patients should be counseled about the benefits to other family members of knowing testing results but, at present, the decision is ultimately the patient's. Extended family members who are notified with the patient's consent may not always be grateful to receive this information and may think that their privacy has been invaded by being contacted.

## **INSURANCE ISSUES**

Insurance companies are, understandably, in the business of making money. Before issuing health insurance policies, some companies determine the risk that an individual carries and adjust the premium to match that risk. <sup>92</sup> Information regarding family history, genetic information, and prior diagnostic testing may very well be used in calculating this risk. This should be clearly conveyed to the patient in the precounseling interview, as it may change the method by which he or she chooses to pay for the session or for testing. These issues should be discussed in detail again in the counseling session. Although individuals and counselors can attempt to keep records and results confidential, there is always a risk that this information will reach insurers.

More and more patients are choosing to submit their genetic counseling or testing charges to their health insurance companies. In the last few years, more insurance companies have agreed to pay for counseling or testing (or both), <sup>93</sup> perhaps in light of decision analyses that show these services and subsequent prophylactic surgeries to be cost-effective. <sup>94</sup> Letters of justification are often required for insurance companies to cover the charges for testing. These letters must clearly delineate the impact of testing on the short- and long-term management of the patient being tested. Justification of testing based on assisting other, unaffected family members is rarely helpful.

## **DISCRIMINATION**

Many health care providers and patients fear that genetic discrimination by health, life, and disability insurance companies resulting from a positive test is a potential hazard of genetic testing. <sup>95,96</sup> Fear of genetic discrimination by patients has been cited as a major deterrent to genetic testing. <sup>15,74,89</sup> Some data indicate that consumer fear of genetic discrimination is out of proportion with the actual amount of discrimination experienced <sup>97</sup>; however, it is well known that current legislation aimed at protecting individuals from genetic discrimination is not without loopholes. <sup>98</sup> Patients should be informed of local and national legislation on genetic discrimination as well as the limitations of these laws.

## **FUTURE DIRECTIONS**

The field of cancer genetic counseling and testing grew tremendously in the late 1990s. Although cancer genetic counseling is targeted at individuals with strong personal or family histories of cancer, it is clear that this focus will broaden over the next decade. Genetic testing may be used to guide surgical decision making, as the risk of new primary tumors is greater in individuals who carry germline mutations. <sup>64,65</sup> Data showing that germline mutations are more frequent in individuals with early-onset breast and colon cancers, even in the absence of a family history of these diseases, will expand the criteria for genetic testing. <sup>21,22,23,24,25</sup> and <sup>26</sup> Specific histologic tumor types may indicate that a patient is at increased risk to carry a germline mutation <sup>99</sup> and may prompt a referral to genetic counseling. The U.S. Food and Drug Administration approval of tamoxifen as a method of breast cancer risk reduction for women at moderately increased risk of the disease will likely bring an onslaught of genetic counseling referrals. These patients will need to know their personal risks of developing breast cancer, and the counseling session will include a detailed discussion of their personal risks for osteoporosis, coronary heart disease, menopausal symptoms, and cognitive deficiencies and the pros and cons of HRT versus selective estrogen receptor modulators, such as tamoxifen. The discovery of modifying genes <sup>100</sup> and specific environmental factors that affect the lifetime risks

of cancer associated with current susceptibility genes will render it possible to refine lifetime cancer risks in individual families.

Perhaps the most profound new direction in cancer genetics will be the integration of genetic testing for high-prevalence, low-penetrance mutations, such as the APC mutation I1307K. I1307K is a common mutation among Ashkenazi Jews that is associated with an increased, but relatively modest, risk of colorectal cancer.<sup>28</sup> The utility of such testing among Jews with a family history of colon cancer has been questioned, as increased surveillance is recommended, owing to the family history, regardless of the test result. Gruber et al.<sup>101</sup> described that Ashkenazi Jewish individuals with no family history of colon cancer may actually derive the most benefit from such testing, as a positive test result would elucidate which patients in that population would benefit from increased colorectal surveillance. This shift in emphasis from rare, high-risk mutation screening to broad screening for lower-penetrance mutations could change the face of the field of cancer genetic counseling.

The combination of technologic advances in genetic testing, new pharmacologic developments for cancer risk reduction, and increased utility for testing in high- and moderate-risk populations will result in a significant expansion in the field of cancer genetic counseling. Maintenance of high standards for thorough genetic counseling, informed consent, and accurate result interpretation will be paramount in reducing potential risks and maximizing the benefits of this technology in the next century.

#### PSYCHIATRIC DISORDERS IN CANCER PATIENTS

One-third of patients with cancer report a degree of anxiety or depression that requires psychiatric treatment.<sup>1,2</sup> In the past, symptoms of emotional distress were often unrecognized, undetected and, as a result, untreated. In this chapter, we review the normal responses to cancer; the most frequently encountered psychiatric disorders; and psychotherapeutic, pharmacologic, and behavioral management of these disorders.

There are characteristic normal responses to receiving a diagnosis of cancer. A period of initial disbelief, denial, or despair is common and generally lasts only a few days. Subsequently, many have a dysphoric mood, with anxiety symptoms, depressed mood, anorexia, insomnia, or irritability lasting a few weeks. The ability to concentrate and to carry out usual daily activities is impaired, and intrusive thoughts of the illness and uncertainty about the future are present. Adaptation usually begins after several weeks and continues for months to years as most patients integrate new information, confront reality issues, find reasons for optimism, and resume activities.<sup>3</sup>

The patient's ability to successfully manage a cancer diagnosis depends on medical, psychological, and social factors and commonly changes over the course of the illness. These factors include the disease itself (i.e., site, symptoms, clinical course, prognosis, type of treatments required); prior level of adjustment, especially to medical illness; the threat that cancer poses to attaining age-appropriate developmental tasks and goals (i.e., adolescence, career, family, retirement); cultural, spiritual, and religious attitudes; the presence of emotionally supportive persons in the patient's environment; the patient's potential for physical and psychological rehabilitation; the patient's own personality and coping style; prior experience with cancer; and history of losses.

#### PREVALENCE

There have been many assumptions about the psychological state of cancer patients, varying between the assumption that all patients must be depressed and need help and the opposite assumption that most manage well and few need psychiatric intervention. Prevalence studies counter these extreme attitudes. In the first comprehensive study, the Psychosocial Collaborative Oncology Group reported that of 215 randomly selected hospitalized and ambulatory patients at three major cancer centers, 47% met criteria for a psychiatric disorder.<sup>4</sup> Of the cancer patients who had an identified psychiatric disorder, 68% had an adjustment disorder with depressed, anxious, or mixed mood; 13% had major depression; 8% had an organic mental disorder (i.e., delirium); 7% had a personality disorder; and 4% had an anxiety disorder. Depressive disorders accounted for the majority of diagnoses. Nearly 90% of the psychiatric disorders observed were either reactions to, or manifestations of, disease or treatment. Only 11% of patients had prior psychiatric illness. Patients with cancer are thus largely psychologically healthy individuals who have emotional distress related to illness. However, there is a significant incidence of psychiatric illness, as approximately 25% of all cancer patients experience significant depression, irrespective of their hospital and physical status.<sup>5</sup>

#### DEPRESSION

Depression is clearly the most prevalent psychiatric symptom in cancer patients. Depression can be distinguished from normal sadness and anticipatory grieving based on the nature and severity of the symptoms, their duration and intensity, and their impact on functioning. Depression in cancer patients results from (1) stress related to the cancer diagnosis and treatment; (2) medications ([Table 56.5-1](#)); (3) underlying neurologic or medical problems, such as nutritional deficiencies (folate, vitamin B<sub>12</sub>), endocrine disturbances (thyroid abnormalities, adrenal insufficiency), brain metastases, and leptomeningeal disease; or (4) recurrence of a preexisting depressive syndrome or bipolar mood disorder. The emotional stress of the cancer experience and medications are the most common causes of depression. Whereas the diagnosis of depression in physically healthy patients depends heavily on the somatic symptoms of anorexia, fatigue, and weight loss, these indicators are of lesser value in the assessment of a cancer patient, since they are common to both cancer and depression. Diagnosis must rest on psychological or cognitive symptoms: anhedonia, dysphoric mood, feelings of hopelessness-helplessness-worthlessness-guilt, poor self-esteem, or suicidality. Cancer patients are at higher risk for depression if they are in poor physical condition, have inadequately controlled pain, are in the advanced stages of illness, have a history of depression, or have other significant life stresses or losses.<sup>5</sup> An increased risk has also been associated with pancreatic, head and neck, and lung cancer.

**TABLE 56.5-1.** Medications That Can Cause Depression in Cancer Patients

Early detection and aggressive treatment of depression is essential in cancer patients. Psychoeducation about normal responses to coping with the stresses of cancer and identification of symptoms requiring treatment is the first step. Despite tremendous advances in efforts to destigmatize psychiatric illness and treatment, many patients continue to be reluctant to seek counseling or to consider psychotropic medications. The oncologist and nursing staff play essential roles in communicating the importance of treating the whole person, and attending to the psychological distress that many patients experience. Referral for psychiatric evaluation when indicated is a significant opportunity to validate the patient's feelings of distress and provide supportive counseling. A recent report by Watson et al.<sup>6</sup> that a high helplessness-hopelessness score has a detrimental effect on 5-year survival in women with early breast cancer and that a high score for depression is linked to a

significantly reduced chance of survival is provocative and calls for more research in the identification and treatment of the depressed cancer patient. Currently, a range of psychopharmacologic and psychotherapeutic treatments is available for depression ( [Table 56.5-2](#)).

Drug Name	Starting Dose (mg)	Therapeutic Dose (mg/d)
<b>Newer antidepressants</b>		
<b>SSRIs</b>		
Citalopram (Celexa)	30-60 q.d.	30-60
Fluoxetine (Prozac)	30 q.d.	30-60
Paroxetine (Paxil)	30 q.d.	30-60
Sertraline (Zoloft)	75-150 q.d.	50-200
<b>Others</b>		
Bupropion (Wellbutrin)	30-75 b.i.d.	300-450
Nefazodone (Desoton)	100 t.i.d.	300-600
Trazodone (Deseryl)	50 q.b.s.	50-300
Venlafaxine (Effexor)	75 b.i.d.	75-225
Mirtazapine (Remeron)	30 q.b.s.	15-45
<b>TCAs</b>		
Amitriptyline (Elavil)	75-150 q.b.s.	30-300
Desipramine (Norpramin)	100-150 q.b.s.	30-300
Doxepin (Sinequan)	150-300 q.b.s.	75-300
Imipramine (Tofranil)	75-150 q.b.s.	30-300
Nortriptyline (Pamobarbit)	75-150 q.b.s.	30-200
<b>Psychostimulants</b>		
Dextroamphetamine (Desoxin)	2-5 b.i.d. t.i.d. b T.p.m. 1	5-30
Methylphenidate (Ritalin)	2-5 b.i.d. t.i.d. b T.p.m. 1	5-30
Pemoline (Elmora)	30-75 once a day	37.5-112.5

**TABLE 56.5-2.** Antidepressants Commonly Prescribed for Cancer Patients

### Selective Serotonin Reuptake Inhibitors and Other New Antidepressants

The selective serotonin reuptake inhibitors (SSRIs) are the first-line antidepressants prescribed in cancer settings because they are effective, with few side effects and few drug interactions. The SSRIs (e.g., fluoxetine, sertraline, paroxetine, and citalopram) have proven as effective as tricyclic antidepressants (TCAs) but with less sedative and autonomic effects. The most common side effects are mild nausea, gastrointestinal disturbance, headache, somnolence or insomnia, and a brief period of increased anxiety. SSRIs can cause sexual dysfunction in both men and women, a side effect that often leads to cessation of the drug, although there are a number of interventions that may address this symptom. There has been contradictory information about the potential for appetite suppression with SSRIs as they have been demonstrated to cause transient anorexia but have also been successfully used in patients with eating disorders to improve food intake. Some cancer patients experience transient weight loss; however, weight usually returns to baseline level, and the anorectic properties of these drugs have not been a limiting factor in this population. The SSRIs do vary in their metabolism, with paroxetine having no active metabolites and sertraline having relatively few and both paroxetine and sertraline having short half-lives. The newest SSRI, citalopram, may be less likely to cause gastrointestinal symptoms and anxiety. Fluoxetine, sertraline, and paroxetine have been used to reduce both the number and intensity of hot flashes in nondepressed women who become menopausal after chemotherapy for breast cancer.

Bupropion and trazodone are prescribed less frequently than the SSRIs for individuals with cancer. Bupropion's activating profile makes it useful in lethargic patients, but it is associated with anorexia and increased seizure risk and should be avoided in patients with a history of seizures or brain tumor and in those who are malnourished. Bupropion has been demonstrated to improve the chances of success for patients attempting to quit smoking tobacco and thus may be especially important in patients with lung or head and neck cancers. Trazodone is strongly sedating and in low doses (25 to 100 mg q.h.s.) is helpful in the treatment of the depressed cancer patient with insomnia. Trazodone has been associated with priapism and should, therefore, be used with caution in male patients. The use of venlafaxine, nefazodone, and mirtazapine has not been studied in cancer patients. Venlafaxine affects both norepinephrine and serotonin neurotransmitter systems, but it does not produce the same uncomfortable antimuscarinic and antiadrenergic side effects as the tricyclic antidepressants. Hypertensive side effects at higher doses can be problematic in medically ill patients. Nefazodone also affects serotonin and norepinephrine systems and is useful in those with agitated depression or insomnia. Mirtazapine, another sedating antidepressant, is similarly efficacious for patients with agitated depression and insomnia and is currently under study for its potential analgesic and antiemetic effects. Bupropion, nefazodone, and mirtazapine are less likely to cause sexual dysfunction than the SSRIs and venlafaxine.

### Tricyclic Antidepressants

The tricyclic antidepressants are still used to treat depression in adults and children with cancer. Nortriptyline and desipramine have the most favorable side effect profiles for cancer patients, with less anticholinergic and sedating symptoms. For reasons that are unclear, depressed cancer patients often show a therapeutic response to a tricyclic at much lower doses (75 to 125 mg/d) than are usually required in physically healthy depressed patients (150 to 300 mg/d). Obtaining serum levels of the medications is helpful in titrating dosages and monitoring toxicity. The beneficial effects on appetite and sleep are frequently immediate, while the effects on mood may be delayed. Tricyclic antidepressants have been favored in medical settings because of their demonstrated analgesic effects in some patients. However, they are notorious for their side effects, such as hypotension and cardiac conduction disturbances.

### Psychostimulants

In cancer patients, low doses of psychostimulants (i.e., dextroamphetamine, methylphenidate, and pemoline) promote a sense of well-being, decrease fatigue, and stimulate appetite. Psychostimulants offer clear benefits, especially in terminally medically ill patients, as there may be an improvement in symptoms within hours to days.

Psychostimulants can also potentiate the analgesic effects of opioid analgesics and are commonly used to counteract opioid-induced sedation. As tolerance develops, an adjustment of the dose is necessary. Side effects at low doses include insomnia, tachycardia, euphoria, and mood lability. High doses and long-term use may produce nightmares, insomnia, and paranoia. Patients should be cardiologically and neurologically stable before starting a stimulant.

Psychostimulant dosing is usually at 8 a.m. and noon to avoid any potential for sleep disturbance. Pemoline, a gentler psychostimulant available in chewable form with buccal absorption, may be chosen for more frail, debilitated patients or for those who cannot swallow. However, pemoline should be used with caution in patients with renal impairment; liver and renal function tests should be monitored periodically. Typically, patients are maintained on a psychostimulant for 1 to 2 months, after which time many can discontinue these medications without a recurrence of depressive symptoms. Those who experience further depressive symptoms can be maintained on a psychostimulant for longer periods, and tapering may be aided by concurrent use of another antidepressant.

### Mood Stabilizers

Patients with a history of bipolar disorder (manic-depressive illness) maintained on mood stabilizers must be continued on their medications throughout treatment. They may require close psychiatric monitoring, as the stresses of their illness and treatment place them at high risk for episodes of severe affective illness. There are few studies of the use of mood stabilizers during cancer treatment. Patients who have been treated with lithium carbonate should be maintained on it throughout their cancer treatment, but close monitoring is necessary, as patients are vulnerable to toxicity in the setting of fluid and electrolyte imbalances, such as during perioperative periods, in critically ill patients with renal dysfunction, or in those receiving potentially nephrotoxic drugs. Use of carbamazepine as a mood stabilizer can be problematic in cancer patients because of its marrow-suppressing properties. Valproic acid, on the other hand, is better tolerated and considered to be quite efficacious. Gabapentin is currently under study as a mood stabilizer. It is well tolerated with few side effects and has a growing role in the treatment of neuropathic pain.

### Monoamine Oxidase Inhibitors

If a patient has responded well to a monoamine oxidase inhibitor (MAOI) for depression before treatment for cancer, its continued use is warranted. Most psychiatrists, however, are reluctant to start depressed cancer patients on MAOIs because of the difficulty of maintaining dietary restrictions in patients who may already be confronting nutritional problems due to their illness and treatment. These drugs may also be contraindicated in patients receiving the antineoplastic procarbazine, because it has some monoamine oxidase inhibitory activity. Although MAOIs have demonstrated efficacy in the treatment of depression, the risk of hypertensive crisis and serotonin syndrome due to drug interactions (i.e., meperidine) has led to substantial concern about their safety.

### Electroconvulsive Therapy

Electroconvulsive therapy is one of the most effective treatments for depression in patients who are medically ill and unable to tolerate psychotropic medications. Electroconvulsive therapy continues to be a viable option for patients who are refractory to antidepressants, for whom medications are medically contraindicated, or for those with psychotic features, dangerous suicidality, or self-injurious behavior. The most common side effects include anterograde amnesia that usually improves within days to weeks of the treatment.

## CANCER-RELATED SUICIDE

Although few cancer patients commit suicide, they may be at a somewhat greater risk than the general population. Passive suicidal thoughts are relatively common; confronting mortality while battling a life-threatening illness leads many to contemplate suicide. Consideration of death and dying is complex for patients who are faced with substantial suffering and are struggling to assess quality-of-life concerns. Suicide may transiently appear to be a means of maintaining a sense of control and a reassuring theoretic alternative for patients overwhelmed by uncertainty, feelings of helplessness, and fears of suffering. The actual suicide rate in cancer patients is difficult to confirm as death certificates may reflect an underreporting of suicide in patients with advanced illness. The degree to which noncompliance or treatment refusal represents a deliberate decision to end life is unknown.

Factors associated with an increased risk of suicide in cancer patients include being male, having tumors associated with alcohol and tobacco abuse, advanced stage of disease, poor prognosis, delirium with poor impulse control, inadequately controlled pain, depression, history of psychiatric illness, current or previous alcohol or substance abuse, previous suicide attempts, physical and emotional exhaustion, and social isolation.<sup>5,7</sup> Suicidal depression has been associated with chemotherapy treatment.<sup>8</sup>

Frank discussion of suicidal ideation is important. Although such discussion is often feared by clinicians, there is no evidence that talking about suicide encourages attempts. Assessment of severity of suicide risk depends on the clinical circumstances, identification of factors that may increase impulsivity or impair judgment (e.g., active substance abuse or delirium), and review of the patient's intent and plan. Emergent psychiatric evaluation is indicated when there is a risk of injury to self or others. Identifying and treating depression among patients with cancer has been shown to decrease morbidity and mortality.<sup>9,10</sup>

## ANXIETY

Anxiety is a normal reaction to the emotionally stressful, even traumatic, experience of cancer. Cancer may force changes in social roles, disrupt personal relationships, cause bodily dysfunction, and alter appearance, in addition to posing a threat of death or significantly shortened life.<sup>11</sup> Anxiety is common at crisis points, such as the time of diagnosis, before the start of any new treatment, when recurrent disease is diagnosed, and when the patient progresses to advanced and terminal illness stages. After initial shock and disbelief, patients may develop symptoms of anxiety, accompanied by irritability, loss of appetite, insomnia, intrusive thoughts about their prognosis, and decreased ability to concentrate and carry on usual activities. Anxiety that persists and causes impairment is considered pathologic. Anxiety disorders may present with a variety of symptoms, including phobias, obsessive-compulsive symptoms, panic attacks, generalized anxiety, or somatic complaints. Severe anxiety can contribute to denial and noncompliance with treatment, disabling anticipatory nausea and vomiting before chemotherapy, avoidance of tests and procedures, panic attacks, and overwhelming distress. Untreated anxiety increases the risk of alcohol and substance abuse. Multiple organic factors may give rise to anxiety disorders in cancer patients, including poorly controlled pain, altered metabolic states (e.g., hypoxia, hypotension), sepsis, neurologic disorders, endocrine disturbances (e.g., thyroid dysfunction), hormone-secreting tumors, and medications (e.g., steroids).

The management of anxiety symptoms begins with the provision of emotional support and information to the patient and family. Patient education may offer substantial relief through identification of anxiety symptoms, explanation of the interplay of psychological and somatic symptoms, and reassurance that severe distress is treatable. Often the physical symptoms, such as sweating, tremor, dyspnea, or chest tightness, cause even greater anxiety in cancer patients who may already be somatically preoccupied. There are many possible psychotherapeutic and psychopharmacologic interventions available for the treatment of anxiety symptoms.

Many patients are helped through behavioral techniques, such as relaxation, distraction, and cognitive reframing.<sup>12</sup> In addition to behavioral treatments, individual psychotherapy and group interventions have been demonstrated as effectively reducing anxiety in cancer patients. Studies of group interventions that included education, emotional support, and behavioral training demonstrated benefits of less tension and fewer phobias (trend) than was found in the control groups.<sup>13</sup> Many patients with intermittent anxiety or simple phobias find relaxation therapy and distraction techniques helpful. When the need for a diagnostic procedure or treatment is urgent, benzodiazepines should be used.

Phobias related to medical procedures are common in children with cancer and also are problematic in some adults. While careful attention to preparation of children in advance of painful procedures (e.g., role playing) may limit the incidence of anxiety, specific behavioral interventions, including relaxation training and distraction, may be indicated for some symptoms.<sup>14</sup> Self-hypnosis is a highly effective treatment for both generalized anxiety and specific phobias in children and adolescents.

Before being treated with an anxiolytic, all patients should be screened for depressive symptoms as well as for other symptoms in the anxiety disorder spectrum, such as posttraumatic stress disorder and obsessive-compulsive disorder. Anxiety and its associated somatic complaints often accompany depression, and effective treatment, therefore, may require use of an antidepressant in conjunction with, or instead of, a short trial of a benzodiazepine. The experience of cancer treatment may reawaken longer-standing problems in patients who have been the victims of previous trauma, increasing their risk of anxiety and depressive symptoms.

Benzodiazepines (lorazepam, alprazolam, and clonazepam) are the drugs of choice for acute anxiety states. [Table 56.5-3](#) lists the usual initial dose of benzodiazepines, approximate dose equivalent, half-life, and presence or absence of active metabolites. The dosing schedule depends on the patient's tolerance and the anxiolytic's duration of action. The shorter-acting benzodiazepines may be given four or more times a day. Lorazepam and alprazolam are favored in the acute setting due to their rapid onset of action and thus are efficacious when prescribed on an as-needed basis. Lorazepam is available in both oral and parenteral forms and has both antiemetic and anxiolytic properties.<sup>15</sup> Clonazepam is substantially longer-acting, offering the benefit of ease of administration as well as avoiding the potential for recurrent anxiety between doses and rebound symptoms of worsened anxiety. It is best to increase the dose before switching to another agent in patients with persistent symptoms, as there is substantial variability in patient tolerance of the benzodiazepines and in effective dosages. The most common side effects of the benzodiazepines are dose-dependent and include drowsiness, confusion, and poor motor coordination. These occur more frequently in older patients and in those with impaired liver function. The synergistic effects of the benzodiazepines with other medications with central nervous system depressant properties, such as narcotics and some antidepressants, can contribute to excess sedation. When the dose is lowered, uncomfortable sedation often disappears, while the antianxiety effects continue. Lorazepam is renally excreted and, hence, is better tolerated by patients with impaired hepatic function and by those taking other medications with sedative effects (e.g., analgesics). There are effective alternatives to benzodiazepines, including other anxiolytics, such as buspirone. In addition, antidepressants with more calming-sedating side effects, such as nefazadone, mirtazapine, and paroxetine, have also been found to be beneficial in the treatment of anxiety. Low doses of neuroleptics (i.e., olanzapine, haloperidol, or thioridazine) are effective in patients with severe anxiety that is not controlled with maximal therapeutic doses of benzodiazepines, in patients whose anxiety leads to frank agitation, and for those who cannot tolerate benzodiazepines due to respiratory problems.

Drug Name	Approximate Dose Equivalent	Initial Dosing (mg PO)	Elimination Half-life Drug Metabolite (h)	Active Metabolite
<b>Short-acting</b>				
Alprazolam	0.5	0.25-0.5 i.i.d.	10-15	Yes
Lorazepam*	1.0	0.5-2.0 i.i.d.	10-20	No
Temazepam†	35.0	15-30 q.h.s.	10-15	No
Triazolam†	0.25	0.125-0.25 q.h.s.	1-5	No
<b>Long-acting</b>				
Clonazepam	0.5	0.25-1 h.i.d.	18-50	No
Diazepam	5.0	5-10 h.i.d.	20-100	Yes
Clonazepam	7.5	7.5-15 h.i.d.	30-200	Yes

\*Lorazepam can also be administered parenterally.  
†Hydroxyl agent.

## DELIRIUM

Delirium is common in cancer as a result of direct central nervous system involvement by tumor, paraneoplastic syndromes, and the indirect effects of toxic-metabolic sequelae of the disease and treatment ( [Table 56.5-4](#)).<sup>16</sup> The hallmark of delirium is impairment of consciousness, usually accompanied by global cognitive dysfunction, and abnormalities of mood, behavior, and perception. The onset is often rapid, and the course is usually fluctuating. The prevalence of delirium in cancer patients ranges from 5% to 25% in various studies and is substantially higher in terminal stages of illness. <sup>17</sup>

**TABLE 56.5-4.** Chemotherapeutic Drugs That Can Cause Delirium

Delirium is a syndrome of symptoms with multiple possible etiologies. Changes in mental status may be subtle or extreme, ranging from an appearance of mild depression or social withdrawal to severe agitation or hallucinations. Early symptoms of delirium are often unrecognized or misdiagnosed by medical or nursing staff as depression. Yet, early recognition of delirium is essential, since the underlying etiology may be a treatable complication of cancer. When faced with an abrupt behavior change in a cancer patient, the physician must investigate a number of potential causes of delirium. Particularly frequent metabolic causes include hyponatremia, hypercalcemia, malnutrition, and liver failure. Altered thyroid or adrenal status may cause delirium. Infections and brain metastases commonly cause delirium. Patients with hematologic malignancies are at especially high risk for opportunistic infection. Other cancers, such as those of the lung and the breast, frequently metastasize to the brain. Head and neck cancer patients undergoing surgery are at high risk for delirium because of their generally older age and the high prevalence of alcohol abuse and withdrawal syndromes. Many antineoplastic and immunotherapeutic agents (i.e., interleukin) <sup>18</sup> can cause delirium and other changes in mental status.<sup>19</sup> Corticosteroids can cause confusion, depression, mania, and anxiety. Antibiotics and antifungals, such as amphotericin B, can cause delirium, particularly with intrathecal administration. In seriously ill cancer patients, the etiology of delirium is often multifactorial. The delirium workup is tailored to the patient's specific cancer and medical condition at the time that the symptoms develop.

The management of delirium includes identification and correction of its underlying causes while symptomatic and supportive therapies are initiated. Symptomatic treatment measures include reassurance and support for the patient and family, manipulation of the environment to provide a reorienting safe milieu, and appropriate use of pharmacotherapy. Measures to help reduce anxiety and mild disorientation include a quiet, well-lit room with familiar objects, a visible clock or calendar, and the presence of family, as these increase structure and familiarity. Judicious use of physical restraints to prevent self-harm, along with one-to-one nursing observation, may also be necessary. Often, these supportive techniques alone are not sufficient, and symptomatic treatment with neuroleptic or sedative medications is necessary.

As with other medically ill patients, neuroleptics are the mainstay in the management of delirium in cancer patients. Haloperidol is particularly useful because of its low incidence of cardiovascular and anticholinergic effects and its availability in parenteral and oral forms. Relatively low doses of haloperidol (1 to 3 mg/d) are usually effective in treating agitation, hallucinations, paranoia, and fear, and most cancer patients respond to less than 20 mg in divided doses over 24 hours. The more common side effects of haloperidol include akathisia and extrapyramidal side effects (cog-wheeling, masked facies, and gait disturbances). Dystonic reactions are treated with anticholinergic medications. Newer neuroleptics, such as risperidone and olanzapine, have not been studied in cancer patients; however, they appear to be well tolerated, with lower incidences of extrapyramidal side effects than haloperidol. They are not yet available in parenteral form. Methotrimeprazine (available in intravenous or subcutaneous form) and midazolam have been used to control confusion and agitation in terminal delirium. <sup>20</sup>

## PSYCHIATRIC SYMPTOMS IN CANCER PATIENTS WITH PAIN

There is clearly an increased incidence of depression and anxiety in patients experiencing severe pain. In the Psychosocial Collaborative Oncology Group study, 39% of patients with a psychiatric diagnosis experienced significant pain. In more than 80% of these patients, a depressive syndrome was diagnosed. In contrast, only 19% of patients who did not receive a psychiatric diagnosis had significant pain. <sup>4</sup>

The psychiatric symptoms of patients who are in significant pain must initially be considered a consequence of their uncontrolled pain. Acute anxiety, depression with despair (especially when the patient believes the pain means disease progression), agitation, irritability, lack of cooperation, anger, and insomnia may be the emotional or behavioral concomitants of pain. These symptoms are not labeled as a psychiatric disorder unless they persist after pain is adequately controlled. Undertreatment of pain is a major problem in both adult and pediatric settings. Aggressive pain management strategies, including narcotics, are essential to the emotional care of both physically ill children and adults. Long-term psychiatric sequelae of cancer are less likely in children whose pain is well treated. There is no evidence of increased risk of subsequent drug abuse in cancer patients receiving narcotic analgesia. In fact, most patients associate the narcotic effects with the unpleasant aspects of the illness and seek to avoid narcotics during their recovery. <sup>21</sup> Effective pain management often requires substantial patient education and has been facilitated by recent advances, such as the growing emphasis on the use of adequate regimens of standing doses of analgesics with as-needed rescue dosing for breakthrough pain, and the advent of patient-controlled analgesia. Collaborative efforts between doctor and patient to identify problematic symptoms and negotiate treatment strategies depend on open communication about pain and its psychological sequelae. A full discussion of issues in pain management is available in [Chapter 56.1](#).

## UNCONVENTIONAL CANCER TREATMENTS

The alternative therapies ranging from herbal treatments and spiritual teachers to acupuncture, physical manipulation, and mental imaging proliferated in the 1990s, and many "traditional" Western doctors are seeking to understand these modalities. Recent surveys suggest that 30% to 40% of the U.S. public use what are described as alternative or complementary therapies. <sup>22</sup> The field is broad and encompasses many modalities and ideas. However, due to the lack of clinical trials of many of these therapies, conventional practitioners and alternative healers exist on opposite ends of the spectrum, often leaving patients confused about how to integrate these differing perspectives. Despite this, the demand for these therapies has led insurers to offer some expanded benefits for alternative medicine.

The overlap of traditional and alternative therapies is particularly complex in the provision of psychosocial and behavioral treatments to cancer patients. Some of the psychological and behavioral methods that are used in medicine (i.e., psychological support, visual imagery, hypnosis, and relaxation exercises) for enhancing quality of life and symptom control are also included in unconventional therapies that promise cancer cure or extended survival. A recent study of 480 women with newly diagnosed early-stage breast cancer found 28% used alternative medicine as a complimentary therapy. <sup>23</sup> Interestingly, the use of alternative medicine was independently associated with depression, fear of recurrence of cancer, lower scores for mental health and sexual satisfaction, and more physical symptoms as well as symptoms of greater intensity. The study suggests that patients seeking alternative medicine therapies may be experiencing anxiety, depression, or physical symptoms that should be addressed by the "traditional" medical system. Further, the study demonstrated that the use of these therapies does not always provide the sought-after panacea.

The urgency with which many cancer patients and families feel the need to seek any potentially beneficial or hopeful treatment option leads many to try any promising therapy that is offered. In the setting of tremendous fear and uncertainty, it is difficult for patients even to choose between conflicting traditional biomedical opinions, much less to navigate the uncharted waters of alternative treatments. Many patients elect untried or unproven therapies in their desperate search for a cure or for a

more acceptable quality of life, attempting any therapy “as long as it doesn't hurt.”

There are real challenges for the clinician attempting to advise patients about the use of unconventional therapies. Many conflicts are born of the desire not to take away hope but also not to condone unproven treatments. There has been concern that some therapies that suggest that personality and behavior are the vehicle for recovery or tumor progression place undue burden on patients who may hold themselves responsible for a negative outcome. Some patients feel empowered in the hopeful “heroic warrior” stance described by Gray and Doan<sup>24</sup> and should be encouraged to maintain it. These patients benefit from the oncologist's admission that there are still many unknowns and encouragement of their use of self-help books, visualization, efforts to improve mental attitude, and diet regimens, insofar as they find them to be helpful. However, there are other patients for whom the warrior myth is a distressing burden, leading to self-criticism and a sense of guilt because they cannot fight hard enough and will be responsible for their own death. Families may contribute to the patient's guilt about illness, offering unrealistic advice and remedies in an effort to overcome their own feelings of helplessness and expressing frustration and anger with the patient's failure to live up to their expectations and to fight hard enough. Further study of alternatives is important, as current research does not support the assertion that unconventional therapies prolong survival.<sup>25,26</sup> However, there is no question that alternative therapies may play a substantial role in the patient's experience of illness and quality of life.

## PSYCHOTHERAPEUTIC INTERVENTIONS WITH CANCER PATIENTS

### INDIVIDUAL PSYCHOTHERAPY

Although psychological interventions for patients with cancer were slow to develop, since the 1950s efforts to implement interventions have grown steadily because of a greater emphasis on quality-of-life concerns. The types of interventions most commonly used by health professionals working with cancer patients are education, behavioral training, groups, and individual psychotherapy. Fawzy et al.<sup>27</sup> have provided a critical review of psychosocial interventions in cancer care that should be read by all individuals who are preparing to establish psychosocial support services for cancer patients.

Although some enthusiasts have advocated offering counseling to all patients on the assumption that they can benefit from help and will take advantage of it, many patients reject the offer of psychological help. In one study, only two-thirds of the patients identified as high-risk accepted counseling.<sup>28</sup> Those who refused had a positive outlook, minimized the implications of their diagnosis, and viewed the offer of therapy as a threat to their emotional equilibrium. Patients who accepted counseling were less able to deny the diagnosis and its implications; they were less hopeful and were more apt to experience their situation in religious or existential terms. Stam et al.<sup>29</sup> found that 20% of 449 ambulatory cancer patients seen in a single cancer center in Canada were referred and seen for psychological counseling over a 1-year period. Family and personal problems were the most common reasons for seeking help. Interventions most commonly applied are either educational or psychotherapeutic, including supportive, insight-oriented, interpersonal, and cognitive behavioral therapies.<sup>30,31 and 32</sup>

Sourkes et al.<sup>33</sup> have described the focus of psychotherapy with the cancer patient as the emotional stress engendered by the illness, rather than the more general intrapsychic and interpersonal concerns of the physically healthy person.<sup>33</sup> The therapist who is outside of the friend and kinship circle plays a useful role by encouraging exploring emotions, which are otherwise unexpressed. Because of the strong bond felt by families for the therapist who took care of their relative over the course of a long illness, families often enter into a one- to ten-session bereavement counseling with the patient's therapist after the patient's death to provide a healing conclusion to a long illness.

### GROUP PSYCHOTHERAPY

Group therapy may be advantageous for cancer patients, allowing them to receive support from others who have experienced and conquered similar problems of medical illness.<sup>34,35</sup> The cancer patient, in a group setting, learns that there is a range of normal reactions to illness and a range of healthy adaptive coping styles and strategies that others have used to make adjustment to illness easier. Group participation helps decrease the sense of isolation and alienation because the patient and the family can see that they are not alone in adjusting to illness. Groups for cancer patients or families (or both) are often disease-specific or targeted for patients at the same stage of different diseases. In the past, doctors had some concern about having the dying patient in a group with patients who recently were given diagnoses or whose prognosis was good, but when directed by skilled leaders, these groups can be highly rewarding.<sup>13</sup> The Spiegel et al.<sup>36</sup> report of greater longevity in a small number of women with advanced breast cancer undergoing group psychotherapy remains controversial, and replication with larger samples is needed.<sup>37,38</sup>

### SELF-HELP AND MUTUAL SUPPORT PROGRAMS

Self-help and mutual support programs are additional potential supports for patients and families. Life crises, such as life-threatening illness and bereavement, often are the impetus for individuals to seek emotional support from others experiencing the same trauma. Uniquely American in their inception, most self-help support networks work closely with professional medical services, thereby offering social support as an adjunct to medical care. Self-help groups or visitation programs help decrease the sense of alienation and isolation of patients because of the unique knowledge and sensitivity that volunteers bring from personal experience. Veteran patients facilitate coping by being a source of credible information about the needs of cancer patients, demonstrating constructive ways of managing and living despite illness, providing the motivation for rehabilitation and enhancement of self-worth, and encouraging patients to participate in their own treatment.<sup>39</sup>

### SURVIVOR ISSUES

Advances in the treatment of cancer in the last 30 years have led to improvement in both prognosis and quality of life, resulting in a rapidly growing population of more than 5 million long-term survivors, many of them children and young adults. Psychiatric sequelae of cancer include those related to the direct effects of the disease as well as those that are consequences of the treatments, of family factors, and of the individual psychology of the person. The long-term adjustment of survivors of childhood cancer appears to be largely unimpaired. Cured cancer patients have special medical and psychiatric concerns, including fears of termination of treatment, preoccupation with disease recurrence, and minor physical problems; a sense of greater vulnerability to illness (the Damocles syndrome); pervasive awareness of mortality and difficulty with reentry into normal life (the Lazarus syndrome); persistent guilt (the survivor syndrome); difficult adjustment to physical losses and handicaps; a sense of physical inferiority; diminished self-esteem or confidence; perceived loss of job mobility, and fear of insurance discrimination. A recent book by Landay<sup>40</sup> teaches patients how to handle many “nuts and bolts” issues of coping, such as insurance, career issues, estate planning, advanced directives, and home and hospice care. Concerns about infertility, often understandably submerged at the time of diagnosis and treatment, reappear when rigorous treatment concludes. The survivor's intellectual functioning is also a major concern. Children and adults with brain tumors or central nervous system involvement and those undergoing bone marrow transplant are at risk from both their disease and their treatment. Most have residual deficits with neuropsychological impairment, including compromised motor and cognitive test performance.<sup>41</sup>

In coping with a variety of physical, social, sexual, employment, and insurance problems, survivors often report psychological distress at subsyndromal levels. The severity of these symptoms may vary by premorbid adjustment personality traits and site of cancer and treatment (i.e., bone marrow transplantation), but they usually do not interfere with reentry to family, social, or employment networks.<sup>41</sup> Survival may be associated with an increased risk for delayed medical complications, including organ failure, central nervous system dysfunction, sterility, secondary malignancies, and decreased physical stamina.<sup>42,43</sup> Sociodemographic, disease-treatment, and psychological distress variables only partially explain the wide variability in survivors' psychosocial dysfunction.<sup>44</sup>

Special attention to identifying adolescent and young adult survivors most at risk for psychosocial dysfunction is needed. Adolescents who have been treated for cancer not only have the substantial physical, cognitive, emotional, and interpersonal tasks faced by all adolescents but have the added burden of integrating a life-threatening disease into their experiences. Persistent body image concerns, somatic preoccupation, disruptions in sexual relationships, and deficits in social competence are not uncommon.<sup>45</sup> Fritz and Williams<sup>46</sup> assessed 52 survivors of childhood cancer and their families who were more than 2 years past treatment. Two-thirds of the patients studied had excellent psychosocial functioning without serious social issues. Many expressed a positive effect of their illness and reported little depression. Illness variables were not predictive of psychosocial outcome, unlike some psychosocial variables, such as communication patterns and peer support. The National Coalition of Cancer Survivorship is an outgrowth of survivors' need for support. The political issues surrounding health and life insurance are a prime example of an area where research is needed to delineate problems, and advocacy is needed to encourage societal solutions.

### Acknowledgment

The authors thank Robert F. Quigley and Theresa A. Carpenter for their assistance in the preparation of this manuscript.

## INTRODUCTION

The impact of changes in the health care system has caused greater numbers of patients to be treated in an ambulatory setting. Services in this setting range from maintenance of central lines to chemotherapy, nutritional support, pain control, intravenous antibiotics, and blood support. Patients are not usually admitted to the hospital unless their condition is so serious that it meets an acute level of care. Ever-changing reimbursement issues along with an ever-increasing number of cancer survivors<sup>1</sup> have placed yet a greater burden on the community to provide services for this often chronically ill population.<sup>2</sup>

Resource directories are regularly updated to include the latest evolving information. The American Cancer Society (ACS) and Cancer Care are just two sources that publish a comprehensive listing of services.<sup>3,4</sup> These guides may be cross-referenced from the general to specific site of cancer and often provide information on a variety of services, including emotional support, financial assistance, and transportation resources. Additionally, increasing access to personal computers and the World Wide Web have allowed individuals to gather information in an unprecedented manner. Rimer points out that "communication is central to effective cancer control, from primary prevention to survivorship."<sup>5</sup> Although this information, along with the increasing fingertip access to the most current information, should theoretically allow patients to gather the assistance they require to live with their illness, a gap still remains between availability of these resources and specific individual needs. These gaps in provision of service occur across many communities and insurance carriers.

The individual diagnosed with cancer undergoes an experience that is intensely personal, that calls into question basic assumptions and expectations about life, and that somehow must be integrated into a sense of self, and thus involves the complexities of individual personalities. To deliver effective service, those who are working with this population must understand the adaptation that occurs. This adaptation involves incorporating a new sense of self after living through the crisis of diagnosis, initial treatment, potential side effects, and emotional impact on one's self and one's family. In addition to discussing individual adjustment, this chapter discusses different types of support and resources that may be beneficial to the patient and family, computer trends, the impact of an evolving health care delivery and reimbursement system, and survivorship issues, and concludes with a list of available resources.

## INITIAL DIAGNOSIS OF CANCER

Cancer is the third major cause of mortality.<sup>6</sup> More than 1 million people are estimated to have been diagnosed with cancer in 1999, and 564,000 people will survive their disease.<sup>1</sup> Although these statistics present an increase in survivorship, the reality of living with cancer represents something quite different. Concerns must be broadened to view cancer as a chronic or curable illness.<sup>7</sup> The majority of those 1 million people diagnosed with cancer must face their own mortality, but they then move from focusing on their mortality to dealing with their illness. It is incumbent on medical providers to help the patient participate in a plan to develop adequate internal and external resources for living with cancer.

The spectrum of reactions includes fear, shock, despair, anger, anxiety and, sometimes, total insensibility.<sup>8</sup> In the 1970s, Weisman and Worden identified the immediate coping response of denial as appropriate, albeit temporarily.<sup>9</sup> This is still valid today, but given the changing nature of today's medical delivery system, we may need to help patients progress from denial to mastery in a more expeditious fashion. Although today's cancer patients experience distress that is often not considered or reflected in the economics of treatment, they still desire and need psychosocial intervention to cope with their cancer. The medical system has resources that can address these emotions and enable a person to function more effectively. The physician may call on members of the team, such as the oncology social worker or oncology nurse, to assist in presenting the diagnosis. These team members can facilitate the understanding of the diagnosis in many distinct ways. The professional oncology team helps the patient move toward a sense of mastery over the situation. Assistance is provided so that a patient moves along a continuum through which control is gained and progress is made from a passive to an active state. This movement promotes an active course of treatment.

## SOCIAL SUPPORT NETWORK

During the 1980s, the literature identified and recognized the importance of a social support network. Research has consistently found that people coping with cancer have difficulty with interpersonal relationships and that one's social support system can alleviate these stressors.<sup>7</sup> Although this network may not prolong the life of a cancer patient, it has been shown to enhance the quality of life one experiences. The providers in a social support network may be professionals from the community,

family, friends, significant others, organizations, and agencies. These providers enable the cancer patient to enhance their coping skills so that they may function in an effective, competent, and proficient manner. The literature continues to report that this social support network impacts positively on the psychological well-being of the cancer patient.<sup>10,11</sup> The constructs of the social support system identified as emotional, informational, or instrumental as defined by Wortman<sup>12</sup> is the structure in which we define support and resources for the cancer patient.

## **EMOTIONAL SUPPORT**

Psychosocial interventions have consistently contributed to a positive outcome on the emotional adjustment of a person coping with cancer,<sup>13</sup> and emotional support is frequently considered to be one of the most essential interventions. Family, friends, and those closest to the patient frequently provide emotional support. Dunkel-Schetter<sup>14</sup> surveyed 79 cancer patients and found that 81% defined emotional support as most helpful, followed by informational support (41%) and instrumental aid (6%).

## **ASSESSMENT AND EVALUATION OF COPING SKILLS**

Individuals deal with problems in diverse ways. It is important that the medical team identify an individual's ability to cope with stress so that they have some indication of how the patient will deal with their cancer. An assessment of other crises endured and how those were handled is particularly helpful in an assessment and evaluation. Studies have led to development of a profile of predictors of poor coping.<sup>15</sup> Some indicators of the inability to cope with crises are character traits such as rigidity of behavior or morose, gloomy outlook on life. This type of patient may not be amenable to the support received or may need more intense intervention. Substance abuse, recent losses, social isolation, unemployment, or other debilitating illnesses may be warning signs that an individual may be more emotionally overwhelmed. Cancer causes much emotional distress in a person's life, and disruptions in routine functioning are normal. Some of these disruptions may have lingering effects and cause enduring problems.<sup>16</sup> Traditional emotional support may not be enough for such individuals. Specialized or very individualized emotional support may be necessary for these patients to cope with cancer.

## **FAMILY AS EMOTIONAL SUPPORT**

As the person diagnosed with cancer enters the health care system it is important for the professionals to recognize that this person rarely functions alone. The person who receives a diagnosis of cancer usually summons his or her closest family to become the immediate support system. As healthcare professionals, we must recognize the significance of including the family at times of diagnosis, recurrence, change in treatment plans, and terminal illness.<sup>17</sup> The family system changes when the diagnosis is made. All members who interact with the patient should be aware of the potential changes and the subsequent impact on the family.

The family value and belief system must be identified so that help can be provided within the context of the sociocultural system. Fears are minimized and coping skills enhanced if understanding is provided within a familiar context. It must be recognized that cancer is not openly discussed in all cultural groups. Certain cultural groups may need special assistance to contend with a health care system in which the patient is expected to be an active participant. Roles within the family frequently change when a diagnosis of cancer is made. Family members may need help in evaluating whether these role changes are comfortable for them. In addition, a family member who is also a health care professional, and particularly an oncology health care professional, may need help in maintaining the role of a family member rather than becoming the resource person. The alacrity to help is frequently seen during the initial crisis of diagnosis. This is the time a family pulls itself together and offers whatever resources they can provide for the newly diagnosed patient. As the illness extends over time and sometimes becomes chronic, family support may wane and become difficult to sustain. It is at this time that patients and families may need to find resources outside the immediate family system.

## **EMOTIONAL SUPPORT OUTSIDE THE FAMILY SYSTEM**

The social support network, as identified earlier, includes friends, neighbors, both self-help and professionally facilitated support groups, religious groups, community agencies, and health care professionals.<sup>15</sup> A review of the literature has indicated that making use of emotional support, whether informal or formal, can relieve distress.<sup>13</sup> It is important that there be some commonality perceived in the support system. People undergoing similar experiences may find it easier to relate to each other because the cancer is accepted more easily. If the perception is that a situation is understood, empathy can be accepted and emotional support to the patient becomes positive. The validity of the cancer patient's experiences must be recognized by the support system for support to be effective. A member of a support system who truly does not understand the trauma cannot minimize the anxieties and fears of the cancer patient. Support is not effective in a situation in which real feelings are not recognized.

## **VISITATION GROUPS**

The changing scene of health care delivery has affected visits by volunteers. The ACS has many groups maintained by volunteers who have had cancer experiences. Reach to Recovery, Cansurmount, and the ostomy programs all have volunteers who have undergone some type of cancer experience. In the past, these volunteers were able to visit with newly diagnosed patients in the hospital. In today's health care system, patients are admitted and discharged quickly, and frequently their procedures are performed in 1-day surgery centers, so there may not be time for these volunteers to visit. Health care professionals must take special care in providing patients with information about these groups, and patients must be encouraged to become proactive and make the first contact themselves. The health care professional that one meets in the hospital or surgical center is an invaluable source of information. Cancer Information Service, reachable at 1-800-4-CANCER, can also help patients with local resources.

## **SELF-HELP GROUPS**

An extensive network of self-help groups exists for the cancer patient. Self-help groups are frequently formed by people with similar interests or concerns, and many of these groups are disease specific. They may meet weekly, biweekly, or monthly. These groups are not professionally led; rather, they are a gathering led by the peer participants, although medical professionals may be invited to present their particular expertise. Information about self-help groups can be accessed through the National Self-Help Network. This organization is listed individually in each state.

## **SUPPORT GROUPS**

Support groups are available in most communities and are facilitated by health care professionals. The professional has the responsibility of establishing a group that is cohesive and has the goals of providing educational and emotional support. Groups may be established for patients, for family members and significant others, or for patients and family together. Although no positive correlation has been made that support groups have cured disease, improved survival of patients in support groups has been found.<sup>18</sup>

Although emotional support and social support are separated for descriptive purposes here, they are frequently intertwined and inseparable. The family member who transports a cancer patient for daily radiation treatments is both part of the social support system and is also providing the necessary emotional support.

## **ROLE OF THE MEDICAL TEAM IN EMOTIONAL SUPPORT**

The medical team is comprised of a number of people who can assist the cancer patient. Social workers, clinical nurse specialists, psychologists, psychiatrists, and nutritionists are often available to provide services. Although these professionals may not be immediately available in every setting, referrals can be made for consultation. Ancillary personnel have become more important in today's system of health care delivery. Many concerns cannot be addressed in the leisurely manner of years ago. Specialized health care professionals can also help a patient navigate the health care system with greater ease and less stress.

## **INFORMATIONAL SUPPORT**

It is axiomatic that knowledge is power and that cancer patients and families who know more about the illness and are actively involved in treatment decisions cope better than do those who are more passive. It is this demand for knowledge and information that helps such individuals feel less powerless and helpless and more in control of the situation. The need for information depends not only on individual preference for control, but on a person's educational, cultural, and financial background.<sup>19</sup> In the past, initial cancer information was obtained in the physician's office or hospital. Today, 22 million adults use the Internet to find health

information, and 70% search for information before even meeting with a physician.<sup>20</sup> Dr. Gaisser, of the Cancer Information Service in Heidelberg, Germany, analyzed when inquiries were made to the service. Forty-three percent of the requests in 1996 occurred before the patient's second treatment, illustrating the patient's need for earlier information.<sup>21</sup>

According to Fernsler and Cannon<sup>22</sup> "patients with cancer benefit from education in terms of their ability to care for themselves, enhanced self-image and self-esteem, improved symptom management, reduced anxiety and reduced disruption in daily life." Other benefits of education include increased participation in treatment decisions and improved understanding of the disease process and treatment options. There may be some inherent differences for some individuals in obtaining information because of personality style. Too much information can increase anxiety for some people and cause greater difficulty in coping. It is therefore important to first assess a person's readiness to receive information by reviewing their cultural and socioeconomic background, literacy, educational level, psychological adjustment, and personal preferences for control.

Because culture influences the very meaning of the disease to the individual, it is imperative to understand that person's background, values, and beliefs. Communities also vary by culture, implying that culturally sensitive material must be developed. Providers must explore the patient's educational level and determine how to maximize both comprehension and retention of material while encouraging greater patient participation in decision making and encouraging greater dialogue with the health care team. Harris<sup>19</sup> talks about individuals with poor reading skills having greater difficulty understanding instructions and integrating them into their activities of daily living. As already mentioned, a diagnosis of cancer is a psychologically traumatic event. One's disposition affects how well the information is integrated and remembered. It has been suggested that individuals who try to maintain self-control are more likely to be compliant with health care regimens. They also tend to seek more detailed information and are therefore more involved in treatment decisions. Those individuals who give more control to the team are more of a challenge to educate and are not as receptive to the information. Lastly, a patient's financial situation directly impacts his or her ability to obtain information.

In summary, the best education occurs when there is open communication, awareness of the patient's needs, minimization of the patient's stress level, and a caring attitude on the part of the professionals. Patients are sensitive to the health professional's voice, body language, eye contact and proximity. It is crucial to meet and talk at an appropriate time and place while being supportive, encouraging, and personal in style. Print materials are often helpful, particularly those endorsed by the physician; however, screening for low-literacy populations is mandatory. Social workers can often remove barriers that may hinder education by facilitating communication or by connecting to community resources whose main goal it is to educate the public.

## INTERNET

The Internet can increase knowledge and hasten the pace of obtaining this knowledge via the following online services <sup>23</sup>:

E-mail: Messages are posted electronically, facilitating instant communication. By 1998, 1,300,000 pieces of e-mail per week were being processed by the cancer-related listservs hosted by the Association of Cancer Online Resources. That same year, 22.3 million Americans performed online searches for medical and health information.<sup>5</sup>

Mailing lists and listservs: Through e-mail, one can subscribe to specific mailing lists, through which information is shared regarding similar interests.

World Wide Web: The Web allows easy access to an unlimited amount of information. One can research particular interests via search engines such as Yahoo, Excite, AltaVista, or a host of others.

Bulletin boards: Electronic message boards allow one to post a message concerning a specific topic while not needing to be on the computer simultaneously with others.

Chat rooms: In these forums, one can participate in "live" conversation, usually in regard to specific topics. These gatherings may be formalized with a facilitator or be used for informal discussion purposes.

Professionals, patients, and caregivers are using these Internet resources regularly. In the past, information was unidirectional, from health professionals to patients; now many patients are seeking out this information for themselves. Although access to this information is valuable, it is not without issue. People on the Internet are not always as they present themselves, and information obtained may be inaccurate or misleading. Because material can be posted on the Internet without proper oversight or professional review and because people have a tendency to believe what they read, reliance on the Internet for information can cause potential harm. Web sites should be evaluated by the same five criteria generally used for printed material, including evaluation of the authority, accuracy, objectivity, currency and coverage, and intended audience of the information.<sup>20</sup> Is an author listed? What are the author's qualifications? How reliable is the information? Has the material been reviewed by editors? Is the information provided without bias? Is the content up-to-date with date listed (of both creation and revision)? To what depth are the topics explored? It is extremely important for health care professionals to encourage access to this new technology but also give caution about the potential pitfalls. In general, it is advisable to encourage patients and family members to start their searches with reputable sites. C. Everett Koop, former Surgeon General, has a Web site (World Wide Web URL: <http://www.drkoop.com>) that rates approximately 10% of the 15,000 health-related sites on the Internet for credibility, content, and opportunity for feedback. A list of cancer-related Web sites appears in the [appendix](#) at the end of this chapter.

## COMPUTER GROUPS

Groups have been long cited in the literature as an effective means of treating individuals with cancer.<sup>24,25</sup> These groups often provide information, education, and support that illustrates positive survival outcomes,<sup>26</sup> but today the strain of diagnosis and the rigors of treatment combined with concerns about confidentiality often discourage patients from attending these groups. In the past, people had to physically leave their homes and go to hospitals, physicians' offices, religious houses of worship, or community centers to attend a support group. With the advent of personal computers, Internet support groups have become popular.<sup>27,28</sup> In 1998, more than 40% of households owned a computer. The ability to use computer technology has assisted individuals in overcoming barriers to group participation, such as groups that meet at an inconvenient time, transportation difficulties, physical ill health, inclement weather, or the stigma that may be associated with attending the group. Computer networks have been described as a "support group without walls."<sup>30</sup> Advantages to computer group membership include increased patient control of both time of participation and of information disclosed or obtained, safety to discuss difficult issues, availability of information, and subsequent support. The system also has been described as empowering.<sup>31</sup> These groups also benefit individuals with hearing or speech disabilities.<sup>32</sup> Logistical obstacles, such as time spent in the assembly of the group or in travel, cost of transportation, facility costs, and scheduling problems, are overcome. An additional important benefit is anonymity. Anonymity may lead to greater self-disclosure, honesty, and intimacy while allowing specific issues to be more quickly discussed as well as discussion of taboo topics that might otherwise not arise. One of the major disadvantages is decreased interpersonal relationships. Although anonymity may be an advantage, the inability to see individuals, hear their voices, or read their body language may encourage isolation or interfere with empathy. Technological problems have been noted, including computer malfunction, cost of telephone lines and computers, access to such equipment, illiteracy, and patient discomfort with technology. Another challenge has been to facilitate group process. Individuals who are less verbal may not be encouraged to participate as much as in a face-to-face group. Trust may take longer to develop, and bonding may be more gradual. Because one must wait for feedback (and some individuals do not have good typing skills), response rate may be altered. The group leader may have more difficulty interpreting, limit setting, and tracking patterns. More recent technological advances now allow individuals to actually "speak" to each other online. The Internet site Yahoo! (<http://www.yahoo.com>) allows individuals with the use of a microphone to download their software for free, thus enabling them to talk and hear others. A "conference" across the Internet can occur, which may counteract decreased proficiency with typing and other discomforts that the patient may have.

Fernsler and Manchester<sup>28</sup> evaluated the use of a computer network (CompuServe Information Service's Cancer Forum) both by individuals and those supporting them. They found that respondents began using the network within 4 months of diagnosis and continued through all stages of the diagnosis. They concluded that "information seeking is a common coping strategy, both initially and throughout the cancer experience." Both patients and caregivers were positive about the information and support received via the computer, and this may be a "convenient alternative to traditional information and support services."<sup>28</sup>

## INSTRUMENTAL SUPPORT

As health care delivery evolved during the 1990s, emphasis shifted to ambulatory care. Most medical care is now provided on an outpatient basis, which can create additional stressors for the patient and support system. In a study done by Emanuel et al.,<sup>33</sup> more than 86% of the population surveyed indicated a need for

assistance. Sixty-two percent indicated a need for transportation assistance, and 55% indicated a need for homemaking assistance.

Transportation can sometimes emerge as a barrier to quality treatment. Medications that were previously administered in the hospital are now given on an outpatient basis and may not be covered by insurance. Home care and medical equipment needs may be intensified as hospital stays have become abbreviated.

## FINANCES

The cost of the illness and the financial impact on the patient and family has been well documented. The direct cost of the illness as well as incidental expenses such as transportation, parking, and child care can be overwhelming to patients. Mor and associates<sup>34</sup> interviewed 217 people with cancer and found that 87% had experienced a significant increase in monthly expenses directly related to the disease. Wang et al.<sup>35</sup> indicated that minorities had more concerns about finances than whites. For the elderly and others on fixed incomes, the uninsured, and the unemployed, these expenses become significant barriers to continuing treatment.

Patients are often reluctant to discuss their finances with physicians and may feel more comfortable with another member of the medical team. A social worker can do an in-depth financial assessment, including a full discussion of insurance coverage and subsequent referral to available resources. Constant reevaluation of insurance coverage is necessary as insurance changes with employment changes, managed care providers differ in services offered, and family income changes. Patients may feel pressure, either self-imposed or by hospital and physicians' offices, for prepayment or payment of outstanding bills,<sup>36</sup> all adding to the stress of contending with cancer.

Coverage for medical care costs in the United States comes from four main sources: the federal government, employers and private health insurance, state and local government, and private households.<sup>37</sup> Exploration of privately funded sources should be made with the assistance of the social worker. Cancer Care is an agency that frequently assists with finances. Hospital and communities may have funds established from donations that help with finances for the cancer patient.

The federal government funds the Medicare program and the Social Security Disability program. Eligibility is governed by age or permanent disability for Medicare application and by work history for Social Security Disability. Eligibility for Medicaid and local welfare programs always involves a means test, although this test differs regionally. Application for Medicaid programs is made through the state department of social services. Local aid is available through individual towns to those who have state applications pending or do not meet a particular state's eligibility requirements. A newly diagnosed, unemployed, uninsured person might be eligible for these entitlements.

## TRANSPORTATION

Patients often live at great distances from treatment centers or are too debilitated to drive themselves. Transportation becomes a major issue in accessing proper care. Family members, although well meaning and caring, may not be able to devote as much time as they wish to provide transportation. Transportation to doctor appointments or home from the hospital is infrequently covered by insurance. In a study of the terminally ill,<sup>33</sup> it was found that 62% of patients indicated a need for help with transportation. Transportation needs for economically disadvantaged patients were particularly troublesome.<sup>38</sup>

The ACS, the American Red Cross, and the Leukemia Society are agencies that exist nationwide and assist in transporting patients to medical care. In many areas, local towns or regional districts provide transportation to medical appointments. Resources change frequently, and it is necessary to investigate local services to assess availability.

## HOME HEALTH CARE

Home health care provides for those patients who do not require hospitalization, and it is the most rapidly expanding segment of the health care industry today. Agencies, visits, and services have multiplied exponentially due to two major influences—demographic changes and managed care. Each year, almost 500,000 new senior citizens are added to the census,<sup>39</sup> and there is steadily increasing pressure from insurance companies and managed care programs to search for the least expensive treatment method and to emphasize the lowest appropriate level of care, low-cost alternatives, and early discharge from hospitals and other health care facilities. As the trend toward home care has grown, patients are becoming more familiar with the concept of this type of care in today's health care delivery system.

To be eligible for home care services, a patient must be homebound and require skilled nursing services. Short-term custodial services are provided after the these criteria are met. The value of home health care to both patient and family has been confirmed in a study by Groebe and colleagues.<sup>40</sup> Home health care also provides for continuity of care between physician visits.

## HOSPICE

Hospice home care is available for patients living at home and requiring nursing care who have a prognosis of 6 months or less. The first hospice was organized in Connecticut in 1974; in 1996, more than 3000 hospice programs were caring for close to 500,000 dying patients in the United States.<sup>41</sup> A patient can be eligible for hospice home care even while receiving chemotherapy or radiation outpatient services. In addition to providing nursing care, emphasis also is placed on patient and family support. Physicians, nurses, social workers, clergy, volunteers, aides, and other ancillary personnel work together to provide services to patients and families from diagnosis through bereavement. This service can be invaluable for those dealing with a terminal illness.

## BARRIERS TO EFFECTIVE HOME CARE

Home care should provide the support, reassurance, and medical assistance necessary to help patients function while remaining in the comfort of their own home environment. The success of a good home care plan depends on the skills of the professional responsible for planning this service before patient discharge from the hospital. A serviceable home care plan also relies heavily on family support and family caregivers. Most insurance companies follow Medicare guidelines and usually provide for a maximum of 2 to 3 hours of home care daily.

The burden of home care usually becomes the responsibility of the primary caregiver, who, although frequently willing to provide care on a time-limited basis, cannot continue to do so for an extended period. Patients may lack knowledge regarding the available services or may be unable to afford services to supplement insurance-covered home care. In some areas, geographic limitations exist, and not all services are available in all areas. Rural regions, in particular, usually have a dearth of available services.<sup>42</sup>

The growing number of home health care agencies, although ensuring a degree of competition, can make it more difficult for patients to select the agency that is most appropriate for them. Selection may be based on availability, patient and family needs, reimbursement, cost, or insurance dictates. Agencies that provide home care services may be Medicare certified, public health departments, and proprietary agencies, both profit and nonprofit. Services offered can include nursing, home health aides, social work, physical therapy, occupational therapy, speech therapy, nutritional assessment and monitoring, laboratory work, and intravenous therapy.

In caring for a patient at home, the caregivers must provide various levels of support. Needs may range from the highly technical to simple companionship and monitoring for safety. Technical support can be received from a home health care agency, whereas less technical support, such as housecleaning, shopping, or cooking, may be available from church or synagogue groups or senior center groups.

## MEDICAL EQUIPMENT

At various times during the course of treatment for cancer, a patient may need special medical equipment or require modification to their home. The medical team should make this assessment before discharge from the hospital or during the course of treatment. Home health care personnel can also complete a safety evaluation. Insurance may cover these items, but only when prescribed by a physician. The ACS and Visiting Nurses Association often have loan closets in which equipment owned by such agencies is stored and available, usually free of charge. It is critical that the patient and those providing care be given ample instruction in the care and use of any equipment, including emergency access numbers for urgent problems.

Case managers now have access to a remote patient monitoring system called a *telemedicine system*. Images are transmitted via telephone lines and a video camera to allow various segments of the health care community, including physicians, clinic staff, and home care companies, to view patient images. More than 250,000

diagnostic teleradiology readings were done in the United States in 1997, and most commonly, telemedicine is used to monitor vital signs. Dr. Ace Allen, editor of *Telemedicine Today*, stated that patients with chronic diseases could be better managed if they received ongoing monitoring at home.<sup>43</sup> Despite the expansion of telemedicine, the volume of patients receiving services that use this technology remains relatively low (approximately 21,000 in 1996).<sup>44</sup> Currently, the evaluative data on telemedicine consultations are not definitive and need further exploration, particularly in the areas of insurance coverage, cost-effectiveness, and state-of-the-art evaluation.<sup>45</sup>

## TRENDS AFFECTING DEMAND FOR COMMUNITY SERVICES

Because significant changes in the health care environment affect the need for specific resources, it is necessary to discuss them even though they remain in a continual state of flux. The maelstrom of public debate early in the 1990s swirled around the concerns of escalating medical spending<sup>46,47</sup> and suboptimal care,<sup>48,49</sup> along with increasing awareness that a significant contingent of Americans has no health insurance or inadequate insurance.<sup>50</sup> Since Congress rejected President Clinton's proposal for health care reform, the most significant issue has been how to protect consumers from restrictions or access to care by managed care organizations. All states have a contact for health insurance complaints at the National Association of Insurance Commissioners (<http://www.naic.org/>).

The percentage of health maintenance organization (HMO) members in for-profit organizations increased from 12% in 1981 to 62% in 1998. Typical issues that have arisen include the fact that the number of Americans without insurance increased to 16.1% in 1997<sup>52</sup> and that 100,000 Americans lose their health insurance each month.<sup>53</sup> According to the latest U.S. census report, a total of 44.3 million Americans were uninsured in 1998,<sup>54</sup> which was 1 million more than just a year earlier. Children, Hispanics, and part-time workers were affected the most by these insurance losses. Kuttner<sup>55</sup> also states that the number of inadequately insured people is growing even faster. This development is related to several trends in coverage,<sup>55</sup> namely the deterioration of employer-provided coverage that insures two out of three Americans. Employers have streamlined employee choice of plans while shifting the costs to the employee and sometimes terminating coverage because of the high cost of premiums. Some plans limit benefits, such as prescription coverage, or charge higher copayments and deductibles. In addition, "casual" employees and part-time workers rarely receive insurance coverage, yet these groups accounted for approximately 29% of working Americans in 1997.<sup>51</sup> Americans with the broadest choice of plans are either government workers or those insured by Medicare or Medicaid.<sup>56</sup>

The 1985 Consolidated Omnibus Budget Reconciliation Act (COBRA) allows people to leave their jobs and pay privately for their insurance, but it does not consider the expense involved. Although the Health Insurance Portability and Accountability Act (HIPAA) prohibits denial of those with preexisting conditions, this cost is so exorbitant that it becomes self-limiting, protecting only a few hundred thousand people instead of the potential 25 million who have lost insurance. A 1998 study by the Lewin Group for Consumers Union<sup>29</sup> found that one in eight families spend 10% of their income on premiums and out-of-pocket expenses, but the number increased to two in ten in families with a family member between the ages of 55 and 64, and to five in ten with a family member older than 65. Thirty-four percent of insured adults have been enrolled in their plan for less than 2 years,<sup>51</sup> which results in lack of continuity of care and inability to track patterns, pointing to additional problems with managed care and needed resources.

Congress has considered patient protection legislation, including allowing subscribers to bring suit against their HMO. Managed care forces practitioners to search for the least expensive treatment method and emphasizes the lowest appropriate level of care. In addition to these issues, it has been determined that trust and confidence in managed care plans decreased 12% from 1998 to 1999 (42% to 30%) in a survey of 160,000 households in 1999 by the National Research Corporation.<sup>57</sup> A Kaiser Family Foundation survey found that physicians overwhelmingly report that HMOs have denied coverage, resulting in a decline in patient health. A Maryland state audit of denial for hospital services concluded that questionable judgment is used in denying care, and a Washington state study found a pattern of improper denials for emergency room treatment.<sup>57</sup> However, according to Karen Ignagni, chief executive officer of the American Association of Health Plans, health plans have heard the public's concerns and have subsequently developed "point of service" plans and grievance procedures and are incorporating independent external review. She believes that if Congress continues down its current path of allowing managed care organization decisions to be questioned in the courtroom, HMOs will not be able to challenge the dangerous levels of misuse of health care resources and that continued variations in medical practice may threaten patient safety.<sup>57</sup> Nonetheless, these coverage denials have placed an all-encompassing burden on the general public, adding the emotional burden of having to advocate for themselves while they are physically compromised and financially vulnerable.

As prescription costs continue to increase, many of the elderly are flocking to "managed Medicare" policies, because traditional Medicare does not cover this service. Although the managed care plans may be enticing, patients may not realize the involved restrictions that are imposed. Many professionals are advocates for the effort to "shift power not from physicians and hospitals to patients but from managed care companies, insurance companies and health care facilities to patients and their physicians."<sup>58</sup> In 1999, a for-profit managed care company hired a liaison to "quell a mounting rebellion by doctors upset with new rules the insurer is trying to impose on them,"<sup>59</sup> including finding the cheapest way to treat patients, even if another treatment would be more beneficial, and penalizing physicians who refer to out-of-network providers, even if the patient requires the specialist services. It is precisely these types of restrictions from which the public must be protected.

Between 1998 and 2002, hospitals nationwide are expecting a \$71 billion reduction in Medicare payments resulting from the Balanced Budget Act of 1997.<sup>60</sup> These reductions, combined with Medicaid shortfalls, will potentially compromise the current level of care provided by hospitals. Because individuals are now hospitalized for shorter periods, the multidisciplinary team often is no longer able to help patients adjust to a new diagnosis while anticipating the next phase of the illness and adaptation to its demands. Often, a social worker or discharge planner assisted the patient and family with transition to the community and assessed the barriers to care and, subsequently, planned for appropriate intervention. Although reimbursable services are obtainable, a wide gap in financial assistance faces patients without adequate coverage. Because of these concerns, many suggestions have been put forward for a universal health policy,<sup>53,61</sup> thereby allowing greater access for a majority of Americans.

## SURVIVORSHIP

The National Coalition of Cancer Survivorship defines survivors as living through and beyond a cancer diagnosis.<sup>62</sup> Today, approximately 8 million cancer survivors are alive,<sup>63</sup> and for the first time since the 1930s, the death rate of this disease has decreased and is leveling off or declining in all major body sites.<sup>1</sup> These statistics are mainly true for the nonminority community. According to McDonald,<sup>64</sup> African Americans continue to have higher incidence rates and are at greater risk of dying from cancer than any other racial or ethnic group.

Dow et al.<sup>65</sup> sent surveys to 1200 National Coalition of Cancer Survivorship members to explore quality-of-life issues for survivors. In a sample of nearly 700 people, the top emerging quality-of-life themes related to fatigue and pain, menopausal symptoms, and reproductive and fertility concerns, as well as to fears related to recurrence and immobility after treatment. Issues such as these encouraged the National Cancer Institute (NCI) to create the Office of Cancer Survivorship in July 1996. Additional issues reported by the NCI include fear of recurrence, late effects of treatment, the economic burden of the disease, physiological difficulties, depression, and sexual problems. Psychosocial difficulties occur more often with those who have had more aggressive initial treatment and those who have experienced a relapse. Additional concerns include cognitive deficits, such as in memory and concentration. Cases of discrimination in the workplace also have been reported, with their subsequent economic burdens. Klausner, director of the NCI, has stated that "the NCI has a responsibility to direct its efforts to issues that concern the many individuals who have survived cancer and their quality of life beyond treatment." The ACS also directs part of its mission toward the needs of cancer survivors, and organizations such as the Leukemia Society are following suit.<sup>66</sup> Continuing assessment of quality-of-life issues, along with appropriate interventions in the community, can enhance the lives of the ever-increasing number of cancer survivors. New and creative resources must be developed to meet the needs of this growing population, such as the technology that now allows for removal, freezing, and reimplantation of a woman's ovary to restore fertility.<sup>57</sup>

## APPENDIX: COMMON RESOURCES

This appendix lists the most commonly used and helpful resources, to which most of the populace can gain easy access.

### BONE MARROW TRANSPLANTATION

- Barbara Ann DeBoer Foundation: Identifies and makes use of resources in the patient's community to raise the funds necessary for the procedure. 1-800-895-8478.
- Blood and Marrow Transplant Newsletter: Provides a newsletter, resource directory, and patient support through telephone or e-mail. Keeps a list of attorneys who advocate for patients where insurance coverage has been difficult. 1-888-597-7674.
- Bone Marrow Transplant Link: Provides educational booklets, resource guides, and peer support via the telephone. 1-800-LINK-BMT.

- Bone Marrow Transplant Family Support Network: Provides support for newly diagnosed patients with recovered bone marrow transplantation patients. Offers counseling, groups, and insurance assistance. 1-800-826-9376.
- Caitlin Raymond International Registry: An international search coordinating center that assists individuals in finding compatible bone marrow donors. 1-800-726-2824.
- National Children's Cancer Society: Provides financial assistance for children diagnosed before 18 years of age in need of a bone marrow transplantation. Assists with fund-raising efforts and provides education, information, and patient advocacy. 1-800-882-6227.
- National Marrow Donor Program: Central registry facilitating searches and matches of donors and recipients. 1-800-654-1247.
- National Transplant Assistance Fund: Helps individuals raise funds for medically related transplantation expenses. Offers direct financial assistance in the form of grants to eligible candidates. 1-800-642-8399.
- Childrens' Organ Transplant Association: Helps families to raise funds for transplantation-related expenses. 1-800-366-2682.
- The Bone Marrow Foundation: Provides limited financial assistance for adjunct costs associated with bone marrow transplantation. 1-800-365-1336.

## CAMPS

Contact the local ACS (1-800-ACS-2345), Cancer Information Service (1-800-4-CANCER), or Children's Oncology Camps of America (803-434-3503) for a listing of local camps.

## CARE FACILITIES

Care facilities provide for the continuous health-related care of patients who are temporarily or permanently no longer able to manage living in their home. Various levels of care are available, and patients should explore these services with their physician or social worker to ascertain the most appropriate level of care. Patients should also confer with their insurance company to determine coverage.

Licensed boarding home: Provides a room and meals to fairly independent individuals. Health aides are often on staff.

Intermediate care facility: Provides limited nursing supervision and care.

Skilled nursing facility: Provides medical and continuous nursing and health-related services to patients who are not in the acute phase of an illness but who require an inpatient setting.

Subacute facility: Provides continuous medical, nursing, and health-related services to patients in a semiacute phase of their illness. These patients usually require high-tech care, such as total parenteral nutrition and intravenous antibiotics.

Hospice: Provides supportive care, terminal care, or symptom control to patients in various stages of cancer.

Rehabilitation: Provides services to patients with the goal of restoring them to an adequate level of functioning.

## CHILDHOOD RESOURCES

Candlelighters Childhood Cancer Foundation: Provides information, support, and advocacy to families of children with cancer, survivors of childhood cancer, and professionals who work with these populations. 1-800-366-2223.

Childhood Leukemia Foundation: 1-732-840-4533.

Children's Hospice International: Provides support, education, resources, information, and referrals for the care of ill children and the professionals who work with them. 1-800-242-4453.

Compassionate Friends: Provides assistance with bereavement issues after the death of a child. 630-990-0010.

Many people coping with a diagnosis of cancer now turn to their computers for cutting-edge information. When researching these databases, patients should always be aware of the source of information. Is it an informed oncology professional organization or credible institution? The following ( [Tables 56.6-1](#) and [Table 56.6-2](#)) is a representative listing of the numerous commercial databases that can assist in accessing oncology information. Many databases and associated links exist for specific cancers. To obtain a more comprehensive list, search engines can be used, such as [About.com](#), Achoo, AtCancer, CiteLine, Physicians' Choice, MedNets, Medscape, Medical Matrix, Medsite, and Yahoo!.

### EMOTIONAL SUPPORT

In the cancer experience, stress commonly occurs at the time of diagnosis, during the treatment phase, at the end of treatment, at time of relapse, or during the terminal phase. To adequately cope with the impact of cancer, emotional support is essential for both the patient and the caregiver. Although some individuals may choose to procure support from intimate sources, others look to the community for support. Community services include self-help, professional, individual, or group modalities. Ambulatory and hospital-based settings may provide social work, psychiatric therapy, and pastoral care services.

American Cancer Society: The ACS sponsors the following programs. Contact your local ACS at 1-800-ACS-2345, as programs may vary.

Cancer Survivors Network: Provides one-to-one telephone or computer support to cancer survivors.

I Can Cope: Support group for individuals with cancer and their families.

Look Good Feel Better: Provides assistance to individuals with cancer regarding skin and hair changes.

Man to Man: Support for men with prostate cancer.

Reach to Recovery: Provides support, information, and education to women who have been diagnosed with breast cancer.

Road to Recovery: Provides volunteer drivers to assist with transportation to and from physicians' offices or hospitals.

Taking Charge of Money Matters Workshop: Provides education about financial concerns during the treatment of cancer, regardless of insurance status.

American Chronic Pain Association: A self-help organization that offers education and peer support to help people live with chronic pain.

Cancer Care: Offers free support services, education, information, and referrals. 1-800-813-HOPE.

Family service agencies: Provides information, emotional support, and psychological assistance.

International Association of Laryngectomies: Works toward the rehabilitation of the laryngectomy patient by providing support to those individuals who have lost their voice box as a result of cancer. 301-983-9323.

Leukemia Society of America: Provides support, education, and limited financial assistance. 1-800-955-4572.

National Self-Help Clearinghouse: Refers individuals to self-help groups in their community. 212-817-1822.

Private practitioners: Provide emotional support and psychological interventions. Many insurance companies have a preferred provider list, which should be consulted for reimbursement purposes.

Bloch Cancer Foundation: Provides information, peer counseling, and support groups. 1-800-433-0464.

Religious organizations: Provide emotional support, pastoral care, and spiritual guidance.

Us Too International: Provides support to men with prostate cancer and their families.

Well Spouse Foundation: Provides support groups and newsletters to partners and caregivers of the chronically ill. 1-800-838-0879.

Y-Me: Provides peer support to women with breast cancer. 1-800-221-2141.

### FINANCIAL ASSISTANCE

#### INCOME-RELATED ASSISTANCE

Short-term disability: Some employers offer short-term disability income with proof of medical necessity.

Social Security Administration: 1-800-772-1213.

Supplemental Security Income (SSI): A federally funded income maintenance program for the elderly, blind, or disabled. SSI has restrictions on income and asset allotments.

Social Security Disability: A federally funded program for the disabled and for survivors of a deceased wage earner.

City, state, or federal assistance

Aid to Dependent Children: Provides financial assistance, medical insurance, and food stamps for eligible families with dependent children.

General assistance/city or town welfare: Financial assistance program for eligible individuals who do not have enough resources to meet basic needs.

Food stamps: A program designed to assist eligible individuals or families to purchase food.

## **TREATMENT-RELATED ASSISTANCE**

State departments on insurance can provide information about local insurance carriers. Once cancer is diagnosed, it is often difficult for patients to obtain commercial insurance, except with an exclusionary clause.

Medicare: A federally funded insurance program for the elderly or disabled. To be eligible as the latter, one must be on Social Security Disability for 2 years. Hospital coverage is called *Part A* and covers the costs of hospitalization, except for the deductible, skilled nursing facility, and home health care. Medical coverage is called *Part B* and pays for a share of the cost for physician, outpatient, and hospital services; ambulance transportation; and physical and occupational therapy. One must be enrolled in Part B and pay monthly for this coverage. Social Security can be contacted at 1-800-772-1213 for more details.

Medicare health maintenance organizations: Similar benefits to Medicare but "managed" differently and may include additional benefits, such as prescription coverage. A preferred provider list is used.

Medicaid: A state program that provides coverage for medical expenses and financial entitlements to eligible individuals. The Department of Social Services can be contacted for more information. Check local phone listings.

Hill Burton: Federal funds are provided to some institutions to cover the cost of care for individuals who are ineligible for other entitlements. Financial restrictions apply. 1-800-638-0742.

American Association of Retired Persons: Organization that assists persons 50 years of age and older. Provides information and supplemental insurance options. Fees vary based on policy choice. 202-434-2277.

Pharmaceutical assistance: Some states offer programs that assist with the cost of prescription drugs for the elderly or disabled who meet financial criteria. Most pharmaceutical companies offer drugs at no cost to people who cannot afford them; however, stringent criteria apply and application is required. A listing can be obtained through PhRMA (America's Pharmaceutical Research Companies; <http://www.phrma.org>).

Transportation reimbursement: Can be obtained through various agencies, such as the Leukemia Society.

## **HOME HEALTH CARE**

Resources can be provided through hospital departments of social work or discharge planning, as well as physicians' offices or ambulatory settings.

Visiting nurse/public health nurse: Provides skilled care, nurses aides, and ancillary staff to eligible individuals. Requires physician's orders and, often, preauthorization. Can also provide information about local resources to supplement these programs.

Hospice: Provides comprehensive home care services, including the use of volunteers, to individuals with a limited prognosis. Requires physician's orders and, often, preauthorization.

Home medical equipment: Usually reimbursed by insurance and is available through local suppliers. Some local agencies, such as the ACS or the Visiting Nurse Association, may have a loan closet.

Proprietary home care agencies: Can provide high-tech services in the home, such as home chemotherapy, total parenteral nutrition, and intravenous administration of antibiotics or other drugs. Preauthorization is needed.

Meals on Wheels: Meals are prepared and delivered to eligible homebound elderly or disabled people. A fee is often charged.

Friendly Visiting: A community outreach program offered through towns, agencies, and religious organizations in many areas.

## **HOUSING**

Ronald McDonald House: Provides housing for families of out-of-town pediatric patients. Some facilities can occasionally accept adult patients on a priority basis. Contact local hospital social work departments or physicians' offices for referral.

Westin Hotels: Some of these hotels offer free accommodations to ambulatory patients and their family members. Contact the hotel directly or the ACS.

National Association of Hospital Hospitality Houses: Provides a resource directory of no-cost accommodation. 1-800-542-9730.

## **SURVIVORSHIP**

Cancervive: Assists cancer survivors to face and overcome the challenges of having cancer. 310-203-9232.

*Coping* magazine: Publication for individuals involved with cancer. 615-790-2400.

National Cancer Survivors Day: National annual celebration of life for cancer survivors.

National Coalition for Cancer Survivorship: Provides information regarding the issues of survivorship and provides peer support. 877-622-7937.

The Wellness Community: Provides psychosocial support to individuals recovering from cancer. 310-314-2555.

## **TRANSPORTATION**

Airlifeline: A nonprofit association of pilots who donate their time, fuel, and aircraft to provide medical transportation to ambulatory patients. 1-800-446-1231.

Ambulance/chair cars (Handivans): Can be arranged for medical appointments and sometimes are covered by insurance. Preauthorization is necessary, except in emergency.

American Airlines Miles for Kids in Need: Provides free transportation to children who demonstrate need. 817-963-8118.

Corporate Angel Network: A nonprofit organization that provides free plane transportation. 914-328-1313.

National Patient Transport Helpline: Assists patients in finding the most economical way of being transported to a medical facility. 1-800-296-1217.

Southwest Airlines: Provides no-cost transportation to medical destinations to patients in medical need. 214-792-4103.

## VETERANS BENEFITS

U.S. Department of Veteran Affairs: Provides benefit information to veterans regarding educational assistance, disability compensation, medical care, life insurance, burial benefits, and dependent benefits. Some states may offer local benefits.

## WISH FOUNDATIONS

A Wish with Wings: Grants wishes to children with life-threatening illness. 817-469-WISH.

Brass Ring Society: Grants wishes to children with life-threatening illness. 1-800-666-9474.

Dream Factory: Grants wishes to children ages 3 to 13 with life-threatening illness in cities where there are chapters. 502-637-8700.

Make-a-Wish Foundation: Grants wishes to children with life-threatening illness. 1-800-722-9474.

## INTRODUCTION

"The functions of medicine are threefold: to relieve pain, to reduce the violence of disease and to refrain from trying to cure those whom disease has conquered, acknowledging that in such cases medicine is powerless."<sup>1</sup>

Hippocrates

Although Hippocrates called for restraint in the presence of terminal illness, research has documented substantial shortcomings in the contemporary care of terminally ill patients. The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT), involving more than 9000 patients hospitalized in five U.S. medical centers, found that end-of-life treatments were overly aggressive and too often not in accordance with patients' wishes. Furthermore, 50% of conscious patients dying in the hospital were reported by their surviving family members to have been in moderate to severe pain in the last week of life.<sup>2</sup> Among 913 Canadian outpatients "respondents were more likely to be dissatisfied with their treatments for their symptoms than for their cancer,"<sup>3</sup> which were similar to findings in Italy.<sup>4</sup> Reasons for inadequate care of the seriously ill range from a basic lack of medical education and experience in palliative care to a professional ideology that precludes the acceptance of death as an outcome of care.

Organized efforts to promote palliative care in the United States are relatively recent. Several U.S. organizations have funded studies and developed programs to promote palliative care (Table 56.7-1). The Robert Wood Johnson Foundation, through Last Acts, has sponsored several initiatives in end-of-life care, and the Open Society Institute's Project on Death in America supports clinicians active in this area of medicine. The American Medical Association has now launched the Education for Physicians on End-of-Life Care (EPEC) Project.

TABLE 56.7-1. Selected Web Sites in Palliative Care

These programs promote integration of palliative care standards into our major health care delivery systems, as well as education for consumers about options at the end of life. Changes in medical education are also occurring.<sup>5</sup> Publishers of medical and nursing textbooks are incorporating new content on end-of-life care. The fifth edition of this textbook received the award for "Best Chapter with End-of-Life Care Content in a Specialty Textbook," sponsored by the Robert Wood Johnson Foundation.

## OVERVIEW OF HOSPICE CARE

### A BRIEF HISTORY

In the second half of the nineteenth century, the Irish Sisters of Charity in Dublin, Ireland, and a group of "pious widows" in Lyon, France, began to provide care specifically dedicated to the dying. In 1905, the Irish nuns opened St. Joseph's Hospice in Hackney, where Cicely Saunders (now Dame Cicely in honor of this achievement) began her work in developing the principles of modern hospice and palliative care. With formal training in social work, nursing, and medicine, Dr. Saunders has continued these efforts at St. Christopher's in Sydenham outside London since 1967. The concept of around-the-clock analgesia, consideration of "total pain," and comprehensive care through the integrated work of an interdisciplinary team (IDT) are hers.

Inspired by visits from Dr. Saunders to the Yale School of Medicine in the early 1960s, a group of forward-looking health care practitioners from several clinical disciplines developed a hospice program that received state regulatory approval. The home hospice served its first patient and family in early 1974, followed by the opening of the first American inpatient facility in Branford, Connecticut, in 1980.

In 1978, the U.S. government established a Hospice Task Force to examine the potential role of the federal government in the development of hospice care. The Health Care Financing Administration funded a project to assess cost and quality of service provided by hospices.<sup>6</sup>

### ORGANIZATION AND FINANCING

The National Hospice Education Project, the political arm of the hospice movement, crafted legislation that eventually became part of the Tax Equity and Fiscal Responsibility Act of August 1982.<sup>7</sup> In 1983, terminally ill patients older than 65 years of age became eligible for hospice services under the Hospice Benefit of the

Medicare program. To qualify for the benefit, a patient must be certified by both the referring physician and the hospice physician as having a terminal illness with life expectancy of 6 months or less. Services were limited by time and a financial cap. Eighty percent of patient care costs for each hospice were allocated to home care services to reduce expenditures for institutional care. Patients receiving services reimbursed by Medicare under the Hospice Benefit relinquished their Part A coverage for any active treatment of their terminal illness. If patients wish to return to active treatment, they may revoke the Hospice Benefit at any time. In later years, Medicaid coverage was approved by the Health Care Financing Administration as a state option. At present, Medicaid covers hospice care in 43 states and the District of Columbia.<sup>8</sup>

## THE ORGANIZATION AND PHILOSOPHY OF HOSPICE TODAY

In 1999, the National Hospice Organization estimated that more than 3000 hospices are operating in the fifty states, Washington D.C., and Puerto Rico. Approximately 540,000 patients and families received hospice care in 1998. Although hospices may exist within institutions, such as a hospice wing in a hospital, or as freestanding hospices, the majority of care is provided as home care.<sup>8</sup>

No standard definition of hospice care exists, but several core principles govern its practice: (1) Hospice work is meant to enhance the quality of remaining life, not to hasten death or prolong life. The goal is to maintain for patients and families the level of comfort and calm that they wish and to offer education and guidance concerning their options at various stages of disease. (2) Delivery of care to patients and family is provided by an IDT that includes nurses, physicians, social workers, pastoral care givers, and volunteers. Often, additional members contribute through the arts, physical therapy, dietary consultations, and alternative therapies. (3) The patient and family group is considered the primary focus of care, not just the patient and not just the disease. After a patient's death, hospice provides bereavement services.

## DIAGNOSES, ADMISSION GUIDELINES, AND ESTIMATING PROGNOSIS

The life-threatening illness most identified with hospice is cancer. In 1995, however, the National Hospice Organization census reported that malignant disease accounted for only 60% of hospice patients.<sup>8</sup> From its beginnings, hospice services have been available to patients with other terminal illnesses, and criteria for admission to hospice with these diagnoses were formulated and, in 1998, accepted by Medicare.<sup>9</sup> Most hospice patients are covered by Medicare under the Hospice Benefit.

Prognosis is generally taken in medicine to indicate whether a given disease is life-threatening and, if so, how long the patient can expect to live. Establishing a prognosis for an individual cancer patient is much more difficult than doing so for a population of such patients.

Three studies that included large numbers of patients with cancer at all stages<sup>10,11</sup> and<sup>12</sup> found that functional or performance status was the most accurate predictor of survival. Decline in activities of daily living, including bathing, continence, dressing, and transfer, were very strongly associated with decreased survival. The Karnofsky performance status is another useful measure of prognosis, and it clearly differentiates the survival time of patients with terminal cancer. The median length of survival for three groups with Karnofsky scores of 10 to 20, 30 to 40, and 50 or higher were 17, 50, and 86 days, respectively. This predictive score was strengthened by five common findings: anorexia, weight loss within 2 weeks, dry mouth, shortness of breath, and dysphagia.<sup>11</sup> Deteriorating mental status and cognitive ability are also predictors of shortened survival in cancer patients.<sup>13</sup>

A model of survival at 2 and 6 months for seriously ill hospitalized patients has been developed as part of the SUPPORT study. This model uses primarily demographic, diagnostic, and physiologic variables as opposed to the symptom-based models. However, addition of a physician's prognosis improved the model's performance.<sup>14</sup>

All authors agree that accurate prognosis for cancer patients is both important and difficult for physicians, patients, and families. Physician prognoses are often too optimistic<sup>15,16</sup> (but not always).<sup>17</sup> Overoptimistic prognoses can inappropriately commit the patient to futile interventions, thereby increasing the anguish of patient and family, and also increase the expenditure of valuable time and resources. In addition, unexpectedly short survival times and resulting late referrals to hospice programs deprive patients and families of available support and of time to settle affairs and achieve closure.<sup>18</sup> More research is needed to improve the accuracy of predicting life expectancy. The ultimate decision to seek admission to hospice must rest on the patient's, family's, and physician's acceptance of the futility of further curative treatments.

## FUTILITY AND THE DECISION TO SEEK PALLIATIVE CARE

In the progression of most serious illnesses, therapeutic response eventually diminishes or disappears; risks begin to outweigh benefits as further therapy becomes futile.

Jecker and Schneiderman<sup>19</sup> identify four common sources for the current debate over futility and health care: (1) Increasing costs raise societal concerns about equitable delivery and possible rationing of health care. (2) Expensive technical innovations make it possible to extend life in ways that only recently seemed impossible. (3) The aging of the population raises concerns about future costs during years of longer life in this increasingly numerous group. (4) The concept of patient autonomy is being challenged as society confronts the new concerns just mentioned. Physicians must be better prepared to educate patients and families about the options of palliative care as a desirable option in progressive terminal illness.

Acknowledgment of futility is a moment when optimal care of the patient shifts from a focus of cure and care to a palliative one of care only. Jonsen<sup>20</sup> has formulated the following situations in which futility should be considered: (1) *futility in process*, in which a long and difficult course continues without any improvement; (2) *futility in prognosis*, when patients start treatment that has rarely or never proved useful in similar cases; (3) *futility in result*, when treatment is technically successful but the resulting quality of life is undesirable. Each of these decision points is frequently encountered by oncologists.

Recognizing these junctures and communicating them to patients and families requires physician sensitivity to the philosophy and practice of palliative care. The patient's concerns, fears, and goals can be elicited by using open-ended questions and probing the patient's response.<sup>21</sup> Some patients sincerely question the advisability of pursuing or initiating new active therapy, thereby providing an opportunity for discussing other options. During such discussions, the physician can state that cure or control of disease is no longer possible. The choice of "no therapy" can hold the same stature as the alternative. Each physician must use his or her experience to influence the proper choice, always supporting the patient in the final decision and never implying disappointment, anger, or abandonment. Where patient and family insist on or demand futile treatments, it is incumbent upon the physician to begin discussion of palliative care as an acceptable option. Furthermore, the possibility for hope and the new goal of maintaining quality of life through palliative care are emphasized. Patients and families should understand that their role in developing symptom management may be greater than their role in directing curative therapies. This shift in goals and participation is a significant part of the process for patients and families in dealing with the end of life.

Many patients have fears and beliefs that make it difficult for them to accept palliative rather than curative care. Patients may fear that accepting death means that they will experience abandonment and isolation as both their families and medical care givers "give up" on them. They may foresee uncontrolled pain and suffering and devaluation of their personhood. Physicians should be mindful that these concerns may hinder patients from finding hope in the decision to seek palliative care, and they should openly discuss the support provided by palliative care programs.<sup>22</sup> The decision for palliative care usually involves the opening of many other emotional, interpersonal, and spiritual opportunities for patients and families. Patients may use this decision point to resolve these interpersonal issues and to seek closure. Hospice caregivers are trained to assist patients in reviewing their lives, thereby affirming self-worth. The IDT includes the pastoral care staff whose members can help patients and families find spiritual meaning as they face the end of the patient's life.

From the physician's perspective, providing palliative care rather than therapy with curative intent implies a change in his or her role with respect to patient and family. Within hospice, the physician is only one member of the IDT. The physician receives support from that team and, in turn, can help empower patients to see their medical care and symptom management as part of a more comprehensive approach to terminal illness.

The following section describes in greater detail the most common symptoms encountered at the end of life and the options available to physicians, patients, and families.

## SYMPTOM MANAGEMENT

### SYMPTOM PREVALENCE IN HOSPICE PATIENTS

Table 56.7-2 lists symptom prevalence as percent of patients affected in the surveyed populations; other comparable studies exist.<sup>11,23</sup> The results allow a few clear-cut conclusions: (1) Weakness, fatigue, pain, dyspnea, nausea, and vomiting remain important symptoms throughout much of the course of the disease. As cancer progresses, some decrease in pain may be due to adequate palliation. Others have noted increasing prevalence of dyspnea at the very end of life.<sup>24,25</sup> (2) Weight loss, anorexia, and insomnia become irrelevant in the last stages of disease, despite earlier importance. (3) Troublesome oral and respiratory secretions (“chesty” symptoms), drowsiness, and myoclonus become prominent in the last days of life.

Symptoms	Prevalence (%)		
	2-Mo Median Survival	During Month Before Death	24-Hr Before Death
Weakness	67	73	77
Pain	67	59*	56
Fatigue	66	58	55
Anorexia	60	50*	45
Confusion and loss thinking	59	56*	53
Dyspnea	58	49*	55
Nausea and vomiting	58	52*	50
Weight loss	53	45*	42
Insomnia	51	40*	37
Depression	50	37	35
“Chesty”	49	45	52
Drowsy	47	52	47
Myoclonus	46	52	55

\*Data from ref. 27: retrospective study of 1000 hospitalized cancer patients seen by palliative care consultation team over the course of approximately 7 months (range 6 to 30 d).  
 †Data from ref. 28: retrospective study of 80 cancer outpatients referred to palliative care team for home care; ref. 29: retrospective study of 180 cancer outpatients referred to palliative care team; and ref. 30: retrospective study of 170 cancer patients cared for at home, in hospice units, or in hospital by palliative care team.  
 ‡Data from ref. 31: retrospective study of 800 patients in hospice care; and ref. 32: retrospective study of 200 patients in hospice care or home or in hospice unit. ††Data from ref. 33: retrospective study of 1000 patients in hospice care.  
 ‡‡Prevalence based on all three reports in refs. 29, 31, and 32. All other prevalences in this column are based on refs. 28 and 30 only.

TABLE 56.7-2. Symptom Prevalence in Cancer Patients at Various Stages of Disease

Several important points about symptom prevalence are not evident from Table 56.7-2: (1) Most cancer patients have multiple symptoms.<sup>24,26,27,28,29</sup> and 30 (2) The most common symptoms are often the most severe.<sup>3,27,28</sup> (3) The constellation of symptoms shows some variation with the site of primary disease.<sup>25,26</sup> and 27,31,32 For example, dyspnea is especially common in lung cancer<sup>25,27</sup>; nausea and vomiting in carcinoma of pulmonary, gastrointestinal, and gynecologic origins<sup>26,27</sup>; dysphagia in carcinoma of head and neck and of esophagus<sup>27</sup>; and pain in bony metastases of any origin and in primary lung, gynecologic, and prostate cancers.<sup>26,27,31</sup> (4) Some symptoms either worsen or recur, and new ones appear as cancer progresses. In one study of the last 48 hours of life, 22% of patients had worsening of previously controlled pain, and 30% had new pain.<sup>33</sup> (5) Older patients tend, as a group, to have less pain than younger patients.<sup>27,31</sup>

In the following sections, palliation of many of these symptoms is discussed; others are treated more fully in Chapter 55.1, Chapter 56.1, Chapter 56.2, and Chapter 56.5. Readers should consult the review by Ingham and Portenoy<sup>34</sup> for extended discussion of symptom assessment tools.

### FAILURE TO THRIVE

The effects of cancer disrupt normal anatomy and physiology, locally in the vicinity of the tumor or its metastases and globally in sites far removed from the tumor. The latter global effects may also be called *constitutional* or *paraneoplastic*. The signs and symptoms of failure to thrive are a prime example of constitutional change and occur in many (and probably most) cancers.<sup>3,35,36</sup> The phrase *failure to thrive* incorporates many terms, including anorexia, asthenia, cachexia, fatigue, lethargy, and weakness, which overlap in etiology and manifestations. *Weakness* implies generalized physical debility and *lethargy* refers to the inability to maintain normal physical and mental effort. In this discussion, fatigue is comprised of weakness and lethargy. Failure to thrive is defined as a symptom complex of anorexia and fatigue.

The intensity of the components of failure to thrive is not necessarily related to tumor size, tissue origin, cell type, or degree of differentiation.<sup>37</sup> Evidence now implicates tumor-associated cytokines and their interaction with normal components of the immune system creating these signs and symptoms.<sup>38</sup>

Anorexia occurs in most patients with cancer at some time.<sup>30,36,39</sup> The goal of its treatment in hospice care is patient satisfaction and, in some cases, nonfluid weight gain.

Pharmacologic therapy can promote nutrition by increasing appetite, controlling nausea and vomiting, improving gastric reflux, and sometimes by relieving obstruction. Clear-cut improvement in anorexia has been documented with progestational drugs, especially megestrol acetate. At 800 mg/d, patients showed improved appetite, nonfluid weight gain, and reduction in nausea and vomiting.<sup>40,41</sup> and 42 Doses of more than 800 mg/d are not more effective. In a trial of chemotherapy with and without megestrol in patients with extensive small cell lung cancer,<sup>42</sup> however, neither quality of life nor survival time was improved with megestrol. Corticosteroids may also be helpful in stimulating appetite and improving mood. Corticosteroids are less expensive than progestational agents but also have more significant side effects.<sup>43</sup> Other agents are being studied as therapy for anorexia and wasting. For surveys of these medications, the reader should consult available reviews.<sup>38,39,44</sup>

Nonpharmacologic maneuvers may be helpful in treating anorexia and promoting nutrition. These maneuvers include mouth care, maintenance of regular bowel movements, and stressing patient choice in food preparation. Meals should consist of small portions served at the proper temperature, usually course by course, and seasoned to the patient's taste. Family and friends eating with the patient creates a shared experience that may be beneficial to all.<sup>45</sup> Mouth care involves simple measures such as gentle cleansing of the tongue, teeth, and gums; moistening with artificial saliva or ice chips; and promoting salivation with tart foods such as lemon ice. On occasion, oral comfort entails more intensive therapy to treat mucositis due to antitumor therapy or oral thrush.<sup>46</sup>

In late stages of cancer, most patients neither wish nor profit from interventions to treat anorexia pharmacologically. Similarly, forced feedings or nutritional supplements urged on the patient by well-meaning clinicians and family often offer more risk (e.g., aspiration, anxiety) than benefit. Enteral and parenteral nutrition have not been shown to be helpful in improving the quality of life or prolonging survival of cancer patients at the end of life.<sup>47,48</sup>

Fatigue is a major symptom in the failure to thrive of progressive illness.<sup>3,24,35,36</sup> The components of weakness and lethargy are multifactorial and appear to be driven by direct effects of tumor products creating deleterious changes in skeletal muscle and the central nervous system.<sup>38</sup> Many common elements of cancer and its treatment may contribute to fatigue: fluid and electrolyte imbalance, infection, anemia, paraneoplastic disorders, side effects of chemotherapy, radiation, other medications, and psychological reactions to disease and therapy.

In evaluation of fatigue, one monitors the patient for potentially correctable causes, such as anemia, dehydration, hyponatremia, hypokalemia, hypercalcemia, hypoglycemia, and renal and hepatic function. Medications that contribute to fatigue, including the opioids, sedatives, antidepressants, and muscle relaxants, can be adjusted by choosing agents for better side effect profiles. Rotation of opioids can maintain analgesia while decreasing side effects. Other medications can be discontinued if not important to comfort.

Nonpharmacologic approaches to improving fatigue include budgeting energy, delegating some daily tasks to others, and rescheduling activities to allow time for rest. Reassessment of goals in everyday life is necessary to form realistic expectations of physical abilities and energy capacity. Controlled programs of exercise and the use of physical and occupational therapy can improve a patient's tolerance of everyday activities.<sup>49</sup>

Medications used to alleviate fatigue include psychostimulants and steroids. Psychostimulants such as methylphenidate<sup>50,51</sup> and pemoline<sup>52</sup> are used in palliative care to counter the sedative effects of opioid analgesia and as antidepressants.<sup>52,53</sup> Steroid therapy has shown some improvement in asthenia,<sup>43</sup> although the beneficial effect seems to diminish 2 to 3 weeks after initial use. As was noted with anorexia, total parenteral nutrition does not reverse fatigue.<sup>47</sup>

Finally, although the emphasis in palliative medicine is symptom control rather than curative therapy, palliative antineoplastic therapy is the most global means of

controlling the cancer and its underlying pathophysiology and improving failure to thrive.

## PAIN

Pain pervades the physical being, social relationships, and spiritual dimensions of those who live with it. The presence or recurrence of pain is perceived as a sign of persistent disease and creates fear and anxiety. However, its treatment by physicians is often inadequate <sup>2,54,55</sup> (see [Chapter 56.1](#) for an extensive discussion of pain and its treatment). Twelve important considerations in pain management relative to the terminally ill patient are emphasized in this chapter:

1. Assess pain carefully and reassess frequently. Believe the patient and treat pain promptly. Successful analgesia is possible in 85% to 95% of cancer patients using basic pain management techniques. <sup>56</sup>
2. The World Health Organization ladder is used to start treatment at the level most appropriate to the degree of pain, with escalation as necessary. <sup>57</sup>
3. Morphine is the standard of opioid therapy for severe pain.
4. The oral route for opioids is preferred whenever possible.
5. Alternative preparations and routes of administration are available, including rectal suppositories, transdermal patches, and both subcutaneous and intravenous parenteral preparations. A percutaneous button for multiple injections provides a single subcutaneous route lasting 3 to 4 days before change of site is needed. Compact portable pumps can deliver medication by both intravenous and subcutaneous infusion.
6. Around-the-clock analgesia controls pain best, with breakthrough doses available as needed.
7. A good command of equianalgesic doses and oral-parenteral ratios of the available opioids is essential. Methadone is gaining more acceptance for chronic pain therapy. <sup>58</sup> Note that the equianalgesic ratio, published as 1:1, may be much smaller, implying that methadone is more potent than anticipated. <sup>59</sup> When switching to methadone, approximately 10% to 30% of the equivalent daily morphine dose should be used. <sup>60</sup>
8. Rotation of opioids can be helpful in controlling side effects. <sup>61</sup> The cross-tolerance of opioids is incomplete, and using one-half to two-thirds of the equianalgesic dose of an alternate opioid can result in the same level of pain control with fewer side effects.
9. Avoid chronic use of inappropriate opioids. Accumulation of the active metabolite of meperidine, normeperidine, can produce central nervous system hyperexcitability with myoclonus and generalized seizures. <sup>62</sup> The mixed agonist-antagonist analgesics have a ceiling dose for pain control and can block the pure agonists at the mu opioid receptor sites.
10. Use adjuvant medications in combination with opioids, particularly for neuropathic pain and pain due to bone metastases.
11. Always begin medications for bowel care when opioid therapy starts.
12. Understand tolerance, dependence, and addiction. Psychological dependence or addiction is extremely rare in the patient with cancer and chronic pain. <sup>63,64</sup> This consideration should never be a barrier to good pain control in cancer patients, including those with a history of illicit drug use.

## DYSPNEA

Dyspnea is the uncomfortable sensation of labored breathing. Shortness of breath can be a terrifying experience, and it frequently increases at the end of life. <sup>24,25</sup> Pain, anxiety, and fear complicate its clinical presentation. For patients with terminal illness but months to live, proper evaluation of dyspnea may lead to at least temporary control of its underlying cause or causes. For those with days or weeks of life remaining and who are unable or unwilling to undergo further testing, one should proceed directly to symptom control.

Dyspnea can be multifactorial in many cancer patients. Investigation of dyspnea is often limited by patient tolerance. Full pulmonary function tests are not usually necessary. However, measuring the forced expiratory volume with and without bronchodilators, standard chest x-rays, ultrasound, and ventilation/perfusion scans are not invasive and can detect abnormalities that respond to tolerable remedies.

Therapy for dyspnea requires addressing both malignant and nonmalignant causes in cancer patients. Treatment of chronic lung disease, pulmonary infection, cardiac failure, and arrhythmias can improve the patient's comfort. Venous thrombosis and pulmonary embolism are common in malignant disease and, barring major contraindication, can be managed with oral or subcutaneous anticoagulants. Thoracentesis and paracentesis can be bedside procedures in a hospice inpatient setting. However, thoracentesis can result in pneumothorax, and the risks must be discussed, particularly when tube thoracostomy is not immediately at hand. For the dyspnea of obstructing pulmonary lesions with atelectasis, a short course of palliative chest radiation may be appropriate. <sup>65</sup> Aspiration of a pericardial effusion can bring dramatic relief of dyspnea, but proceeding to a pericardial window requires careful consideration of benefits to the patient. Maximal supportive care may be more appropriate. Similarly, laser therapy of obstructing pulmonary lesions and endobronchial stents <sup>66</sup> are available for patients who can tolerate the procedures. High-dose corticosteroids can temporarily improve the dyspnea of metastatic pulmonary lesions, especially that of the lymphangitic type. Steroids also are effective in treating superior vena cava syndrome and, to a lesser extent, radiation pneumonitis.

Respiratory sedatives must be considered for those patients very near the end of life who are in respiratory distress and cannot tolerate the treatments just mentioned. The benefit of these medications, including alcohol, barbiturates, benzodiazepines, phenothiazines, and opioids, comes from suppression of respiratory awareness. Parenteral opioids have become an established treatment of dyspnea in cancer patients, without causing significant deterioration in respiratory function. <sup>67,68</sup> Morphine sulfate, 2.5 to 5.0 mg, subcutaneously as a single dose can be effective in the opioid naïve patient or in patients receiving only intermittent analgesia. It may be necessary to repeat two or three doses at 20- to 30-minute intervals for satisfactory relief. For those patients already receiving opioids for pain on a regular basis, a larger dose is needed, one that is 1.5 to 2.5 times the patient's q4h dose. Morphine for dyspnea is usually prescribed on an as-needed basis, but for chronic dyspnea, administration is needed every 4 hours.

Nebulized morphine has been proposed as an alternative route of administration for therapy of dyspnea. Its use has been reported in both cancer patients <sup>69,70</sup> and <sup>71</sup> and those with nonmalignant chronic lung disease. <sup>72,73</sup> and <sup>74</sup> Although several authors report relief with nebulized opioids, the studies are uncontrolled case reports and retrospective chart reviews. Morphine and hydromorphone were the most commonly used medications. A subset of patients responded to this treatment, but additional randomized and controlled studies are needed.

Morphine is prepared for inhalation by addition of 5 mg of the standard parenteral product to 3 mL of normal saline as a starting dose. Doses as high as 50 mg have been used without undue side effects. <sup>70,71</sup> In both normal volunteers and patients at surgery, systemic bioavailability of morphine after inhalation is only 5% to 35% of the comparable parenteral dose. <sup>75</sup> Patients familiar with nebulizer therapy may prefer this route. Nebulizer therapy is easily used at home and is inexpensive. However, a word of caution is necessary. Rarely, inhaled morphine can induce bronchospasm, possibly related to the preservatives present. <sup>69</sup> The first dose by inhalation should be administered in a controlled situation. In some patients, severe unremitting cough can contribute to breathlessness, and relief can be obtained with nebulized anesthetics. Nebulized lidocaine can be an effective cough suppressant.

Audible congestion in the last hours of life, the death rattle, is very disturbing to caregivers and family, if not the patient. Scopolamine can reduce secretions and control noisy respiration. A scopolamine patch may be sufficient, but a subcutaneous dose of 0.4 to 0.8 mg of scopolamine every 2 hours as needed is more potent and more rapid in onset. Scopolamine is sedating and may not be appropriate in some situations.

## NAUSEA AND VOMITING

Increasingly, interest in nausea and vomiting has been directed toward terminally ill cancer patients not receiving chemotherapy. <sup>76</sup> Prevalence can be as high as 40% to 46% in the last 6 weeks of life <sup>77</sup> and, in the final days, may be so refractory that patients require sedation. The physiology of nausea and vomiting and appropriate therapies are reviewed in [Chapter 55.1](#), especially as related to chemotherapy.

Workup of this problem in a terminally ill patient begins with a history and physical examination. Diagnostic studies must be consistent with the patient's condition and goals of palliative care. Invasive diagnostic studies may not be appropriate when no primary therapy exists.

Four anatomic centers initiate stimuli that produce nausea and vomiting: the central nervous system, the vestibular apparatus, the chemoreceptor trigger zone, and the viscera. <sup>78</sup>

Recurrent primary or metastatic brain tumors often cause emesis. Dexamethasone up to 30 mg/d may relieve symptoms associated with increased intracranial pressure due to either primary or metastatic tumors. Fear, anxiety, and pain can cause nausea and vomiting, and can be controlled by benzodiazepines and

analgesics, respectively.

Vestibular causes may respond to anticholinergics (scopolamine), antihistamines (meclizine), and phenothiazines with H<sub>1</sub> antagonism (promethazine).

Relief of nausea and vomiting due to stimulation of the chemoreceptor trigger zone requires adjustment or replacement of medications. Chronic medications previously tolerated may become toxic because of altered drug metabolism or excretion as cancer progresses. Evaluation of metabolic abnormalities, such as hypercalcemia and uremia, may reveal correctable causes of nausea and vomiting.

The most problematic and refractory causes of emesis in advanced cancer patients result from gastrointestinal or visceral disease. If gastric irritation is suspected, as from nonsteroidal antiinflammatory drugs, cytoprotectants and acid-blocking agents can be effective without the need for antiemetics. New medications time-related to onset of nausea and vomiting can be stopped or replaced.

Overfeeding can lead to vomiting; and small feedings satisfy anorexic patients. At the end of life, tube feedings are associated with large gastric residuals, gastric distension, vomiting, and increased risk of aspiration.<sup>48</sup> Prokinetics, such as metoclopramide, may be helpful, but it is often appropriate to reduce or discontinue feeding. Effective bowel care controls nausea and vomiting associated with constipation. Laxatives must accompany routine opioid use. Urinary catheterization with relief of retention can end nausea, agitation, and restlessness.

The pain and nausea of hepatic metastases presumably caused by stretching of the liver capsule are relieved by nonsteroidal antiinflammatory drugs and corticosteroids with gastroprotection. Paracentesis for tense ascites controls one cause of the "squashed stomach syndrome," with restricted gastric volume, early satiety, and nausea.

Gastrointestinal obstruction, commonly due to ovarian, colonic, pancreatic, and gastric carcinomas, results in nausea and vomiting<sup>78</sup>; metastases from extraabdominal cancers, such as lung and breast carcinoma and melanoma, can also obstruct.<sup>80</sup> Gastric outlet obstruction from benign or malignant causes produces large-volume vomiting. A percutaneous endoscopic gastrostomy (PEG) tube allows gastric drainage and relieves vomiting, while a jejunostomy tube provides feeding and medication.<sup>81,82</sup>

Obstruction of both small and large bowel is a frequent terminal event in cancer patients. Obstruction may be partial or complete at single or multiple sites and may be due to benign causes (adhesions, radiation bowel damage, hernia) or malignant causes (new or recurrent tumor, abdominal carcinomatosis).<sup>80</sup> Tumor infiltration of mesentery or bowel wall and, occasionally, of celiac plexus, may cause mechanical obstruction of the lumen or paralytic ileus. Common symptoms include intestinal colic, abdominal pain, and vomiting.

Surgical treatment of bowel obstruction remains controversial. Review of therapies for gastrointestinal obstruction compared exploratory laparotomy with bowel bypass and more conservative therapy with gastrostomy drainage. The authors<sup>83</sup> concluded that intestinal obstruction due to chemotherapy-resistant tumors and peritoneal carcinomatosis associated with ascites or palpable masses should not be treated surgically, and neither should patients with intestinal paralysis secondary to tumor involvement of the mesentery. PEG tube placement was a simple procedure for drainage, and it improved quality of life without other surgical intervention.<sup>83</sup> Consideration for surgical palliation of malignant obstruction requires careful individual patient evaluation.

The goal of medical management of bowel obstruction is relief of abdominal pain and vomiting in patients in whom surgical intervention is contraindicated.<sup>78,80</sup> In partial obstruction, clear liquid diet, corticosteroids (dexamethasone, 12 to 24 mg/d) to reduce peritumoral edema, and bisacodyl suppositories to decompress the colon can improve intestinal passage. The steroid dose can be tapered and the diet advanced if bowel function resumes. In complete obstruction, drainage by PEG tube is the most important intervention to relieve nausea and vomiting, but antiemetics (haloperidol or prochlorperazine) may be needed. Intestinal colic is controlled with scopolamine (0.15 to 0.30 mg subcutaneously every 6 to 8 hours as needed), and abdominal pain is controlled with opioids. Octreotide (0.1 to 0.2 mg every 8 to 12 hours subcutaneously) reduces intestinal epithelial electrolyte and water secretion.<sup>84,85</sup> This reduces bowel distention, vomiting, and pain and may preclude the need for gastric drainage.

Research has revealed four major neurotransmitter receptor systems involved in emesis: muscarinic (M, one of the cholinergic subclasses), dopaminergic (D<sub>2</sub>), histaminic (H<sub>1</sub>), and serotonergic (5-HT<sub>3</sub>). No one broad spectrum antiemetic is effective in all pathways<sup>78</sup> despite the fact that many antiemetics affect more than one neurotransmitter pathway as shown in [Table 56.7-3](#).<sup>86</sup> Furthermore, nausea and vomiting in a patient may have more than one cause. When the probable causes of nausea and vomiting are established, the most effective medication should be selected from the appropriate class of medications.

Medication (Receptor)	Dose
Scopolamine (M)	0.15 mg SQ q6-8h; transdermal patch 0.5 mg q72h
Meclizine (H1)	12.5-25.0 mg PO b.i.d.
Promethazine (H1, M, D2)	12.5-25.0 mg PO, IM, PR q4-6h
Haloperidol (H1, D2)	0.5-3.0 mg PO, SQ q6-8h
Prochlorperazine (D2, H1, M)	5-10 mg PO, IM q6-8h; 25 mg PR q8-12h
Chlorpromazine (D2, H1, M)	10-25 mg PO, IM q4-6h; 25-50 mg PR q6-8h
Hydroxyzine (H1)	25-50 mg PO, IM q4-6h
Metoclopramide (H1, D2)	10-15 mg PO, IM q.i.d. (before meals, at bedtime)
Ondansetron (5-HT3)	32 mg IV x 4 days, then 8 mg PO, SQ q8-12h
Dexamethasone	4-8 mg PO, SQ q8-12h

**TABLE 56.7-3.** Medications for Nausea and Vomiting with Associated Neurotransmitter Receptors

Among commonly used antiemetics, phenothiazines such as perchlorperazine and chlorpromazine have a broad range (i.e., affect several pathways) and offer several routes of administration; chlorpromazine, however, is sedating and may cause hypotension. Haloperidol is available in concentrated solution (5 mg/mL) so that effective doses can be given subcutaneously in small injected volumes. Metoclopramide promotes gastric emptying. In severe nausea and vomiting, 5-HT<sub>3</sub> antagonists such as ondansetron, granisetron, and dolasetron can bring relief. One protocol for ondansetron is given in [Table 56.7-3](#). In addition to control of intracranial pressure, adjuvant corticosteroids (dexamethasone) empirically enhance many antiemetics.

## FLUIDS AND NUTRITION

Provision of fluids and nutrition to terminally ill patients may be a contentious issue between families and hospice caregivers.<sup>87</sup> Families often feel that fluids and nutrition prevent suffering by reducing dehydration and starvation. The issue often intensifies as patients begin to lose the ability to take sustenance and medications orally. Even a balanced discussion of not starting artificial fluid and nutritional support may cast the caregivers in the eyes of the family as threats to the patient's comfort. At the same time, hospice caregivers differ personally and professionally concerning provision of nonoral fluids and about the degree of suffering resulting from thirst.<sup>88,89</sup>

Estimation of the prevalence of thirst and dry mouth among cancer patients in palliative care ranges from 28%<sup>90</sup> to 83%.<sup>91</sup> Clinical concerns favoring provision of fluids include protection of patients from bed sores, constipation, nausea, delirium, myoclonus, and accumulation of drug metabolites with significant risk to patient comfort. Commonly used palliative medications (e.g., opioids, tricyclic antidepressants, phenothiazines, some antiemetics) all promote dry mouth. In some cases, intravenous fluids are delivered because the benefits to the family outweigh any risks.<sup>87</sup>

On the other hand, intravenous hydration and nutrition may prolong life so that patients die from other less comfortable causes. They may cause prolonged suffering from other symptoms, including increased respiratory and gastrointestinal secretions, phlebitis at the intravenous site, ascites and edema, and need for a urinary

catheter with its accompanying risks and discomfort. Some of these objections may be avoided by using subcutaneous delivery of fluids by hypodermoclysis. <sup>89,92,93</sup>

The symptom of thirst is not identical to dry mouth or other signs of dehydration, often defined clinically as serum sodium, osmolality, and azotemia above normal values. Thirst is best assessed by patient report. Substituting a workup of dehydration by physical and laboratory examinations may be misleading.

It is difficult to draw firm conclusions about the relations among thirst, dry mouth, dehydration, and suffering from the few clinical studies published. <sup>94</sup> As a group, these studies <sup>90,91,95,96</sup> and <sup>97</sup> support but do not prove the following statements:

1. Thirst, dry mouth, and fluid retention are not closely associated with demonstrable dehydration. <sup>95,96</sup>
2. Intravenous fluids do not uniformly alleviate dehydration or thirst nor improve awareness. <sup>96,97</sup>
3. Assiduous mouth care and small amounts of ice chips or fluid may or may not relieve dry mouth or thirst. <sup>90,91</sup>
4. Dehydration is associated with decreased awareness and may not be improved by intravenous fluids. <sup>97</sup> In contrast, in a large study of a palliative care center, <sup>61</sup> decreased prevalence of delirium was associated with increasing use of hydration and opioid rotation.
5. Thirst was not significantly related to length of survival in one study, <sup>95</sup> although taken together, the studies cited show increasing prevalences of thirst and dehydration as patients approach death. Of note, these studies do not define subgroups of patients whose symptoms improve with hydration.

In hospice care, no single approach to provision of fluid by nonoral routes is used. Most caregivers would agree that the patient's choice is paramount. At the same time, institutional preferences for providing or withholding nonoral fluids exist and have been discussed. <sup>89</sup> The scientific basis for such patterns is still not clear and needs more study.

The issues surrounding nutrition in terminally ill patients are simpler than those concerning fluids. As cancer progresses, patients become increasingly anorexic rather than hungrier. Fewer than one-third of patients admitted to the hospice unit complained of hunger, and that occurred only during the first quarter of their stay. <sup>90</sup> The issue of hunger is rarely mentioned among symptoms in patients in the last 24 to 48 hours of life. Furthermore, little or no evidence shows that enteral feeding by either nasogastric or by gastrostomy and jejunostomy tubes prevents malnutrition, infections, or pressure ulcers or that it improves functional status or survival compared to patients without feeding tubes. <sup>48</sup> Conservative measures may be helpful to the patient and family without subjecting the patient to what appears to be a futile intervention in most cases, especially in the terminal phases of illness. Such measures involve frequent, careful feeding of small bites or boluses (generally less than a teaspoon) placed carefully into the mouth, encouragement to chew and to swallow, use of a patient's favorite foods, use of flavorful food and fluids, diets ad lib enriched with cream and fats, and the company of family and friends when desired. <sup>48</sup>

## PSYCHIATRIC SYMPTOMS

The major psychiatric complications in terminally ill cancer patients are anxiety, depression, and delirium. Uncontrolled physical symptoms, especially pain, increase their prevalence and intensity. <sup>98</sup>

### **Anxiety**

In many cancer patients, anxiety is a pervasive feeling of dread for themselves and others in their lives. Beginning in some patients before diagnosis, anxiety produces easy distraction, poor attention and concentration, and physical signs of autonomic activation. At times, anxiety may escalate into panic. Control is important for patient comfort and for adequate calm so that the patient can understand and cooperate with caregivers during workup and treatment of physical illness and psychosocial issues.

Diagnosis is based primarily in observing and talking to the patient and family; the goal is to elicit any previous history of anxiety disorders and treatment, as well as current history and symptoms. We ask the patient to describe the major sources of anxiety so that we can respond to them. Anxiety commonly concerns both self and others. The physical examination may reveal anxious facies; tics; and signs of autonomic hyperactivity, such as palpitations, tachycardia, dyspnea, sweating, nausea and vomiting, diarrhea, and paresthesias.

Some patients calm adequately in response to information and to empathic support from members of the IDT and from family and friends. Others require therapies and medications designed to control anxiety. Nonpharmacologic therapies include relaxation techniques such as meditation, biofeedback, and guided imagery, as well as "talk therapy." <sup>99,100</sup> Such therapy should be tried, but success may depend on addition of medication, usually a benzodiazepine. A wide variety of benzodiazepines is available with differences in duration of action, metabolites, timing of onset, and routes.

In urgent situations, short-acting benzodiazepines, such as alprazolam and lorazepam, are used; the latter can be given intramuscularly or by slow intravenous push as well as by mouth. Shorter acting benzodiazepines provide easier titration of the medication. Longer acting benzodiazepines, such as diazepam and clonazepam, are used for routine control of anxiety and may be given two or three times a day.

Selective use of benzodiazepines depends on the clinical situation. Anxiety due to ongoing pain should be addressed first with analgesics. Anticipated pain can be treated with both analgesia and a benzodiazepine; lorazepam in this situation not only acts as an anxiolytic and adjuvant analgesic but also provides anterograde amnesia. Similarly, lorazepam given before chemotherapy works to relieve anxiety as well as nausea and vomiting. <sup>100</sup>

Anxiety is a concomitant of dyspnea. Relief of dyspnea with oxygen and, in some cases, morphine may relieve anxiety. If not, trial of an antihistamine such as hydroxyzine may be effective and prevent the use of benzodiazepines, which can interact with opioids to depress respiration. Opioids and benzodiazepines used together for rapid relief of dyspnea are appropriate at the very end of life when more concern is focused on providing dying patients with calm and comfort during this irreversible process and less on drug interactions.

Benzodiazepines protect patients during withdrawal from habit-forming substances (e.g., barbiturates, alcohol, opioids, and other benzodiazepines). After 2 to 4 weeks of routine use, benzodiazepines should be tapered to prevent physiologic withdrawal.

On occasion, the clinical situation suggests that other medications be used to treat anxiety or supplement the benzodiazepines already used. Butyrophenones such as haloperidol or a lower potency phenothiazine such as thioridazine may be appropriate, especially in anxious patients with psychotic features of hallucinations and delusions. More sedating drugs, such as thioridazine and chlorpromazine, are helpful in agitated or insomniac patients. Methotrimeprazine is a phenothiazine that combines relief of both pain and anxiety. Like chlorpromazine, however, it is associated with sedation, hypotension and orthostasis, and the anticholinergic side effects. Anxiety escalating into panic attacks can be treated with tricyclics such as imipramine, the benzodiazepine clonazepam or a selective serotonin reuptake inhibitor such as paroxetine. <sup>100,101</sup>

### **Depression**

Diagnosis of depression in cancer patients relies heavily on psychological and cognitive signs and symptoms (e.g., feelings of guilt, worthlessness, futility, suicidal ideation) because many of its physical signs and symptoms (e.g., fatigue, anorexia, weight loss) can result from underlying cancer and its treatments. <sup>102</sup> Prevalence of self-reported depression in cancer patients is near 25% <sup>103</sup> and increases with poor symptom control. <sup>98</sup> Among hospitalized cancer patients referred for psychiatric consultations, almost 60% were seen for depression, suicidal ideation, or both. <sup>104</sup>

Diagnosis and treatment for depression in early stages of cancer have been reviewed <sup>105</sup> and are discussed in [Chapter 56.5](#). In this chapter, we concentrate on depression in the last stages of disease, when patients and families cannot wait weeks for therapeutic response.

Psychostimulants such as dextroamphetamine, methylphenidate, and pemoline may improve depression in a few days, as well as counteract sedative side effects of opioids and promote appetite and concentration <sup>51,53</sup>; in the presence of opioids, they also provide adjuvant analgesia. <sup>51,106</sup> Initial dosing of methylphenidate is 2.5 mg at breakfast and lunch. The dose is increased every 3 to 4 days until relief of depression or unacceptable side effects (e.g. anxiety, autonomic hyperactivity, confusion) intervene; it is rarely necessary to go beyond 30 mg/d. Relief of depression is usually evident in a few days, as opposed to the few weeks with tricyclics and selective serotonin reuptake inhibitors. Pemoline is reported to be as effective as dextroamphetamine and methylphenidate and has fewer sympathomimetic side

effects, although it should be used with caution in patients with liver dysfunction. <sup>52</sup>

Patients with poor symptom control, especially pain and depression, are at high risk for suicidal ideation. Members of the IDT must be alert to protect them through symptom control, counseling, and pharmacotherapy. <sup>101</sup>

### Delirium

Clinically, confusion is most often divided into delirium and dementia, although other categories of cognitive disorders exist. *Delirium* refers to a fluctuating complex of mental states of “altered alertness and impaired cognition,” <sup>107</sup> including some or all of the following presentations: variable attention, shifting awareness, disturbed sleeping patterns, disorientation, hallucinations, and difficulties of memory and speech. <sup>101</sup> In delirium, changes in mental status occur over hours to 1 or 2 weeks, which is much more rapidly than in dementia. Fluctuations of mental status and, in some cases, reversibility of delirium also distinguish it from dementia. Differentiation of dementia and delirium is especially difficult when they coexist, as they commonly do in older patients.

Prevalence of delirium increases as cancer progresses, estimated variously at 10% to 27% early in the course to 85% near death. <sup>103,108,109</sup> At the very end of life, it may be a major component of terminal restlessness or terminal agitation. The inability of patients to communicate with families and caregivers is frustrating. Stress created by a delirious patient can produce the “destructive triangle” <sup>110</sup>: a distressed family creates pressure for relief on the nurse who then adds his or her own distress to the pressure transmitted to the prescribing physician who may treat by sedating the patient without an appropriate workup. At the very end of life, however, proceeding directly to sedation may be the most effective and appropriate help.

A wide range of etiologies exists for what is called by the single name *delirium*, and Table 56.7-4 lists some of these. In earlier stages of disease, when a desirable quality of life can potentially be restored, search for and treatment of causes related to both cancer and to comorbid conditions is appropriate. Causes may not be found, even in this multifactorial condition. In one study of confused terminally ill patients, only 44% had identifiable causes of confusion. <sup>13</sup>

<b>Primary cancer and metastases</b>
Neoplasms of central nervous system
Cerebral and meningeal metastases, especially lung and breast primaries
<b>Antineoplastic therapies</b>
Chemotherapeutic agents: asparaginase, vincristine, irinotecan, mitomycin, ifosfamide, 5-fluorouracil, cyclophosphamide, cytarabine, azacitidine, idarubicin, procarbazine, topotecan, estramustine, estradiol, tamoxifen, and megestrol acetate
Endocrine therapy for primary tumors or metastatic disease
<b>Corticosteroids</b>
<b>Pharmacological recovery</b>
<b>Constitutional and comorbid states</b>
Age
Neurodegenerative cerebral disease (e.g., dementia)
Organ insufficiency (e.g., lung disease promoting hypoxia, renal and hepatic disease disrupting metabolism of medications)
Seizure
Severe anemia (e.g., myelodysplasia, B <sub>12</sub> deficiency)
Electrolyte imbalance, especially hyponatremia, hypercalcemia
Hypoxia or hyperglycemia
Anoxia
<b>Painful medications</b>
Opiate analgesics
Pharmacokinetics
Antiemetics
Anti-histamines
Anticholinergics
Antidepressants
Corticosteroids

**TABLE 56.7-4.** Delirium in Cancer Patients: Etiologies and Facilitators

Several tools exist to aid in predicting, diagnosing, and following the evolution of delirium. <sup>111,112</sup> The Mini-Mental State Examination measures cognitive function and has the advantage that it can be administered in a few minutes by caregivers without special training. Other instruments may be used to measure aspects of delirium other than cognitive failure and to check the validity of the Mini-Mental State Examination if in doubt. <sup>111</sup>

Treatment of delirium, usually begun during workup, involves several steps: stabilization of the environment, modification of medications, and correction of contributory conditions when appropriate. <sup>113</sup>

At all stages of disease, a stable environment minimizes delirium (e.g., the presence of trusted family and friends at the bedside, use of consistent and trusted caregivers, a well-lighted environment with date and time readily available). Efforts to engage patients in conversation help to reorient and to distract them from distressing thoughts and hallucinations. Personal observation is usually better than physical restraints in maintaining patients' safety.

All patients should have medications reviewed to eliminate unneeded medications and substitute others less harmful whenever possible, including rotation of opioids to take advantage of partial cross-tolerance. Hydration and rotation of opioids may produce or contribute to clearing of mental status. <sup>61</sup>

Pharmacotherapy for delirium varies depending on the stage of illness. Haloperidol has the advantage for some patients of being less sedating than other phenothiazines. Because haloperidol administered parenterally has a faster onset and is approximately twice as potent as the same dose orally, it is used intravenously or subcutaneously in urgent cases. For agitated delirium, the initial dose is 2 to 5 mg, preferably by the intravenous route, repeated every 15 to 30 minutes with a maximal dose of 5 mg every 15 minutes. For calmer patients, starting doses are 0.5 to 1.0 mg orally or parenterally, then titrated up every 45 to 60 minutes as necessary. <sup>101</sup> Ultimately, most patients receive 0.5 to 3.0 mg three times a day by mouth or parenterally. Side effects of haloperidol and other phenothiazines include extrapyramidal effects, including akathisia and, rarely, neuroleptic malignant syndrome.

At times, confused patients may be aided by a sedating benzodiazepine used with haloperidol (e.g., lorazepam, which has no active metabolites), initially started at 0.5 to 1.0 mg every 1 to 2 hours by mouth, intravenously, or intramuscularly. Effective doses of these two drugs are then adjusted so that haloperidol is given every 8 hours and lorazepam every 6 hours.

Alternatively, the sedating phenothiazine chlorpromazine is usually successful in calming an agitated patient at doses of 12.5 to 50.0 mg given by mouth, intravenously, or intramuscularly every 4 to 12 hours. <sup>102</sup> As death nears, the benefit of imposing calm outweighs the risk of hypotension associated with chlorpromazine. In dying patients with poorly controlled agitation, a very short-acting benzodiazepine with rapid onset, midazolam, is used intravenously or subcutaneously for sedation; it does not correct disordered thought. Initially, midazolam is started at 0.4 mg/hr and is titrated up to control agitation, usually in the range of 20 to 60 mg/d, although higher doses up to 200 mg/d have been used. <sup>114,115</sup>

### ACTIVELY DYING PATIENTS: CALM, COMFORT, AND REFRACTORY SYMPTOMS AT THE END OF LIFE

Several groups have confirmed significant improvement in symptom control, especially pain, during hospice care. <sup>24,25,29,116</sup> Good control of overall symptom distress increased from 64% of patients on admission to a palliative care unit to 84% on the day of death, <sup>117</sup> and Saunders notes that only 2% did not die peacefully in her survey. <sup>32</sup> In contrast, the National Hospice Study showed that only 19% of patients were pain free at the time of last pain measurement before death, whereas 18% had persistent pain. <sup>31</sup>

Management of refractory symptoms was sharply focused in 1990 by a prospective study of 120 Italian home care hospice patients with cancer, 52% of whom had such severe symptoms that only sedation provided comfort. <sup>26</sup> Subsequent reviews reported a range of 18% to 48% of hospice patients with refractory symptoms. <sup>117,118</sup> and <sup>119</sup> The most common symptoms requiring sedation were dyspnea, pain, delirium, and nausea. Time from starting sedation to death was, on average, 2 to 4 days. <sup>26,118,119</sup>

Refractory symptoms, as thoughtfully discussed by Cheney and Portenoy, <sup>120</sup> are those for which no adequate relief can be found despite rational and thorough trials of conventional approaches. In addition, other options cannot be effected in an acceptable length of time or may cause further suffering in trying them. These authors discuss efforts to control terrible pain as a guide to the workup of other symptoms before their classification as “refractory.” The emphasis on interdisciplinary teamwork is further stressed in a brief discussion of intolerable psychological or existential suffering.

In the studies cited, the most common medications used to produce sedation were midazolam (more than any other benzodiazepines); neuroleptics, such as haloperidol and chlorpromazine; opioids; and barbiturates. Choice of sedating medications depends in part on the symptom to be controlled—for example, opioids for pain, opioids and benzodiazepines for dyspnea, and neuroleptics for agitated delirium. In some cases, higher doses entrain unacceptable side effects (e.g., myoclonus with opioids); in this particular case, rotation of opioids may be helpful. Additional medication may be needed. At the beginning of sedation, medications with shorter half-lives provide physicians with better control, which is especially important when varying degrees of sedation may be sought. Among benzodiazepines, midazolam offers not only a short half-life but also a variety of routes. Special attention has been given to primary use of chlorpromazine<sup>121</sup> and of barbiturates<sup>122,123</sup> as agents of sedation for refractory symptoms.

Among the most difficult of all tasks for caregivers are withdrawal of life support<sup>124,125</sup> and sedation for refractory symptoms to provide patients with calm and comfort as they die. Both professionally and personally, caregivers often feel frustrated and threatened by not being able to provide adequate comfort; this frustration can lead to a sense of division among members of the caregiving team. Some clinicians may have qualms that symptom control may hasten the patient's death rather than preserving or improving the quality of life. The principle of the "double effect" provides comfort to some caregivers. The double effect refers to the fact that medication given for the purpose of symptom relief carries foreseeable risk and may unintentionally hasten a patient's death. This principle recognizes the ethical desirability of promoting symptom relief and is meant to protect caregivers so long as they have sought comfort for their patients and not their deaths. These situations are often complex, however, and a simple statement of benign intent may not encompass all components of decision.<sup>126</sup> Clinicians unable to accept the distinction between intended benefit and an unavoidable risk of death for the treated patient may need to transfer the patient's care to another colleague.

## CONCLUSION

Although still relatively recent in American medical history, hospice is becoming accepted practice in caring for the terminally ill. Insurers, providers, and patients and their families are increasingly aware that hospice is available to them and that it is often the best choice for care at the end of life. Nevertheless, hospice and palliative care practice standards remain outside the mainstream of medicine and are only now being included in medical education curricula at all levels of training from medical school to oncology fellowships.

Practitioners, researchers, and funders are beginning to establish a clinical knowledge base, which can be used to guide the practice of palliative medicine that will grow with experience and systematic research. However, the practice of hospice care will face many challenges as well. Hospice stays have been shortening in many programs, suggesting that patients may be referred to hospice later than is desirable.<sup>18</sup> Research is needed to understand better the sources of this shift, including problems with prognosis, institutional barriers, physician knowledge and attitudes, and the views of families and patients. Better understanding of the underuse of hospice can inform a variety of approaches, including policy changes, health education interventions, and professional training resources. The desired outcome is continuing growth of knowledge and training in palliative care and its expanded use for patients with terminal illness.

### INTRODUCTION

The American Cancer Society predicts 1.2 million new cases of cancer diagnosed in 1999 and 8 million cancer survivors requiring care for cancer-related problems.<sup>1</sup> These patients are likely to be older, will survive for years with their cancers, and will present considerable challenge to health professionals.

The incidence of cancer climbs appreciably with each decade of life, and the population is aging.<sup>2</sup> The 5-year survival has improved over the last 20 years, such that more than 50% of those with cancer of the prostate, colon, bladder, breast, uterus, thyroid, and some lymphomas will survive 5 years.<sup>2</sup>

Patients with cancer, in part because of the likelihood that they are older and have preexisting medical conditions, are likely to present significant challenges and complex management decisions. They are complex because, often, cancer has many phases and may recur and remit throughout multiple life stages. The illness may not be stable, and the functional impact may vary with disease stage and may change with remote effects of treatments. [Table 57-1](#) outlines one scheme for conceptualizing this view of cancer management needs.

Phase of Disease	Issues to Address
Diagnosis to treatment planning	Anticipating the impact of cancer treatment on function, understanding and preventing dysfunction, using comprehensive geriatric or other indicators (e.g., RCM, ASM, strength)
Treatment	Evaluating effects of treatment on function (e.g., fatigue, anorexia, weight loss, hair loss, alopecia, mucositis, neuropathy, myopathy, myalgia, arthralgia, myelopathy, myeloma, osteopenia, osteoporosis, lymphedema, edema, skin toxicity, alopecia, and TEWS)
Posttreatment	Developing and implementing a program to help to restore daily function and to promote a healthy lifestyle (e.g., exercise, nutrition, weight, and self-management strategies, RCM, edema, pain, etc.); implementing a maintenance program of exercise, edema management, and mobility
Recurrence	Evaluating patients about impact of recurrence and its effect on function, addressing common issues when to reenter in the context of new clinical status, supervising patients in an appropriate program to restore function or prevent its decline, monitoring patients to maintain activity and quality of life
End of life	Evaluating patients and families about mobility, training, goal setting, motivation, and supportive services; managing pain, cachexia, neurologic, hematologic, and cardiovascular symptoms; and maintaining independence and quality of life

ASM, activities of daily living; RCM, range of motion; TEWS, weakness-related physical therapy interventions.

**TABLE 57-1.** Rehabilitation Support throughout Phases of Cancer

The pretreatment and treatment phases should include a functional assessment to help to identify what the patient is able and wishes to do and to predict what is likely to influence function subsequently. A systematic evaluation of the neuromusculoskeletal system is essential for targeting areas likely to need intervention for maintaining or restoring function. Often, instruction in the use of gait aides can best be given before treatment, when pain and mobility loss have not occurred. Prosthetic and orthotic devices can be planned and provided intraoperatively when needed.

The post-definitive treatment phase is an opportunity for initiating preventive measures. Early mobilization, the use of wraps, and limb massage may help to mitigate disuse and deconditioning or control lymphedema and limb swelling. This phase usually includes preparing the patient and family for discharge and educating them about what the course is likely to be and what they (collectively) should be doing to keep the functional level high.

The intercurrent period, when the definitive treatment has been complete, may be psychologically difficult and require guidance to assist patients and family to enter or reenter an active and healthy life program and resume usual activities, when possible. Patients may need to plan for adjusting to late neurologic sequelae (plexopathies, neuropathies) or musculoskeletal sequelae (fibrosis, atrophy) of disease or treatment. Chronic pain, weakness, fatigue, and lymphedema may require ongoing and intensive therapy.

Recurrence may require that the cycle of assessment and treatment begin anew. This process may be fairly psychologically demanding and anxiety-provoking. The goals of rehabilitation management are to provide education about problem solving for issues relating to functional loss.

Rehabilitation professionals also have significant contributions to make at the end of life. During this phase, rehabilitation professionals can assist in answering

questions pertaining to nonpharmacologic treatments for pain control and strategies for enhancing quality activities and independence and can help families, friends, and patients address issues at the end of life.

Cancer is common, chronic, and complex. Decision making about primary cancer treatment often factors elements reflective of these features. In fact, patients (our consumers) are not only requesting participation in decision making, they are asking for information about the impact of the tumor and its treatments on function and their quality of life. Patients, especially cancer patients, fear disability and have identified a host of concerns that include fatigue, independence, and pursuit of valued activity, in addition to mortality, that influence their ultimate treatment choices.<sup>3</sup> Many concerns and needs of patients throughout the phases of cancer treatment can be ameliorated by rehabilitation professionals. [Table 57-2](#) describes the functional areas affected by various symptoms and in need of rehabilitation.

Phase of Cancer	Symptoms	Functional Area Affected
Prevention and evaluation	Pain, anxiety, depression	Daily routines, sleep, fatigue
Treatment	Pain, anxiety, loss of mobility, wound and skin care, speech and swallowing	Daily routines, sleep, stamina, self-care, concerns, motivation
Posttreatment	Pain, weakness, anxiety, depression, loss of mobility, edema, fatigue, stamina	Sleep, fatigue, ADL, vocational and avocational concerns, stamina
Recurrence	Pain, weakness, anxiety, depression, fatigue, stamina, edema, loss of mobility, anorexia	Sleep, fatigue, disability, disruption of routines, concerns in vocational and avocational concerns
End of life	Pain, fatigue, anorexia	Dependence, mobility

**TABLE 57-2.** Patient Functional Areas Affected by Cancer Symptoms in Various Phases of Disease

## CANCER REHABILITATION TEAM

Rehabilitation specialists most frequently involved in treatment of the cancer patient include physiatrists; occupational, physical, and recreation therapists; speech-language pathologists; audiologists; and vocational counselors. Other health care professionals join the team as needed for particular problems (e.g., orthotists-prosthetists, psychologists, dietitians).

Physiatrists are trained in the specialty practice of physical medicine and rehabilitation. This training enables them to assess functional ability, relative strength and stamina, the basics of human mobility (biomechanics), the design and appropriate use of adaptive equipment, and orthotics and prostheses. Physiatrists often combine information about disease and its treatment with the impact it is likely to have on function. It is usually physiatrists that coordinate rehabilitation services and prepare a comprehensive plan for treatment and follow-up.

Occupational therapy is an integral part of the rehabilitation of the cancer patient. Therapists evaluate the impact of disease or treatment on function, roles and daily routines, and the coping strategies needed to compensate for changes in a person's ability to participate as fully as possible in activity. Occupational therapists (OTs) determine which strengths and support networks are available to a person and identify interventions that are critical to potentiate quality of life for those who are terminally ill. Adaptive device training and safety training for activities of daily living (ADL); fabrication of splints or prosthetic training to maximize upper extremity function; counseling for the development of coping strategies; fracture risk education and assistance with mobility; and seating and environmental adaptations are examples of interventions that an OT can provide. Preparation for discharge requires input from an OT, with concentration on environmental safety (e.g., home, bathroom) and functional independence ([Table 57-3](#)).

Self-care, activities of daily living
Exploration of important roles, daily routines, personal values
Adaptive device training and environmental adaptations
Mobility and transfer safety
Wheelchairs, scooters, customized seating
Orthoses and prostheses
Fracture risk education
Help for pain, edema, sensory changes, and weakness
Joint contracture prevention
Psychosocial issues, coping
Family education and support system development

**TABLE 57-3.** Occupational Therapy: Evaluation and Treatment

Physical therapists (PTs) provide evaluation and treatment of human motion. Treatments include strategies and exercises to improve mobility, strength, and stamina. Therapists often help to relieve painful musculoskeletal symptoms using nonpharmacologic modalities and postural treatment. If therapy is instituted early, it can prevent muscle atrophy and joint contractures and maintain or promote fitness. Typically, PTs assess range of motion (ROM), muscle strength, exercise tolerance, gait, shoulder and trunk strength, and balance. PTs usually apply orthotics and prostheses for the lower extremities, apply modalities of heat and cold, and help to manage peripheral edema using compression pumps and stockings. Standardized evaluations are listed in [Table 57-4](#).

Range of motion and strength assessment
Bed mobility and transfers
Gait evaluation
Prostheses, orthoses, and assistive devices
Pain and edema management (compression garments, compression units)
Modalities (heat, cold, electrical stimulation)
Exercise and endurance
Contracture prevention

**TABLE 57-4.** Physical Therapy: Evaluation and Treatment

Rehabilitation counseling addresses the educational-vocational issues of the cancer patient. [Table 57-5](#) summarizes this information.

---

Educational, vocational, avocational functioning  
 Psychosocial issues, adjustment, coping  
 Vocational and career counseling  
 Vocational testing and assessment  
 Work adjustment  
 Résumé, job seeking, interviewing  
 Essential functions of a job  
 Job analysis  
 Job accommodation  
 Job modifications  
 Community resource development and referral  
 Volunteer work  
 Disability laws and legislation

---

**TABLE 57-5.** Rehabilitation Counseling: Evaluation and Treatment

Recreation therapists (RTs) are part of a comprehensive cancer rehabilitation program. RTs evaluate whether areas of function that have been adversely affected by disease or its treatment are amenable to interventions aimed at enhancing leisure activity. Interventions designed to address the primary and secondary symptoms and side effects related to cancer and cancer treatment include behavioral and cognitive strategies for pain, anxiety, and stress management; recreational activities for fine and gross motor function and stamina building; games for cognitive stimulation; age- and developmentally appropriate activities to ensure normalized experiences for hospitalized children and adolescents; and creative and expressive outlets for thoughts and feelings. Further, RTs assist patients in identifying opportunities for developing interpersonal and social supports through avocational activities; in enhancing patient management by providing clinical information; in motivating patient compliance; and in educating the patient and significant others about strategies for coping and maintaining quality of life. A summary of what RTs provide is found in [Table 57-6](#).

---

Leisure function and satisfaction assessment  
 Treatment tolerance and protocol compliance  
 Coping and behavioral strategies for psychosocial sequelae  
 Management strategies for pain, edema, sensory changes, and other secondary symptoms  
 Relationship issues and identification and development of social support  
 Exploration and clarification of roles, habits, and values  
 Developmental and age-appropriate activities  
 Leisure education and counseling (individual, family)  
 Avocational interest and leisure skill development  
 Medical play  
 Activity adaptation  
 Community reintegration

---

**TABLE 57-6.** Recreation Therapy: Evaluation and Treatment

Speech-language pathology provides oral motor evaluation of speech and swallowing and assessment of cognition for patients with cancer diagnoses, as needed. Specifically, patients with central nervous system (CNS) tumors or head and neck tumors are evaluated for communication skills, comprehension, and memory. Speech pathologists assess functional integrity and compensatory ability of structures and mechanisms needed to achieve adequate communication, deglutition, and cognition. They evaluate dysphagia and work with gastroenterologists to identify its causes. They frequently collaborate with maxillofacial prosthetists in the restoration of facial appearance and oral function.

## FUNCTIONAL ASSESSMENT

There has been substantial improvement in the ability to assess function, its limitations, and quality of life during the last decade. Measures are available to quantitate performance and activity of daily routines and assess changes in social and psychocognitive function. <sup>4,5,6 and 7</sup> When these assessments, which incorporate multiple domains, add measures of value, they are termed *quality-of-life measures*. Many of these have been developed specifically for those with cancer diagnoses. <sup>8,9</sup>

## COMMON FUNCTIONAL IMPAIRMENTS IN ONCOLOGY

### IMMOBILITY AND ITS IMPACT

One of the most significant problems facing cancer patients is the impact of relative or absolute immobility. Bed rest in cancer patients is associated with numerous metabolic and physiologic changes that may impair the patient's medical and functional recovery. <sup>10</sup> Bone loss is well documented and, in extreme cases, may lead to hypercalcemia. <sup>11,12 and 13</sup> In patients who are already osteoporotic or who have metastatic involvement of the skeletal system, this may predispose to pathologic fractures and further disability. Muscle atrophy can be fairly rapid, often leading to an inability to walk in as short a time as a week. Decreased activity may result in contractures and changes in muscle and joint physiology. <sup>14,15</sup> Lack of mobility can also lead to the development of deep venous thrombosis and pulmonary embolus. <sup>16</sup> Changes in muscle physiology and fiber type have been documented as well. <sup>17,18</sup> This is particularly true of patients with gastroenterologic tumors in which weight loss, anorexia, and inflammatory cytokine production negatively impact on function and quality of life. <sup>19,20</sup> As muscle mass becomes reduced, the amount of soft tissue covering bony prominences can become marginal, predisposing to the development of pressure (decubitus) ulcers. In this state, pressure over peripheral nerves, especially as it crosses bony prominences, may lead to a neuropraxia. All these factors can significantly reduce mobility and independence.

### MUSCLE WASTING AND CACHEXIA

Patients with a variety of tumors, including gastrointestinal tract, breast, colon, prostate, lung, small cell, and the like, may develop muscle wasting and cachexia. Cachexia is a condition characterized by weight loss, anorexia, weakness, loss of functional capacity, and fundamental changes in metabolic processes. <sup>21</sup>

Some of these changes include presence of inflammatory cytokines (tumor necrosis factor- $\alpha$ , interleukin-6), severe negative nitrogen balance, increased proteolysis, and gluconeogenesis. Muscle mass, body fat mass, and energy stores all are decreased. Interestingly, parenteral nutrition seems to maintain body hydration and fat stores but has little effect on loss or restoration of lean mass and, as such, cannot reverse muscle wasting.

Exercise, long used to build lean mass, is often ineffective in this population. In the setting of cachexia, the effects of exercise on nitrogen balance and other metabolic abnormalities are fairly modest. Rigor of exercise is significantly curtailed, in part limited by symptoms of pain, fatigue, depression, and aesthenia. <sup>22</sup>

### GENERALIZED DECONDITIONING

As a rule, each week of immobility requires as much as a month of rehabilitation to regain functional mobility. Complications such as pathologic fractures and pressure ulcers can further delay recovery. Although it is sometimes impossible to fully mobilize a patient receiving chemotherapy or major surgery, some degree of mobilization under a PT's supervision may significantly reduce morbidity. For the patient who is mildly restricted by disease or treatment, active ambulation at least once or twice daily is strongly encouraged. If this is not possible, an exercise program in bed may be started, using resistance against gravity or against an elastic band. A tilt table may be used to maintain sympathetic tone, reduce orthostatic hypotension, or restore cardiovascular conditioning in the patient who is unable to stand. This also helps to minimize heel cord contractures, increase muscular tone, and facilitate venous compression and helps to maintain cardiovascular volume. In patients with severe dependent edema, compressive garments or manual therapy, such as massage and lymph drainage, may help to maintain the vascular volume

and to reduce the degree of the edema while facilitating ambulation. Passive or active assistive stretching may be needed to maintain joints in functional alignment.

## SKIN BREAKDOWN

Prevention of skin breakdown is critical for the bed-bound patient. Above all else, the patient must not be allowed to remain in a single position for more than 2 hours. If patients are unable to position themselves in bed, repositioning should be done with pillows or cushions, taking care not to encourage the development of contractures by, for example, persistently flexing the neck, hips, or knees. Air-cushioned beds can help to reduce the incidence of pressure injuries.

Shear forces and direct pressure are important in the development of decubitus ulcers. Care should be taken, therefore, to avoid dragging patients across sheets or examination tables.

If skin becomes dry, aqueous moisturizing creams should be applied. Healing is promoted in a moist wound environment. Greasy agents can predispose to maceration and breakdown. Irradiated skin is of particular concern, due to the loss of normal resilience and healing capacity. Hygiene is important with irradiated skin, and all open cuts and abrasions should receive scrutiny, because they can easily become infected.

When complications arise, they should be treated promptly. Areas of skin redness that do not blanch should be considered early pressure ulcers (stage 1) and treated by removing pressure over the affected area. Most tissue damage in pressure ulcers occurs in the deep layers of the dermis and underlying tissues, such that the visible portion of the ulcer may represent only a fraction of the total extent. In many instances, hydrotherapy (whirlpool) can aid in the process of debridement and cleansing.

Packing the wound with an antiseptic solution should be done only when proven infection is present. In the case of noninfected small lesions, absorptive hydrocolloid occlusive dressings can be effective in promoting healing, provided that they are used in accordance with the manufacturer's recommendations. The use of occlusive dressings with larger wounds is controversial. Management should include mechanical and enzymatic débridement when necrotic tissue is present. Although we have seen many cases of complete resolution with the use of absorptive granules and occlusive dressings in deeper wounds, the potential exists for developing a superinfection. Occlusive dressings cannot be used as a substitute for adequate nursing care.

## CONTRACTURES

In cases of prolonged disuse or fixed joint positions, collagen fibers within muscles, tendons, and ligaments shorten, leading to contractures. Shoulder, heel cord, hamstring, and hip flexor contractures are most common.

ROM exercises should be practiced actively by the debilitated patient or passively by nursing or by the family at least two to three times each day, moving all major joints through their full ROM in all directions. In the case of the shoulder, this includes external and internal rotation, full abduction, and flexion. If flexion and abduction need to be limited, (e.g., in the patient after mastectomy or axillary lymph node dissection), internal and external rotation should be performed to stretch the joint capsule.<sup>23</sup> Splinting may be used to maintain functional hand and foot position.

The role of upper extremity bracing during the acute or chronic stages of disease or treatment should not be overlooked. Because of the complexities of movement patterns and compensatory adjustments, patients can continue to manipulate objects despite progressive changes that, if left unattended, may render them nonfunctional. Splints are designed to maintain soft tissue length, place joints in functional positions, and align hands and wrists to prepare for grasp and release activities. Thumbs can be positioned to oppose fingers for pinch, fingers can be pulled into extension with dynamic forces to compensate for weakness, wrists can be supported to allow for better mechanical advantage of forearm finger tendon function, and elbows or shoulders can be positioned by slings or splints to aid in the prevention of joint subluxation and ligamentous laxity. Rehabilitation goals are to prevent contractures, when possible. Uses for splinting devices are summarized in [Table 57-7](#).

---

Static splints
Fracture stabilization
Joint immobilization
Contracture prevention
Functional positioning (wrist, thumb, fingers)
Compensation (weakness, sensory loss)
Dynamic splints
Joint and soft tissue mobilization
Contracture reduction and prevention
Functional positioning (wrist, thumb, fingers)
Compensation (weakness, sensory loss)

---

**TABLE 57-7.** Upper Extremity Orthoses

When neuropathy from disease or treatment results in dysfunction, splints can be applied to hand and wrist to compensate for loss of proprioception. If sensory loss is severe, splint design can foster safety as well as positioning during manipulation. When weakness is severe or prolonged, splints aid by preventing or improving contractures. Long finger flexors contract quickly; thus, night resting splints are indicated to position the wrist and fingers in a functional position (i.e., 30 degrees wrist extension, 50 degrees metacarpophalangeal joint flexion and 20 degrees proximal interphalangeal joint flexion, and 10 degrees distal interphalangeal joint flexion, with the thumb opposed).

When neuropathy, immobility, weakness, pain, or the disease process itself has an impact on hand and wrist manipulation, appropriately designed splints need to be applied immediately, adjusted over time in accordance with the condition of the individual, and monitored for effectiveness. They also need to be used in conjunction with exercises and education regarding wearing schedules and precautions. When used appropriately and in a timely fashion, splints can make a difference in the functional outcome of patients and help to preserve alignment.

Radiation may potentiate fibrosis and the development of joint contractures. The effect of radiation on soft tissues is often long term, rendering recovery of ROM especially difficult. The rehabilitation team should instruct the patient in a home stretching program when radiation is initiated, and it should be continued for the life of the patient because of the tendency for irradiated tissues to develop persistent fibrosis.

If contractures do occur, affected areas may require months of therapy to regain full or functional motion or they may never achieve this. Stretching exercises should be performed at least once or twice daily under the guidance of a PT. This may be supplemented by the use of superficial or deep heating modalities, particularly ultrasonography, which can help to increase the distensibility of collagen, facilitating stretching. However, ultrasonography is contraindicated in an area of tumor. It has been shown to increase blood flow and tumor size and may increase the tendency for metastasis.<sup>24</sup> In extreme conditions of fixed, painful, and unresponsive contractures, surgical release or manipulation under anesthesia may be considered.

## TUMOR-ASSOCIATED MYOPATHY

Tumor-associated myopathy may result in immobility and ADL deficits. The myopathy may be a result of direct tumor invasion of muscle and other soft tissues, paraneoplastic syndrome, carcinomatous myopathy, steroid myopathy, or carcinomatous neuromyopathy.

## PARANEOPLASTIC SYNDROME

Nonmetastatic paraneoplastic syndromes of malignancy have been recognized with polymyositis and dermatomyositis. Malignancy occurs primarily in association with

dermatomyositis rather than with polymyositis.<sup>25</sup> The incidence is thought to be higher in men older than 50 years.<sup>26</sup> A study by Lakhanpal et al.<sup>27</sup> mentions a 25% incidence of malignancy in a polymyositis and dermatomyositis group and a 17% incidence in the control group. Breast cancers (18%) and lung cancers (16%) are most frequently associated with polymyositis and dermatomyositis.<sup>28</sup>

Patients with paraneoplastic syndrome have decreased endurance, muscle weakness, pain, decreased joint motion, and problems with ambulation, self-care, sexual performance, and work-related activity. Treatment to increase joint motion with stretching exercise, to increase muscle strength with isometric exercise, to improve mobility with gait aides and bracing, and to improve ADL with assistive devices are all appropriate. The patient should be instructed in energy conservation, joint protection, and sexual and vocational counseling.

### **CARCINOMATOUS MYOPATHY**

Carcinomatous myopathy may be seen with metastatic malignant disease. Histologically, there is widespread muscle necrosis and minimal or no inflammatory response. Clinically, there is proximal muscle weakness in this type of myopathy.<sup>29</sup> Because of the necrosis of muscle, it is thought that these patients would probably not respond well to an exercise program, but function should be maintained if possible. They should be given appropriate pain-relieving modalities and assistive and mobility devices to help with ADL and safe ambulation. The environment should be altered to help to ensure safety and easy access.

### **CARCINOMATOUS NEUROPATHY AND MYOPATHY**

Simultaneous carcinomatous neuropathy and myopathy occur with metastatic disease and affect peripheral nerve and muscle due to either toxic or immunopathologic effects of the tumor. Diminished reflexes and diminished sensation ensue.<sup>29</sup> The rehabilitative treatment is similar to that recommended in the management of carcinomatous myopathy. However, distal weakness occurs in addition to the proximal weakness, and appropriate bracing to improve ankle dorsiflexion may be needed. If weakness is severe, an electric scooter may be needed. Several assistive devices to help with hand function are useful.

### **STERIOD MYOPATHY**

Steroid-induced muscle weakness is really a selective atrophy of type II fibers in proximal muscles. It tends not to affect neck flexor muscles. It may be superimposed on the weakness of carcinomatous myopathy or polymyositis- and dermatomyositis-associated myopathy and exacerbate it. It is caused by catabolic and anabolic effects of steroid on muscle. Amino acids leak into the circulation, and there is decreased incorporation of protein into muscle. The condition may be diminished by providing exercise to enhance protein metabolism by muscle.<sup>30</sup> Isometric exercise can be used to accomplish this goal. It may take up to 1 year after cessation of steroids for muscles weakened by steroid use to return to normal.<sup>31</sup>

### **BONE REPLACEMENT BY TUMOR**

Bone can be invaded by tumor via direct extension, as is frequently seen in sarcoma; via embolization through the right side of the heart, the most frequent cause of distant metastasis; or via direct venous spread through Batson's plexus involving vertebral bodies and pelvis, the most frequent cause for metastatic bone disease in prostate cancer. Some tumors, such as leukemias, lymphomas, or myelomas, invade bone marrow.

Bony metastatic disease is most frequently associated with breast, lung, prostate, colon, or kidney tumors. It is important to note that the survival for patients with these tumors and bony metastases is years. Although any tumor can metastasize to bone, the most likely to spread are prostate, breast, lung, kidney, and thyroid.<sup>32,33,34</sup> and <sup>35</sup> The hematologic malignancies do frequently as well. Nearly 20% of tumors with distant spread will involve bone. Bony involvement is the third most frequent site for metastasis, with vertebral bodies, pelvis, femur, and ribs affected in order of frequency. Often, multiple sites are involved, of which 20% are in the upper extremities.<sup>36</sup>

Pain is the most frequent symptom associated with bony metastasis. This is characteristically dull, aching, and nocturnal. The spine is the most frequently involved area for metastatic spread, and the lumbar region is the most common site. When there is vertebral involvement, 50% of patients will have radicular symptoms. Cord compression, on the other hand, most frequently results from thoracic region involvement. Pain on weight bearing may be a sign of bony involvement or even a pathologic fracture. A bone scan is the simplest means of screening for bony tumor. Plain films offer definition of the local extent of the tumor, although computed tomography (CT) may be needed for better quantification of involvement.

### **PREVENTION AND MANAGEMENT OF PATHOLOGIC FRACTURES**

Pathologic fractures can limit mobility in a marginally functioning patient and, in some cases, lead to significant morbidity and mortality. Hip fractures are particularly debilitating and often difficult to stabilize, and they may lead to a significant hemorrhage. Prevention of pathologic fracture is important. Fracture should be considered imminent when the size of a lytic lesion exceeds 60% of the total bone width (usually >2.5 cm in lower and >3.0 cm in upper extremities), if cortical involvement exceeds 50%, or if the axial extent of cortical destruction exceeds 13 mm in the femoral neck and 30 mm elsewhere.<sup>37</sup> These calculations are difficult to measure accurately, in part because local osteopenia is common and margins are often irregular and difficult to distinguish.

Pain with weight bearing suggests a need to reduce load on or immobilize the affected structure. A cane used in the hand opposite the affected lower extremity can theoretically remove approximately 50% of body weight from that extremity. Such attachments as a quadruped base (quad-cane) or a forearm support (forearm or Lofstrand crutch) may help to stabilize the cane, but they cannot overcome the simple physics of gravitation loading. Canes or a single crutch can be used for the patient who has pain with weight bearing, but they should not be used for the patient with a fracture or one that is imminent.

Bilateral support is essential for the patient in whom no weight bearing is required. For the more debilitated patient, a simple walker suffices. For the more active patient, axillary or forearm crutches may be used. Toe touch of the affected leg can usually be allowed but, in the patient who has difficulty coordinating the use of crutches or walker, total avoidance of weight bearing may be needed to avoid sudden weight bearing if the assistive device is not properly placed. Patients need to be evaluated for metastatic disease in the upper extremities. It is fairly possible to develop a pathologic fracture of an involved humerus if it is used as a weight bearing structure. The patient should be cautioned against torquing the affected extremity, because this can often lead to fracture, even without weight bearing.

After an affected extremity has been unweighted, options for stabilization can be considered. Radiation often can be used to treat lesions of the long bones. Irradiation does not directly repair damaged bone, and irradiated bone heals much more slowly than normal bone. For small lesions, irradiation, along with the use of a cane, may be all that is required. For larger lesions, surgical stabilization should be considered if possible. Intramedullary rods or methylmethacrylate can be used to increase strength of the invaded bone or, if used prophylactically, to stabilize a painful lesion and prevent fractures.<sup>38</sup> This gives the patient a more functional limb and allows increased mobility.

Destruction of the femoral head or acetabulum may be treated with hip joint arthroplasty, rendering ambulation a possibility while providing excellent palliation of pain. Fractures of the ischium may be painful during sitting and should be treated with cushions to reduce weight bearing over the fracture. Fractures of a single portion of the pelvic ring are generally not a problem. Multiple fractures, however, can interfere with ambulation and should be addressed appropriately. Fractures of the iliac wing may be painful during active hip flexion and abduction, due to the attachments of the iliacus and gluteal abductors, respectively. Assistive devices used to avoid activation of these muscles during ambulation can provide significant relief of pain.

When lower extremity and upper extremity are involved, use of gait aides may be contraindicated either because of pain or impending fracture. In this situation, a wheelchair may be needed until internal fixation can be performed. When upper extremity involvement is associated with pain but there is no immediate threat to bony integrity, a thermoplastic splint for forearm or a humeral cuff for lesions of the humerus may provide stability and symptom relief.

Ribs are also a common site of bony involvement and fracture. Generally, only a rib belt will be required. Pathologic fractures of non-weight-bearing bones can be managed with splinting or sling immobilization while irradiation is delivered. ROM or isometric exercises may be appropriate to maintain function. If a dominant upper extremity is involved, assistive devices and training in one-handed strategies by an OT can significantly improve function. Devices such as reachers and dressing aids can help the patient to avoid torquing the spine or hips if the risk of fracture is high.

In the patient who presents with neurologic deficits, the physician must always rule out spinal cord compression by tumor. Other causes of paraparesis in the cancer

patient include peripheral neuropathy, lumbosacral plexitis, radiation myelitis, and pseudotumor, often from radiation fibrosis. Radiation-related paraparesis may not occur for some time after the completion of all treatment. We have seen patients with radiation myelitis presenting as long as 7 years after having been declared free of disease. Hyperreflexia may be masked by peripheral neuropathy or plexopathy related to chemotherapy or irradiation, and patients with extensive metastatic involvement of the vertebral column may even have little or no pain.

The prevention of serious spinal cord injury should be the primary goal of the cancer rehabilitation team in treating the patient with known vertebral destruction by primary or metastatic disease. Although radiation treatment may be used to control tumor growth and to relieve spinal cord compression, this does not address the issue of spinal stability.

Although no good models of vertebral collapse from tumor exist, it has been assumed that spinal stability in the cancer patient can be addressed in much the same way that it is in the patient with a traumatic injury of the spine.<sup>38</sup> The most widely accepted method of stability evaluation involves the concept of three columns.<sup>40,41</sup> This method considers the spine to be made up of three supporting columns—the anterior, middle, and posterior structures of the vertebra—roughly divided into equal thirds. Any two of these supporting columns must be intact for the spine to be stable. For example, complete destruction of a vertebral body puts the spinal cord at risk for compression, because the posterior structures (facet joints) can easily sublux. A simple compression fracture, however, is usually stable because the posterior and middle columns are relatively intact. Of particular concern are lesions at the atlantoaxial and thoracolumbar junctions, due to the significant bending and torquing moments generated at these interfaces.

Whenever possible, an unstable lesion of the bony spine should be stabilized surgically, because virtually no brace can be completely effective in preventing subluxation. Irradiated bone heals slowly and often incompletely, and continued malignant destruction may sometimes occur. It is desirable from the rehabilitation standpoint to mobilize the patient as quickly as possible to prevent the complications associated with immobility. Even if there is extensive vertebral destruction, surgical stabilization can usually be accomplished by means of rods, strut grafts, and cement.<sup>42,43</sup> Occasionally, extensive multilevel involvement may render it impossible to find adequate healthy bone to which stabilizing hardware can be attached, or the patient's health may preclude any surgical option. In such cases, bracing may provide the only means of protecting the spinal canal.

If it becomes necessary to use a more "practical" cervical stabilization, orthosis selection should be based on the level of potential instability and the directions of motion that might lead to instability.<sup>44</sup> The Philadelphia collar, consisting of a foam collar with rigid supports, provides moderately successful stabilization of higher segments in flexion and extension but inadequate stabilization at lower levels and inadequate stabilization for side bending and rotation, and it is of limited usefulness as a spinal stabilization brace.

Two alternatives that provide excellent stabilization of lower segments in flexion and extension are the two-poster and sternal occipital mandibular immobilization (SOMI) braces (Fig. 57-1). The SOMI is particularly useful in managing debilitated patients, due to its open design and the ease with which it can be applied, because all components are attached from the front. It can be used with a light-weight chest piece, as supplied, or it can be bolted onto a lower spinal orthosis, making it useful in cases of multilevel instability (Fig. 57-2). An alternative cervical thoracic orthosis is the Yale brace, which essentially consists of a Philadelphia collar attached to a thoracic extension. With any of these orthoses, the patient must be informed that the brace is a compromise solution and that care is indicated, particularly with motions not well supported by the particular brace.

**FIGURE 57-1.** Cervical orthosis: two-poster support with sternal occipital mandibular immobilization reduces triplanar motion.

**FIGURE 57-2.** Sternal occipital mandibular immobilization orthosis with extended chest support reduces triplanar motion.

Stabilization of the thoracolumbar regions is generally achieved using two basic types of bracing. Metal braces, such as the Jewitt or the Taylor-Knight (Fig. 57-3) orthoses, can be fit to the patient rapidly, providing optimum limitation of flexion and extension. The custom-molded plastic thoracolumbosacral orthosis, or body jacket, additionally provides limitation in rotation as well. These braces are frequently poorly tolerated in the debilitated patient with atrophic skin. Elastic back braces and corsets, often used in the management of mechanical low back pain, do not provide adequate spinal stabilization, although rigid corsets may be worthy of consideration in the patient who absolutely cannot tolerate anything else.

**FIGURE 57-3.** Thoracolumbar stabilization device (Taylor-Knight).

High thoracic lesions and cases of extensive vertebral involvement may require the use of a combination orthosis. A cervical extension or SOMI brace can, for example, be attached to a body jacket (Fig. 57-4), providing restricted mobility of the entire spine. These braces should be worn whenever the patient is upright or travels in a motor vehicle. When the patient lies in bed without the brace, the head of the bed should not be elevated more than 30%. Patients should be cautioned against twisting or torquing their backs, because this may potentiate the injury. Cervical orthoses should be worn even when the patient is recumbent and should be removed only in a supervised setting.

**FIGURE 57-4.** Body jacket for thoracic support and triplanar movement control.

The prescription of exercise and participation in vocational-avocation activity should be written by knowledgeable professionals. The goals for treatment should be limited to what the patient can do safely, and should promote independence and quality function at minimal risk. Exercise to promote fitness with minimal bony impact, such as aquatics; strengthening by using isometric rather than resistive exercise; and activity patterns that minimize single-limb weight bearing for lower extremities are recommended strategies. Education to help patients and caregivers to maximize safety is also important.

### **SPINAL CORD INJURY SYNDROMES AND REHABILITATION OF IMPAIRMENT**

Spinal cord disorders in cancer patients may result from malignant invasion; bony compression or trauma; syrinx or hematoma formation; radiation myelitis; or vascular events. Radiation myelitis is directly related to radiation dose and often does not develop until years after the completion of therapy.<sup>45</sup> Spinal cord dysfunction has been associated with high-dose intrathecal chemotherapy.<sup>46,47</sup>

The degree of functional impairment in a spinal cord disorder is related to the level of the lesion and to its degree of completeness. The level of a lesion is, by American convention, the last fully functional spinal root level. For example, a C-5 (cervical root 5) quadriplegic has intact function of the biceps brachii (innervated primarily by C-5 and C-6), with intact sensation over the shoulders and lateral aspects of the arms. A C-5 quadriplegic is able to bring the hand to the mouth but will require assistance for most self-care. A level of C-4 is required for unassisted breathing. C-6 quadriplegics will have intact wrist extension, allowing some light grasp through the tenodesis effect. C-7 quadriplegics are able to extend the elbows, making it possible for them to lift themselves, performing their own weight shifts. C-8 and T-1 are required for intact hand function.

The remaining thoracic segments are of significance primarily in the motor control of trunk stability. In the lower spine, the degree of functional use of the legs is more vague, due to the extensive overlap of motor segments. Generally, hip and knee extensor strength of sufficient magnitude to overcome gravity (3/5) is essential for safe ambulation. Although long leg braces can be used for paraplegic ambulation, the level of energy required is usually beyond the capability of many healthy persons, let alone the patient debilitated by cancer. Short leg braces, or ankle-foot orthoses (AFOs) can be used effectively to compensate for the loss of ankle dorsiflexors and plantar flexors. In selected patients with intact hip musculature, AFOs that limit dorsiflexion can be used to create an extension moment at the knee, substituting for quadriceps function during the stance phase of gait.

Damage of the central portion of the spinal cord may occur, with the outer portions being spared. This may occur with intramedullary tumors, with syrinx formation, or in certain vascular events. The central cord syndrome is characterized by loss of upper extremity function, with relative sparing of function in the legs. If only one side of the spinal cord is involved, the Brown-Sequard syndrome results, in which motor function is affected on the ipsilateral side while most sensory function is affected on the contralateral side.

Because of the complexities involved with spinal cord dysfunction, rehabilitation should be provided by those familiar with management of spinal cord injury. Assisted mobility using manual or motorized wheelchairs or crutches or canes with braces will usually be required. Adaptive equipment and strategies for self-care may be needed in the cancer patient with spinal cord involvement.

Bowel and bladder dysfunction in this patient population is virtually universal, requiring particular attention. Even in the patient with apparent normal voiding, silent bladder and sphincter spasticity may lead to infection, bladder reflux, and significant morbidity. We have seen cases of hydronephrosis with almost complete destruction of the kidneys in asymptomatic persons. Foley catheters may be used for short-term management if there are other medical indications. Otherwise, intermittent catheterization done frequently enough to keep the bladder volume at less than 500 mL is the method of choice during the acute phase. A urologist should be consulted after the patient has stabilized. Regular use of laxatives as part of a bowel-training program is frequently required.

Autonomic dysreflexia or hyperreflexia is a true emergency in the spinal cord-impaired patient. When the spinal cord level is T-6 or above, uncontrolled vasoconstriction and severe hypertension may result. Paradoxically, the heart rate is often slowed, due to the intact vagus nerve. The first objective should be to lower the blood pressure as quickly as possible. Sitting the patient upright will help to reduce intracerebral pressure. A fast-acting agent, such as sublingual nifedipine, may be used initially, followed by a longer-acting agent, such as nitroprusside, if needed. After the blood pressure has been stabilized, the cause usually a noxious stimulus should be isolated and corrected. The most common cause is an overdistended bladder, and distended bowel and skin trauma are other possible explanations.

### **NEUROPATHIES AND PLEXOPATHIES**

Peripheral nerve involvement is a common diagnostic dilemma in the cancer patient. Dysfunction of peripheral nerves usually results from the use of cisplatin or vincristine and irradiation.<sup>48,50</sup> Peripheral neuropathies and plexopathies can also be the result of direct tumor invasion or a paraneoplastic syndrome.

#### **CHEMOTHERAPY-INDUCED NEUROPATHIES**

Generally chemotherapy-related neuropathies tend to be distal and symmetric. Occasionally, initial symptoms are unilateral, mimicking a mononeuritis or invasive lesion. Vincristine and cisplatin are documented causes of autonomic neuropathies.<sup>51,52</sup> In some instances, this has been severe enough to mimic spinal cord involvement.<sup>53</sup> Cytarabine has caused brachial plexus neuropathy.<sup>54</sup> Suramin, largely an experimental drug, has caused a profound polyneuropathy, mimicking Guillain-Barré syndrome. Agents that are lipid-soluble or that have metabolites with a prolonged half-life may lead to a progressive neuropathy, even after discontinuance of the drug.<sup>55</sup>

Vincristine seems to induce distal axonal degeneration similar to that of other toxic neuropathies.<sup>48</sup> Because of this, the duration of the neuropathy tends to be prolonged because of the time needed for nerve fiber regeneration. Many patients receiving this agent develop sensory complaints of numbness and paresthesias. Some patients develop severe neuropathic pain. Often, the degree of motor neuropathy is significant, sometimes resulting in a virtual quadriparesis. Although it may take months after cessation of chemotherapy to recover function, recovery is usually complete. Neurotoxicity is one of the most common reasons for limiting the dosage of vincristine chemotherapy.

Neuropathies due to cisplatin generally tend to be less frequent and often milder. We have treated several patients who have developed a severe permanent neuropathy from the use of cisplatin. There does not seem to be any common factor that can be used to predict the development of lasting neuropathy. Rarely is an adjustment in cisplatin dosage indicated.<sup>49</sup>

## BRACHIAL PLEXOPATHIES

Radiation-induced brachial plexopathy is an uncommon problem in the conservative management of breast cancer if supraclavicular and axillary lymph nodes are irradiated. It may be seen as a late effect of mantle irradiation for Hodgkin's disease. Onset of symptoms is usually delayed. In one study, symptoms began more than 1 year after therapy, and the overall prognosis for recovery was poor.<sup>56</sup>

Differentiation of radiation from neoplastic plexitis is essential. Severe pain has been documented in 80% of patients with infiltrating tumor, but only 19% of patients with radiation injury described this finding.<sup>57</sup> Horner's syndrome is more common in cases of tumor involvement, and lymphedema is a much more common concomitant finding in radiation injury. The distribution of involvement of the brachial plexus is an important diagnostic criterion, with 72% of patients with invasive tumor having involvement of the lower trunk and 78% of patients with radiation injury having involvement of the upper trunk.

Electrodiagnostically, myokymic discharges are virtually diagnostic of radiation plexitis, occurring in 63% of patients.<sup>58</sup> Other abnormalities are common in both types of injury, with nerve conduction studies being of limited usefulness.<sup>59</sup> Tumor detection by magnetic resonance imaging (MRI) provides definitive evidence of neoplastic involvement. Even without visible tumor during surgery, neoplastic disease has sometimes been found microscopically, and it may not be possible to rule out neoplastic plexopathy for many months after the onset of symptoms.<sup>60,61</sup>

## LUMBOSACRAL PLEXOPATHY AND RADICULOPATHY

Involvement of the lumbosacral plexus is common in pelvic tumors due to direct invasion.<sup>62</sup> In a study of 11 patients with lumbosacral plexopathy, 6 had metastatic involvement, 2 had radiation-induced plexopathy, 1 had a primary tumor, and 2 had neuritis due to intraarterial chemotherapy.<sup>63</sup> Direct imaging of tumor with CT or MRI may be difficult after irradiation or surgery. We have seen a preponderance of delayed painful plexopathy in patients receiving intraoperative radiation. It is important to attempt to differentiate plexus lesions from those of the spinal cord, due to the difference in treatment, rehabilitation management, and prognosis.

Neuropathic pain is commonly seen with peripheral neuropathies. Loss of sensation may render the patient susceptible to skin injury. The patient with insensate skin should be cautioned about the avoidance of potential injuries from burns and sharp objects and about the need for daily skin inspection to avoid the development of infection. Loss of proprioceptive feedback, particularly in the patient with impaired vision, may interfere with simple fine-motor tasks and with ambulation. A cane can provide proprioceptive feedback to the upper extremities in the patient with impaired proprioception in the lower extremities. Motor impairment is treated similarly to other neurologic disorders, with bracing and adaptive devices as needed.

In addition to the use of narcotic agents, which has become the mainstay of palliative treatment in the cancer patient, the physical modalities of pain control may significantly help to alleviate suffering. More aggressive approaches, including nerve blocks and rhizotomies, have been used with limited success. Sympathetic nerve blocks and sympathectomies may be effective in patients with the reflex sympathetic dystrophy syndrome. Trigger point injections are also sometimes helpful in musculoskeletal pain disorders.

The use of physical modalities can be a particularly effective adjunct in the management of pain in the cancer patient. Heat modalities, including superficial heat, shortwave diathermy, and ultrasonography, may provide relief in musculoskeletal pain syndromes, but ultrasonography may help to spread lymphatic disease. Other heat modalities increase circulation to the affected area, questionably increasing the potential for metastatic spread. Therapeutic cold can also sometimes help to reduce pain.

Electrical stimulation has met with increasing criticism in the literature, but we have found electrical stimulation to be effective in reducing narcotics usage in a variety of cancer patients with a variety of pain syndromes. It seems to be particularly effective in the management of phantom limb pain and in treating radiculopathy and incisional pain. If effective, the patient can be provided with a pocket-sized transcutaneous electrical nerve stimulation (TENS) unit, which can be used as needed. Electrodes should be placed at the site of maximum pain or, in the case of referred pain, at the site of the lesion. A conventional high-frequency setting is usually most effective. Many TENS units are available at modest cost. Progressive muscle relaxation has also been reported to be useful.

## LYMPHEDEMA AND DEEP VEIN THROMBOSIS

The swollen extremity is often a diagnostic dilemma in the patient with a history of cancer. Because of the possibility of malignant compression or invasion of lymphatics or venous drainage, and because of the possibility of deep venous thrombosis, a swollen extremity should always be fully evaluated in the cancer patient or cancer survivor. Idiopathic lymphedema, rather than edema secondarily caused by infection or tumor, should be a diagnosis of exclusion. Tumor can usually be excluded by imaging studies, such as CT, MRI, or bone scan or, in extreme instances, by lymphangiogram.

Deep venous thrombosis can usually be ruled out using impedance plethysmography or ultrasonography.<sup>64,65</sup> If certainty is required, a venogram can be performed. Suspected pulmonary embolism can be evaluated with a ventilation-perfusion scan or, more definitively, by pulmonary angiography. The greatest risk of embolization is from proximal thromboses.

Lymphedema in the cancer patient is frequent, with lymph node involvement or after lymph node dissection. Late edema is usually related to radiotherapy and the gradual development of fibrous tissue and change in the protein content of the fluid. Edema in a nonirradiated extremity should always be thoroughly evaluated, and remediable causes, such as infection or cardiovascular causes, should be treated.

The simplest means of minimizing edema is to keep the affected extremity elevated as much as possible. Legs should be placed on an elevated foot support, preferably keeping the feet above the level of the heart. Arms should be rested on a high table surface. A sling may be of short-term benefit. Isometric exercises, by increasing muscle tone, may help to minimize edema.

The management of lymphedema varies from treatment center to treatment center and from country to country. Rehabilitative therapies have typically included education about limb position to minimize gravity, use of massage, exercise to enhance lymph flow and maintain mobility, and the use of pneumatic compression devices and compression garments to reduce lymphedema in the involved extremity. Because of a better understanding in the anatomy, physiology, and pathophysiology of the lymphatic system, a combination of techniques has evolved to manage lymphedema better.<sup>66</sup>

Manual lymph drainage (MLD)<sup>67</sup> is a specialized massage technique based on the concept of emptying the central regions first, to give the lymph from the periphery somewhere to go.<sup>68,69</sup> The lymph is moved proximally and, across lymphatic watersheds, into the nearest normally drained lymphotomes. The proximal region of the limb is always cleaned first, then the massage is extended distally; effleurage that starts at the distal end and attempts to push the lymph into the unemptied, proximal regions is ineffective.<sup>70</sup>

After MLD, some treatment centers will continue lymph drainage with the use of a sequential pneumatic compression device. Other centers will follow MLD immediately with compression bandaging, using the low-elastic Comprilan (Beiersdorf, Germany) applied over padding (Artiflex Soft, Beiersdorf, Germany) and an undergauge (Tricofix, Beiersdorf, Germany).<sup>70</sup> Once the compression bandages have been applied to the extremity, special exercises are performed to supplement the effects of the MLD.

The frequency and duration of the foregoing techniques vary from treatment center to treatment center. However, the greatest reduction in lymphedema usually occurs within the first week of treatment (when the treatment is provided by a highly trained and skilled PT). Just before discharge from the treatment program, the extremity is fitted with a compression garment to maintain the reduction in lymphedema. An example of a wrapped upper extremity is presented in [Figure 57-5](#). The National Lymphedema Network located in San Francisco has a list of manual lymphatic drainage therapists and treatment centers throughout the United States.

**FIGURE 57-5.** Wraps to reduce limb edema.

## BOWEL AND BLADDER DISORDERS

Bowel obstruction or ureteral or urethral compromise is usually the result of malignant invasion or spinal cord or nerve root compression. Constipation and urinary hesitancy are frequently related to the use of medication, particularly narcotics and drugs with anticholinergic properties. Input from the rehabilitation team is most often needed if there is neurologic dysfunction or in ostomy care.

### MANAGEMENT OF BOWEL DYSFUNCTION

Disorders of fecal elimination are frequently the most significant complaint of the cancer patient. Constipation is extremely common and is best treated using dietary modifications and medication. Often, a high-fiber diet with copious fluid intake will be all that is required to ensure regularity. If fiber supplements are used, the patient should be cautioned about the absolute need for fluid intake, because bulk in the absence of fluid can lead to impaction. If necessary, stool softeners (e.g., docusate sodium, 50 to 200 mg/d) can be added to reduce straining. A stimulant medication (e.g., metoclopramide hydrochloride, 10 mg 30 minutes before meals and at bedtime) can be used for delayed gastric emptying.

When spontaneous defecation does not occur, a stimulant agent may be required. A mild preparation with a well-controlled transit time, such as an over-the-counter senna preparation, is preferred. A standard dose of senna (e.g., Senokot, two tablets) at bedtime usually results in controlled defecation in the morning. Stronger agents, such as bisacodyl (5 to 15 mg) or magnesium hydroxide (milk of magnesia, 30 mL) may be used in more recalcitrant cases, although it should be kept in mind that magnesium is mildly nephrotoxic. Such cathartics as magnesium citrate should be used as a last resort and only if there is no suspicion of obstruction or impaction.

In the patient with neurogenic bowel dysfunction, stimulation from below may be required. Digital stimulation or, if needed, use of a glycerin or bisacodyl (10 mg) suppository should usually be sufficient to initiate evacuation. Rarely, an enema may be required. By instituting a regular bowel-training program in which full evacuation is achieved on a daily or every-other-day basis through the use of medications and rectal stimulation, it is usually possible to achieve continence.

Diarrhea in the cancer patient is usually the result of chemotherapy. Standard antidiarrheal preparations, narcotics, and anticholinergics may be used. If diarrhea occurs in the face of antibiotics, pseudomembranous colitis resulting from infection with *Clostridium difficile* should always be ruled out. Other bacterial or parasitic diarrhea should be treated with appropriate antibiotics, as determined by stool culture or smear. Narcotic antidiarrheal agents should be avoided in this case due to the potential for toxic megacolon development. Viral diarrhea should generally be allowed to run its course.

### MANAGEMENT OF THE NEUROGENIC BLADDER

Proper evaluation and management of bladder dysfunction in cancer patients with neurologic abnormalities is essential to prevent significant morbidity. Although bladder dysfunction is often arbitrarily divided into disorders of incontinence or reduced bladder capacity and disorders of retention, this model is overly simplistic. Patients with spinal cord or brain stem involvement should always undergo formal evaluation of bladder function.

There may be various combinations of a spastic or flaccid bladder and a spastic or flaccid urinary sphincter.<sup>71</sup> The combination of a spastic bladder and sphincter is the most dangerous, because this can lead to reflux, causing hydronephrosis or upper tract infection or to autonomic hyperreflexia. Such medications as oxybutynin chloride, 5 mg two to four times daily, can be used to reduce bladder spasticity, but mechanical means of drainage may be needed.<sup>72</sup> Urinary tract infections are frequent in the patient with neurogenic bladder, and proper evaluation and treatment are mandatory.

In the acute phase of management, an indwelling catheter is usually sufficient if there are appropriate medical indications. Catheters should be removed as soon as the patient is stable, so as to minimize the risk of infection. In the patient who appears to be voiding normally, evaluation for possible retention should still be done. Postvoiding residual urine volumes as determined by catheterization or by ultrasonography should be less than 50 mL. If the patient does exhibit retention, intermittent catheterization should be instituted, taking care to catheterize frequently enough to keep bladder volumes at less than 500 mL. In the incontinent patient without retention, condom (Texas) catheters may be used for men. Collection devices for females are often less than satisfactory.

### MANAGEMENT OF THE OSTOMY PATIENT

Cancer patients may have ostomies for a variety of reasons. Ureteral stents are often used in patients with ureteral obstruction, occasionally in combination with a temporary ostomy for kidney drainage. Patients with bladder carcinoma may have a ureteral diversion to an ileal loop, which is drained through an ostomy. Patients with bowel carcinoma or other types of bowel obstruction may need a temporary or permanent ostomy for fecal elimination. This may be required at any level of the small bowel or colon. Ileostomies, involving diversion of the terminal small bowel, are sometimes problematic because of the volume of fluid present in the fecal contents before entry into the colon. An ileal pouch is sometimes created surgically as a reservoir for urine or ileal fluid as a means of providing continence.

In cases of neck tumors or if there is impaired swallowing, a gastrostomy may be required for supplemental nutrition. This can often be placed by percutaneous endoscopic gastrostomy, eliminating the need for major surgery. Tracheostomies are often used in cases of head or neck tumors or if there is a need for prolonged access to the airway, as in the patient with severe cognitive impairment and uncontrolled tracheal secretions.

Ostomy training should be a regular part of the cancer patient's rehabilitation process.<sup>73</sup> Proper cleaning technique avoids the likelihood of infection. Proper attention to skin care should avoid maceration and breakdown. Occasionally, a bowel-training program can be instituted for colostomy patients, regularizing emptying and sometimes eliminating the need for an ostomy bag. A variety of ostomy collection systems are available, including one-piece collection bags, applied directly to the skin using an adhesive, and two-piece collection bags involving an occlusive seal that is applied to the skin and a separate detachable bag.<sup>74</sup> Collection bags may be closed and disposed of with each use or may be open, allowing for drainage and reuse. One- and two-piece barriers may be used to help patients to maintain continence. Support groups for ostomy patients are available in most areas, and a variety of patient information materials are available.<sup>75,76 and 77</sup>

## PSYCHOSOCIAL ASPECTS OF CANCER REHABILITATION

Accommodating to change in daily performance, to loss of function, and to modifications in life style that accompany the diagnosis and treatment of cancer has relevance for all individuals. However, life management goals vary widely and may be influenced by each individual's values, stage in life and phase of disease, life experiences, and temperament. The challenge facing oncologists is identifying and addressing unique psychosocial reactions presented by the patient during all stages of oncologic management, including the terminal phase.

[Table 57-8](#) summarizes some common emotional reactions to oncologic illness as they may be manifested during different stages of treatment. Also included are

intervention approaches. Pivotal in medical and rehabilitation intervention is interdisciplinary management of these reactions to facilitate mastery of the long-term impact of cancer on function. With proper management, the likelihood of developing handicapping conditions and of impairing quality of life is decreased.

Psychosocial Aspect	Diagnosis Stage	E	F	A	T	Recommendations for Oncology Management	Rehabilitation Interventions
Denial	1					Allow expression of denial; avoid pressure to accept	Support self-expression strategies; building coping strategies
Anxiety fear	1	X	X	X		Knowledge correct facts; focus on self; separate from disease; genetic transmission	Teach relaxation and exercise; increase sense of control; use adaptive aids; exercise readily
Negative body image	1		X			Anticipate change in body and image; recommend adaptive behavior	Reassess priorities and realistic desires; suggest and participate in styling
Distal death and being	1			X		Encourage self-expression; enable involvement in life	Provide support groups; help building self-esteem; provide supportive interaction
Dependence on others	1		X	X		Encourage self-expression; help patient understand need for knowledge and goals	Provide support groups; suggest lifestyle change; have someone discuss care to include exercise, stress education, and counseling
Prostration and anger	1	X	X	X	X	Advocate for patient and identify anger; offer possible solutions	Advise role to allow enough time to complete; encourage expression of feelings; give advice
Dependency	1		X			Encourage self-responsibility	Reduce dependence on aids; increase self-competence
Resentment and maladaptation	1	X	X	X	X	Advocate for patient behavior; anticipate change in function	Provide challenges with explained activity on realistic expectations; small goals; adapt all environments; and take, check status and take from community participation

TABLE 57-8. Psychosocial Aspects of Cancer Rehabilitation

## REHABILITATION AND MANAGEMENT OF SPECIFIC TUMORS

### SARCOMA OF THE EXTREMITIES

Ablative extremity surgery (amputation), formerly the treatment of choice for local control of sarcomas, has been replaced by limb-sparing surgery in the majority of cases.<sup>76,79</sup> Since clinical trials indicate no benefit from amputation in overall survival rate in selected cases<sup>80,81</sup> and function and desirability favor limb preservation in many, limb-sparing surgery has become more prevalent.

Clinical trials have shown reduction of local tumor recurrence in soft tissue sarcomas (STS)<sup>82,83</sup> and<sup>84</sup> with preoperative and postoperative radiotherapy treatments and brachytherapy and of distal metastatic disease in osteosarcoma (OS)<sup>85</sup> with the use of preoperative and postoperative adjuvant chemotherapeutic regimens. Limb perfusion has reduced tumor size even when advanced, to permit limb-sparing surgery.<sup>86</sup> For those in whom there was still no option for limb-sparing surgery, a reduction in tumor size is often associated with palliation of pain and better cosmesis.

Tumor size, pathologic type, and adequacy of excision remain the main predictors of local control. Tumor location, involvement of neurologic tissue, and size often are the better predictors of function.

In recent years, the chance for better functional outcome in limb-spared patients has resulted from (1) refined surgical interventions (abandonment of origin-to-insertion whole-muscle group excision in favor of partial group excisions); (2) use of endoprostheses and bone allografts, muscle transfers, and sophisticated soft tissue reconstructive procedures; (3) refined radiotherapy procedures (abandonment of full-dose radiotherapy to the entire port in favor of advanced simulation techniques), which permit a cone-down high dose to the direct tumor site and lower doses to the rest of the port, with corrections also made to reduce dose and scatter to joints; and (4) the development of specific rehabilitation programs to follow up the limb-spared patient throughout the trajectory of the disease process.

In some patients, amputations are still needed. These tend to occur for large tumors involving other critical structures in which resection would result in poor functional outcome or poor local control. Often, these are high-level amputations. Amputation also occurs more often for hand and foot tumors where there is little leeway to obtain an adequate excision without severely compromising function. However, more sophisticated reconstructive procedures have recently been reported to salvage the hand and thumb.<sup>87,88</sup> Children younger than 13 years with OS are too young for limb-sparing procedures using endoprostheses. Other procedures may be used in some cases.

Functional deficits, impairments, and symptoms from limb-sparing surgery result from (1) the local procedure itself (depending on the extent of the resection and resection of adjacent structures, such as nerves and vessels); (2) adjuvant therapy (chemotherapy, radiotherapy, and limb perfusion); (3) the effects of local recurrence and distal metastasis; and (4) premorbid patient characteristics.

Specific impairments and symptoms include pain, edema, fatigue, reduced strength and joint motion, stress, and depression. Functional deficits occur in the areas of mobility; ADL; vocational, social, and sexual adjustment; and recreation and leisure.

Rehabilitation plays a major role in assessing the person's potential for limb sparing, predicting their functional outcome after the procedure, maximizing their function by treating their impairments and symptoms, and educating them in the proper care of their spared or amputated limb to prevent complications and encourage preservation and coping strategies related to impairment and handicap. Rehabilitation interventions should occur over the trajectory of the patient's life span as new problems emerge in different disease phases.

### Role of Rehabilitation

Resection may involve partial muscle group removal, muscle transfer, and bony replacement by endoprosthesis or allograft (and less often, vessel and nerve removal). The surgeon predicts which structures will need to be removed for an adequate tumor excision. Based on the extent of the planned surgery, the physiatrist anticipates the level of function of the limb after surgery. Both surgeon and physiatrist discuss and concur on this prediction. A judgment is then made whether this would be acceptable function for the patient. A comparison of functional outcome resulting from amputation and limb sparing should be made before treatment selection. These discussions should be shared with affected patients before a treatment choice is selected, should be the best from such patients' perspective, and should be supportive of their needs.

For adequate function, the limb may need some permanent postoperative bracing or splinting. These are usually needed if there has been sacrifice of a key nerve or muscle. The patient should be informed preoperatively that these adjunctive devices may be necessary for independent functioning. Special age, wear, and fracture risk considerations take place if an endoprosthesis is used. In OS, usually a longer endoprosthesis must be placed, rendering the spared limb longer for patients aged 15 to 17 years. This compensates for growth arrest in the operative limb. A major growth plate may need to be stapled on the normal side in OS if the limb grows disproportionately and exceeds the affected side by more than 2 cm. A heel lift of up to 1 inch may be used if the endoprosthetic side is shorter than on the normal leg. Endoprosthetic loosening may occur, depending on the amount of wear and tear from activities, but endoprostheses can last up to 10 years. For long-term survivors, endoprosthetic replacement will be needed. There is generally a limit of two to three replacement reconstructions. Reconstructions are also necessary for prosthetic dislocation, bone fracture, and loosening. Removal of the prosthesis is often necessary for serious bony infection. Infections with some organisms (*Staphylococcus epidermidis*) have been successfully treated with 3 months of appropriate intravenous antibiotics.<sup>89</sup> Therefore, some patients who initially underwent limb-sparing procedures will need amputations later in their life. They need to be aware of the possibility of these problems preoperatively when choosing a limb-sparing surgery.

If the patient needs an amputation, the physiatrist should evaluate the patient preoperatively and recommend the most functional level. A very short above-knee amputation (AKA) can be fitted with a prosthesis and is much more functional and energy-efficient than a hip disarticulation. In some cases, a hip disarticulation can be converted to a short AKA by use of a custom-made short femoral endoprosthesis. A short below-elbow and below-knee amputation can be fitted appropriately with a prosthesis and is much more functional than its counterpart (above-elbow and AKA).

### Treatment during Phases of Disease

**INITIAL PHASE.** Rehabilitation interventions begin preoperatively with instruction about crutch usage. The type of interventions and the rate at which rehabilitation progresses depend on a number of factors. Although general statements can be made about how a patient progresses, each resection is somewhat different, and the

treatment plan and progression of treatment are individualized to each patient. Progression and intensity of rehabilitation are slower for bony reconstructive procedures.<sup>90,91</sup>

**POSTSURGICAL PHASE.** Postoperatively, the patient is reevaluated for level of pain, fatigue, stress, motivation, muscle strength, and joint motion. In general for STS patients, early treatment begins with correct positioning in bed to facilitate lymph drainage; a posterior splint or sling may be needed. Passive ROM by a PT or OT therapist is performed for joints distal to the resection and, in other joints, active motion is performed by the patient. On day 2, the patient is allowed to transfer out of bed with assistance and sit in a chair with proper limb positioning. For lower limb procedures, non-weight-bearing gait with crutches or a walker and posterior knee splint are initiated; if the upper extremity is the operative site, an appropriate sling or splint is used. The patient engages in active ROM of joints distal to the surgery. As drainage decreases and the drain is removed, gait progresses with toe touch and partial weight bearing. The joint near the surgical procedure receives active assistive ROM with the PT or OT therapist. Arc of motion is increased as the wound heals. Assessment of wound healing is made before ROM progression. When the staples are removed at around 14 days, the patient should be fully weight bearing and can come off crutches in a week.

Special procedures, such as the Tinkoff-Lindberg procedure for shoulder STS, require extensive soft tissue reconstruction and an endoprosthesis. The rehabilitation course is slower and similar to that of resections for proximal humeral OS tumors. The functional outcome is also the same.

Early rehabilitation for bony reconstruction is usually performed for OS but has a longer postoperative rehabilitation course, and the progression of treatment is highly dependent on the type and extent of the excision. Any complications that occur postoperatively alter the progression of rehabilitation. Two of the complications that occur are skin breakdown at the initial closure site and soft tissue or joint infection. The former often requires reoperation for closure or skin grafting (or both), and the latter requires intravenous antibiotic therapy and sometimes endoprosthesis removal. During these complications, rehabilitation is often put on hold and restarted when appropriate.

If no complications occur, patients with humeral excisions can be given passive hand ROM on day 2 and actively use their hand 2 weeks postoperatively. Passive ROM is performed on the elbow for 3 weeks postoperatively. Patients usually lack approximately 40 degrees of extension. Use of moist heat over the elbow followed by gentle stretching can be started at approximately 4 weeks after the reconstructive procedure involving the shoulder if the wound is sufficiently healed and can withstand the tension of biceps lengthening. The therapist performs progressive passive ROM of the shoulder beginning with 20 degrees flexion-extension, then adding abduction and internal-external rotation. Close contact with the surgeon is maintained in increasing the degree of ROM. Usually, passive ROM in abduction and internal-external ROM attained is approximately 60 degrees. Active ROM is not expected to be functional.

Patients with distal femoral endoprosthetic replacements generally wear a knee immobilizer for 3 weeks. The therapist performs passive ROM of distal joints. The therapist is allowed to perform limited-arc passive knee ROM of the involved joint between 2 to 3 weeks, carefully observing the wound closure for any signs of potential breakdown from increased tension with ROM. When the sutures are removed, active assistive ROM is performed, and the ROM arc is gradually increased. The patient should be able to perform some isometric exercise in the immobilizer on day 3 and begin active ROM at 1 month. Quadriceps strengthening to improve knee biomechanics is very important. Exercise intensity is advanced with addition of some isotonic light weight at 6 weeks. From a mobility point of view, patients walk with crutches and immobilizer and are non-weight bearing from days 4 to 10. Gradual weight bearing starts then with toe touching and progresses to tolerance, while monitoring pain and looking for development of any knee effusion. Usually, weight-bearing status is decreased if the latter occurs. By 2 to 3 months, when the quadriceps is sufficiently strengthened to support the knee and affected patients have no complications, they ambulate with a cane. Independent ambulation without a cane occurs anywhere from 3 to 4 months postoperatively.

Patients with proximal tibial resections have a slower course. One main reason for this is that the surgical procedure requires quadriceps reconstruction with a gastrocnemius flap and reattachment of the quadriceps mechanism to the metal endoprosthesis. Healing of the reconstruction takes longer. The limb is elevated for 10 days. Quadriceps isometrics are started on day 2. ROM and weight bearing are introduced at a slower pace. The patient wears a bivalved cast for a month. Knee ROM begins when the cast is removed. Active motion exercise starts when the patient is able to extend the knee. Often, the patient wears a long leg brace for an additional 2 months, which allows 30 degrees of flexion. Full weight bearing with a cane is not expected before 4 to 5 months. The quadriceps mechanism is initially weaker than with the distal femoral procedure, due to the quadriceps reconstruction. A more significant knee extension lag can occur. More intensive quadriceps strengthening is needed to help to reduce knee extension lag, allow for active knee extension, and ensure safe gait. Final functional outcomes are pain-free, independent ambulation without a cane and ADL around 6 to 8 months.

Early rehabilitation for amputees begins with fitting the residual limb with an immediate postoperative cast in the operating room. This is achieved for above-elbow amputation, below-elbow amputation, AKA, and below-knee amputation levels. The purpose is to shape the residual limb and to reduce pain and edema.

High-level amputees, or hemipelvectomies, may have considerable phantom pain because of surgical severance of large nerve trunks. Often, reduction of edema by elastic compression on manual drainage, use of TENS, and pharmacologic interventions help with pain reduction.

In most centers where limb-sparing surgeries are performed, the patient's function is evaluated at intervals to document clinical progress and to follow function in drug trials. Patients are followed up long term for 10 to 15 years and are often evaluated at 6-month intervals the first 3 to 5 years and yearly thereafter. If they are disease-free at 10 to 15 years, they are usually discharged.

Functional assessments include objective measures of strength (manual muscle test), ROM (goniometer), edema, and pain and fatigue by visual analog scales. A functional questionnaire may be used for determining level of participation in ADL and use of assistive devices and to identify psychosocial and vocational problems. A cancer-specific questionnaire is the Cancer Rehabilitation Evaluation Systems.<sup>5</sup> A combined physical evaluation and patient questionnaire for assessing function of OS patients is the Enneking or Musculoskeletal Tumor Society Rating Scale.<sup>92</sup> A recent questionnaire, the Toronto Extremity Salvage Score, was developed and validated for both STS and OS patients.<sup>93</sup> Patients with STS and OS may also be assessed from a biomechanical standpoint in motion analysis laboratories looking at velocity, stride length, and substitutive gait patterns.

Patients with STS who undergo wide local excision generally have satisfactory to excellent functional outcomes because one of the criteria for surgery is predicted satisfactory outcome. The specific outcome depends on the extent of the excision and adjacent structures and postoperative complications.<sup>94,95</sup>

Patients are generally independent either with or without assistive devices and braces. Some patients may need a change in vocational status. OS limb-spared patients generally have good to excellent function, as judged by the Enneking Assessment and Gait Analysis.<sup>96</sup> Some, however, fall into the poor to fair categories. Gait analysis reveals that such patients may have slower cadence and uneven stride lengths. They often use substitutive muscle strategies.<sup>97</sup> These vary widely. For instance, in the presence of a weak quadriceps, such patients strike their toe first on stance rather than heel strike. This creates an extension moment at the knee to help to stabilize it and, therefore, to improve gait safety. Limb-spared procedures require a reconstruction if there is dislocation, fracture at the bone cement interface, serious infection unresponsive to intravenous antibiotics, or worn-out components. Studies of these reconstructions are limited to case reports but indicate good to excellent function.<sup>98</sup>

Amputations are still necessary if limb salvage cannot be performed or if a former limb-sparing procedure cannot be done. Amputation levels for sarcoma (OS and STS) are performed at all levels, depending on tumor site and size. Skip lesions often occur in OS; thus, the amount of bone involved by the primary tumor in these lesions requires a higher amputation level for cure. In comparison to amputations for diabetes and vascular disease, which are usually midlevel below-knee amputations and AKAs, those for sarcomas tend to be high-level procedures (hemipelvectomy, hip disarticulation, high AKAs, short below-elbow amputations, and forequarters). Prosthetic fitting in these cases is more difficult. Achieved functional level and compliance with use of some prosthesis, as hemipelvectomies, is low, and energy requirements for use are higher. Forequarter prostheses are rarely functional and often not used.

In general, amputees are usually independent in mobility and ADL with or without crutches. Vocational status often needs to be changed. Phantom pain may interfere with function and needs to be treated.

The function of limb-spared patients versus amputees has been addressed. Some amputees may be more functional than limb-spared patients and vice versa. Since some prosthetic limbs are durable, participation in contact sports, running, high-impact dances, tennis, and golf are no problem. However, amputees with cosmetic limbs, humeral OS or lower limb sparing, should have more restriction in sport activities. Limited sport may be needed to preserve endoprostheses. However, an upper extremity Tinkoff-Lindberg procedure for humeral OS is much more functional than a forequarter amputation.

*Pain.* Management of pain postoperatively is essential. Pharmacologic management with narcotics is essential in the first postoperative week. Rehabilitation treatments begin with proper limb positioning to reduce edema and avoid contracture. Immobilization of operative sites using splints and use of TENS are common adjuncts. Acupuncture may also be useful to reduce pain.

*Lymphedema.* Edema can cause pain and interfere with function. Significant lymphedema commonly occurs with STS resections involving the adductor and hamstring, anterior compartment muscle groups, and breast sarcoma. This is controlled by proper positioning and the use of a compression garment. With these four excisions, edema is often chronic and needs to be treated long-term with combined modalities of massage, wrapping, and pumping. It can usually be well controlled or reduced. A new technique of nonelastic wrapping has proven very effective in management.<sup>69</sup>

*Mobility.* OS and STS limb-spared patients have short- and long-term mobility problems.

In the immediate postoperative phase, crutches and walkers are often needed. Often, patients will not need these devices at 6 months. Orthoses are needed after some soft tissue resections to replace lost function. The most common brace used is for knee control after excision of the quadriceps; for ankle control after gastrocnemius with peroneal nerve removal; and for wrist extension after radial nerve or forearm extensor removal. For knee control, an AFO with 5-degree plantar flexion is often used. This creates an extension movement to stabilize the knee. The peroneal nerve brace is a plastic AFO to correct equinovarus of the foot. A cock-up splint is used to maintain wrist extension or a dynamic outrigger brace is used to restore finger extension if the long extensors have been resected.

Below-knee and above-knee and above-elbow and below-elbow amputees are fitted with an immediate postoperative cast, after the suture line is closed, and a temporary pylon and foot are added at day 10 postoperatively for the below-knee and above-knee amputees. A permanent limb is ordered when the residual limb is well shaped and the patient does not have fluid and weight shifts from chemotherapy. If no chemotherapy is involved, a permanent prosthesis is made 6 weeks postoperatively. For chemotherapy patients, this may be delayed by 3 months.

Two main types of prostheses are used: endoskeletal and exoskeletal. Endoskeletal prostheses have an internal metal support system and an external molded, soft skin-color cover. They are more cosmetic and lighter in weight than exoskeletal. However, they will tear when subjected to contact sports or even walking in the woods. They are cosmetically more acceptable to many. Exoskeletal prostheses have a hard durable shell and can be used for sports activities and are heavier.

New components using graphite for joint components have lessened the weight of prosthesis. The choice of the particular types of components, such as knees and ankles, and strength of cables for an upper extremity prosthesis depend on the activities in which the patient is engaged. Young amputees (common in the case of OS) prefer hydraulic knees that facilitate such activities as dancing and ankles that are flexible, which facilitate push-off in the gait cycle and render gait more propulsive. These are useful for sports activities.

Better form-fitting, more naturally aligned prosthetic sockets are routinely used. More sporty socket suspensions and prostheses are available, including swim legs and adaptations for skiing. Myoelectric upper extremity prostheses with switches are sometimes used but are very expensive. They are more cosmetic, but the hand component can lift only light objects.

*Cosmesis.* Cosmesis is very important to cancer patients. Wide local excision of STS often causes soft tissue deficits. Some of these can be ameliorated by soft, contoured fillers. Some examples of these are a buttock prosthesis for buttectomies, a gastrocnemius prosthesis, a shoulder prosthesis for forequarter amputations and after the Tinkoff-Lindberg procedure, and a foot prosthesis after partial-ray resection. Breast prostheses made of various materials (gels, fluff, etc.) are used for mastectomies secondary to sarcoma.

*Fatigue.* Fatigue results from inactivity, the disease itself, depression, and chemotherapy (Adriamycin). Exercise to increase strength and joint motion is an important component in facilitating and maintaining regain of function in limb-spared patients. Often, low-intensity, low-impact aerobic programs are prescribed. Frequently, particular muscles are targeted for exercise (e.g., quadriceps in distal femoral and proximal tibial limb-sparing procedures for OS and partial quadriceps removal for STS). General strengthening and ROM exercises are performed for uninvolved muscles. Isometrics and isotonic strengthening with weights to 2 pounds using a short lever arm are permitted in patients with endoprostheses. Isokinetic machine exercise is not permitted.

Maintaining at least critical joint motion for function is important. It is not necessary that the joint motion be completely normal for adequate function.

*Vocational Activity.* STS can occur in all age groups, but the median age tends to be midlife and later. This places people in that part of their lives when they are working and supporting families. As a result, some may need to change their vocation, though many remain in their jobs with reasonable accommodation. Some studies have shown individuals with STS often enter into retirement.<sup>99</sup>

OS occurs in children and young adults. Often, they are faced with career choices influenced by their level of physical as well as cognitive abilities. Career counseling is advised.

*Recreational Activities.* Recreational and social activities are important to cancer patients. Patients with wide local excision often can continue their pre-morbid recreational and social activities. With resections requiring bracing, some activities are not possible. Patients with STS and radiated bone and OS with endoprostheses must avoid contact sports and activities that cause torquing. In addition, impact activities (running, some dances) are not appropriate for limb-spared OS patients. These more aggressive activities can result in bony fracture, bone-prosthetic interface fracture, endoprosthetic dislocation, and early breakdown of prosthetic components.

Education of the patient about which activities are appropriate is important in preventing complications. Adaptive methods of participating in some sports are appropriate. For instance, modification of stance, position, and swing may reduce torque and allow some lower limb-spared patients to play golf. Doubles tennis played at less aggressive levels may also be appropriate. A young teen going to the prom can dance but needs to avoid torquing and high-impact dances.

**LONG-TERM CARE PHASE.** Limb-spared patients have had decreased morbidity, owing to appropriate adjunctive chemotherapeutic and radiotherapy regimens and defined and innovative surgical techniques. Limb-spared patients should be followed up from a rehabilitation standpoint to ensure that they are not developing any long-term radiotherapy problems (motion loss, radiculopathy, and cord syndromes) that would decrease function. Any new development of pain should signal local reoccurrence or fracture at the endoprosthetic junction. Amputees generally need new prostheses every 4 to 5 years, depending on level of use.

Special problem areas that arise in this treatment phase include adjustment to disability and vocational change and recreational, social, and schooling issues. The important goal is to maintain function.

**METASTATIC DISEASE AND LOCAL RECURRENCE PHASE.** When metastases occur with OS, they are most commonly to the lung or other bones. Often, it is a single metastasis or a few, possibly amenable to local resections. With STS, lung metastases occur. Patients may have multiple surgical procedures over time, usually a median sternotomy or thoracotomy with pleura and chest wall resections. A newer procedure allows for removal of lung metastases without major chest surgery. Chemotherapy is reintroduced after the local chest resection. These surgical treatment interventions often are associated with postoperative chest pain. The patients may become deconditioned and experience fatigue, anxiety, and weight loss during these treatment periods and may require rehabilitation interventions much as they did in the initial phase. Vocational and educational endeavors are disrupted. Rehabilitation strategies to relieve postoperative pain (TENS) and reduce fatigue (assistive devices, energy conservation techniques) and anxiety (stress management, relaxation techniques, and imagery) are helpful. Referral to a dietitian is made to support good nutrition.

When metastases return and are inoperable, experimental chemotherapy regimens are used. Often, these have low success rates and high toxicities. Likewise, local reoccurrence may happen, particularly with STS. These also require additional therapies. At this stage, emotional support, comfort, and education about problem solving to promote and preserve independence can be provided by the rehabilitation team.

## **MELANOMA**

In advanced or recurrent melanoma, oncologists have reported the efficacy of isolated limb perfusion with various chemotherapeutic agents (e.g., melphalan) and

biologic response modifiers (e.g., tumor necrosis factor and interferon) where mild to moderate limb toxicity has been reported.<sup>100</sup> Complications resulting from these procedures include transient peripheral neuropathy, edema, skin breakdown, and vascular compromise with tissue necrosis. As a result of these complications, rehabilitation of these patients is often protracted and requires careful daily monitoring of the skin for areas of pressure combined with an active program of exercises and progressive ambulation. Management of edema, using compression garments and inelastic wraps, may be achieved for symptom relief and control. Amputation rarely must be performed to treat complications of limb perfusion. Prosthetic fitting and training may be undertaken.

## LUNG CANCER

Lung cancer patients may benefit from rehabilitation interventions addressing pain control, cardiopulmonary conditioning, and work and home modifications. Rehabilitation of the patient with lung cancer is generally divided into a preoperative or pretreatment phase and a postoperative phase. The pretreatment phase consists of a medical review of the chart to ascertain the stage and type of the tumor and whether metastases are present. The physician should review the planned medical treatment. In addition to assessment of current medical status in regard to cardiopulmonary function, tests should be performed for hemoglobin, hematocrit, and electrolyte levels. The current vocational status and family support situation should be assessed. A preoperative physical examination, with particular attention to chest wall expansion, musculoskeletal status, and cardiopulmonary status, is requisite. The patient is generally educated in proper coughing and breathing techniques (e.g., diaphragmatic, segmental). It should be explained to the patient that these exercises help air to enter the lungs better, increase the efficiency of the respiratory muscles, increase chest mobility, and decrease risk of pneumonia. Lower extremity exercises after surgery to prevent thrombophlebitis are also explained.

During the postoperative stage, the patient's pulmonary function and chest excursion are again assessed. Specific breathing exercises are started after the patient is extubated. Posture and lower extremity exercises are addressed. Chest wall pain is often relieved by use of a TENS unit. After pain is controlled and the patient is allowed to ambulate, some assessment of endurance should be made. Endurance exercises should be gradually introduced into the rehabilitation program.

In patients with metastatic disease of the brain, speech and language deficits should be included in a cognition, language, and swallowing evaluation. Depending on the location of the metastasis, there may also be focal motor and sensory deficits. Ambulatory aids, bracing or splinting, and occupational therapy intervention for assistive devices and safety equipment may be needed. Bone metastasis may need unweighting with crutches or a walker and spinal bracing and pain management.

Depending on the prognosis of patients, there should be discussions with them and their families about adjustment to whatever disabilities there may be. Careful assessment of whether such persons can continue working should be made.

## CENTRAL NERVOUS SYSTEM NEOPLASMS

Brain damage may result from primary tumors of the brain, from metastatic disease, or from treatment of the cancer: surgery, radiation, or chemotherapy. The resultant symptoms, impairments, and disabilities may vary considerably but are similar to those that are seen in patients who have sustained a cerebrovascular accident or traumatic brain injury (TBI) affecting different parts of the brain. The crucial difference here is the potentially progressive or recurrent nature of the brain cancer and its uncertain prognosis. The greatest deficits are frequently seen immediately after surgery or during radiation and chemotherapy, after which extraordinary improvement may occur. Late brain injury from radiation with infarction or necrosis also may occur, but the subsequent disability has a less favorable prognosis for recovery.

Simple rehabilitation treatments can help the majority of patients, whereas those with more severe disease and deficits may require comprehensive inpatient rehabilitation, which should be provided when longer life expectancy allows. Structured, comprehensive cancer rehabilitation services have not been widely available, especially to patients with brain tumors. Nevertheless, there is good evidence that cancer patients can benefit significantly from rehabilitation intervention and that recurrent or metastatic tumors and ongoing aggressive tumor therapy should not preclude admission to a rehabilitation unit.<sup>101</sup>

Philip et al.<sup>102</sup> demonstrated that after definitive treatment of primary brain tumors in children, rehabilitation significantly improves outcome in self-care activities, transfers into and out of bed, and locomotion by a wheelchair or walking. Furthermore, preliminary evidence supports the efficacy of post-acute brain injury rehabilitation services for patients with primary malignant tumors, resulting in sustained increases in productivity.<sup>103</sup> Specific program interventions for these successful services include evaluation of cognitive, behavioral, affective, and social functioning; identification of impairments and their impact on patients' daily functioning; individualized therapies to improve functioning; and return to desired vocational status.

Rehabilitation intervention most commonly begins after removal of the brain tumor. When affected patients are medically stable, a referral to rehabilitation should be initiated so that they can be helped to sit up, get out of bed, and start an active restoration program that is tailored to their general condition. Recovery may be fairly rapid, initially due to control of edema. Hemiplegia or hemiparesis is a common sign of brain cancer and is often most profound just after the brain surgery. Some return of motor strength is common and may continue for several weeks or months. While muscles that are still paralyzed 4 to 8 weeks postoperatively generally remain so, functional improvement can still occur through routine daily activity as well as therapeutic exercise and use of appropriate assistive devices (orthoses or gait aids). Encouragement in the use of the affected limb is recommended, rather than learning to substitute for the affected side using one-sided activity. Data suggest that recovery of motor and language function can proceed over significant periods with proper encouragement and stimulation.

If patients are kept in bed, they should be placed on a special mattress designed to prevent pressure sores. To prevent capsular contractures of the shoulder, patients should lie with the affected arm abducted, externally rotated, and slightly elevated. The lower extremity should be positioned to minimize hip-knee flexion. Passive joint ROM exercises should be applied to the paralyzed extremities and active exercises to the unaffected parts twice a day.

Most patients are able to ambulate with assistive devices and training. Good sitting balance and standing balance are prerequisites for functional transfers and ambulation. Therapists use feedback mechanisms to correct patients' tendency to lean toward the affected side. For example, "handling" is a therapeutic technique designed to establish normal alignment, reduce or eliminate abnormal tone and movement, reeducate muscles in normal patterns in the trunk and limbs, and produce an active movement pattern in hemiplegic patients. "Inhibition" techniques are manual techniques and hand placements used to decrease or eliminate spasticity. Dynamic sitting balance is achieved through trunk exercises, use of mirrors, and verbal feedback regarding position. Potential ambulatory ability should be assessed by standing patients in the parallel bars. Patients should be taught bed-to-chair transfer activities as soon as sitting balance and weight shifting allow. Patients whose hip flexors and extensors remain weak will not ambulate independently because no satisfactory hip bracing is available. Weak knee extensors can be stabilized with a temporary knee-ankle-foot orthosis, which locks the knee in extension during weight bearing. Weak ankle dorsiflexors are often the last muscles to recover and can be stabilized with a plastic ankle-foot orthosis (AFO) to prevent toe dragging during the swing phase of gait. Elevation activities, such as climbing and descending stairs, ramps, or curbs, are started when a good gait pattern on level ground has been achieved. Patients with severe neurologic deficits may require a wheelchair, either for mobility at all times or only when ambulation endurance or safety is impaired.

The major goal in the rehabilitation of the patient with brain cancer is independence in ADL, which may be obtained through training, prescription of proper assistive devices (e.g., adaptive eating utensils, bathroom equipment, positioning and transferring equipment, and gait aids) and modification of the patient's home and work environment (Fig. 57-6).

**FIGURE 57-6.** Adaptive eating utensils for patients with upper extremity spasticity or weakness.

Spasticity is a frequent impediment to mobility and performance of ADL. Factors that may aggravate spasticity, such as skin lesions, infections, and anxiety, need to be identified and treated. Thorough stretching of all joints should be performed daily. Medications, such as dantrolene, baclofen (starting at 5 mg three times daily and titrated until therapeutic dose is reached, usually 40 to 80 mg/d), and diazepam (2 to 10 mg three to four times daily), may be of some benefit but should be used sparingly because of their potential for producing somnolence. Selected nerve root blocks with dilute solutions of phenol or concentrated alcohol are usually effective in reducing spasticity. Botulinum toxin injections are also used, and proper dosage and administration site are essential for a favorable response. Surgical procedures for reducing spasticity in this population are rarely indicated.

Joint contractures may be caused by muscle imbalance, spasticity, poor nursing care, prolonged immobility, improper bed positioning, or an inadequate exercise program. Whatever the cause, the contractures may adversely affect the rehabilitation prognosis. For example, development of a frozen shoulder may render independent dressing impossible. Therefore, prevention of contractures by proper positioning and posture and joint ROM exercises is imperative, since treatment of contracture is relatively ineffective.

Cancer of the brain may cause pain in different parts of the body. Pain in the hemiplegic shoulder is common and may benefit from shoulder support by an arm sling or a lap board, administration of analgesics, application of heat or cold modalities, and gentle ROM and strengthening exercises. Complex regional pain syndrome of the shoulder (previously known as *shoulder-hand syndrome*) may also occur and requires similar treatment, but more effective relief may be obtained by prescribing oral steroids. Dysesthetic thalamic pain is notably refractory to treatment, though various centrally acting agents may be helpful.

Varying degrees of sensory loss are commonly seen in patients with brain cancer, either in the distribution of the cranial nerves or on one or both sides of the body. They may interfere with balance and mobility, since patients who cannot feel motion are unable to control it. Training with adaptive gait aids may help such patients to ambulate functionally again.

Vision deficits, such as double vision, homonymous hemianopsia, and anosognosia, may greatly interfere with function, especially in patients with a right brain lesion. Fortunately, specialized programs of cognitive remediation have been found to be effective with these patients.<sup>104</sup> Such programs include basic scanning training, somatosensory awareness and size estimation training, and complex visual perceptual training.

Aphasia, a disorder of both the expression and reception of propositional language secondary to cortical or subcortical disease, may be seen in patients with cancer in the left dominant hemisphere of the brain. Listening, speaking, reading, and writing are usually affected to varying degrees; thus, several types of aphasia are recognized. Expressive or nonfluent aphasia is caused by lesions in the Broca area of the brain. Reduced language production, vocabulary, and grammar are characteristic. The patient is well aware of these difficulties and becomes easily frustrated. Receptive or fluent aphasia is caused by lesions in the Wernicke area of the brain and results in difficulty in understanding language, both the patient's and that of others. Patients may be able to speak continuously at normal speed and with normal melody without giving any relevant information and be unaware of the errors. Speech therapy is indicated, whenever available, not only for psychological support but to stimulate patients to use their maximal speech ability and to adjust to new circumstances. It is also helpful to instruct affected families in proper communication with involved patients by such means as using proper sentences at a normal voice volume and using gestures and facial expressions while increasing respect, optimism, patience, and encouragement.

Dysarthria is a motor disturbance of speech characterized by weakness, slowness, or incoordination of the muscles that produce speech. Therefore, there is complete understanding of written or spoken language. The main problem is articulation, though speed, rhythm, sound, and intonation may also be impaired. Speech therapy emphasizes teaching the patient to use the remaining speech muscles more effectively or to bypass the effects of disturbed function.

Aprosopia is a communication disorder caused by lesions of the nondominant right hemisphere. It results in the inability to express and comprehend variations in pitch, rhythm, and stress, which give emotional meaning to speech. Affected patients may speak in a relatively flat voice and are often unable to recognize the emotional tones of speech, including the meaning of nonlanguage speech sounds, such as grunts or sighs. Therefore, the clinician and family should communicate with the patient strictly by words, because specific therapy does not exist. Fortunately, considerable improvement usually occurs over time.

Dysphagia, or impaired swallowing, is most commonly seen in lesions involving the brain stem. With severe involvement, the patient may be totally unable to swallow or, in milder cases, there may be difficulty only with the swallowing of liquids. Whatever the degree of severity, the patient is at risk for aspiration with resulting pneumonia, so suspicion of the condition with timely intervention is key to treatment. Serial radiographic swallowing studies are indicated for proper monitoring of the condition until it resolves or other and safer means of nutrition are provided. Speech therapy may institute a swallowing training program in which patients attempt to swallow food of different consistency using different techniques and positions. If indicated, a nasogastric tube can be used for several weeks while waiting for spontaneous recovery. A more persistent dysphagia may warrant a gastrostomy tube for prolonged feeding.

Neurobehavioral problems often have an underappreciated but large impact on the quality of life of patients with tumors and their families. Implementation of services directed toward these problems is only now receiving attention. The use of traditional cognitive and vocational rehabilitation for patients with brain tumors is complicated by the fact that existing programs are not entirely appropriate. The patterns and types of cognitive deficits experienced by these patients are different from those experienced by stroke or TBI patients. Anderson et al.<sup>105</sup> found that patients with brain tumors have milder cognitive deficits and greater variability in the nature and extent of their deficits, compared with people who have strokes that affect the same neuroanatomic site. Furthermore, the natural history of the disease process is different from that of cerebrovascular disease or TBI. The latter two are usually characterized by an acute onset and gradual recovery, while the onset of disease in brain tumors is relatively insidious. Although some recovery of function may be seen after surgery or other therapy, most patients experience a gradual deterioration of function as the tumor progresses.

The most common type of neurobehaviorally oriented program is the day treatment program, which emphasizes cognitive and vocational rehabilitation. Although these programs are frequently affiliated with an inpatient rehabilitation program, many are located in the community to provide better access to resources. The first step in cognitive and vocational rehabilitation is to identify realistic goals for the patient. Formal neuropsychological and vocational testing to identify preserved skills have been found to be useful. The major goal is to train patients to compensate for their neurobehavioral deficits at home and on the job. Memory, problem-solving skills, and social behavior are typical areas targeted for retraining. For example, patients with memory deficits may compensate by using tools, such as written reminders and alarm watches. Patients with behavioral problems should be taught to inhibit socially inappropriate remarks or to reduce frustration intolerance. Furthermore, patients and family members should be counseled about the need to select jobs that are less demanding although not as financially rewarding or prestigious.

In addition to providing rehabilitation to appropriate patients with brain cancer, patients' families should be offered education and emotional support. Families of such patients are often burdened by the patients' cognitive and behavioral changes in addition to the typical psychological problems of coping with cancer in a family member. Support groups for patients with brain cancer and their families may be of great benefit.

## HEMATOPOIETIC TUMORS

### *Leukemias*

Leukemia is the uncontrolled proliferation and incomplete maturation of leukocyte and lymphocyte precursors appearing in bone marrow and peripheral blood. Leukemia may occur in acute or chronic form. The acute leukemias include acute myelogenous leukemia (AML) and acute lymphoblastic leukemia (ALL). They are more common in childhood. Both leukemias are associated with anemia, fatigue, fever, bleeding gums, gastrointestinal tract or urinary tract symptoms, easy bruising, and pallor. Headache, mental changes, and cranial nerve palsy are common in ALL with CNS involvement. Joint pain is often seen with ALL but rarely in AML. The prognosis for AML, even with treatment, is poor. ALL responds much better to treatment, and complete remissions are often seen. Treatment of AML consists of cytarabine, daunorubicin, and amsacrine. The mainstay treatment in ALL consists of vincristine and prednisone.

Chronic myelogenous leukemia is not usually seen before 20 years of age, and chronic lymphocytic leukemia is generally seen after 50 years of age. Both present with abdominal discomfort, organ enlargement, malaise, and fatigue. Anemia, low platelet count, bruising, and cutaneous bleeding are seen with chronic myelogenous leukemia.

The rehabilitation team must address the effects of the leukemia itself and the side effects of medications and irradiation. A leukemia that does not respond completely to treatment has a course of remissions and exacerbations that seriously affects the ability to attend school or continue working. Long periods of rest may

be needed during treatment or during times of low platelets. Generalized deconditioning and decreased muscle strength occur. Steroids contribute to decreased strength when they cause a myopathy. They may be associated with osteoporosis, compression fractures, and painful aseptic necrosis of bone. CNS leukemia is associated with altered cognition, cranial nerve abnormalities, and other neurologic deficits. Vincristine causes peripheral neuropathy. Hair loss occurs with some chemotherapeutic agents. Bone marrow transplantation requires a 6-week hospital stay, usually with confinement in a bone marrow hospital unit because of the necessary immunosuppression (e.g., leukocyte count  $<1000/\text{mm}^3$ ).

Management of muscle weakness, decreased endurance, focal neurologic deficits, joint pain, cosmesis, and psychosocial and vocational problems are a challenge to rehabilitation specialists dealing with this group of patients. The type and intensity of exercises allowable depends mainly on the platelet count and hemoglobin level. Exercise should be nonresistive when the platelet count is less than  $50,000/\text{mm}^3$ . No exercise is performed with counts below  $20,000/\text{mm}^3$ .<sup>106</sup> Aerobic or endurance exercise is limited when hemoglobin measures less than 8 to 10 g/dL. Whenever exercise and activity are possible, they should be encouraged. Patients undergoing bone marrow transplantation are always placed on an exercise program to increase strength and endurance. Recent studies demonstrate the safety and efficacy of aerobic conditioning during bone marrow transplantation and during treatment with chemotherapy.<sup>107,113</sup> Exercise should be performed either 2 hours before or 2 hours after radiation is delivered, to avoid a radiation-enhancing effect that occurs during increased blood flow resulting from exercise. Those who are on high-dose steroid therapy and are particularly susceptible to steroid myopathy, osteoporosis, and aseptic necrosis. Their exercise program includes weight-bearing activities, upper extremity ROM, an isometric program, and back extension exercises. An aerobic program is introduced when platelet and hemoglobin levels permit. Exercise also seems to be effective for reducing symptoms of nausea and fatigue and for improving psychological well-being.<sup>114</sup>

Bracing and splinting are needed for neurologic deficits. A wig should be provided at initiation of treatment in anticipation of hair loss due to chemotherapy. Assessment of ADL and issuance of safety equipment and assistive devices may be needed. Energy conservation education is important. Assisting patients and their families in coping with acute and chronic problems is essential.

## Lymphomas

Lymphomas constitute a group of malignant tumors that arise principally from lymph node cellular structures, other reticuloendothelial organs, and bone marrow. These tumors are classified as Hodgkin's disease and non-Hodgkin's lymphomas (NHLs). The type of cells and their growth pattern help to differentiate the types of lymphomas. Knowledge of the stage of the disease is important because medical and rehabilitation treatment regimens are oriented to the stage-specific problems and prognosis.

Treatment consists of combination chemotherapy and radiotherapy. Many multidrug regimens exist. Choice of an appropriate drug regimen depends on the stage of the disease. Most of the regimens include prednisone, and side effects of osteoporosis, compression fracture, myopathy, and aseptic necrosis may be seen in 10%.<sup>114</sup> Other drugs with potential side effects that need to be addressed by rehabilitation include doxorubicin, which produces decreased cardiac ejection fraction, and vincristine, which causes peripheral neuropathy. Combination regimens may result in hair loss, aspermia, and early menopause. Prolonged bed rest results in muscle weakness and decreased endurance. Treatment with radiotherapy can result in skin tightness, restricted joint motion, and aspermia.

The disease itself can be asymptomatic (subtype A) or symptomatic (subtype B). Systemic symptoms of fever, night sweats, weight loss, and decreased endurance are present with stage I through IVB disease.

Aggressive high-grade lymphomas, such as Burkitt's, have a high propensity for metastasis to the CNS (e.g., meningeal carcinomatosis), causing symptoms of headache, diplopia, cranial nerve palsy, and weakness. Spinal cord compression can occur if lymphoma involves the epidural space. CNS and spinal cord involvement can occur with NHL and Hodgkin's disease.

Other problems that arise with lymphomas include increased susceptibility to infection, pleural and pericardial effusion, and superior vena cava syndrome due to compression of the superior vena cava by enlarged lymph nodes.

Chemotherapy and irradiation regimens for NHL are chosen according to the grade and type of tumor. Vincristine, prednisone, and cyclophosphamide are commonly used in these regimens. (Side effects are similar to those described in [Chapter 45.6](#) on Hodgkin's disease.)

As for patients with any type of cancer, it is important to know the type and stage of lymphoma, the treatment indicated, and side effects and the general prognosis when planning a rehabilitation regimen. In general, patients have to cope with disease-related problems and the effects of complex chemotherapeutic and radiotherapy regimens. Some patients may have an early complete cure and be left with no residual problems. Others may have had more advanced or more malignant disease with incomplete remissions or recurrences and disease- and treatment-related morbidity. In this latter group, vocational and school status should be assessed. All members of the rehabilitation team are involved in the management of these patients.

Neurologic involvement may require bracing, mobility aides, assistive devices, and speech and language evaluation. Unweighting lower extremity joints involved with aseptic necrosis is appropriate. Muscle weakness and deconditioning should be addressed with appropriate strengthening and endurance exercises. The same precautions about platelet and hemoglobin levels hold true for lymphomas and leukemias. Particular attention should be paid to unweighting bony lower extremity lesions if there is more than 50% cortical involvement. Appropriate spinal bracing for vertebral involvement should be addressed. Unstable lesions should be evaluated surgically. If the patient has advanced disease and surgery cannot be done, choice of a body jacket for thoracic and lumbar lesions and a four-poster brace for cervical lesions may need to be used to help prevent spinal cord compression. When treating patients in rehabilitation, any early signs of spinal cord compression, such as new weakness, sensory deficits, or reflex changes, should be reported to the primary physician, because radiotherapy may be effective in reducing the size of spinal metastasis and relieving spinal compression. Likewise, any signs of superior vena cava syndrome, such as increased dyspnea, facial edema, and dilated chest wall veins, should be reported, because radiation may palliate these symptoms.

## CONCLUSION

The cancer population presents a significant challenge to health care professionals because management is complex and is unique to individual patients and their phase in life and stage of disease. A model for planning treatment for the entire life expectancy of these patients, which is likely to be measured in years, is that of managing a chronic illness. This chronic illness may also have acute phases. Treatment goals should always support those of the patients and promote, restore, or preserve functional activity that has value to patients in their unique social, vocational, and physical environment.

[Chapter References](#)

#### INTRODUCTION

The current health care environment has influenced the delivery of cancer care, with shifts in patient acuity levels, volume, and management of patients across care settings. In response to the dynamic health care changes and therapeutic advances in oncology over the past decade, a growing trend is evident to use advanced practice nurses (APNs) and midlevel practitioners [i.e., physician assistants (PAs)] in the effort to provide high-quality, cost-effective oncology care. This chapter describes the preparation and role implementation of the PA, defines the oncology APN, identifies the professional issues that influence regulations of practice, delineates the role components of the oncology APN, and identifies the benefits of a collaboration between physicians, APNs, and PAs in oncology practice.

#### PHYSICIAN ASSISTANTS

The first PA education program began at Duke in 1965. It was designed to train a general assistant, who could develop areas of expertise over time under the direct supervision of a physician, initially in the areas of primary care and general surgery. The American Academy of Physician Assistant estimates that there are 34,192 PAs practicing, predominantly in primary care (53%), family practice (40%), general surgery (19%), and emergency medicine (10%).<sup>1</sup> Currently, less than 6% of the PA population practices in one of the subspecialties of internal medicine, and only 1% work in adult or pediatric oncology.<sup>2</sup> PA practice includes history and physical examinations, diagnosis and management, prescription of controlled and noncontrolled medications in those states allowed by law,<sup>3</sup> screening procedures, ordering and interpreting laboratory and diagnostic tests, referrals and consultations, and counseling patients. Approximately one-half of the PAs in practice report performing invasive procedures, including bone marrows, lumbar punctures, and suturing and repair of lacerations.<sup>1</sup>

#### EDUCATION AND CERTIFICATION

There are 116 PA training programs in the United States, with 42% offering a master's degree. Among the PAs in practice, 64% hold bachelor degrees and 22% hold master's degrees.<sup>1</sup> Programs are divided into a didactic phase and a clinical phase. Postresidency programs at selected teaching hospitals offer advanced training in a specialty area.

Certification of PAs occurs at both national and state levels. National certification requires a certificate of completion from an accredited PA educational program and passing the Physician Assistant National Certification Examination, which is administered by the National Commission of National Certification of PAs. To maintain certification, PAs must fulfill annual continuing medical education requirements and must recertify every 6 years by written examination. Similar to initial certification, recertification focuses on primary care knowledge.

At the state level, 49 states plus the District of Columbia have licensing boards, which control prescriptive authority, reimbursement, and scope of practice. All states require physician collaboration in practice and for prescribing drugs.<sup>3</sup> Most states have legislation that mandates Medicaid and Medicare coverage for PAs, but few have statutes requiring reimbursement from private insurers.

#### FUTURE DIRECTIONS FOR PHYSICIAN ASSISTANTS

In 1998, the Department of Health and Human Services asked the American Association of Physician Assistant Programs to develop a 3-year strategic plan stimulated by the current environment of the medical profession and the proliferation of training programs for nonphysician clinicians.<sup>4</sup> Highlights of the plan include that education should continue to focus on primary care and allow for specialty developments over the course of one's career through continuing education requirements; competency should be promoted through continuing education programs and recertification examinations; PAs should continue to function in a delegated role under physician supervision, work with other health care disciplines to focus on underserved populations, enhance and empower patient populations through education, and attempt to provide cost-effective high-quality care.

#### ADVANCED PRACTICE IN ONCOLOGY NURSING

The oncology APN is defined as "a registered nurse, prepared with a minimum of a master's degree in nursing, who has acquired advanced, in depth knowledge and preceptored clinical experiences in oncology that enable her or him to exhibit a high degree of independent and collaborative judgment and clinical skill in providing nursing care to patients with cancer and their families."<sup>5</sup> In 2000, the Oncology Nursing Society includes nearly 5000 members who are prepared at the master's degree level or higher (World Wide Web site: <http://www.ons.org>). The acquired knowledge and clinical practice experience at the graduate level prepares the APN for expansion within areas of practice that overlap traditional medical practice and for integration of theory and research into practice.<sup>6</sup> Improved patient outcomes, cost-effective care, and improved quality of life for patients and family are well-documented advanced practice nursing outcomes.<sup>7,8 and 9</sup> Nursing, the core of advanced practice, is defined as assisting the individual in activities that contribute to health, recovery, or death<sup>10</sup> and the diagnosis and treatment of human responses to health and illness.<sup>6</sup> Collaborative practice between APNs and physicians results in better quality health care by combining the unique, documented contributions of the nursing discipline with the expert medical treatment of the illness.<sup>11,12 and 13</sup>

#### EDUCATIONAL PREPARATION OF ONCOLOGY ADVANCED PRACTICE NURSES

Understanding the educational preparation of APNs is critical to decision making for employment and role implementation. The current recommendation for a master's degree with a specialty in advanced practice oncology ( [Table 58-1](#) ), is designed for both the clinical nurse specialist (CNS) and nurse practitioner (NP), allowing for flexibility in emphasis of content for specific role preparation. Precepted clinical experiences in programs range from 600 to 800 hours.<sup>14</sup> These recommendations are consistent with national recommendations for advanced nursing practice education and should prepare nurses to practice across settings of care.<sup>15,16 and 17</sup>

Course Area	Major Course Recommendations
Clinical practice	Pathophysiology, cancer epidemiology, advanced health assessment, principles of disease treatment, principles of management across the continuum of care, pharmacology and therapeutics, clinical diagnosis, theories and models for clinical practice, ethical and legal aspects of nursing practice
Education	Teaching and learning theories, patient and family and community learning needs assessment, teaching objectives and strategies, development of educational programs
Coordination	Theories and practice, consultative skills, business and marketing strategies
Collaboration	Collaborative practice models, role delineation, negotiating skills, communication skills, team building, shared decision making
Science	Organizational and change theories, health economics, delivery systems, health care reform, quality improvement, evidence and practice, information systems
Role competence	Role theory, education, socialization, advanced practice nurse role, scope of practice, certification, licensure, professional and legal standards
Research and evidence evaluation	Research process, skill in critique of research, scientific integrity, research utilization
Program development	Principles of program planning, program models, implementing and evaluating program outcomes, assessment activities
Leadership	Group leadership skills, networking, mentoring, accountability and authority, support systems, development of standards and policies

**TABLE 58-1.** Recommended Course Content for a Master's Degree with a Specialty in Advanced Practice Oncology Nursing

The Oncology Nursing Society annually publishes a listing of master's programs in oncology nursing.<sup>18</sup> Common program characteristics of the schools that have provided information include four semesters of full-time study with greater than or equal to 600 clinical hours required. These programs include curriculum that prepare APNs as CNS, oncology NP, and acute care NP, and the majority provide a postmaster's option. The foundation for many of the oncology NP programs is the primary care adult NP curriculum, preparing students with a broad base of knowledge about common clinical problems of midlife and older adults, such as hypertension, upper respiratory infections, arthritis, cardiac disease, and diabetes. The combination of primary care and oncology knowledge provides a strong foundation for assessment and management of patients with noncancer as well as cancer-related health problems.

### REGULATING PRACTICE: CERTIFICATION, LICENSURE, AND PRESCRIPTIVE PRIVILEGES

Regulation of advanced practice nursing is the responsibility of state legislators and boards of nursing. There are four levels of regulation and it is important to know the individual state regulations as they affect implementation of the role and prescriptive authority.<sup>19,20</sup> The least restrictive is designation and recognition of the credentials of an APN, which in oncology is the CNS and the NP.<sup>21</sup> The second level of regulation is registration with the state board of nursing, and certification is the third level of regulation. Certification for advanced practice nursing is a process, usually a written examination, that a nongovernment organization uses to establish that a licensed registered nurse has mastered a certain body of knowledge and skills.<sup>22,23</sup> Certification is a voluntary professional activity but becomes mandatory for advanced practice licensure in most states.<sup>20</sup> The American Nurses Association has provided leadership for certification and established a credentialing center in 1993,<sup>19</sup> which offers advanced practice nursing certification (Table 58-2). Specialty organizations also offer certification. The Oncology Nursing Certification Corporation has objectively established criteria for delineating the role of advanced practice nursing in oncology.<sup>24</sup> Eligibility for the Advanced Oncology Certified Nurse certification is open to those not only with advanced clinical preparation but anyone with a master's degree or higher degree in administration, education, or research. Specialty certification is highly valued and recommended, but because Advanced Oncology Certified Nurse certification is *not* recognized by all states for licensure, many oncology APNs hold dual certification, one for licensure and one for specialty recognition (see Table 58-2).

Certification	Master/Program	Certifying Body	Eligibility Criteria
Mid-care practitioner	Mid-care practitioner; working nurse practitioner	American Nurses' Credentialing Center	Current RN license; master's level nurse practitioner or formal postmaster's program at graduate level
Mid-care practitioner	Mid-care practitioner; working nurse practitioner	American Academy of Nurse Practitioners	Current RN license; master's level nurse practitioner or formal postmaster's program at graduate level
Acute care nurse practitioner	Acute care nurse practitioner	American Nurses' Credentialing Center	Current RN license; master's level acute care nurse practitioner program or formal postmaster's program at graduate level
Clinical nurse specialist/medical-surgical specialty	Clinical nurse specialist with or without working specialty	American Nurses' Credentialing Center	Current RN license; master's level nurse practitioner program or formal postmaster's program at graduate level
Advanced practice certified nurse	Master's degree or higher in nursing, preferably with a working license	Oncology Nursing Certification Corporation	Current RN license; master's degree or higher; greater than or equal to 36 months' RN experience within 3 years of application; greater than or equal to 2000 hours of oncology nursing practice within 3 years

**TABLE 58-2.** Certification for Advanced Practice Nurses Who Practice in Adult Oncology

Licensure is the fourth regulatory level that defines the scope of practice and qualifications, designed to protect public health, safety, and welfare and is associated with a high level of accountability.<sup>19</sup> Advanced Practice Registered Nurse (APRN) licensure is granted by a governmental agency at the state level, and Pearson<sup>20</sup> provides an annual review of the variations by each state on legal authority, reimbursement, prescriptive authority, scope of practice, and titling.

Reimbursement is provided by for-profit corporations and insurers, government [Medicare, Medicaid, Civilian Health and Medical Program of the Uniformed Services (CHAMPUS)], nonprofit, and self-insured corporations.<sup>23</sup> Federal and state legislation dictate the level of reimbursement and the 1997 Balanced Budget Act provides direct reimbursement for NPs and CNSs across a variety of settings. NPs and CNSs are required to submit their own provider number in addition to the group practice number where applicable. Payments made to NPs and CNSs are "80% of the lesser of either the actual charge or 85% of the physician fee schedule amount."<sup>25</sup> The Health Care Financing Administration rules require a master's degree, state authority granted to practice as an NP or CNS, and certification by a nationally recognized certifying body (World Wide Web site <http://www.nurse.org/acnp/medicare/hcfa9804.shtml>). The educational requirement does not include a grandfather clause for NPs who were not prepared at the master's level and, thus, their services are not reimbursable under the current rules.

Prescriptive authority is part of state regulation and ranges from the APN as an independent prescriber to an interdependent relationship with a physician to the most restrictive, which only allows an APN to prescribe drugs from a list that has been preapproved by the state.<sup>23</sup> Prescriptive authority includes controlled substances, as allowed by the individual state law (Table 58-3). For those states that include prescriptive authority for controlled substances, the APN can apply to the Drug Enforcement Agency and obtain individual Drug Enforcement Agency authorization.

**TABLE 58-3.** Nurse Practitioner Prescriptive Authority by State<sup>a</sup>

*Credentialing* is a general term that refers to validation of the educational preparation, licensure, credentials, certification, and advanced scope of nursing practice.<sup>15</sup> *Credentialing* is the term often used by institutions for the process of evaluating and granting clinical practice privileges.<sup>23</sup>

### ROLE IMPLEMENTATION OF ADVANCED PRACTICE NURSES

The APN implements the role as a direct caregiver, educator, consultant, administrator, and researcher. A role-delineation study<sup>24</sup> confirmed that these role components were relevant to both the CNS and NP APNs in oncology, with less than 10% of the items differentiating the roles. This study supports the standards of practice for advanced practice nursing in oncology,<sup>5</sup> supports identified competencies for role implementation,<sup>17</sup> and further validates the similar and overlapping role

functions of the CNS and NP in clinical practice. <sup>12,13,26,27</sup>

### **Direct Care Provider**

In provision of direct care to the patient, the roles of the CNS and NP are more blended than distinct, reflecting the similarity in advanced physical and psychosocial assessment and management.<sup>13</sup> The distinction between these APNs lies in the emphasis and time spent on specific role functions. <sup>24,28</sup> The NP direct care role is defined by comprehensive health assessment, diagnosis, health promotion, prescriptive authority, and management of acute and chronic problems. <sup>6,12,20</sup> Oncology NPs also perform procedures, write orders, prescribe chemotherapy, admit patients to the hospital, and write inpatient progress notes. <sup>28</sup> Some CNSs have adopted a practice model, in which the individual patient is the primary focus. In that model, the practice of the CNS and NP have little, if any, distinction. However, many CNSs continue a practice model, which was designed to promote improvement of nursing care by all nurses to a population of patients. <sup>6</sup> Thus, the direct hands-on care role for the oncology CNS refers to direct patient care but also to the supportive role for nursing staff related to assessment, clinical decision making, introducing new skills into practice, and interventions. <sup>28</sup> The reality of fewer professional registered nurses in hospitals, increased numbers of unlicensed personnel, continued specialization, and high patient acuity across settings of care have "recreated the scenario that first produced the need for specialized nurses earlier in the century." <sup>30</sup> In oncology, there is a real and persistent need to provide direction and consultation for direct patient care to less well-prepared nursing and nonnursing staff in order to deliver high-quality, safe, and competent nursing care.

### **Practice Setting**

The changing nature of oncology practice creates continuous opportunities for diversity in role implementation across practice settings. The practice setting of the oncology APN is diverse, ranging from screening, detection, and genetic counseling programs to care of patients in the hospital, ambulatory clinics, private office practices, radiation therapy centers, home care, and hospice. <sup>31</sup> In the hospital, implementation of the role of the acute care NP with critically ill cancer patients is increasingly evident, <sup>32,33</sup> and <sup>34</sup> and a subacute NP role has been described for routine admissions of patients on a medical oncology service. <sup>35</sup> Consistent with changes in the health care environment, there has been a recognized shift of the oncology APN role to nontertiary settings, specifically home care, <sup>8,36</sup> palliative care, <sup>37,38</sup> ambulatory clinics and comprehensive cancer centers, <sup>39,40</sup> and <sup>41</sup> and radiation therapy. <sup>42,43</sup> and <sup>44</sup> Many APNs in clinics and private office settings have hospital privileges and provide care across settings. <sup>28,39,45</sup>

### **Educator**

The APN's educator role addresses the learning needs of the patient and family, other nurses, disciplinary colleagues, and the community. Teaching the patient and family is a primary role of the NP and the CNS across all settings <sup>46</sup> and may include identification and use of appropriate culturally sensitive educational materials, development of practice standards for patient teaching, and evaluation of the effectiveness of educational interventions.

Another major responsibility of the oncology APN is to improve patient care through staff education. <sup>47</sup> In the current health care climate of high acuity and shortened stays in acute care settings and high volume and more complex care required for patients in ambulatory settings, informal on-site education for nurses by the APN for diagnostic, therapeutic, and ethical reasoning in clinical judgment provides a critical method to improve nursing care and patient outcomes. <sup>46,48</sup> Oncology APNs have made significant contributions to nursing education and clinical care through dissemination of clinical knowledge in specialty journals such as *Cancer Nursing*, *Oncology Nursing Forum*, *Clinical Journal of Oncology Nursing*, *Cancer Practice*, *Seminars in Oncology Nursing*, and oncology nursing texts. <sup>49,50,51,52,53,54,55,56,57,58,59,60,61,62</sup> and <sup>63</sup> Many of these texts serve as excellent on-site resources for clinical staff.

### **Consultant**

Providing expert advice to nursing and professional colleagues on individual patient cases and on complex problems of a specific patient population is a well-established function of the oncology APN. Consultation can be informal (verbal) or formal (written) and can be initiated with APNs from within or outside of the oncology specialty or practice setting. <sup>64</sup> Symptom management, the need to acquire new skills, understanding and use of innovative technology, chemotherapy information for the nononcology staff, and complex clinical problems are common examples for consulting with the oncology APN. In addition, the oncology APN provides important consultation in the development and revision of institutional policies, procedures, and clinical practice guidelines <sup>32</sup>; and professional consultation, such as educational programs and peer review for journal articles.

### **Clinical Leader**

The clinical leader role should not be confused with institutional leadership activities of management. <sup>32</sup> The APN leadership is directed at the practice environment, patient outcomes, and improving nursing care. The APN functions as a change agent, the primary purpose of which is to effect change to maintain or improve the quality of care delivered. The oncology APN by virtue of specialty knowledge and change agent skills is uniquely qualified to assess the process of care delivery; evaluate the clinical, psychosocial, functional, fiscal, and patient satisfaction outcomes across the continuum of cancer care; determine what needs to be changed to achieve desired outcomes; and effectively implement change. <sup>7</sup> Creative change agency is needed to challenge the status quo, introduce new skills or technology, integrate research findings into practice, and adapt care delivery within and across settings to improve continuity. <sup>65</sup>

### **Researcher**

Use of research in practice is dependent on the available body of research, dissemination of findings, and integration of the research findings by nurses in their clinical practice. Oncology nurses prepared at the doctoral level have made significant research contributions to the care of patients and families, with progression from earlier descriptive studies to intervention research. Symptom management is a major nursing focus <sup>50</sup> and a consistent research priority. In 1994, a metaanalysis was performed on 28 studies that addressed nausea and vomiting, pain, anxiety, alopecia, infection, chemotherapy side effects, shivering, radiodermatitis, anorexia, and mucositis. <sup>66</sup> Overall, interventions were successful in relieving symptoms and significant effectiveness was obtained for interventions used in the management of nausea and vomiting, pain, anxiety, alopecia, infection, and side effects of chemotherapy. <sup>66</sup> In that same year, a State of the Knowledge Conference on the symptom of fatigue summarized existing data. <sup>67</sup> That conference summary provided direction for future research, which has resulted in multiple publications from studies on measurement, prevalence, severity, perceived distress, and intervention effectiveness for the symptom of fatigue in cancer patients. These examples provide a small glimpse of the extent and scope of oncology nursing research that directly relates to practice.

**RESEARCH UTILIZATION.** Nursing is accountable to use research findings to support practice and maintain an evidence-based practice. As an example, Bookbinder and colleagues <sup>68</sup> spearheaded a research utilization project at Memorial Sloan-Kettering Cancer Center that was designed to improve quality patient care through integration of the Agency for Health Care Policy and Research Cancer Pain Management Clinical Practice Guideline into practice. APNs provided leadership for this project, which resulted in an organized clinical pain management program, pain management education programs, revision of assessment forms to include pain assessment and relief as the fifth vital sign, standards of care for professional and patient education and patient satisfaction, a systematic method to continually improve pain, and improved treatment outcomes. Collaboration of doctorally prepared clinical nurses and researchers with oncology APNs in clinical settings offers an opportunity to create environments that bridge the gap between practice and research, stimulate critical thinking among staff nurses, foster the value of research and application to practice, enhance practice-relevant nursing research, and ultimately, achieve the goal to improve patient care outcomes. <sup>69,70</sup>

**NURSES' CONTRIBUTION TO THERAPEUTIC CLINICAL TRIAL RESEARCH.** The growth in numbers of APNs over the next 10 years presents an opportunity to develop a unique role in clinical research. <sup>4</sup> Oncology nurses have traditionally played a major role in cancer clinical research by assuming the responsibility of safe study drug administration but also providing a full range of responsibilities related to research, including input into study design, feasibility assessments, and budgetary analysis; recruitment and education of patients; maintenance of regulatory documents; collection of data; and study summary and analysis. <sup>71</sup> The role and number of APNs currently working in clinical trial research is unknown. However, the depth of specialty knowledge, research preparation, and advanced clinical nursing skills of the oncology APN offer unique qualifications to meet the challenges of a research coordinator for clinical trials. <sup>72</sup> Additionally, the APN's autonomy as a direct care provider in toxicity assessment and in the management of complex cancer patients offers a model of care that combines resources to provide comprehensive care and maintain a high level of rigor in the research process. Few medical oncologists report any clinical research training, and many nurses involved in clinical trials do not have master's degrees. Thus, nursing has identified the need for advanced level knowledge and skill in this area and has implemented programs for master's degrees and postmaster's certificates in clinical trials management at Duke University, University of California in San Francisco, and Columbia University. The content includes

protocol design, development strategies for drug development, principles of data management, and business practices for clinical research. Other schools such as Georgetown University have collaborated with pharmaceutical companies to offer continuing education programs in clinical research management. The courses at Georgetown include an explanation of the drug development process and preparation for advanced management of multisite trials.

Professional training in federal regulations governing clinical research, business aspects, and overall management roles are also addressed by the Cooperative Group Training Sessions, the Society of Research Nurses, the Association of Clinical Research Professionals (ACPR) and the Society of Clinical Research Professionals (SOCRA).

## COLLABORATIVE PRACTICE

Collaborative practice among physicians and APNs or PAs is an appropriate model for oncology. The current health care environment and the increasing complexity of oncology have highlighted the need for professional interdependence and collaboration in order to provide safe care. <sup>73,74</sup> A multidisciplinary approach has been an established cornerstone of oncology practice, contributing to a more comprehensive plan of care and better overall patient outcomes. The PA and APN offer significant contributions to the delivery of high-quality comprehensive oncology care, although educational preparation and disciplinary practice focus differentiates their unique contributions. All APNs are prepared at the master's level and most within the specialty of oncology. Nursing is a distinct health profession and nurses practice under a professional nursing license. Primary care is the focus of the PA's educational preparation and PAs practice within the medical model in a delegated role under the supervision of a physician.<sup>3</sup> APNs may practice independently or collaboratively with physicians, as permitted by individual state law. <sup>2c</sup> Collaborative practice between a physician and an APN represents a relationship in which both disciplines share knowledge and have diverse but complementary expertise and skills.<sup>9</sup> This type of interdisciplinary relationship between a physician and APN enhances communication and understanding, provides mutual support and results in an efficient approach to the delivery of comprehensive quality care, improved patient outcomes, and increased patient satisfaction. <sup>38,43,45,75,76</sup> and <sup>77</sup>

The current health care environment presents significant challenges to the delivery of high-quality patient-centered oncology care. Innovative collaborative models of care among providers can create environments that support the oncology health care team to achieve high-quality clinical outcomes, efficient use of resources, empowerment of the patient and family, and successful clinical research and maintain a state-of-the-art evidence-based practice.

#### INTRODUCTION

This chapter begins with an overview of clinical medical ethics and the doctor–patient relationship (DPR) and then examines ethical issues, primarily in medical oncology, relating to both clinical care and clinical research. With regard to cancer clinical care, an effort has been made to cover those topics of greatest importance to the cancer physician: informed consent and decision making; prognosis determination and communication; and ethical issues in the care of patient with life-threatening and life-ending disease, including palliative care, advanced care planning, specific dilemmas related to providing end-of-life cancer care, and physician-assisted suicide (PAS). In examining cancer clinical research, the chapter focuses on specific ethical principles that ought to guide such research; the issues surrounding the concept and practice of informed consent for clinical trials; and the ethical issues and dilemmas associated with phase I, II, and III trials in oncology. Wherever possible, available empiric research is used in an attempt to address, and even resolve, the ethical issues and dilemmas that arise in cancer care and research settings.

#### ETHICAL ISSUES IN CANCER CLINICAL CARE

##### DOCTOR–PATIENT RELATIONSHIP AND CLINICAL MEDICAL ETHICS

To practice medicine competently and to provide high-quality care for cancer patients and others, physicians require both scientific and technical proficiency as well as a working knowledge of medical ethics.<sup>1</sup> This specialized knowledge and proficiency is used to assist patients, sometimes by curing or managing their illness and disease and sometimes by helping them overcome the fear, pain, and suffering that are often associated with illness. Competent physicians need not only practical and technical skills, but also the ability to manage such issues as informed consent, decision making, as well as end-of-life and palliative care. A working knowledge of practical ethics is not a substitute for the traditional standards of character and virtue expected of the good physician: competency, integrity, honesty, compassion, and respect for patients and colleagues. Since 1985, medical ethics has emerged as a new and useful component of medical practice and has assisted physicians and patients to reach ethically acceptable decisions. Clinical ethics focuses on how patients and physicians work within existing administrative, economic, and political structures to reach mutual agreement on clinical decisions that affect the patient.

The DPR is at the center of clinical medical ethics.<sup>2</sup> Most day-to-day ethical problems that arise in patient care present in the context of the DPR and most are resolved within this relationship. In the United States, the DPR has undergone two major changes in the past generation. Initially, in the 1970s and 1980s, the relationship began evolving from a paternalistic one, in which physicians made choices for patients based on physicians' values, to a more equal relationship of shared decision making, in which physicians advised patients, but patients ultimately made their own health care choices. Patient preferences are the ethical and legal nucleus of the DPR. In addition, respect for patients and their preferences is a clinical obligation because patients who reach a shared health care decision have greater trust and loyalty in the DPR, cooperate more fully to implement the shared decision, express greater satisfaction with their health care, and most important, have been shown to have better clinical outcomes in several chronic diseases.<sup>3</sup>

The second major change in the DPR has occurred more recently and relates to cost containment and managed care. To curtail health costs, private and government payers for health care have attempted to limit the freedom of decision making of both patients and physicians. Such actions have given rise to new and recurring ethical concerns within the DPR, as well as to potential repercussions<sup>4</sup> (e.g., the so-called patient bill of rights). Changes in the relationship between patients and physicians to a more equal relationship of shared decision making demand attention to ethical issues such as honest disclosure, effective communication, and informed consent.

Sound ethical analysis in clinical settings rests on a foundation of trust between the patient and physician, in other words, within the DPR. Crucial components in the analysis of any ethical issue include an understanding by both parties of the medical and scientific facts; the preferences, values, and goals of both patient and the physician; and the external constraints such as cost, limited resources, and legal duties that shape or restrict choices.<sup>5</sup> For instance, in the cancer setting, physicians have the excellent opportunity to cement trust and reduce the chances of conflict arising with respect to end-of-life care decisions by communicating clearly with patients about prognosis and treatment goals.

For a variety of reasons, ethical issues arise in oncology practice more frequently than in the past. Scientific advances and new technologies have raised unprecedented ethical problems: When should efforts to prolong life with ventilators or dialysis machines be stopped? To what populations of patients should potentially life-saving or life-prolonging (but highly toxic) therapies such as stem cell transplantation be applied? Changes in molecular medicine and genetics are generating new and different ethical problems in such traditional areas as informed consent and confidentiality: Who should have access to an individual's results of BRCA1 testing, and how should such information be used? Managed care has given rise to new ethical issues such as limitations on decision-making freedom for patients and physicians, and potential financial conflicts of interest associated with limiting the use of health resources.

Despite scientific developments of the past century, and despite the financial changes alluded to, the role of the medical profession in human societies has changed surprisingly little since the time of Hippocrates. In general, the DPR has also changed little and the encounter of healer and patient has remained the principal means by which medicine achieves its goals. Several reasons explain the extraordinary continuity over time of the DPR: (1) Medicine serves a universal and unchanging human need by responding to a patient's sense of illness or *disease*; (2) medicine has an unchanging central goal, which is to help patients; and (3) most medical help is delivered in the direct encounter of patient and physician (i.e., in the DPR). It is hardly surprising, therefore, that the DPR is the context in which the important ethical issues such as informed consent, decision making, prognosis communication, and the care of those with life-threatening and life-ending cancer diagnoses (e.g., advanced care planning, end-of-life care, and PAS) must be examined.

##### INFORMED CONSENT AND SHARED DECISION MAKING

The process by which physicians and patients make decisions together is often summarized in the phrase *informed consent*. This doctrine, which reflects respect for patients, is at the heart of the DPR and is based on the ethical principle of respect for individual autonomy, dignity, and self-determination.<sup>6</sup> Informed consent has three key components: disclosure, competency, and voluntariness.

*Disclosure* means that physicians tell patients about the medical diagnosis, prognosis, and risks and benefits associated with possible treatment options. Patients are entitled to enough information to permit them to ask reasonable questions about the diagnosis and the options that are available. *Competency* means that patients are

able to understand relevant information, appreciate their own needs and values, manipulate information rationally, and communicate a treatment choice. *Voluntariness* means that a patient chooses freely, without coercion from the physician or anyone else.

Informed consent is not an event, nor does it refer to a patient's signature on a consent form. It is a process of continuous communication and dialogue between doctor and patient. In this process, physicians can help to empower patients to act in an autonomous manner by educating them about the nature of their medical problems and reasonable medical alternatives to resolve (or cope with) them. Patients are then in a position to choose treatment based on their own personal preferences, values, and goals. This subsequently enables them to directly exercise their autonomy or control over treatment decisions. <sup>7,8,9 and 10</sup>

From an ethical perspective, no cancer patient can make a truly informed decision about a particular plan of care until he or she has been made aware of, and understands, the potential alternatives. For cancer patients and others, either in clinical research or receiving clinical care, disclosure by the patient's health care provider of treatment alternatives is one of the central components of the informed consent process. <sup>1,6,11</sup> Such disclosure is essential if shared decision making is to occur. <sup>6,7</sup> Patient participation is also advocated because it has been linked to better health outcomes, including decreased anxiety, increased patient satisfaction, and improved compliance. <sup>3,12,13,14,15,16,17 and 18</sup> Moreover, many practitioners believe that improvement in overall quality of life can occur only when patients are fully informed of all reasonable alternatives and become equal partners in the decision-making process. <sup>7,19</sup>

### **Decision Making versus Information Seeking**

The idea that treatment decision making and information seeking are distinctive and separate components of the medical encounter has become increasingly recognized within the doctor–patient communication literature. <sup>14,20,21</sup> Traditionally, the link between patients' desire for decision-making control has been assumed to be directly related to their information-seeking patterns. <sup>18,22,23 and 24</sup> It has also been assumed that patients are unable to achieve more involvement in treatment decision making because they have insufficient information. <sup>22</sup> Similarly, it has been expected that patients who want more control will also want more information about their treatment options. <sup>22</sup> Conversely, those who are information seekers are assumed to prefer involvement in decision making because of their proactive approach to maintaining their health. Increasingly, however, evidence suggests that, while patients generally express *preferences* for information about their illness and treatment, <sup>11,18,22,23,24 and 25</sup> they do not necessarily engage in information-*seeking* behaviors. <sup>25</sup> Further, their preferences for participating in treatment decision may vary and may not be linked to their wish for information. <sup>24,25 and 26</sup> In fact, several studies have shown no correlation between many cancer patients' information-seeking and decision-making preferences <sup>11,24,26</sup> or between information seeking and their level of participation in actual treatment decisions. <sup>27</sup> Many other variables seemingly unrelated to decision participation may also influence cancer patients' information-seeking patterns. <sup>18,24,25,28</sup>

### **PROGNOSIS DETERMINATION AND COMMUNICATION**

Considering the life-threatening severity of their illness, it is not unreasonable to assume that prognostic information would play a pivotal role in shaping the overall medical decision-making process of cancer patients and lead to the most appropriate treatment decisions. In fact, from an ethical perspective, a discussion of prognosis should be an integral and necessary part of the communication and decision-making processes for cancer patients. This is the case, in part, because prognostic information has been shown to be significantly associated with cancer patients' treatment choices. <sup>29</sup> Nevertheless, several studies have suggested that advanced cancer patients have an inadequate understanding of their prognoses, <sup>29,30,31 and 32</sup> with patients generally overestimating the probability of their long-term survival. As well, many terminally ill cancer patients believe that the purpose of their treatment, even in the palliative care setting, is to cure them. <sup>30,32,33</sup> Despite this available empiric data, it should be recognized that this issue (i.e., awareness of prognosis) remains a difficult one to study because patient anxiety, fear, and the need to maintain hope in the face of a grave prognosis may affect advanced cancer patients' understanding of their prognoses. In addition, this research may be limited because, from a methodologic standpoint, these same emotions may affect their measured responses to queries about their awareness of when they believe they are going to die. Thus, these measured responses may not necessarily be an accurate reflection of cancer patients' true awareness of prognosis. Moreover, no studies have examined the effect of physician anxiety and physician desire to help patients maintain hope on actual communication of prognoses to cancer patients.

### **Physician Disclosure of Prognosis**

Early research, some of which dates from the 1940s and 1950s, examining physician communication with cancer patients, clearly documented a great reluctance to disclose a cancer diagnosis and virtually no willingness to discuss prognosis. <sup>34,35,36,37,38 and 39</sup> Of those physicians surveyed in even the earliest of studies (most of whom did not disclose a cancer diagnosis), the majority said they would disclose the diagnosis if there was no other way to get the patient to comply with a needed diagnostic or therapeutic intervention. <sup>34,35</sup> Thus, it was not that cancer physicians did not wish to tell a *diagnosis*, but rather that they did not want to give a terminal *prognosis*. Interestingly, improvements in nonsurgical methods of evaluation (predominantly including radiologic, i.e., computed tomographic scans, and lesser invasive biopsy techniques) for confirming a cancer diagnosis have undoubtedly only resulted in the increasing need to better inform patients in order to obtain compliance for more complicated interventions. In addition, during the interval between these studies of the 1940s and 1950s and the late 1970s, when full disclosure of a cancer diagnosis had become the norm, <sup>40</sup> the perceived threat of a cancer diagnosis as a fatal disease has lessened. This is a result of multiple factors, including community and public health education efforts toward early cancer detection, and the U. S. government's declaration of the "War on Cancer," and the ever increasing range of treatment options now available (including many with high rates of success). <sup>41</sup>

Considering, and even in spite of, these events, it is still not difficult to imagine that physicians would remain reluctant to want to give a terminal prognosis. In fact, with regard to current practices toward disclosure of prognosis to cancer patients, the limited available empiric data document that physicians withhold information. <sup>42,43</sup> Physicians would appear to be reluctant to disclose grim prognostic information for the same ethical and psychological reasons they traditionally withheld a diagnosis. <sup>39,44</sup> Physicians may fear that the revelation of a grim prognosis would psychologically damage patients' hope to survive. <sup>43,44 and 45</sup> Physicians may also feel discomfort when placing odds on survival, recurrence, and cure. Thus, while the behavior of physicians has changed regarding disclosure of diagnosis, only limited information is available regarding whether they have changed in regard to practices of disclosure of prognosis.

While, from an ethical perspective, physicians have obligations to disclose a terminal prognosis, a question remains as to how such prognostic information ought to be provided. <sup>10,46,47</sup> Some cancer patients may better understand their prognosis when it is discussed through the use of numeric descriptors, <sup>48</sup> whereas others understand their prognoses when it is conveyed in qualitative descriptors. <sup>49</sup> Patients may also discern important information about their prognoses based on physicians' use of euphemisms, vague estimations, and nonverbal or nonlinguistic cues, for example, tone of voice, word choice, extent of eye contact, and so forth. <sup>43</sup> Further, situational factors, including the seriousness of the disease, patient characteristics, and seniority of the physician, have been shown to influence the extent to which physicians disclose prognostic information. <sup>50</sup> As mentioned, quantitative research has shown that patients generally have inaccurate estimates of their prognoses. <sup>29,30,31 and 32</sup> Most studies investigating how physicians foresee cancer patients' prognoses reveal that physicians themselves are often overly and incorrectly optimistic in their predictions of individual cancer patient survival. <sup>51,52,53,54,55,56,57 and 58</sup> Yet, how, and even whether, physicians' communication may contribute to patient misunderstanding remains unknown.

How oncologists make decisions about presenting prognostic information is undoubtedly a complex process, potentially influenced by multiple factors, including the patient's clinical condition and sociodemographics. As well, the physician's own sociocultural background may influence the depth and style of presenting prognostic information. In addition, the relationships between a particular oncologist and patient, the perceived patient desire for control over medical decisions, and a patient's information-seeking preferences may influence a physician's information-giving practices. An oncologist may provide more information about a patient's prognosis when a patient requests it, or may present little information based on their understanding of a patient's psychological state.

### **ETHICAL ISSUES IN THE CARE OF PATIENTS WITH LIFE-THREATENING AND LIFE-ENDING DISEASE**

Oncologists deal almost exclusively with patients with serious and life-threatening diseases, many of whom are terminally ill. It is therefore essential that oncologists have a working knowledge regarding the ethical issues related to palliative care, advanced care planning, the specific dilemmas present in end-of-life cancer care, and PAS.

#### **Palliative Care**

Oncologists must become experts in providing excellent palliative care, including both pain management and the relief of other symptoms such as nausea, dyspnea, and anxiety. Although palliative care has often come to be specifically emphasized in the setting of end-of-life care, oncologists must be equipped to provide excellent

palliative care to all of their patients, not just to those who are terminally ill. For a complete discussion, see [Chapter 56.1](#), [Chapter 56.2](#), [Chapter 56.3](#), [Chapter 56.4](#), [Chapter 56.5](#), [Chapter 56.6](#), [Chapter 56.7](#).

### **Advance Care Planning**

**ADVANCE CARE PLANNING FOR AWAKE PATIENTS WITH DECISION-MAKING CAPACITY.** When oncologists and patients reach joint decisions about a plan for diagnosis and treatment, they are engaged in advance care planning. A fundamental ethical principle that underlies advance care planning is informed consent. Adult patients who have decision-making capacity, sometimes referred to by the legal term *competence*, have a right to make their own health care choices after being provided with appropriate information about the risks and benefits of reasonable alternative approaches. The principle of informed consent applies even to treatments that may be necessary to save a patient's life. Competent adult patients have the ethical and legal right to decline, or ask to have discontinued, treatments that may be life-saving, including intensive care unit care, life support measures such as dialysis and mechanical ventilation, and chemotherapy. Before accepting a patient's statement or decision, physicians must assess the following: (1) Has the patient been provided with adequate information to make life and death choices? (2) Does the patient understand the risks and benefits of the physician's recommendation and the alternatives? (3) Does the patient understand that the refusal of the proposed treatment will result in death? (4) Why is the patient making the choice against treatment? (5) Does the patient have adequate decision-making capacity to make a life and death choice?

None of these questions is easy to answer, but physicians nevertheless have a responsibility to make a good faith effort before acceding to a patient's wish to refuse life-sustaining treatment. Sometimes consultations with colleagues, including psychiatrists, may be necessary to resolve the question of decision-making capacity. In the end, however, the central principles of autonomy and patient rights mean that a competent patient may refuse life-sustaining treatment even if the physician believes such a refusal is a bad choice or is not consistent with the patient's prior wishes or is morally wrong.

**ADVANCE CARE PLANNING FOR PATIENTS WHO LACK DECISION-MAKING CAPACITY.** Decision making for unconscious patients, or for patients who are conscious but lack decision-making capacity, follows the same informed consent model as applies to competent adults. Essentially, incompetent patients are accorded the right to have their previous wishes made known and acted on by their physicians. Advance care planning is a process in which patients, their families, and their physicians plan in advance for treatment decisions, including decisions about life-sustaining treatment, that may have to be made when the patient is no longer capable of participating in the decision. During the past 30 years, the traditional approach used for advance care planning in the United States has involved formal, written advance directives that indicate who should serve as the patient's proxy or surrogate and what end-of-life choices a patient would want if he or she were unable to participate in the decision. In our view, advance directives have not been a successful strategy for achieving patients' wishes and goals. There are many reasons to explain the failure of advance directives, but simply put, most people have not completed written advance directives and when they have, they are often overruled by a patient's family, ignored by physicians, or simply misunderstood.<sup>59</sup>

To achieve more successful advance care planning, written formal advance directives should not be exclusively relied on to make such extremely important decisions, but rather oncologists should commit themselves to the *process* of advance care planning. The process, rather than the simple *event* of signing a written advance directive form (sometimes months or years in advance of the need to make a decision), involves a series of conversations over time between the treating oncologist and the patient (and often the patient's family) in which the patient's goals and preferences are discussed and clarified. Such conversations should always be specific to the individual patient and to the actual clinical circumstances that are likely to be present at some near or distant future time when the patient may have lost decision-making capacity.

These conversations should determine two things: (1) Who would the patient want to serve as a proxy decision maker if the patient were unable to make decisions? (2) Based on the most likely future scenario for a particular patient, what choices would the patient want the surrogate to make (e.g., for aggressive or curative care, palliative care, or focusing more exclusively on end-of-life care). These conversations should be documented in the physician's notes and such conversations likely should occur on more than one occasion as the patient's clinical and life circumstances change. These are not easy conversations to have, and many physicians feel ill prepared to discuss these matters with their patients. This is an educational and behavioral failure. Physicians must learn how to conduct these important conversations. Good patient care requires that we advise and counsel our patients on what is possible and what is reasonable. The advance care planning process is an opportunity to do that.

### **Ethical Dilemmas in End-of-Life Cancer Care**

As previously discussed, in the setting of cancer care in which prognosis is known to result in eventual death (i.e., advanced cancer) how and when such prognoses should be communicated remain matters of concern and controversy. In addition, several equally important concerns arise in the specific setting of advanced cancer regarding how and when palliative care may be implemented, as opposed to care that includes further attempts with anticancer agents. For advanced cancer patients who, by definition, have a life-ending diagnosis for which an anticancer standard of care has failed (or is unidentified), it remains unclear what factors influence their decisions to receive any particular form of care. For the more than 500,000 advanced cancer patients who die each year in the United States,<sup>60</sup> from both societal and medical perspectives, it is accepted that the ideal alternatives of care include receiving state-of-the-art palliative care, as available in hospice, and participation in clinical research involving an experimental agent (e.g., phase I trials). For reasons to be discussed, because of the complexities related to predicting time to death in those with advanced cancer, it may be difficult to know when referral to hospice might be appropriate or when it is still medically appropriate to continue attempts at anticancer therapy, including experimental agents.<sup>51,61,62,63 and 64</sup>

For advanced cancer patients to formally receive hospice care in the United States, through Medicare and insurance hospice benefits, they must be documented by their physician as having a prognosis of 6 months or less. Interestingly, for cancer patients participating in phase I trials of experimental agents, their median survival has been described as being almost identical to this prognostic milestone—6.5 months.<sup>65</sup> It is not clear which of these alternatives, experimental agents or hospice care, results in longer life or improved quality of life.<sup>52,66,67 and 68</sup> As well, there is limited data on the cost effectiveness of these alternatives.<sup>69,70,71 and 72</sup>

With regard to hospice care, as it is currently provided within third-party payer systems, it is clear that it remains greatly underused for advanced cancer patients. Only approximately 20% to 30% of cancer patients die each year while under hospice care. In addition, available Medicare data have shown that the median survival of cancer patients in hospice is only on the order of 2 to 3 weeks.<sup>73</sup> It has been argued that one of the obstacles to providing appropriate palliative care, as available in hospice, is a result of physician inaccuracy in predicting time to death.<sup>52,73,74</sup> While this undoubtedly plays some role in many physicians' hesitancy (and even unwillingness) to refer cancer patients to hospice, it does not provide a complete explanation for the apparent underuse of hospice services. Other reasons clearly exist for this hesitancy and unwillingness including perceived dilemmas related to physicians' desire to effectively communicate terminal prognoses to cancer patients and their families and still be able to facilitate the maintenance of hope; patients' and families' hesitancy or unwillingness to accept such prognoses; physician concerns regarding loss of control over their patients' medical care; and concerns about the methods by which the majority of hospice care is paid for in the United States, which may be insufficient to meet the needs of the dying.

Perceptions about damaging patient's and family's hope in the face of communicating a terminal prognosis remain a matter of concern among many clinicians. In fact, many clinicians believe that if they were to *effectively* communicate a terminal prognosis to a patient, they would essentially destroy the patient's hope.<sup>44</sup> Many physicians maintain that regardless of how sensitively or compassionately a terminal diagnosis is communicated, the ability of patients to sustain any meaningful hope is compromised. The effect of this physician belief clearly creates obstacles to quality end-of-life care and should not be underestimated.

In addition, for patients and families to accept referral to hospice, they presumably must (in some way) accept a terminal prognosis. This may not necessarily have to be the case, but patients or family members must sign consent forms for hospice care documenting that the terminal prognosis of the patient has been disclosed (even understood), and that they wish to receive no further treatment aimed at reversing their cancer. In addition, they must sign an advance directive stating that they wish no life-sustaining interventions be used in their care. Physicians often perceive that such disclosure of a terminal prognosis, and the requirements associated with signing such forms, may also severely damage a patient's and family members' hopes. As well, physicians may believe, with patients and family members often sharing this belief, that to agree to such care is to essentially give up. Patients are known to deny their terminal prognoses even in the face of explicit physician disclosure.<sup>75</sup> If this is the case, it obviously will be more difficult, perhaps even unethical, to refer such patients to hospice who willingly choose not to accept their terminal prognoses, as compared with those who have accepted their prognoses.

Some physicians and patients may also have fears or concerns regarding patient abandonment if and when they are referred to hospice. This may be the case in settings in which a cancer patient has been receiving significant amounts of anticancer therapy (e.g., chemotherapy) for several months or years before the recognition of a terminal prognosis. Now, with the introduction of the potential for hospice care, the care environment may be perceived as changing in dramatic ways. For example, such patients will no longer be receiving chemotherapy, or undergoing the pattern of physician and nursing visits as they had previously. This may be

particularly true for those patients who have received their cancer care almost exclusively at hospitals or medical centers some distance from their homes or communities. Traditionally, when patients are referred to hospice in the United States, they typically undergo fewer (if any) physician office visits, receiving the vast majority of care in the home. Thus, patients may feel as though they are being abandoned by their physicians and health care providers. Some physicians may even perceive this threat of abandonment (real or otherwise) within patients or family members and, as a result, not pursue the option of hospice care.

Even further complicating matters, physicians may develop conflicts of interests when an appropriate time comes when adequate palliative care could be provided in hospice. These conflicts can relate to both financial and psychological issues. In a not uncommon example, consider a patient who is appropriate for referral to hospice yet a physician continues to make medical decisions that involve chemotherapy and receives reimbursement for such care. Here, a physician may have financial conflicts of interest and may be unwilling to refer to hospice for fear of lost income. Another more common (and perhaps more acceptable) example is physicians may perceive referral to hospice as implying loss of decision control and may be unwilling to refer because they have psychological needs to maintain decision control or maintain emotional attachments to their patients.

A final example of the dilemmas present in providing end-of-life care to advanced cancer patients relates to the Medicare and insurance benefits that exist to provide reimbursement for hospice care in the United States. In 2000, such care is paid for through a per diem benefit, with the Medicare per diem being approximately \$120 a day (the actual rate depending on the region of the country in which the care is provided). A clear dilemma arises for some cancer patients, whose prognoses are undoubtedly terminal (i.e., consistent with less than 6 months of life) but who may have an otherwise excellent performance status and show evidence for continuing to benefit from rather expensive or aggressive palliative interventions. These might include such interventions as antibiotics, blood transfusions, and possibly even chemotherapy in some specific circumstances, for example, palliative chemotherapy for pancreatic carcinoma, indolent breast cancer, hormone-refractory prostate cancer, or those with hematologic malignancies. In these advanced cancer patient examples, such a per diem would not cover the costs of aggressive palliative care. As a result, physicians may not ever refer certain populations of patients to hospice. Or, they may perceive that hospices are not particularly interested in caring for such patients because of the high cost of such palliative interventions. Indeed, many hospices do have practical and appropriate concerns about cost containment. Thus, for a hospice that is attempting to maintain its solvency and continue to care for many terminally ill patients, many aggressive interventions may be financially prohibitive.

Some of the dilemmas present in providing end-of-life cancer care in the United States might be eliminated, or at least reduced in magnitude, by increasing or restructuring the Medicare hospice benefit.<sup>76</sup> As well, continuing medical education programs designed at improving communication techniques among oncologists may be effective in improving the ability of cancer physicians to communicate a terminal prognosis without the perceptions, real or otherwise, relating to the destruction of patient and family hope.<sup>77</sup> However, as long as perceptions and beliefs (appropriate or otherwise) exist among physicians, patients, and families that to accept (or disclose) a terminal cancer prognosis is equivalent to giving up hope,<sup>78</sup> there will likely always be hesitancy, resistance, and even unwillingness to accept end-of-life care as it has been traditionally provided.

### **Physician-Assisted Suicide**

Oncologists must be informed about PAS so they are prepared to discuss this controversial issue if it is raised by patients or their families. Whenever PAS is raised in the clinical context, oncologists should be certain that the patient's pain is being controlled, that symptoms other than pain such as dyspnea, pruritus, and constipation are adequately managed, that advance care planning has been done, and that the patient is given the opportunity to maintain control over his or her situation (e.g., by being permitted to make medical choices).

**RELEVANT DEFINITIONS AND DISTINCTIONS.** PAS is defined as a physician prescribing a lethal dose of medication, and sometimes providing technical advice to a patient, who subsequently commits suicide without further assistance from the physician. The distinction between PAS and euthanasia is generally based on who administers the lethal dose: the patient (in PAS) or the physician (in euthanasia). PAS also differs from a competent adult patient's right to decline life-sustaining treatment in terms of the actual cause of death, the class of patients potentially affected by the practice, and the legality of the action. For example, PAS is currently illegal except in Oregon, whereas the right of patients to decline or forgo life support is clinically, ethically, and legally the standard of care throughout the United States.<sup>1</sup> The final distinction is the most subtle one (i.e., between PAS and aggressive pain management as occurs when a morphine drip is hung). Essentially, if the morphine drip is being used to palliate the patient's symptoms of pain, nausea, anxiety, and so forth, its use does not represent PAS, whereas if the morphine drip is being used deliberately to hasten the patient's death or kill the patient, it probably represents euthanasia rather than PAS.

**ARGUMENTS FOR AND AGAINST PHYSICIAN-ASSISTED SUICIDE.** The strongest arguments favoring PAS are claims based on autonomy and beneficence. The autonomy argument maintains that individuals have moral authority over their lives and should be permitted to control all aspects of life based on their own assessment of benefits and burdens, including the timing and means of their deaths. In this context, patients not only have a right to refuse treatment but also have a right to request PAS. Patients may exercise this choice if they are in pain, or are suffering, or perceive a loss of dignity, or indeed if they offer any reason, or none at all, for doing so.

The beneficence argument favoring PAS claims that the relief of pain and suffering is a central aspect of medical care and, therefore, PAS should be viewed as part of the continuum of care to relieve a patient's pain and suffering. Patients who have received appropriate pain management and adequate palliative care, but who continue to experience physical pain or unremitting suffering should be permitted to request PAS from compassionate physicians who are capable of providing the means to end the patient's life painlessly and efficiently.<sup>79</sup>

Both the autonomy and beneficent claims favoring PAS can be answered. The autonomy claim for PAS can be countered with the argument that no rights are absolute and the demand to be assisted by physicians to commit suicide must be balanced against the clinical, psychological, legal, and moral prohibitions against suicide and against assisting others to commit suicide. The central argument against the beneficence claim is that all physicians, especially oncologists who frequently care for patients who experience pain, must improve their ability to provide better pain management and comfort for patients, but this intervention does not have to include PAS.

Additional arguments against PAS are based on the following three risks of adverse consequences for individuals and for society:

- The risk that those requesting PAS are clinically depressed.
- The "slippery slope" risk that PAS may be performed in some patients who have not voluntarily requested it.
- The risk that PAS may harm the DPR by undermining trust between patients and physicians.

**PHYSICIAN-ASSISTED SUICIDE AND DEPRESSION.** Depression rather than physical pain is often associated with patient requests for PAS. Among cancer patients, depression is fairly common, probably two to four times more frequent than in the general population. Studies have found that 25% of cancer patients meet criteria for major or minor depression,<sup>80</sup> whereas another series reported that 25% of patients on palliative care services are depressed.<sup>81</sup> For these reasons, it is not surprising that suicide rates among cancer patients are substantially higher than those among the general public.<sup>82</sup> Most important, as in other populations, there is a high association between suicide and depression in cancer patients.<sup>83,84</sup> and <sup>85</sup> Among terminally ill patients with cancer, the disease often produces somatic symptoms of depression (insomnia, anorexia, fatigue) and makes it difficult to reach a diagnosis of depression. Furthermore, many physicians view depression following a diagnosis of cancer as *appropriate*, rather than as a symptom that needs treatment. Yet, depression among terminally ill patients can be treated with medications or with counseling. Despite the prevalence of potentially treatable mood disorders, data from the Netherlands suggest that only 3% of requests for PAS resulted in a psychiatric consultation.<sup>86,87</sup>

These data suggest that many depressed oncology patients who express an interest in PAS may have a reversible condition, depression, that often is not diagnosed and frequently is not treated. In addition, current safeguards in the Oregon PAS laws are inadequate and contain no mandatory requirement for a formal psychiatric evaluation of the patient, even in cases in which the diagnosis of depression is suspected.

**PHYSICIAN-ASSISTED SUICIDE AND THE SLIPPERY SLOPE.** One potential slippery slope concern is *encouraged* PAS, in which chronically ill or terminally ill patients may be encouraged or pressured by their families to choose PAS. In a benign variation of this approach, patients without direct coercion from their family may feel that the availability of the PAS option requires them to do the *noble* thing to prevent becoming a burden to their families.

Data on PAS and the slippery slope have come primarily from the experiences in the Netherlands. One of the most important findings to emerge from the empiric studies of Dutch practices regarding PAS and euthanasia concern the practice of voluntary euthanasia. A report commissioned by the Dutch government to empirically evaluate the practice of euthanasia reported that there were approximately 2300 cases of euthanasia per year (1.8% of all deaths) and 400 cases of PAS

per year (0.3% of all deaths) in the Netherlands.<sup>87</sup> In addition, there were 1000 cases (0.8% of all deaths) in which patients received euthanasia either without explicitly requesting it or while deemed incompetent to make such a request.<sup>88</sup> In 56% of these cases, the patient was no longer competent when euthanasia was performed. Overall, 27% of Dutch physicians who were interviewed indicated that they had performed euthanasia at least once without an explicit voluntary request for euthanasia by the patient.

These data suggest that in the Netherlands a slippery slope has developed in which euthanasia has been extended from competent adults who voluntarily request it to incompetent patients (both adults and children) who have never made such a request. More recently, a group of Dutch physicians reported on the high complication rate (23%) associated with efforts to perform PAS in 114 cases.<sup>89</sup> In 21 of the 114 cases (18%), the physician decided to administer a lethal medication, which thus transformed the situation from PAS to actual direct euthanasia. This is another variation on the slippery slope that American physicians must be concerned with before PAS is legalized generally.<sup>90</sup>

Two studies of physicians in the state of Washington have been published to help characterize the current status of PAS in this country. In a 1994 study by Cohen and colleagues of 938 physicians (69% response rate),<sup>91</sup> although 54% thought that euthanasia should be legal in some situations, nearly one-half agreed with the statement that euthanasia is never ethically justified. Hematologists and oncologists were most likely to oppose PAS. Two years later, more research from Washington reporting on actual requests for PAS and physician responses was published.<sup>92</sup> The major finding of this 828 physician survey study was that 12% had received one or more explicit requests for PAS and 4% for euthanasia in the past year. The requests were generally from patients with cancer, neurologic disorders, and acquired immunodeficiency syndrome. Patients requests were most often based on concerns about loss of control, being a burden to others, and loss of dignity. Physicians in this study reported providing PAS in 24% of cases in which it had been requested and intended to provide PAS more often to patients with physical symptoms. The authors express concern that physicians did not consult their colleagues in many cases, raising questions about the appropriate regulatory framework to ensure quality in the evaluations of patient requests for physician-assisted death.

Further information regarding attitudes and practices regarding PAS in the United States is available from an empiric, vignette-based study, by Emmanuel et al. The investigators examined the experiences of the public, cancer patients, and oncologists.<sup>93</sup> In the setting of unremitting pain, approximately two-thirds of cancer patients and the public found both euthanasia and PAS acceptable. They found it less acceptable in the setting of existential suffering, or in the setting in which there was the potential for a patient to be a "burden on the family" (vignette wording). Among patients actually experiencing pain, they were more likely to find euthanasia and PAS unacceptable. Among oncologists, more than one-half stated they had had a request for either euthanasia or PAS, and one in seven said they had performed either practice at least once. In a related set of data, nearly one-half of these oncologists could imagine a situation in which they would want PAS or euthanasia for themselves.<sup>94</sup> These oncologists were more than twice as likely to find euthanasia or PAS acceptable for their patients, as compared with oncologists who could not imagine a situation in which they would want PAS or euthanasia for themselves (86% vs. 42%, respectively). Many oncologists (42%) who would find PAS or euthanasia unacceptable for themselves still found these practices ethical for their patients.

These data can be viewed as concerning as they suggest that there is significant, although not majority support, for the use of PAS and euthanasia in at least some cancer care cases, and that as many as 15% of oncologists have carried out such practices at least once in their professional careers. Interestingly, in subsequent research, Emmanuel found that some oncologists suffered adverse consequences (emotional or psychological) from having performed PAS or euthanasia.<sup>95</sup> Further research is undoubtedly needed to better understand oncologists' attitudes to PAS and their perception of pain and suffering and their perceived obligations in helping cancer patient to end their lives.

Another data source that is being closely scrutinized for evidence of the slippery slope derives from the experience in the state of Oregon, which legalized PAS on October 27, 1997. During the first year of PAS activity, 23 persons requested lethal medications and 15 died after taking the medication.<sup>96</sup> Reports of the second-year experience indicate that 33 persons requested lethal medications and 26 died after taking the medication.<sup>97</sup> In both years, the median age of the patients was 69 to 71; the most common underlying diagnosis was cancer; and the most common reasons for PAS were not physical pain but rather "loss of autonomy due to illness, loss of control of bodily functions," and a wish to determine and control the manner of one's death. Based on the first two reports from Oregon, the use of PAS occurs infrequently and has generally involved patients who were well-insured, educated, and already in hospice programs. It is too soon to know whether vulnerable populations will also be recruited to participate in Oregon's PAS initiative.

**THREAT TO PROFESSIONAL INTEGRITY AND TRUST BETWEEN PATIENT AND PHYSICIAN.** Cancer patients often have a heightened sense of their own mortality and a need to trust a physician in a relationship that is based on honest communication but nurtures hope.<sup>44</sup> The conflation of the concept of healing with procedures designed to bring about the patient's death creates a serious threat to the integrity of the medical profession.<sup>98</sup> PAS and euthanasia distort the fundamental norms of medicine in at least three ways: (1) by diverting attention from the substantive issues of providing good care for dying patients; (2) by subverting the social role of the physician as healer; and (3) by often undermining the trust that patients place in their physicians. Many patients benefit from knowing that PAS is not an option that their physician would contemplate, and this reassurance strengthens the trust that cancer patients place in their doctors. Similarly, physicians efforts to prolong life and aggressively relieve pain and suffering are bolstered by the fundamental prohibition against actively ending the lives of their patients with PAS and euthanasia.

Based on our analysis of the scanty but worrying data on these practices (especially those available from the Netherlands), along with our view that PAS and euthanasia will ultimately weaken, not strengthen, the relationship of oncologists and patients and will attenuate the fundamental prohibition against killing in the medical context, we recommend that at this time oncologists resist appeals to participate in PAS and euthanasia.

## **ETHICAL ISSUES IN CANCER CLINICAL TRIALS**

This section of the chapter examines the ethical issues associated with the clinical research of cancer. Following a brief overview of certain principles that guide the ethical conduct of clinical research, the chapter discusses the history and development of ethical guidelines and requirements regarding human experimentation. Further discussion and background pertaining to the concept and process of informed consent as it specifically relates to cancer patients and clinical research, including the use of consent forms for research, is also provided. The ethical aspects of clinical trials in oncology, including phase I, II, and III studies, are then examined. Wherever possible, empiric information is incorporated into these discussions from research on the informed consent and clinical trial process in cancer.

### **ETHICAL PRINCIPLES GUIDING CLINICAL RESEARCH**

The main objective of clinical research in oncology is to improve medical care for future cancer patients. From both a societal and ethical perspective, this is viewed as a laudable and important goal. As such, no meaningful criticisms can truly be offered against the need and desire to better care for those with cancer. However, when one examines the methods by which this goal is pursued, problematic issues can be found. As is discussed, it is the process of using current patients as research subjects to achieve this goal in which true ethical dilemmas are created.

Whether in the context of clinical practice or clinical research, several specific principles guide the management of patients by physicians.<sup>99,100</sup> The first such principle worthy of mention in this context is, "One ought not to use others as means to an end." In the process of clinical research this general ethical principle is, in many ways, allowed to be violated. However, to allow violation of this principle, it is expected that no patient can participate as a research subject unless there is the potential for benefit. No doubt, in considering what is an acceptable degree of potential benefit, this safeguard is in place for a great proportion of clinical research. (Here, benefit is implied as it is traditionally measured in oncology, i.e., as a specific anticancer response or improvement in a patient-subject's symptoms.) However, as is discussed in the section regarding phase I trials (see [Ethical Issues in Phase I Trials](#), later in this chapter), ethical dilemmas that challenge this safeguard are created in the early drug development process in which the potential for such benefit may be exceedingly small for involved cancer patients.

A second related ethical principle that must guide behavior in the research setting is, "One should not allow harm to come to others." Certainly, oversimplification or generalization of this principle would lead to the prohibition of specific patterns of behavior in the clinical (nonresearch) setting of cancer care, where the harm from toxicities is deemed acceptable because of the known benefits to be achieved. Thus, as with the first principle mentioned, the specific issue of harm cannot truly be weighed without consideration of the relative benefit that may be achieved for cancer patients. However, when cancer patients participate as research subjects in early clinical trials of anticancer agents, there is a greater relative potential for harm to come to patients as a result of the specific methodologies and research objectives employed in these trials. In addition to the recognition that benefit is not likely, there is even an expectation that harm will come. In fact, it may even be a goal of the study to produce harm. The safeguard that must be in place to allow violation of this principle is that the potential for harm to participating subjects must be warranted either as a result of the potential benefits to be achieved or (more commonly) that, given the circumstances of many advanced cancer patients participating in such trials, there are perceived to be no other available meaningful anticancer alternatives.

A third ethical principle that guides behavior in this context is, "One ought never to deceive others." Within clinical research, several safeguards are in place that are designed to prevent the deception of patients who become the subjects of research. The informed consent process itself, and other federal and institutional regulations, provide mechanisms in which oversight of both specific research protocols and the described methods of information provision are present to prevent any intentional deception of patients. More importantly, the conscientious communication efforts of participating physician–investigators are also relied on to prevent deception. However, in the setting of early trials of investigational agents, in which research subjects are most often those with far advanced disease, many have wondered about the potential vulnerability of these subjects and the potential for them to be unintentionally deceived. Indeed, the very fact that the agents under study in early drug trials have shown promise in preclinical models creates a variety of stated or unstated inducements that may play on some advanced cancer patients potentially overwhelming desire for therapeutic benefit and lead to a process akin to deception, albeit unintentional.

In a final principle worthy of mention, medical ethics itself teaches us that, "The interests of an individual physician's patient should be placed above the interests of others." One can easily argue that placing a cancer patient on a clinical trial involving a new investigational agent does not at all compromise their interest in receiving state-of-the-art care. However, one must keep in mind that the overall goal of clinical research (improving care for future patients) remains intact whenever a patient enters a clinical trial. Thus, at the very least, other interests beyond the individual care of a patient are present when that patient enters a clinical trial. As is discussed, these potentially competing interests can lead to dilemmas. Further insight into these issues and dilemmas can be gained by specifically examining the early phases of cancer clinical research and the attendant informed consent process.

## INFORMED CONSENT FOR CLINICAL RESEARCH

The concept of informed consent, which acknowledges the rights of patients to voluntarily participate in health care, applies both to clinical practice and clinical research.<sup>6,101</sup> Informed consent in clinical research is related to, but recognized as being more stringent than, informed consent outside the context of clinical trials.<sup>102</sup> This heightened consent standard exists for at least two reasons. First, from an ethical perspective, a patient considering clinical trial participation is always viewed as potentially vulnerable.<sup>103</sup> As a result of this potential vulnerability, he or she may have great difficulty in appreciating the differences between the therapeutic and research aspects of a given alternative of care or treatment. Without this distinction, patients cannot make uncoerced and autonomous health care decisions. Thus, the informed consent process, and the ethics of clinical research, require that such a clear distinction be made.<sup>8,104</sup> Second, the physician–investigator is seen as having an intrinsic conflict of interest in the role both as a physician for an individual patient and as a scientific investigator attempting to develop improved methods of medical care and treatment.<sup>102,103,105</sup> As previously mentioned, within the sole context of a therapeutic relationship, the physician places his or her patients' interests above all else.<sup>1</sup> However, within the context of clinical research, investigators have additional interests that may not be relative to their patients' interests.<sup>105,106,107,108,109</sup> and <sup>110</sup> From an ethical perspective, many concerns exist about the ability of clinical investigators to provide the requisite information to patients regarding participation in research in such a way that allows patients to recognize the distinction between research and therapy.<sup>8,111,112</sup> and <sup>113</sup>

A definition of informed consent for clinical research that encompasses all relevant aspects of the process remains somewhat elusive, with varying definitions having been described.<sup>6,101,102</sup> and <sup>103</sup> Generally, it is viewed as a process of communication between a patient–subject and a clinician–investigator regarding an investigational or experimental treatment. Within this communication process, several elements must be disclosed. These include the disclosure of the type of research to be performed, the risks and benefits of the treatment or research, the unproven nature of the research, the alternatives other than participation in the clinical trial, and finally, disclosure of the subject's freedom to withdraw or not to participate in the research without any detrimental effect on the patient's continued access to adequate health care. Separate from the issue of disclosure within this process is the issue of actual understanding on the part of the patient with regard to these disclosed elements. Whether the definition of informed consent should include an actual understanding of these elements, or how much of an understanding it should include, remain matters of controversy.<sup>6,112,114</sup> However, from an ethical standpoint it is accepted that the process of informed consent requires at least some attempt on the part of the clinician–investigator to help a patient understand those aspects of the consent process that have been disclosed so that the patient may autonomously and voluntarily decide to participate in research.<sup>100,115</sup> Other elements that have been described as important parts of the informed consent process include maintaining the confidentiality of a research subject's participation and, controversially, possible disclosure of potential conflicts of interest on the part of the clinician–investigator.

In an attempt to emphasize the importance of the distinctions between research and therapy, most ethical regulations governing clinical research have focused on the informed consent process as a means of protecting potentially vulnerable research subjects from physical and psychological harm.<sup>102,103,113</sup> These regulations have relied heavily on written informed consent documents to achieve full disclosure of the important elements of consent, including the risks of research participation, the nature of the research, and alternatives to research participation. Thus, informed consent is currently and most commonly viewed as a means of protection of a potentially vulnerable research subject from harm.<sup>102,103</sup> However, from their inception to the present day, many critics have recognized the imperfect nature of the methods used to regulate the informed consent process.<sup>112,116,117,118,119</sup> and <sup>120</sup> More recent empiric research on informed consent, a great proportion of which as been conducted in the cancer setting, may be helpful in attempting to objectively identify the current problems and deficiencies associated with written consent documents and their oversight. As reviewed elsewhere, several studies reported since 1980 have increasingly demonstrated that although regulations are being followed, informed consent documents have become increasingly unreadable, lengthy, and uninformative.<sup>121,122</sup> and <sup>123</sup> Indeed, they may actually be interfering with what might otherwise be an ethically appropriate informed consent process for patients, including not only those with cancer, but any patient considering therapeutic clinical trial participation.

### **Shaping of the Regulatory Process for Consent**

Beginning in the 1960s, several events occurred that significantly changed the practice and process of informed consent in therapeutic research. One of the most important events, and clearly of greatest significance with regard to cancer and other related therapeutic research, was the publication of Henry Beecher's paper in the *New England Journal of Medicine* in 1966.<sup>124</sup> Beecher, a clinical investigator and anesthesiologist at Harvard, assembled 22 recent research reports that he pulled from the peer-reviewed medical literature that contained, in his view, clear violations of both patients' human rights and the recognized ethical principles of informed consent. Of note, several of the research reports that he described were specifically related to cancer clinical research. One such case was a published report regarding a young woman with metastatic melanoma. In this report, the investigators described excising one of the melanoma lesions from the patient and transplanting it onto the patient's mother. Subsequently, serum was withdrawn from the mother and given to the patient in hopes of producing an immune-mediated tumor response. The patient went on to die relatively quickly of widespread metastatic disease. Even more horrific, the mother subsequently died of metastatic melanoma approximately 1 year later. Another of Beecher's examples, although described without identifiers, clearly included the much publicized case of the Jewish Chronic Disease Hospital.<sup>111</sup> Researchers in this published study, in an attempt to gain information relevant to organ transplantation, injected malignant cells from cancer patients into elderly and debilitated noncancer patients at the hospital.

Beecher's cancer research examples, and the other reports described, put a great deal of the medical research process into the public spotlight. The subsequent outcry from the public and medical community led to regulations in the late 1960s and early 1970s that resulted in greatly increased scrutiny of government-sponsored clinical research.<sup>102,111,125</sup> Clinical researchers themselves undoubtedly became more sensitive to the issues regarding the use of patients, including those with cancer and others, as research subjects. Other events, including the disclosure to the public regarding the United States Public Health Service Syphilis Studies (also known as the Tuskegee Syphilis Study)<sup>96,102,126</sup> as well as the thalidomide experience and subsequent passage of the 1962 amendments to the Food, Drug, and Cosmetic Act,<sup>127</sup> also had a great effect on the regulatory requirements for informed consent in clinical research. All of these events eventually led to the creation of the National Commission for the protection of human subjects in biomedical and behavioral research. The resulting recommendations of the National Commission led to the now required and pervasive practice of formalized institutional review of clinical research protocols.<sup>103</sup>

Undoubtedly, the use of consent forms for clinical trials of new anticancer agents is one such setting in which these issues take on great significance, especially if we are to continue to recognize the value of patient–subject autonomy and the moral importance of the consent process as a mechanism of protection for potentially vulnerable patients attempting to make difficult decisions regarding their medical care. Separate from the content of the consent forms themselves, concerns also exist about the overall effect of the forms on different aspects of the consent process, including its outcome and the decision-making process of patients before the eventual decision to actually participate in a therapeutic clinical trial.

In the clinical trial setting, several studies have examined the potential effect of different information-provision methods on the informed consent process.<sup>10,128,129</sup> and <sup>130</sup> It is interesting to note that in a review by Edwards et al. of different methods of information provision in clinical trials across the entire spectrum of disease processes,<sup>130</sup> nearly 60% of these studies were conducted by cancer investigators and focused on clinical trials involving cancer patients as research subjects. In the review by Edwards et al., and as evidenced by the previously mentioned research, despite the format of presentation, information provision may have little effect on

patient–subject understanding. Other significant research contributions within the cancer setting to the informed consent literature can be found elsewhere. [121,122,129](#)

In considering this available empiric data, one is certainly left to wonder about the utility and value of the current consent process for therapeutic clinical trials. Particular concerns develop when one recognizes that great emphasis continues to be placed on consent forms and their content. Such concerns become even more challenging in areas in which consent forms detail investigational therapies with relatively extreme toxicities, and in which the therapeutic goals of the alternatives to clinical trial participation may be quite different from the inherent or perceived goals of investigational therapy.

## ETHICAL ISSUES IN PHASE I TRIALS

It is in the specific setting of cancer trials involving new agents (i.e., phase I trials) in which the general concerns about informed consent in therapeutic clinical trials become especially troubling and challenging. [103,131,132](#) and [133](#) This is because phase I trials typically involve patients with advanced, eventually life-ending disease in a research endeavor where the chance of meaningful objective therapeutic benefit has traditionally been described as being quite low, less than 5%. [134,135,136](#) and [137](#) As a result of the dose-escalation methods in these trials, [131](#) a more specific dilemma is the relative ratio of toxicity and benefit for patients who participate. Further complicating this is the need to adequately inform patients about these particular issues and then allow them to willingly and freely consent to participate in such studies. The complexities of the consent process for advanced cancer patients in phase I trials relate both to what degree such patients should be viewed as vulnerable, and to what extent a participating physician's own expectations and interests play a role in guiding patients to decide to participate. This unique form of therapeutic clinical research creates an intense environment of medical decision making in which arguably, many patients may not benefit from the traditional informed consent process.

If patients were to participate in phase I trials solely for altruistic reasons, in other words, to help forward cancer research and potentially help future cancer patients, phase I trials would probably carry less ethical conflict. As well, this would imply that the traditional informed consent process might more readily achieve the desired ideal outcome of understanding all elements of consent, including an understanding of the nature of phase I research and the alternatives to trial participation, as these less vulnerable patients would not necessarily be seeking benefit for themselves. However, the objective information available regarding the informed consent process for patients participating as research subjects in phase I trials tells us that altruism is not the primary motivating factor for patients participating in such clinical research. As reviewed in this section, the empiric studies examining the phase I consent process highlight the true ethical dilemmas associated with this early stage of clinical research.

In the first such study, Rodenhuis et al. evaluated the quality of informed consent among patients with advanced cancer who were offered participation in a phase I trial. [138](#) The majority of patients who gave their consent was motivated either by hope for improvement of their condition, pressure exerted by relatives and friends, or simply because they felt they had “no choice.” Some patients did mention the desire to contribute to the progress of medicine. The investigators concluded that encouragement by relatives or friends appears to be a powerful force in motivating some patients to participate in phase I trials. In a similar but much smaller series of European advanced cancer patients, Willem and Sessa found corroborating results with regard to patient motivations for participation in such trials. [139](#)

Investigators at the University of Chicago conducted an in-depth survey study of 27 cancer patients who had given informed consent to participate in phase I trials at their institution. [33](#) Concurrently, the oncologists identified by the surveyed patients as responsible for their care and consent were surveyed as well. Eighty-five percent of patients decided to participate in a phase I trial for reasons of possible therapeutic benefit, 11% because of the advice or trust of physicians, and 4% because of family pressure. Ninety-three percent said they understood all (33%) or most (60%) of the information provided to them about the trial in which they had decided to participate. Only 33% were able to state the purpose of the trial in which they were participating, with patients able to state the purpose of phase I trials as dose-escalation or dose-finding studies being more educated ( $P = .01$ ). The surveyed oncologists had wide ranging beliefs regarding expectations of possible benefits and toxicities for their patients participating in a phase I trial. The authors concluded that patients who participate in phase I trials are almost exclusively motivated by the hope of therapeutic benefit. Altruistic feelings, while perhaps present, appear to have a limited role in motivating patients to participate in these trials. Subsequent studies conducted by these investigators in a much larger series of subjects have found similar findings. In fact, in larger series of subjects, quantifiable survey data show that patients may even be less aware of the research purposes of phase I trials and are unable to recall whether alternatives to clinical trial participation, including palliative care or other nonexperimental therapies, were either discussed with or disclosed to them. [140](#) This is despite the fact that all surveyed patients had signed consent forms detailing the research purpose of phase I trials and the alternatives to trial participation.

Tomamichel and colleagues conducted an analysis of the communication process involved in informed consent for cancer patients agreeing to participate in phase I trials. [141](#) The authors concluded that the informed consent procedure was satisfactory from a quantitative point of view. Interestingly, they found that the most important items of information were acceptably communicated to patients. However, they also stated that greater attention should be paid to the indirect messages and implied criticism of patients to improve their participation in decision making. They also conclude that physicians should become more skillful in providing adequate information and to improve their methods of communication.

Yoder and colleagues conducted a prospective study involving entry and exit interviews of 37 advanced cancer patients participating in phase I trials. [142](#) The investigators found that patients expected slightly increased support from family members and received more support than expected. Perhaps not surprisingly, patients' expectations for tumor response and increased communication with their physician were not met. Their expectations were also not met with regard to improvement of symptoms such as fatigue, nausea and vomiting, and weight loss. They noted that one strong theme that emerged from the data was hope and optimism. They conclude that an issue that needs further exploration is the extent to which patients accurately understand information in the consent form and in the consent process itself. Their findings also support the importance of communication between the patient and family and all members of the health care team, and stress the importance of oncology nurses who may be able to mediate the flow of information between physicians and patients.

Research results providing a cross-cultural perspective are available as well. Japanese investigators, conducting a similar study, attempted to characterize the motivation, comprehension, and expectations of patients who had given informed consent to participate in phase I trials at the National Cancer Center in Japan. [143](#) Before receiving any investigational agents, 32 of 33 subjects were approached and completed a multiple choice questionnaire addressing these issues. When questioned regarding their expectations, more than one-half the subjects indicated that there might be personal benefit to themselves. As well, slightly more than one-third of the subjects (35%) believed that it was possible that their cancer could be cured, and 12 subjects fully expected to be cured as a result of participation in a phase I trial. The investigators found that older adults had slightly higher expectations of cure from participation in a phase I trial (although this did not reach statistical significance). With closed ended questioning, most patients appeared to comprehend the major features of a phase I trial, namely its investigational nature, the unknown effects of the agent investigated, and the unclear benefit to themselves. As well, nearly 60% of the patients anticipated they might suffer severe or life-threatening side effects from participation. As many as 43% of subjects were able to accurately indicate (again, in closed ended questioning) the research purpose of a phase I trial as a dose-determination study.

One disturbing finding from these studies is the potential discrepancies among what has been disclosed to patients, what they think they understand, and what they may actually understand. For example, the University of Chicago study found that 90% of patients stated they understood all or most of the information provided to them about the phase I trial in which they had agreed to participate. [33](#) However, only approximately one-third of the patients could state the purpose of a phase I trial, and an even smaller proportion of patients could state the research purpose of phase I trials in a much larger study. [140](#) This discrepancy likely results from several factors, including inadequate informed consent. It may also lie in the methodologic difficulties of determining what a patient actually understands in relation to the information they have been given.

The information gained from this research strongly supports the argument that the current process of obtaining informed consent for phase I trials may be inadequate to appropriately ensure that such advanced cancer patients understand both the nature of the research in which they are participating and the alternatives to trial participation. In addition, despite recognizing the existence of their potential vulnerability, we do not know how that vulnerability specifically affects an advanced cancer patient's ability to give what is otherwise perceived to be adequate informed consent. It is possible that several poorly understood and seldom studied factors play a vital role in shaping the informed consent process for potentially vulnerable advanced cancer patients considering participation in phase I trials. These likely include relatively subtle and less apparent factors as may exist in other health care decision-making environments for advanced cancer patients, for example, a patient's awareness of the certainty of his or her death [42,78,144](#) and the patient's cultural and ethnic background. [145](#) In addition, advanced cancer patients' religious or spiritual beliefs, their degree of hope and emotional well-being, and their attitudes toward medical decision making may likely influence the shape of the consent process in this setting. Further research will be required to better understand and delineate these issues and their importance on the informed consent process in this difficult and highly charged setting.

## ETHICAL ISSUES IN PHASE II TRIALS

Some of the ethical issues related to phase II trials of new agents are similar to issues in phase I trials with regard to the participation of human subjects with otherwise incurable illnesses in biomedical research and the potential vulnerability of these patients in seeking therapy. <sup>131,132 and 133</sup> Although still troubling, issues in phase II trials can be viewed as potentially less complex for several reasons. In the phase II setting, there is less of the unknown for both oncologist–investigator and patient, as all agents studied in phase II trials have completed toxicity finding and dose-determination (phase I) studies. Thus, there may be greater attitudes of certainty with regard to expected toxicities. There may also be greater hope or expectations of benefit, in part because these agents are being administered at or near the maximum tolerated dose. Therefore, one unique issue in the phase II trial is the higher likelihood of toxicity developing for all patients in a trial, as they are being administered agents at relatively higher doses, as compared with patients in a prior phase I study investigating the same agents. The intentions and motivations of a participating oncologist, in the role of physician–healer or physician–investigator, are central issues in both phase I and II trials. Again, however, expectations or hope of benefit for their patients may be greater in the phase II setting. This may translate into greater therapeutic intent and subsequently be communicated to patients, resulting in greater expectations or hopes on their part as well.

Although these issues may be less complex and more easily examined in the phase II setting involving new agents, they are still troubling as there is an overall low probability of benefit with regard to tumor responses in these trials. <sup>146</sup> In fact, this concern may actually increase even as a phase II study is accruing patient–subjects. This relates to the accepted statistical requirements of phase II trials of new agents that are present to exclude, with an accepted amount of certainty or confidence, a low level of efficacy for a new agent. <sup>147</sup> Traditional stopping rules for many phase II trials would allow as many as 14 consecutive nonresponders to accrue to a trial before concluding that the agent lacks disease-specific efficacy. Yet, physician–investigators' attitudes and beliefs may change significantly with regard to an agent under study as response data accumulate that suggest a lack of efficacy, but the trial remains open in order to reach the statistically required accrual.

How should evolving data be handled during a phase II trial that suggests a lack of efficacy, but is not sufficiently substantiated from a statistical standpoint? In a study of even a small number of patients, if an agent is given to initial patient–subjects without apparent benefits or tumor responses, but not enough patients have been involved to satisfy statistical requirements, what information should be provided to prospective patient–subjects? For example, in a simple phase II single-agent study seeking to accrue 14 to 20 patients, if six evaluable patient–subjects have been administered the agent and are known to have not received any apparent benefits, what should the informed consent process consist of for prospective patient–subjects with regard to risks and benefits?

We know oncologists' attitudes, perceptions, and biases toward clinical trial chemotherapy may substantially affect clinical trial accrual. <sup>148,149 and 150</sup> These factors are likely to be important for phase II trial accrual. How oncologists, either as investigators or practitioners, interpret clinical trial data from ongoing trials could have a significant effect on their views toward continued accrual. How oncologists assimilate this information and communicate it to prospective cancer patient–subjects likely changes over the course of a trial. Yet, the consent forms for such trials are almost always static, potentially leading to subjects receiving conflicting information. As well, oncologists' enthusiasm or beliefs toward the potential efficacy of an agent may decline as information is acquired regarding nonresponders. What is troubling about this is that, quite often, accrual will continue unabated using the same consent process until the statistical requirements for accrual have been satisfied. This may well be justified in order to establish confidence regarding lack of efficacy of a new agent in a specific disease, but the potential dilemma remains and is no less troubling. Some might argue that as nonresponse information accumulates, such declining enthusiasm for a new agent should be allowed to affect accrual and should be uniformly communicated to prospective patient–subjects. However, traditionally, after the initiation of a phase II trial, subsequent patients are accrued with little formal response or toxicity information available to prospective subjects about prior evaluable patients in the trial. Interestingly, if such information could be fully and appropriately withheld from involved clinician–investigators, some of the described dilemmas in phase II trials might resolve themselves. As well, if one could guarantee an unprecedented quick rate of accrual of all the subjects necessary to meet the statistical requirements to a phase II trial, these dilemmas could potentially be less challenging. Practically speaking, these actions are not likely to be routinely achievable. Research on these issues in the phase II setting is needed.

## ETHICAL ISSUES IN PHASE III TRIALS

Although ethical issues are present throughout all phases of clinical research, and early trials of new agents certainly present troubling dilemmas, it is randomized phase III trials that have undergone the most intense scrutiny. Indeed, much of this scrutiny has centered on the randomized trial process specifically in *cancer* clinical research. The overall informed consent process in phase III trials and, more specifically, how disclosure to potential subjects regarding the randomization process itself should be conducted, remain issues of controversy. An even more basic and primary ethical concern is the application of the phase III trial design itself, with much debate and controversy focused on when, rather than if, it is ethically appropriate to perform randomized comparative trials. Indeed, no ethical arguments have been made against the actual intended goals of phase III trials. Rather, it is phase III methodology, in which patient–subjects are randomly assigned to receive either an investigational therapy or a standard of care, that has caused concerns for some. <sup>151,152,153,154,155,156 and 157</sup> Such concerns deal with a perceived dilemma for the treating physician of a specific patient, and whether the physician's therapeutic responsibilities to that individual patient overwhelm any responsibilities to clinical research and the needs to improve medical care for future patients. Some have described this as a potential conflict that arises between the physician as investigator and the physician as healer for an individual patient. <sup>110,155,156</sup> Supporters of this view have argued that the responsibilities of the physician as healer carry far greater moral weight than those of the physician as investigator, to the extent that it becomes unethical to allow a random process to be the determining factor in what therapy a patient receives. Complicating this further is the fact that in the phase III setting the lines separating research from therapy are sometimes less clear. <sup>8,104,153</sup>

Much of the debate regarding ethical issues in phase III trials has centered around the issue of equipoise. As originally defined by Fried, <sup>158</sup>equipoise is viewed as a state of genuine uncertainty on the part of a clinical investigator or treating physician regarding the comparative merits of different treatments for a patient's specific disease process, such as cancer. Some have argued that equipoise must exist for an individual investigator or physician in regard to an individual patient, in order that he or she can ethically ask (or encourage) that patient to participate in an appropriately designed phase III trial. Others have argued that a broader definition of equipoise be accepted to justify randomized phase III trials; specifically, that clinical equipoise need not exist for an individual physician or investigator, but need only exist within a specified medical community. <sup>159,160 and 161</sup> In the cancer setting, clinicians, researchers, and ethicists have debated this issue of equipoise (whether it should be applied as an individual versus a community standard), and whether randomized studies are ethical at all. <sup>155</sup> The empiric research available from the cancer setting strongly suggests that the issue of equipoise remains quite unresolved for investigators, clinicians, and even patients. <sup>162,163,164,165,166,167,168 and 169</sup> The available evidence also suggests that many oncologists view the informed consent process requirements within randomized clinical trials as too cumbersome or potentially threatening to the patient, DPR, or both to the extent that they are a significant obstacle to patient accrual to phase III trials. <sup>162,163,168</sup>

Keeping this issue of equipoise in mind, and returning to the process of informed consent in phase III trials, Freedman has quite rationally argued that an individual physician or investigator is not the sole arbiter of appropriate or acceptable medical practice. <sup>159</sup> Rather, the medical community as a whole determines equipoise and, as long as equipoise truly exists, an individual physician can remain ethically and morally justified in consenting patients to participate in a phase III trial, even if the physician is not in equipoise. With regard to the informed consent process itself, Royall has extended this argument, noting that in situations involving an autonomous patient, the decision to participate in a randomized study does not rest with the physician but with the patient. <sup>170</sup> This is certainly the case as long as an adequate (perhaps ideal) process of informed consent can be carried out, including full disclosure of alternatives to randomized trial participation. Royall argues that what is needed for randomized trials to be justifiably conducted, beyond the presence of medical uncertainty (or equipoise) regarding particular therapies, is not physicians without preferences. Rather, it is patients who are informed of the uncertainty (i.e., the existence of perceived equipoise and are autonomously willing to consent to randomization). Thus, within the context of phase III trials, the informed consent process becomes one of utmost importance. In the cancer setting this may be especially true because of the life-threatening nature of these diseases and the relative toxicities of potential therapies contained within arms of many randomized trials.

Some efforts have been undertaken to examine different methods of obtaining consent for randomized trials and the effect of these methods on the quality of consent. <sup>171,172 and 173</sup> Many of these investigators have examined alternatives to the conventional methods of informed consent for phase III trials (i.e., in which subjects are first consented to the trial and then randomized to either standard or experimental treatment). The alternatives to this conventional method of consent and randomization include so-called preconsent randomization, where subjects are first randomized to one arm of the trial and then asked to consent to participation.

As reviewed by Altman and colleagues, <sup>174</sup> and originally proposed by Zelen, <sup>175</sup> these alternatives include single- and double-randomized consent designs. In the single-randomized consent design, eligible subjects are first randomized to one of the treatment arms under study in a trial before consent and without their knowledge. Subjects randomized to standard treatment are simply evaluated with routine follow-up and nothing is said to them about the trial or their participation (i.e., no formal consent is obtained from them). Subjects randomized to the experimental arm in such designs are consented to receive the investigational therapy. If these subjects refuse participation, they would then receive standard treatment and be followed similarly to those originally randomized to standard treatment. In the double-randomized consent design, all subjects are first randomized without their knowledge, then asked if they would consent to participate, receiving either the

standard treatment or the experimental treatment to which they had already been randomized. Those refusing trial participation would then be offered treatment with the opposite arm to which they had been randomized (e.g., those refusing standard treatment would be treated with the experimental therapy).

Such designs were proposed in order to make the informed consent process less cumbersome and threatening for a participating physician–investigator. In fact, Zelen proposed such trial designs because of practical difficulties in getting physicians to participate in randomized trials, hoping to increase their willingness to participate.<sup>175</sup> The common theme of such designs is that patients are asked to consent to a specific treatment, rather than to participate in a randomized trial. Many statistical difficulties arise with such randomized consent designs, including an inability to blind subjects to the treatment. As well, such designs create both an underestimation and a dilution of possible differences in treatment effects, resulting in larger (and even unpredictable) accrual goals. Significant ethical issues also arise with such designs, including the fact that some subjects would be unaware that they are in a clinical trial. In addition, many subjects would likely receive biased information about the particular treatment to which they had already been prerandomized by the participating physician–investigator approaching them for inclusion in the trial.

Interestingly, even considering such criticisms, nearly a dozen cancer clinical trials have employed these or similar consent designs. As reviewed elsewhere,<sup>174,175</sup> many of these trials were in the cooperative group setting. Most of these trials had been originally initiated with conventional consent designs, but were then modified to include randomized consent designs in order to improve on slow patient accrual. Several of these trials increased their accrual rates substantially, some by a factor of three to six times the initial accrual rates.<sup>176,177</sup> and <sup>178</sup> Despite these improvements in accrual, these consent designs remain controversial. Gallo and colleagues examined the use of such trial designs, comparing different preconsent procedures for a hypothetical randomized trial among more than 2000 healthy subjects.<sup>171</sup> The investigators conclude that preconsent randomization methods are highly inefficient with regard to improving accrual, as subjects knowingly randomized to receive standard treatment would be likely to refuse clinical trial entry. In general, the ethical and statistical difficulties have prevented their implementation on a routine basis and they have not been recommended for such use.

## CONCLUSIONS

If cancer physicians and investigators are to provide high-quality cancer care and conduct research according to the highest possible standards, they must maintain a heightened sensitivity to the ethical issues discussed. Certainly, continued study and debate regarding these complex issues is unquestionably needed if the dilemmas present in cancer care and research are to be addressed and, it is to be hoped, resolved. Considering their long-standing awareness, cancer physicians and investigators remain well qualified to continue to provide guidance in shaping this future study.

#### INTRODUCTION

As the twentieth century slipped into history, there could be little doubt that we live in an age in which information technology will continue to catalyze dramatic changes in society that affect our daily lives, especially in the field of health care. The Internet has revolutionized telecommunications, enabling electronic devices with different operating systems and data formats to communicate with each other seamlessly and making the “Net” and the “Web” ubiquitous terms in our lives. Computing power continues to increase steadily as more powerful chips become available, and powerful hand-held computers with wireless access to the Internet are now available. Direct Internet connections, once only available in academic centers, are now readily available in the home, workplace, and a growing number of public settings, such as public libraries and shopping malls. Internet access is available through dial-up, cable, and wireless Internet service providers at a reasonable cost. The simplicity and accessibility of Internet access have now made the Web a primary mechanism for communicating health information. As a result, the Internet has rapidly become an extremely popular vehicle for information queries and research.

Effective communication is central to efficient, high-quality health care. Information empowers individuals, enabling them to make informed decisions. Changes in the accessibility of medical information and the way the public can acquire it are altering the field of health care and the relationship between health care professionals and patients. A federally funded science panel on interactive health communication has concluded that few other interventions have greater potential to improve health outcomes, decrease costs, and enhance consumer satisfaction than communication.<sup>1</sup> Data from CyberDialogue, a group that has followed Internet trends since 1993, reported that, in 1999, more than 69.3 million adult Americans (35% of the adult population) were actively online; more than 26.3 million (38%) searched the Internet to obtain health and medical information.<sup>2</sup> In 2000, more than 33.5 million adults are expected to use the Internet to search for health information.<sup>3</sup> Use of the Internet as a channel for communicating health and medical information will continue to increase as interactive health communication applications become more sophisticated and the cost of electronic devices and Internet access decreases. However, major gaps in knowledge exist about how consumers process and use health information; distinguish important from insignificant health risks; decide to modify risky behavior, such as smoking; resolve contradictory health messages; and make decisions about their health care options.<sup>4</sup>

Many of the health care applications currently in development are designed to support complex user interactions and sophisticated decision-making tools. Increasingly, applications feature multimedia assets that enable designers to communicate complex information on health to users in ways that can be tailored to the user's unique needs and perspectives. Applications are being designed for a variety of dissemination vehicles, including standalone systems; locally networked computers; and Internet access via personal computers, mobile wireless digital devices, kiosks, and Web television.

Innovative strategies to ensure that communication technologies fulfill the inherent promise they offer must take into consideration the “digital divide” that exists between those that can readily access computers and the Internet and those who cannot. This digital divide reflects the societal gap that exists between the “haves” and “have nots.” Internet use by those who live in rural settings; blacks, Hispanics, and other central city minorities; and households headed by the poor, by females, and by the young (younger than 25 years of age) lags behind white users.<sup>5</sup> Efforts to address barriers to access for these disadvantaged populations deserve high priority by developers, because underserved and minority populations often carry a particularly heavy burden of one or more cancers. Studies have shown that patients in underserved populations do use computer-mediated advice services and rate them highly.<sup>6,7</sup>

The availability of accurate, credible information is essential for anyone making decisions about cancer care. Cancer patients, their families, and many of those who perceive themselves at risk of developing cancer face the arduous task of gathering and interpreting information they find or are given to make well-informed decisions about their care options. Cancer patients learn about their diagnosis and management options from many sources and, in today's health care environment, are more likely to ask health care providers sophisticated and pointed questions. When faced with the task of gathering cancer information either for oneself or for a family member, the Internet provides an instantaneous, inexpensive, and voluminous source of information. Valuable information resources are available on Web sites, e-mail services, news and usenet groups, and online discussion groups to anyone seeking information on cancer, whether the focus of the search is on treatment, prevention, screening, or support. An increasing number of cancer-oriented Web sites offer significant opportunities for individuals to profile themselves so that they can tailor information on the site to meet specific needs and preferences.

However, as Internet access and Web site development tools have become basic software for computer systems, anyone with a computer, an Internet connection, and the appropriate software can create a Web site, a fact with staggering implications for the amount and quality of medical information available to consumers. A search on the term “cancer” via any of the popular Web search engines retrieves more than 2,000 Web sites offering cancer information from one of the more than 20,000 health-related Web sites.<sup>8</sup> For patients and the lay public, the plethora of health information on the Internet often represents a mixed blessing. At present, the Internet is still an unregulated, uncensored medium. Information that is anecdotal, unreviewed, and undated can be found on many Web sites, e-mail services, and news and usenet groups. In an article on the accuracy of medical information on the Web, an oncologist searching the Web for information on Ewing's sarcoma found that 50% of the online material was irrelevant and 6% contained major errors. Inaccuracy of information is not the only cause for concern. Some health-oriented sites hawk health care products or refer users to e-commerce partners and then take a cut of the sales.<sup>9,10</sup> Some post information in an attempt to advance unproven approaches to disease management that are not medically or scientifically sound.

It can be difficult for a novice to determine whether the information is current, accurate, and complete unless the information provider clearly articulates the standards of quality that are being used for the inclusion of materials on the site and the criteria for linking to other Web sites. Users must prepare to take responsibility for making decisions about the value and applicability of the information, just as those using more traditional information sources do.

The National Cancer Institute (NCI) has always had a formal review process for the inclusion of content in its databases and information services.<sup>11,12,13,14</sup> and <sup>15</sup> It has established a formal process for ensuring that its Web site only provides hypertext links to Web sites that are accurate, useful, and current, and it provides information on how to evaluate electronic information ([Table 60-1](#)).<sup>16,17</sup> Other medical information providers have begun to recognize the need to take responsibility for ensuring that patients are not exposed to bogus and potentially harmful cancer information by using criteria for selecting information they disseminate.<sup>18,19,20,21,22,23</sup> and <sup>24</sup> To help users determine what Web sites are credible, the Health on the Net Foundation has established criteria for evaluating Web sites ([Table 60-2](#)).<sup>25,26</sup> The principles embodied in these criteria have been widely adopted by credible health-related Web sites.

**TABLE 60-1.** Cancer-Oriented Web Sites

Criteria	Description
Authorship	Authors and contributors, their affiliations, and relevant credentials are provided. Medical and health professionals (per medical and health advice)
References	References and sources for content are clearly listed and relevant copyright information is noted. The site requires citation with clear reference to scientific research results or published articles.
Disclosure	The site has a clear statement about the funding for the site. Web site "soliciting" should be prominently and fully disclosed (e.g., sponsorship, advertising, underwriting).
Contact	Hours of posting and updates are indicated. The last update date is clearly displayed. The site's Web page displays the contact e-mail address of the webmaster or a link to e-mail pages.
Linkage site	An accurate description of the link site's content, size, and location is provided. The site and its linkages respect the legal requirements of medical information and privacy that apply. The information from other sources with a link is valid and regularly updated.
Other unique or innovative features	In addition, other variables that might be useful, such as interactive or educational, surveys, and search options, might make it a user-friendly site.
Peer-reviewed journals	Is there an editorial board or review process for the information included?

**TABLE 60-2.** Health on the Net Criteria for Site Evaluation

As profiling of users becomes a more common feature of interactive health communication, understanding a site's position on the confidentiality of personal information is becoming increasingly important. Users should determine what personally identifiable information is collected from them by the Web site; how the information will be used; with whom the information may be shared; what<sup>27</sup> choices they have regarding the collection, use, and distribution of the information; the kind of security procedures that are in place to protect the loss, misuse, or alteration of information; and how they can correct any inaccuracies in the information. TRUSTe is an independent, nonprofit initiative whose mission is to build trust and confidence in the Internet by promoting these principles of disclosure and informed consent. Many health-related sites explicitly state their privacy policy or display the TRUSTe mark.

### NATIONAL CANCER INSTITUTE'S INFORMATION SERVICES

For more than two decades, the staff of NCI's International Cancer Information Center (ICIC) have striven to meet the challenge of assisting health professionals and the public to effectively use current medical knowledge by providing current, high-quality information through a variety of media. The primary information resources are Physician Data Query (PDQ), a comprehensive database of current, peer-reviewed syntheses of state-of-the-art information on cancer care (<http://cancer.net.nci.nih.gov/pdq.html>), and CANCERLIT, a comprehensive source of bibliographic citations on published cancer research (<http://cancer.net.nci.nih.gov/cancerlit.html>). These databases are distributed through a variety of media, including CancerFax, one of the first fully automated fax-back services; CancerMail, an automated e-mail service; and CancerNet (<http://cancer.net.nci.nih.gov>), an Internet Web site that provides point and click access to NCI's information resources and has become a primary mechanism for disseminating PDQ and CANCERLIT information. These information resources undergo well-established peer-review processes that draw on a broad base of cancer experts to ensure that content is current and accurate. These systems are updated on a monthly basis, which ensures that users are provided with more current information than can be provided by most hard-copy publications.<sup>9,10,11,12,13 and 14</sup>

### PHYSICIAN DATA QUERY

PDQ, the NCI's comprehensive cancer information database, first became available to health professionals in 1984.<sup>9,10,11 and 12</sup> It is unique in the fact that its content is developed based on systematic reviews of the medical literature and expert opinion. Five editorial boards synthesize information from the literature into concise, clear summaries that are updated on a regular basis.

PDQ consists of three main types of information: (1) literature-based, full-text summaries that reflect current, state-of-the-art information on the treatment of adult and pediatric malignancies, the prevention and screening of cancer, the supportive care for cancer and its complications, and cancer genetics; (2) summaries of clinical trials currently accruing patients and those that are closed or completed; and (3) directories of physicians who provide cancer care and listings of health professionals who provide services related to cancer genetic risk assessment, counseling, and testing.<sup>13,14</sup>

### Cancer Information Summaries

**TREATMENT OPTIONS.** PDQ contains treatment information on all major types of cancer in children and adults, including autoimmune deficiency syndrome-related cancers (<http://cancer.net.nci.nih.gov/treatment.html>). For each cancer, a detailed summary, designed to meet the information needs of health professionals, is provided that contains an overview, information on staging, and information on treatment options by important disease-specific parameters (e.g., stage, histology, anatomic location). Key citations to the literature are referenced to enable users to see the research data on which the texts of the PDQ summaries are based. Users can retrieve abstracts of these citations for review. Levels of evidence are provided for each summary ( [Table 60-3](#)). A limited number of brief summaries on more rare cancers are also available. In addition, PDQ provides treatment summaries that contain similar information written in nontechnical language for patients and their families. All of the summaries are available in English and Spanish.

Rank	Type of Evidence
Strength of study design (ranked in descending order of strength)	
I.	Randomized controlled clinical trial(s)
i.	Double-blind level
ii.	Nonblinded (allocation schema or treatment delivery)
II.	Nonrandomized controlled clinical trial(s)
III.	Case series
i.	Population-based, consecutive series
ii.	Consecutive cases (not population-based)
iii.	Nonconsecutive cases
Strength of end points (ranked in descending order of strength)	
A.	Total mortality (or overall survival from a defined point in time)
B.	Cause-specific mortality (or cause-specific mortality from a defined point in time)
C.	Carefully assessed quality of life
D.	Indirect surrogates
i.	Disease-free survival
ii.	Progression-free survival
iii.	Tumor response rate

**TABLE 60-3.** Levels of Evidence for Therapeutic Benefit from Treatment Interventions

**COPING WITH CANCER.** PDQ contains summaries on issues that relate to coping with the management of side effects of cancer treatment, complications caused by

cancer, and the psychosocial aspects of cancer and its treatment (<http://cancer.net.nci.nih.gov/coping.html>).

**SCREENING AND PREVENTION.** The screening information in PDQ includes summaries on screening for breast, cervical, colorectal, endometrial, gastric, liver, lung, neuroblastoma, oral, ovarian, prostate, skin, and testicular cancers (<http://cancer.net.nci.nih.gov/testing.html>). Each summary contains the available data concerning screening for that particular disease site, the levels of evidence for that summary, and the significance and evidence of benefit for the summary statement ([Table 60-4](#)). They include references to the current literature that support the information in the summary. In addition, PDQ contains a version of the summary on screening for breast cancer written for non-health professionals.

- 
- Evidence obtained from at least one randomized controlled trial
  - Evidence obtained from controlled trials without randomization
  - Evidence obtained from cohort or case-control analytic studies, preferably from more than one center or research group
  - Evidence obtained from multiple-time series, with or without intervention
  - Opinions of respected authorities based on clinical experience; reports of expert committees
- 

**TABLE 60-4.** Levels of Evidence for Physician Data Query/CancerNet Screening Summaries

PDQ also contains summaries on the prevention of breast, cervical, colorectal, endometrial, gastric, lung, oral, ovarian, prostate, and skin cancer ([http://cancer.net.nci.nih.gov/genetics\\_prevention.html](http://cancer.net.nci.nih.gov/genetics_prevention.html)). Similar in format to the PDQ information on screening, these summaries contain level(s) of evidence of the supporting research ([Table 60-5](#)).

- 
- Evidence obtained from at least one randomized controlled trial with:
    - A cancer mortality end point
    - A cancer incidence end point
    - An accepted validated nonendocrine end point
  - Evidence obtained from controlled trials without randomization with:
    - A cancer mortality end point
    - A cancer incidence end point
    - An accepted validated nonendocrine end point
  - Evidence obtained from cohort or case-control analytic studies, preferably from more than one center or research group with:
    - A cancer mortality end point
    - A cancer incidence end point
    - An accepted validated nonendocrine end point
  - Evidence obtained from multiple-time series, with or without intervention, with:
    - A cancer mortality end point
    - A cancer incidence end point
    - An accepted validated nonendocrine end point (e.g., large adenomas, colon polyps, or colorectal precancers)
  - Ecologic studies (observational) (e.g., interventional genetic studies, migration studies) with:
    - A cancer mortality end point
    - A cancer incidence end point
    - An accepted validated nonendocrine end point (e.g., large adenomas, colon polyps, or colorectal precancers)
  - Opinions of respected authorities based on clinical experience, or reports of expert committees (e.g., use of the above study designs using unvalidated surrogate end points)
- 

**TABLE 60-5.** Levels of Evidence for Physician Data Query/CancerNet Prevention Summaries

**CANCER GENETICS.** An editorial board was established in 1998 to address issues that relate to the impact of research in cancer genetics on cancer prevention, screening, and treatment strategies ([http://cancer.net.nci.nih.gov/genetics\\_prevention.html](http://cancer.net.nci.nih.gov/genetics_prevention.html)). An overview of cancer genetics and the genetics of breast and ovarian cancer are currently available. Summaries on the genetics of colorectal and prostate cancer, the elements of cancer risk assessment and counseling, and the multiple endocrine neoplasia type 2 syndrome are in preparation.

**COMPLEMENTARY AND ALTERNATIVE APPROACHES.** In collaboration with the National Institutes of Health's National Center for Complementary and Alternative Medicine, ICIC staff are preparing evidence-based summaries on nontraditional approaches to cancer prevention, treatment, and symptom control. An advisory board composed of oncologists and representatives of the complementary and alternative medicine community review the summaries to ensure that they are accurate, informative, up to date, and well balanced. Summaries on cartilage and hydrazine sulfate are currently available, and summaries on Laetrile, antineoplastons, essaic, MTH-68 (Newcastle disease virus), 714-X, green and black tea, coenzyme Q10, mistletoe, IP-6 (inositol hexaphosphate), Cancell, and *Coriollus versicolorare* are in preparation (<http://cancer.net.nci.nih.gov/treatment.html>).

**Peer Review: The Process**

The information in PDQ is reviewed by five core editorial boards, each handling one of the following topics: adult treatment, pediatric treatment, supportive care, screening and prevention, and cancer genetics. These core boards are comprised of more than 80 cancer specialists who meet regularly to review the current literature and to update PDQ summaries based on scientific data. Most (67%) are not government employees. Each core board is supplemented by an external advisory board that reviews summaries annually. More than 100 additional health professionals with expertise in cancer screening, prevention, treatment, genetics, coping, and complementary and alternative care serve on these advisory boards.

A process has been developed to assist board members to efficiently identify literature with important new data. Each month, more than 80 biomedical journals are screened by professionals who identify citations of potential relevance. The boards may also review papers submitted for consideration by investigators, including important, but unpublished, manuscripts that have been accepted for publication.

After the articles are screened, those considered the most relevant and significant are sent to appropriate board members for review. If the board members believe the data warrant a change in a state-of-the-art summary, the manuscript is put on the agenda of an upcoming board meeting. At the meeting, members discuss the positive and negative points of the research and make decisions about whether to modify summaries based on the data. Changes may involve the addition of a new management option, the deletion of one that is no longer supported by data, the integration of new data that lend additional support to existing options, or an interpretation of controversial data. Literature citations are provided for each option so that users can make their own assessment of the current literature. Users can link to these citations as well.

**Use of Formal Evidence-Based Criteria in Physician Data Query/CancerNet**

Editorial board members understand the volume of medical knowledge and the increased emphasis on physician accountability and cost-effective practice. In an attempt to assist health professionals to apply data from the medical literature in clinical practice, all of the editorial boards have moved from a consensus development approach to summary development to an evidence-based approach to evaluating the literature and summarizing it. The practice of developing evidence-based summaries of the existing literature enables the editorial boards to draw attention to significant gaps in medical evidence that are important to consider in making patient management decisions.<sup>28,29</sup> Pointing out these gaps is not only important for health professionals and patients in decision-making decisions; it also helps to define areas that are most in need of additional research.

Evidence-based criteria have been used exclusively by the screening and prevention board to develop and refine screening and prevention summaries since the board's inception. This approach has proven to be useful in the consideration of scientific data on cancer screening and prevention and has proven to be well suited to the presentation of controversial information. Evidence-based methodology allows editorial board members to summarize the information currently available on a particular topic and to indicate the strength of that evidence. Annotations on the strength of the evidence for a particular approach afford the user a good

understanding of the intervention and the strength of the data supporting it (see [Tables 60-3](#), [Tables 60-4](#), and [Tables 60-5](#)).

In therapeutic studies, a variety of end points may be measured and reported. These end points include total mortality (or survival from the initiation of therapy), cause-specific mortality, quality of life, or indirect surrogates of these three outcomes, such as disease-free survival, progression-free survival, or tumor response rate. End points may also be determined within study designs of varying strength, ranging from the gold standard (the randomized, double-blinded, controlled clinical trial) to case series experiences from nonconsecutive patients. The adult treatment editorial board uses a formal ranking system of levels of evidence to help the reader judge the strength of evidence linked to the reported results of a therapeutic strategy. For any given therapy, results can be ranked on each of the following two scales: (1) strength of the study design and (2) strength of the end points. Because studies or clinical experiences are ranked both by strength of design and importance of end points, a given study has a two-tiered ranking [e.g., I(ii)/A for a nonblinded randomized study showing a favorable outcome in overall survival, and III(iii)/D(iii) for a phase II trial of selected patients with response rate as the outcome]. Thus, the two rankings give an idea of the overall strength of evidence (see [Table 60-3](#)).

In addition, all recommendations try to take into account other issues that cannot be so easily quantified, such as toxicity, width of confidence intervals of observations, trial size, quality assurance in the trial, and cost. Depending on their perspectives, different expert panels, professional organizations, and individual physicians may use different cut points of overall strength of evidence in formulating therapeutic guidelines or in taking action. <sup>30</sup> Nevertheless, this ranking system does provide an ordinal categorization of strength of evidence as a starting point for discussions of study results, and the formal descriptions of the levels of evidence provide a uniform framework for the data. The editorial boards are currently integrating information on the levels of evidence into the summaries as they review and update summaries.

PDQ's state-of-the-art summaries are dynamic and can be updated as frequently as each month. On average in 1999, 15% of the summaries were revised each month. Approximately 90% of the changes were revisions of the summaries, and approximately 30% of the summaries underwent substantial revisions. All licensees are required to ensure that the information a user prints from PDQ is dated so that it is clear to the user when the information was retrieved from the database.

### **Physician Directory**

The PDQ physician directory contains names, addresses, and telephone numbers for more than 25,000 physicians who devote a major portion of their practice to the treatment of cancer patients. Also included is information on medical specialties, oncologic subspecialty board certification, and organizational affiliations for each of these physicians. Physicians listed in the membership directories of major oncologic societies or organizations and clinical investigators who have protocols in PDQ or are members of NCI-sponsored clinical trials groups are also listed in this directory.

### **Organization Directory**

The PDQ organization directory contains information on more than 3000 health care institutions that provide care for cancer patients, including NCI-designated comprehensive and clinical cancer centers, community clinical oncology programs, clinical trial groups, and members of the Association of Community Cancer Centers. Information on organizations is retrievable by any combination of name, city, state, country, or zip code. These directories are not yet available through CancerNet.

### **Cancer Genetics Services Directory**

Cancer Genetics Services (<http://cancer.net.nci.nih.gov/genesrch.shtml>) is a directory of approximately 300 health professionals of various disciplines, such as genetic counseling, oncology, nursing, psychology, social work, and clinical genetics, who provide services related to cancer genetics, including cancer risk assessment, genetic counseling, and genetic susceptibility testing. Each individual listed must be licensed, certified, or eligible for board certification in their profession; have specific training in cancer genetics; and be affiliated with an interdisciplinary team with substantial expertise in cancer genetics. They must also be members of one of the professional organizations listed on the application for inclusion in the directory ([http://cancer.net.nci.nih.gov/genetics/gc\\_application.html](http://cancer.net.nci.nih.gov/genetics/gc_application.html)) and be willing to accept referrals.

### **Clinical Trials**

PDQ and CancerNet contain more than 1700 summaries of clinical trials that are open or approved for patient accrual (<http://cancer.net.nci.nih.gov/trialsrch.shtml>). Treatment, screening, prevention, and supportive care protocols supported by the NCI are listed in PDQ. Each can be retrieved by diagnosis, stage, treatment modality, phase of investigation, location, and drug name, or any combination of these and other parameters. Approximately 45% of the active trials in PDQ are not directly sponsored by NCI and are submitted voluntarily by the study chairperson; 10% are submitted by the pharmaceutical industry. Criteria for including voluntary submissions include whether the study design is reasonable, whether the trial is based on rational scientific information, whether the trial is likely to yield some useful information or is unduly risky to patients, and whether the entry criteria and statistical section are clear and complete. Trial summaries can be submitted to CancerNet online (<http://cancer.net.nci.nih.gov/protosub/protocol.html>). CancerNet's trial summaries can also be found on ClinicalTrials.gov (<http://www.clinicaltrials.gov>), a Web site developed by the National Library of Medicine to provide patients, family members, and members of the public information about clinical research studies currently under way for anyone with a life-threatening disease. Collaboration with U.S. Food and Drug Administration and other National Institutes of Health staff to encourage submissions from the pharmaceutical industry is ongoing.

A member of the clinical trials review editorial board reviews protocols voluntarily submitted by investigators who are not directly supported by the NCI before their inclusion. Phase II and III trials that have been submitted to the Food and Drug Administration under the investigational new drug application regulations do not require further editorial review. Foreign clinical trials are included after the review process of the sponsoring organization is approved by the PDQ editorial board. If the clinical trials editorial board finds a reason not to include a trial in PDQ and CancerNet, a letter containing the board's concern(s) is sent to the investigator, who is invited to respond by either modifying the protocol document according to the reviewers' comments or by clarifying the information in the protocol document. Once a response is received from the investigator, the protocol is re-reviewed by the clinical trials review board. More than 90% of the trials submitted for review are included.

An archival file of more than 10,800 closed protocols provides a rich source of data on previously completed clinical research, some of which is not published and is not available elsewhere. Whenever possible, ICIC staff link the protocol summaries to published reports on trial outcomes.

Since 1996, PDQ and CancerNet also has contained consumer-oriented summaries of active clinical trials. On CancerNet, the technical terms in each summary are hyperlinked to a glossary. The technical and consumer-oriented trial summaries are also linked to one another.

Since April 1998, NCI staff has provided additional contextual information on clinical trials on its cancerTrials Web site (<http://cancertrials.nci.nih.gov>). The site was established to raise awareness about clinical trials and to address some of the perceived barriers to participation. The information contained on cancerTrials falls into the following categories: a framework for understanding what clinical trials are and deciding about participation; information about clinical research grouped by type of cancer; information on how to find trials, which features a hyperlink to the CancerNet clinical trials search form (<http://cancer.net.nci.nih.gov/trialsrch.shtml>); news and features highlighting topics under clinical investigation and trial results; and resources for researchers, such as a library of downloadable resources for clinical investigators that includes templates, guidelines, and policy documents. Information on specific cancers features hypertext links to the cancer information summaries in PDQ on CancerNet, as well as news about clinical trials.

### **CANCERLIT**

CANCERLIT is a bibliographic archival database containing more than 1.5 million citations and abstracts of published research in cancer biology, etiology, screening, prevention, and treatment published from 1963 to the present from more than 4000 different sources. It is updated monthly and provides a comprehensive, up-to-date resource of cancer literature. Preformulated search "digests" for more than 90 clinical topics are also available (<http://cancer.net.nci.nih.gov/canlit/canlit.htm>). The complete database can be searched on CancerNet (<http://cancer.net.nci.nih.gov/cancerlit.shtml>).

### **Access to Physician Data Query, CancerNet, and CANCERLIT**

The CancerNet Web site has become NCI's primary dissemination vehicle for PDQ and CANCERLIT data. At the end of 1999, monthly user statistics documented more than 9 million "hits" (2 million page views) in more than 400,000 user sessions per month. In addition to its own distribution outlet, staff manage a licensing

program that allows for use of the databases by a variety of commercial and nonprofit distributors. Through a trademark license, these distributors deliver PDQ and CANCERLIT data to worldwide audiences through a variety of media. The mechanisms fall into two general categories: online time-sharing systems with dial-up or Internet access; and "local" implementations in which the database resides on a computer, CD-ROM, kiosk, or local area network. CANCERLIT is also available online through a variety of commercial database vendors as an online or CD-ROM product. The program began in 1982 with one agreement, has grown to 72 agreements (39 for PDQ, 15 for CANCERLIT, and 18 for CancerMail), and continues to grow. All new requests to license are reviewed and evaluated on the following criteria:

- Does the organization share NCI's goal of disseminating and sharing cancer information?
- What is the impact of the organization's efforts?
- Would licensing the information to the organization enable ICIC to reach a larger or new audience?
- Is the organization willing and able to update the information monthly and provide ICIC with user feedback and statistics?

Licensing efforts include partnerships with vendors that produce Web sites and public kiosks with credible health information, as well as those that are developing health information "portal" sites.

### ***Toll-Free Search Services***

One of the problems faced by those responsible for disseminating health care information is how to make it easily accessible to people without direct personal access to the technology. The Cancer Information Service (CIS) is an NCI-supported nationwide network of 14 regional offices located at 34 sites in the United States, Puerto Rico, and the U.S. Virgin Islands. Through its toll-free telephone service (1-800-4-CANCER) and Web site (<http://cis.nci.nih.gov>), certified information specialists trained by the NCI use a variety of printed and computer resources to provide accurate, up-to-date information on cancer. In 1999, the CIS responded to more than 890,000 calls from patients, family members, health professionals, and the general public. More than 300,000 inquiries came over the Internet, and 17% of callers reported that they obtained the toll-free number from the Internet. CIS staff conduct customized searches of PDQ and make more than 100,000 referrals to clinical trials from PDQ each year. Staff also interpret research findings; explain diagnostic and treatment information; inform callers about emerging areas of science, such as hereditary risk; clarify media stories about scientific discoveries; and provide smoking cessation counseling.

The CIS makes available nearly 600 publications and materials on a range of topics, including treatment information and research studies, specific types of cancer, community services, screening tests and examinations, adopting healthier behavior, coping with cancer, and cancer risk. The CIS offers printed and audio-visual materials that are easy to read and culturally appropriate; materials are also available in Spanish. A Web-based publication-ordering service is available (<http://publications.nci.nih.gov>).

Each year, the CIS Partnership Program assists 4500 organizations that serve minority and medically underserved populations within their communities. CIS staff provide partners with access to the latest, most accurate cancer information; assist with coalition building and networking; offer program planning, implementation, and evaluation assistance; provide media assistance; identify resource experts; and assist with training. Efforts involve breast and cervical cancer, tobacco education, science awareness, and overcoming barriers to clinical trial participation.

The CIS serves as a health communications laboratory through an NCI-funded research consortium. CIS staff are involved in studies that test and identify the most effective ways to communicate health information to help people adopt healthier behaviors. These studies have evaluated types of information messages provided, the manner in which they are delivered, how often messages should be communicated to affect health behaviors, and the value of tailoring messages to an individual's particular perspective.<sup>31</sup>

The CIS intends to apply the strengths of the telephone service to the Internet and plans to provide real-time interactions over the Web to position the CIS as the world's premier cancer information navigator. Under development is instant messaging, Web-based tailoring, Webcasting, an interactive voice response system for the publication ordering, and an interface with mobile wireless digital devices.

### ***Physician Data Query/CANCERLIT Service Center***

The PDQ/CANCERLIT Service Center provides customized searches from the NCI's PDQ database to health professionals, who can request and receive information through a toll-free telephone service, e-mail, or facsimile. The goal of the service center is to make the information from PDQ available to health professionals who do not have the time or resources to access electronic systems directly. The service center can be reached by calling toll-free 1-800-345-3300 (in the United States), Monday through Friday, 9 a.m. to 6 p.m. Eastern time. Alternatively, requests can be faxed to 1-800-380-1575 or sent via e-mail to [pdqsearch@icicc.nci.nih.gov](mailto:pdqsearch@icicc.nci.nih.gov). More information on the search center can be found on the Web site.

### **PHYSICIAN DATA QUERY/CANCERNET REDESIGN**

In mid-1990, ICIC staff recognized that the infrastructure supporting PDQ, CancerNet, CancerFax, and CancerMail was old and obsolete. The legacy system had become increasingly difficult to adapt for cutting edge information technology. It could only produce simple text (ASCII data) and could not support commonplace features, such as metatags, that make information easier to find on the Internet. Production processes were also hampered by a paper-based workflow/document management system used to identify, track, process, and update more than 480 peer-reviewed information summaries from more than 80 core editorial board members, many of whom receive materials for review every month.

In 1998, ICIC staff embarked on an initiative to restructure the infrastructure to take full advantage of advances in computing technology. A 2-day formal needs assessment was performed in February 1998 to identify functional requirements for the new system. This meeting provided an opportunity for more than 190 patients, advocates, clinical investigators, practicing oncologists, oncology nurses, librarians, health educators, social workers, and other health professionals, as well as experts in medical and consumer informatics and representatives from the pharmaceutical and insurance industries, to advise NCI on what should be included in the new system. Participants in the meeting provided specific input on the range of content, ease of navigation, user interface issues, use of current and emerging technologies, and barriers to access. Operational, marketing, and evaluation issues were also discussed. The recommendations were used to develop the specifications for a more robust and flexible system that could accommodate real-time updates and multimedia data and provide advanced concept search capabilities. Participants also directed NCI to develop evaluation strategies to ensure that user feedback is obtained on an ongoing basis and that enhancements are integrated and reevaluated in an iterative fashion.

Fundamental to the redesign initiative was the development of a flexible and scalable infrastructure to support a dynamic, broad-based, and modular information system. To meet this need, ICIC computer specialists developed a universal database (UDB) server that is both a repository and a powerful retrieval engine. It also contains pointers to data located in other databases and Web sites. The power of the UDB enabled ICIC staff to develop a flexible and scalable new user interface to CancerNet. The UDB allows users to search across different data types with a single query and obtain information on a specific topic from resources in Web sites and databases produced and maintained by other divisions, institutes, and organizations. The UDB links and organizes on the fly related documents for users to review, supports multiple dissemination media and delivery mechanisms, and can accommodate future delivery mechanisms with the addition of new access modules that will not require changing the system's infrastructure. Also under development is a new workflow/document management system that will enable ICIC staff to streamline the review and updating of peer-reviewed summaries and provide users with real-time updates to CancerNet as soon as quality control procedures are complete.

Additional research and development is under way and includes instant messaging; the development of a CancerFax system that does not require handsets on facsimile machines; CancerVoice, an automatic text-to-speech conversion and speech recognition system that will permit the physically challenged and those without access to computers, fax machines, or the Internet to access CancerNet information via the telephone; audio supplements that will enable CancerNet users to simultaneously see and hear information, a feature that will be beneficial for the elderly and vision-impaired; a Web-based protocol assembly application that will permit online clinical trial protocol submission, review, and updates; content enhancements that will provide information in additional levels of technical detail; intelligent software tools that will enable ICIC staff to customize output in response to user requests, download information to hand-held wireless communication devices, and dynamically link terms requiring explanation to the glossary; search wizards to help users find information; and improved indexing that will enhance search functionality. The UDB will enable ICIC staff to metatag each section of more than 480 PDQ information summaries as "independent" documents with unique identifiers, indexes, and links, so that it can compile responses on the fly that are precisely tailored to a user's requests. This feature will also enable ICIC staff to provide advocacy organizations serving highly focused audiences with information on specific cancers and import trial summaries from trusted partners for

distribution, eliminating the need to duplicate their efforts.

Another core principle is that this new information infrastructure will be tightly integrated into the NCI clinical trials system, an apparatus that is undergoing change. Staff are working in other NCI offices to develop a comprehensive cancer informatics infrastructure that will support secure access to systems for electronic submission, review, manipulation, and updating of clinical trials data. The development of such resources will facilitate the rapid and efficient communication of information across systems and among the various components of the National Cancer Program.<sup>32</sup>

The NCI designated health communication as one of the extraordinary opportunities for investment in the bypass budget for 2001. ICIC staff are active participants in the development of a comprehensive strategy for funding research in cancer communications and developing strategies for improving access and use of cancer information regardless of race, ethnicity, health status, education, income, age, gender, or geographic area.<sup>4</sup>

### Site Design

In a study of 15 large Web sites, users clicked away in frustration, complaining that they could not find the information they sought 58% of the time.<sup>33</sup> Despite attractive graphic identities and volumes of valuable content, these sites did not provide intuitive access to information because the information architecture did not assist users in finding information quickly and easily. Often, the site architecture is confusing because the developers did not obtain user input on the organization of information; hierarchy and layout of menus; ease of navigation; usability of search forms, site indexes, and instructions for users; and the overall graphic design of the system.

To ensure that the new CancerNet Web site would not fall prey to such problems, ICIC staff made use of emerging research on Web site usability engineering. The principles of usability engineering provide guidance on overall Web site design, navigation, and functionality. Usability engineering assists Web designers in achieving their objectives by requiring them to identify and focus on the goal of the Web site, the needs of the target audience, and the technical constraints that a typical user faces with regard to hardware, software, access, and experience *before* developing the Web site. It is a cost-effective technique that eliminates the need to build a site until key components of its functionality are evident from user input.

An integral part of the redesign was the prospective gathering of data on the information needs of the full spectrum of current and potential users. An online questionnaire provided input from more than 600 individuals; 37% were accessing the site for the first time, 23% were looking for information on a specific cancer, and 11% were seeking clinical trial information. After this stage, personal interviews were conducted with current and potential users to further define their information requirements. Based on this feedback, the first prototype was constructed and then subjected to iterative evaluations with current and potential users to see if their needs were being served by the prototype. Test participants representing the various target audiences were recruited to search for information in response to a series of specific questions. While attempting to find the information required to answer the questions, test participants were asked to "think out loud" so that their thought processes could be captured and recorded on videotape to identify flaws in terminology, layout of information, hierarchy, menu structure, and navigational elements. The process proved to be an effective method of validating the information architecture and drove the redesign process. For example, usability tests conclusively documented that there was no single preferred way to search for information. Therefore, the new site was designed to permit users to find information in multiple ways, with each path linking to the same page, so that a primary document exists in only one place on the Web site.

In November 1999, ICIC staff launched the first version of the redesigned CancerNet Web site. One of the things that ICIC staff were most proud of was the fact that the new site was built with user input at every stage of development. Major enhancements include a new user interface that makes site navigation easy; cancer-specific pages that provide ready access to all of the information on the site about that cancer (<http://cancernet.nci.nih.gov/cancertypes.html>); powerful new search capabilities (<http://cancernet.nci.nih.gov/searchoptions.html>); a network of hyperlinks between PDQ summaries, clinical trials, and CANCERLIT citations; a guide for first time visitors with hyperlinks to the information described (<http://cancernet.nci.nih.gov/firsttime.html>); a site map; a dictionary of more than 1200 medical terms; a greatly expanded list of hyperlinks to other cancer-related Web sites; and a publication locator that allows users to view and download NCI publications or order them by e-mail. Updates on new enhancements, content, search tools, and other changes are featured in a What's New area (<http://cancernet.nci.nih.gov/whatsnew.html>). This area also will be used to highlight feedback from users, enable them to automatically receive updates on enhancements to CancerNet, and sign up for the CancerNet listserv. Feedback from this area and iterative usability testing will continue to drive development and implementation activities.

Multiple approaches for increasing awareness about the new site are being used to heighten the visibility of CancerNet as a primary source for high-quality cancer information, including a robust system of metatags, an e-mail notification service for users, and reciprocal linking agreements with other Web sites. Licensing efforts include partnerships with vendors who produce kiosks and those developing health information "portal" sites. ICIC staff will also continue to work with public libraries to increase awareness and use. CancerNet information is featured in MEDLINE *plus*, the National Library of Medicine's health and medical information service for the public (<http://www.nlm.nih.gov/medlineplus>).

The "reinvention" of PDQ represents more than the mere updating of PDQ's content or the elaboration of new technologies. At a fundamental level, the redesign involves a complete rethinking of how technology products such as PDQ should be designed and maintained over time through a process of continuous refinement.<sup>34,35</sup> The phases of product conceptualization, development, testing, and dissemination are no longer thought of as being consecutive; rather, all of these phases overlap by design. Consumer input throughout product conceptualization helped to focus the developers. Continuous feedback from consumers during early stages of product development helped to inform and reshape the initial conceptualization, sometimes in dramatic departures from the site as originally conceived. Continued usability tests will provide additional input and result in further refinements and enhancements that are driven by continuous consumer review of blueprints and prototypes before new versions and major refinements are implemented and marketed.

## CONCLUSION

The Internet will continue to revolutionize the way the world obtains and disseminates information, and rapidly advancing technology promises to continue to revolutionize the way that medicine is practiced. It is clear that computing and communication technologies have a major role to play in decision support in medicine. Medical students have access to huge collections of information and can participate in training sessions anywhere in the world. Collaborating physicians can share patient charts, laboratory results, and x-rays and other images without considering distance or time delays. However, legal considerations, such as malpractice liability, licensure, accreditation, and reimbursement for teleconsultation, remain to be addressed. With encryption authentication, some sites are already offering automated claims and payment services, and sensitive materials, such as digital medical records that contain digitized images and full-motion video clips, will cross the Internet, opening the doors for innovative patient evaluation and consultation, as well as remote assessment and monitoring of patients.

### DEFINITIONS

*Alternative medicine* is a somewhat contentious but generally accepted term that refers to a diverse assortment of philosophies, theories, and diagnostic, preventive, and therapeutic practices not generally viewed as arising from or belonging to the modern Western biomedical paradigm. Many of these interventions are used around the world by indigenous peoples of non-Western cultures as their primary form of health care.<sup>1</sup> However, in most developed countries, these practices generally are used along with conventional Western medicine. Consequently, the terms *complementary medicine* and *integrative medicine* are used often to acknowledge the blending of these world views and therapeutic approaches. The term *complementary medicine* can be used also to refer to conventional modalities used in unconventional ways or to achieve unconventional end points (e.g., psychosocial support groups to prolong cancer patient survival).

In April 1995, the National Institutes of Health Office of Alternative Medicine established a Panel on Definition and Description, charging it “to establish a definition of the field of complementary and alternative medicine (CAM) for purposes of identification and research; and to identify factors critical to thorough and unbiased description of CAM systems and practices that would be applicable to both quantitative and qualitative research.”<sup>2</sup> The panel defined CAM as follows:

Complementary and alternative medicine (CAM) is a broad domain of healing resources that encompasses all health systems, modalities, and practices and their accompanying theories and beliefs, other than those intrinsic to the politically dominant health system of a particular society or culture in a given historical period. CAM includes all such practices and ideas self-defined by their users as preventing or treating illness or promoting health and well-being. Boundaries within CAM and between the CAM domain and the domain of the dominant system are not always sharp or fixed.

Other authors prefer to define complementary therapy separately, believing that it encompasses practices that can be integrated with conventional medicine, whereas so-called alternative medicines often are promoted as independent therapeutic approaches not amenable to combination with conventional therapy.<sup>3,4</sup> Many other terms have been used to define this subject: *unconventional*, *unproved*, *unorthodox*, *unsound*, *nontraditional*, *holistic*, and *non-Western*. [Table 61-1](#) presents a partial list of CAM modalities used for the prevention or treatment of cancer, of cancer symptoms, or of conventional treatment side effects.

TABLE 61-1. Commonly Used Complementary and Alternative Medicine Modalities in Cancer

### PHENOMENOLOGY OF COMPLEMENTARY AND ALTERNATIVE MEDICINE IN CANCER

CAM usage by cancer patients is very prevalent all over the world ( [Table 61-2](#)). Recent surveys have reported CAM use by cancer populations in Austria,<sup>5</sup> Australia,<sup>6</sup> Finland,<sup>7</sup> Germany,<sup>8,9</sup> Italy,<sup>10</sup> the Netherlands,<sup>11</sup> Norway,<sup>12,13</sup> and <sup>14</sup> Taiwan,<sup>15</sup> the United Kingdom,<sup>16</sup> the United States,<sup>17,18,19,20,21,22</sup> and <sup>23</sup> and Canada.<sup>24,25,26,27</sup> and <sup>28</sup>

TABLE 61-2. Prevalence of Alternative Cancer Therapy Use among Cancer Patients

A systematic review of surveys of various cancer populations has given some validation to the general gestalt that the prevalence of CAM usage is increasing.<sup>16</sup> However, accurate assessment of trends in CAM usage by cancer patients is rendered difficult by the lack of consistency in the definition of CAM, by survey methodology, and by population demographics.

One study specifically attempted to gauge the change in prevalence of CAM use by cancer patients. Abu-Realh et al.<sup>29</sup> reviewed data from a subgroup of responders to the 1992 National Health Interview Survey to determine the growth in use of self-help therapies (e.g., relaxation exercises, imagery, humor, laughter, meditation, prayer, affirmations, self-hypnosis, and music, aroma, and color therapy) and psychosocial therapies (i.e., counseling and support groups). The authors compared the percentage of CAM users among individuals with diagnosed cancer prior to and after 1986 and found a 63% increase in use of those modalities (8.3% prior to 1986 vs. 13.6% after 1986).

The growth of general CAM usage in the United States has been investigated more thoroughly. Eisenberg et al.<sup>30</sup> reported results of a follow-up to their 1990 survey<sup>31</sup> of the American public for CAM use. The 1997 survey found that 42% of the interviewed participants had used at least one CAM modality in the last 12 months. Of the CAM users, 46% had at least one visit to an alternative medicine practitioner. These figures were significantly greater than the 34% overall CAM usage and the 36% of those visiting an alternative medicine practitioner reported in the 1990 survey. These surveys, and others from various countries, also found that CAM use was more prevalent among younger patients<sup>5,26,28</sup> and those with higher education<sup>18,19,26</sup> and higher income.<sup>18,28</sup>

The largest survey of CAM use by U.S. cancer patients was reported by the American Cancer Society in 1992.<sup>32</sup> Telephone interviews of approximately 36,000 households across the nation led to the identification of a group of 3272 living individuals who had had a cancer other than a nonmelanomatous skin cancer. Approximately two-thirds of these patients were interviewed, and information about the other one-third was obtained from family members. The authors found that 9% of cancer patients used CAM and that subpopulations of patients with certain tumor types had rates as high as 21% (e.g., brain cancer).

Ernst and Cassileth<sup>16</sup> performed a comprehensive review of surveys of cancer patients' use of CAM. Surveys of cancer patients in various settings have yielded rates ranging from 9% to 91%. Selected surveys are summarized in [Table 61-2](#). The differences between the prevalence figures obtained likely are due to differences in the demographics of the populations, the definition of CAM, and the survey methodology.

Some recurring themes are seen across surveys. Most cancer patients who use CAM use more than one modality, often simultaneously.<sup>18,19,33</sup> Greater use has been noted among patients with advanced disease or a poor prognosis (or both).<sup>9,11,32,34</sup> Many studies have found that most users of CAM therapies for cancer judged them to be effective and were satisfied with their outcomes.<sup>10,19,24,27</sup>

Both similarities and some important differences are seen in the types of CAM modalities used by the general public, by individuals with a known noncancer illness, and by cancer patients. The most commonly used U.S. CAM modalities identified among patients with a variety of noncancer illnesses are chiropractic, relaxation, massage, herbal medicines, spiritual healing, and imagery.<sup>30</sup> Among U.S. and Canadian cancer patients, the modalities identified most frequently in the 1990s have been mind-body approaches (mediation, relaxation, hypnotherapy, visualization, and other imagery techniques); specialized diets and dietary supplements; herbal preparations; megavitamin therapy; and spirituality, prayer, and spiritual healing (see [Table 61-2](#)).

Two surveys reported the use of CAM approaches by pediatric cancer patients. Fernandez et al.<sup>24</sup> surveyed patients attending the only tertiary-care pediatric oncology center in British Columbia, Canada, and found that 42% of the patients in the study used a CAM modality, with herbal teas, plant extracts, relaxation therapy-imagery, and therapeutic vitamins being the most common. In a smaller study in the Netherlands,<sup>11</sup> 31% of the patients were using alternative treatments, with a greater rate of usage among the subgroup of relapsed patients (46%).

## REASONS FOR CANCER PATIENT USE OF COMPLEMENTARY AND ALTERNATIVE MEDICINE MODALITIES

Many patients use CAM approaches to “boost” the immune system,<sup>9,24</sup> but many also choose them with hopes of slowing the progression of tumors or ultimately obtaining a cure.<sup>24,26</sup> Even in a study of patients referred to a pain and symptom management clinic, most CAM users had used the modalities for a potential anticancer effect.<sup>26</sup>

Some observers have suggested that disease recurrence or progression is the primary trigger for patients to seek CAM therapies.<sup>35</sup> However, for many patients, the initial diagnosis of cancer raises enough concerns to investigate alternative or complementary modalities.<sup>18</sup> For some patients, experimentation with CAM modalities may be due to fear of the uncertainty of response to conventional therapy; for others, this choice may be simply an attempt to participate in the healing process.<sup>27</sup>

Burstein et al.<sup>16</sup> reported that new use of CAM among a group of women with recently diagnosed early-stage breast cancer correlated with significantly more depression, less sexual satisfaction, greater fear of recurrence, and somatic symptoms. The problems of low sexual satisfaction and fear remained at the 12-month observation point, but the other areas improved and were not significantly different from those of nonusers. The authors suggested that initiation of CAM use should alert clinicians to inquire about anxiety, depression, or physical symptoms.

## COMPLEMENTARY AND ALTERNATIVE MEDICINE THERAPIES

CAM therapies for cancer are legion, and many have multiple variations. In this section, some of the more prevalent therapies are described briefly, primarily from the standpoint of the published evidence. Other therapies are listed in [Table 61-1](#) with references for those not discussed here. For most of these approaches, definitive clinical trials to assess their potential efficacy have not been performed. For many others, their use continues despite results of randomized controlled clinical trials indicating no efficacy.

### ANTINEOPLASTONS

In the 1960s and 1970s, Dr. Stanislaw Burzynski reported the identification of small peptide molecules in the blood and urine of normal humans, which he called *antineoplastons*.<sup>36,37</sup> Burzynski postulated that these compounds were components of a natural anticancer defense system or “chemo-surveillance system”<sup>38</sup> and named them for the original designation of the urine fractions from which they were extracted. Antineoplaston A10 is a 1:4 ratio of phenylacetylisoglutamine and phenylacetylglutamine, and AS2-1 is a 1:4 ratio of phenylacetylglutamine and phenylacetic acid.<sup>39</sup>

Burzynski reported his clinical experience with antineoplastons in cancer patients.<sup>40,41</sup> and <sup>42</sup> However, as pointed out in a comprehensive review of the subject,<sup>43</sup> the use of unconventional definitions of response and the confounding factors of concurrent conventional therapies hamper the interpretation of the results of these studies. One study by a Japanese group<sup>44</sup> evaluated the toxicity, and preliminarily evaluated the response rates, of patients with various tumors to AS2-1 and A10. Some of these patients received concurrent chemotherapy. The authors reported responses in 3 of 46 measurable tumors but gave insufficient information about the patients to assess the role of antineoplastons in these responses.

In 1991, the National Cancer Institute (NCI) reviewed a series of seven case reports of patients with brain tumors treated with antineoplastons. The reviewers found that presumptive evidence of antitumor activity was demonstrated, and phase II trials were initiated.

A trial of patients with recurrent high-grade glioma was designed and initiated with significant input from Burzynski.<sup>39</sup> Nine patients were treated with AS2-1 and A10 in the study before accrual was halted, owing to an inability to reach agreement with the supplier of the antineoplastons on protocol modifications designed to increase accrual. None of the six assessable patients manifested a radiographic remission, and all had progressive disease within less than 10 weeks of starting treatment. A recent study of continuous infusion of phenylacetate alone in patients with recurrent malignant gliomas has revealed low-level activity (3 partial responses of 40 patients).<sup>45</sup>

### METABOLIC THERAPIES

## **Gerson Therapy**

A therapy for cancer and other illnesses was developed empirically by Max B. Gerson, a German-born physician, and was administered in his sanitarium during the 1930s, 1940s, and 1950s until his death in 1959.<sup>46,47</sup> Gerson sought to “balance” potassium and sodium, as their “imbalance” was thought to support tumor growth. His therapy consisted of a low sodium, high potassium, lactovegetarian diet that emphasized fresh vegetables and fruit juices and vitamin supplements. Frequent enemas, including coffee enemas, and injections of a liver extract also were part of the regimen. Raw veal liver juice was discontinued in 1987, owing to contamination with *Campylobacter fetus*.

In 1977, the Gerson Institute was founded and based in Bonita, CA. The Institute oversees a clinic in Tijuana, Mexico [Centro Hospitalario Internacional del Pacifico, SA (CHIPSA)] where the Gerson therapy is offered along with other adjunctive measures.<sup>48</sup>

A retrospective study of 235 melanoma patients treated from 1975 to 1990 at the CHIPSA clinic has been published.<sup>49</sup> This report evaluated the 5-year survival rates of the 153 patients for which adequate staging information was available and compared them to historical controls. The authors reported 100% survival for stage I and stage II disease and a 71% survival for stage III disease, comparing favorably with the historical control. Other researchers have claimed that the Gerson regimen is useful to palliate pain and diminish the side effects of conventional irradiation and chemotherapy.<sup>50</sup>

## **Macrobiotic Diet**

Apparently, the macrobiotic philosophy was developed by George Ohsawa (1893 to 1966) (also known as *Yukikazu Sakurazawa*), who first introduced his concepts to the United States in 1959. Subsequently, macrobiotic theories and practices were developed and promoted by Michio Kushi who, in 1978, founded the Kushi Institute. This establishment offers courses in physical and psychological health and in ecology, spiritual development, and world peace.

Originally, Ohsawa described 10 stages of diet designated -3 to +7. The +7 diet consisted of 100% cereals and was prescribed for short periods to patients with various illnesses, including cancer.<sup>51</sup> Reports of clinically significant vitamin and mineral deficiency states were reported with some versions of this diet.<sup>52,53</sup> However, the standard macrobiotic diet currently recommended by Kushi<sup>54</sup> is a better-balanced, high-complex carbohydrate, low-fat vegetarian diet that may include small amounts of seafood. Individuals consuming a macrobiotic diet have been found to have urinary levels of diphenolic phytoestrogens much higher than those of control groups of lacto-ovo vegetarians or omnivores.<sup>55</sup>

Two unreported retrospective studies of survival of patients with pancreatic and prostate cancer and a series of case reports were reviewed by the Unconventional Cancer Therapies Panel of the Office of Technology Assessment.<sup>51</sup> Despite this, no consensus of compelling evidence for activity was obtained.

## **Kelley-Gonzalez Regimen**

In the 1950s and 1960s, Dr. William D. Kelley,<sup>57</sup> a dentist from the Midwest, developed a theory of health and illness that classified people as metabolic types, with physiologies in which the activity either of the parasympathetic or of the sympathetic nervous system was dominant or the two were balanced.<sup>56</sup> He then prescribed diets ranging from purely vegetarian (for sympathetic types) to predominantly meat-containing (for parasympathetic types) to compensate for years of “wrong” diets that had resulted in illness. Kelley also believed that pancreatic proteolytic enzymes were secreted into the blood stream and acted as the body's first line of defense against malignancy.

The Kelley program for cancer treatment consists of six basic components: (1) the appropriate diet, (2) vitamin and mineral supplementation, (3) concentrates of raw beef organs and glands in pill form, (4) digestive aids, including pepsin, hydrochloric acid, bile, and various pancreatic enzymes, (5) frequent doses of proteolytic pancreatic enzymes between meals, and (6) a “detoxification” regimen that included frequent coffee enemas.<sup>57</sup>

Currently, variations of the Kelley regimen still are practiced by a few individuals in the United States. Dr. Nicholas Gonzalez has used this approach for several years and recently reported the results of a small prospective study in advanced pancreatic cancer patients.<sup>58</sup> Over the period of the study, 36 patients with pancreatic cancer were seen. Eleven of these patients were considered assessable, and the other 25 were deemed unassessable because they either did not start the regimen or stopped taking the therapy in less than 8 weeks (n = 13) or had one of six other exclusion criteria (n = 12). The patients had stage I to stage IV pancreatic cancer. All patients' tumors either were unresected or resected incompletely. The median survival was 17.0 months in the treatment group, compared to a literature control showing a 4- to 6-month median survival. A trial of this regimen versus gemcitabine in patients with advanced pancreatic cancer is under way at Columbia University.

## **BIOLOGICALLY BASED THERAPIES**

### **Cartilage (Shark and Bovine)**

Cartilage products of various sources long have been suspected of having anticancer activities and have been the subject of much lay literature. Frequently, shark cartilage is used by U.S. and Canadian cancer patients.<sup>19,24</sup> Estimates for 1992 maintained that more than 50,000 Americans used shark cartilage products.<sup>59</sup>

Some shark cartilage extracts and various isolated molecular species have *in vitro* antiangiogenesis and matrix metalloprotease inhibitor activity.<sup>60,61,62</sup> and<sup>63</sup> Evidence of oral bioavailability of the active components on a water-soluble shark cartilage extract has been demonstrated in a rat model.<sup>64</sup>

Reports of positive results from a Cuban trial of shark cartilage were aired on the television news magazine “60 Minutes” in 1994<sup>65</sup> but have not been followed by a published scientific article. Miller et al.<sup>66</sup> reported a phase I and II trial of a powdered shark cartilage product in which 60 patients with advanced, previously treated cancers were treated with 1 g/kg/d orally. The dose was increased to 1.3 g/kg if no response was seen after 6 weeks. No patient experienced a complete or partial remission, but 10 of 50 assessable patients had stable disease for at least 12 weeks. Another single-arm trial has been reported, but the results were confounded by the presence of concurrent conventional therapy.<sup>67</sup> Phase III trials of two oral shark cartilage products in advanced cancer patients are planned by the M.D. Anderson Community Clinical Oncology Program and the North Central Cancer Treatment Group.

Bovine cartilage has been administered either subcutaneously only<sup>68</sup> or both orally and subcutaneously.<sup>69,70</sup> Puccio et al.<sup>70</sup> reported 3 partial remissions in 22 metastatic renal carcinoma patients. Another study by Romano et al.<sup>68</sup> obtained one complete remission in nine patients with various types of tumors. The complete remission is reported to have been the resolution of lung metastases and a flank mass in a patient with metastatic renal cell carcinoma. This response had been continuous for 9 months when the trial was reported. The largest experience of human cancers treated with bovine cartilage was reported by Prudden.<sup>69</sup> He reported a 90% response rate (61% complete response) in 31 cases of a variety of malignancies.

### **Herbal Mixtures**

**ESSIAC.** The Essiac herbal mixture has been used widely in Canada since the 1920s. The original recipe for this mixture is said to have been developed by an Ojibwa healer and was given to Rene Caisse (*Essiac* is *Caisse* spelled backward), a nurse working in Ontario, Canada, by a woman who believed herself to have been cured of breast cancer through its use.<sup>71</sup>

The original recipe contained four main herbs: burdock root (*Arctium lappa*) (also used in the [Hoxsey treatment](#), discussed next in this chapter); Indian or turkey rhubarb (*Rheum palmatum*); sheep or sheepshead sorrel (*Rumex acetosella*); and the inner bark of slippery elm (*Ulmus fulva* or *Ulmus rubra*). Later, watercress (*Nasturtium officinale*), blessed thistle (*Cnicus benedictus* L.), red clover (*Trifolium pratense*), and kelp were added.<sup>72</sup> This mixture is manufactured by Essiac Products (New Brunswick, Canada) and is available directly from the manufacturer or, for Canadian patients, through the Emergency Drug Release Program of Health Canada.<sup>73</sup>

The individual herbal components of Essiac have been tested, and reports show varying activities despite the fact that certain purified chemical moieties from each of the herbs have reproducible antitumor activities.<sup>72</sup> To date, no published clinical trials have evaluated Essiac in cancer patients, but this product continues to be one

of the CAM anticancer therapies used most commonly by American and Canadian cancer patients.<sup>19,24</sup>

**HOXSEY TREATMENT.** The Hoxsey therapy is composed of a variety of herbal preparations made famous by Harry Hoxsey beginning in the 1920s. After attaining a wide-ranging popularity in the United States, a series of violations of U.S. Food and Drug Administration regulations resulted in the closing of the U.S. clinics and the export of the treatment to a CHPSA clinic in Tijuana, Mexico (see [Gerson Therapy](#), earlier in this chapter).

The internal Hoxsey treatment is composed of licorice (*Glycyrrhiza glabra*), red clover (*Trifolium pratense*), burdock (*Arctium lappa*), stillingia root (*Stillingia sylvatica*), berberis root (*Berberis vulgaris*), poke root (*Phytolacca americana*), cascara (*Rhamnus purshiana*), aromatic USP 14 (artificial flavor), prickly ash bark (*Zanthoxylum americanum*), and buckthorn bark (*Rhamnus frangula*).<sup>74</sup> The clinic treatment includes other dietary and hygiene manipulations. As with Essiac, some of the purified components of individual herbs within the mixture have reproducible anticancer activities, but the whole form of the herbs have yielded variable results. Neither clinical trials nor *in vitro* or animal model testing of the entire mixture has been reported. Series of case reports were submitted to the NCI in 1945 and 1950 but were judged to contain no evidence of anticancer activity.<sup>74</sup>

**MISTLETOE.** Mistletoe (*Viscum album* L.) is used extensively in Europe and is one of the CAM modalities used most frequently in Germany.<sup>9,12,75</sup> A semiparasitic plant member of the Loranthaceae family, mistletoe draws water and minerals from host trees but produces carbohydrates by its own photosynthesis. Loranthaceae species were proposed in 1916 to be useful in cancer by Rudolf Steiner, an Austrian who founded a system of health promotion called *anthroposophy*, attempting to link science and spirituality.

The active moieties in mistletoe are thought to be lectins (glycoproteins) and viscotoxins (proteins). The lectin component has been demonstrated to have immunostimulant activity *in vitro*. It induces macrophage production of tumor necrosis factor<sup>76</sup> and increases interleukin-1 and interleukin-6 production.<sup>77</sup> The viscotoxins have been shown to have direct cytotoxic activity against certain cancer cell lines.<sup>78</sup>

The currently available mistletoe products are Iscador, Helixor, Abnoba Viscum, Isorel, and Eurixor. They are whole or purified extracts, fermented or nonfermented. Iscador also has added metals (silver, copper, and mercury).

A large body of clinical literature (case reports, retrospective analysis, and a variety of clinical trials) deals with the commercially available mistletoe products. A few randomized, controlled cancer clinical trials of mistletoe have been reported from Europe. In the largest study, 677 women who had received radical or simple mastectomy for breast cancer were randomly assigned to Helixor (parenterally) with or without radiation therapy; to chemotherapy with cyclophosphamide, methotrexate, and fluorouracil with or without radiation therapy; or to no treatment.<sup>79</sup> A statistically significant survival advantage was identified for the Helixor arm as compared to no treatment, but no significant difference was found between the Helixor arm and the chemotherapy arm. Although side effects reportedly were not documented systematically, the primary adverse reactions associated with Helixor were said to be primarily inflammatory reactions at the injection site and occasional fevers.

In a study of patients with metastatic colorectal cancer, patients were randomly assigned to Helixor and fluorouracil and folinic acid (n = 20) versus fluorouracil and folinic acid (n = 20). Ten complete remissions were reported in the Helixor group, and six were reported in the control group. Median survival time was 14 months for controls and 26 months for the Helixor arm (P = .06). The difference in side effects between the two arms was small. Further randomized, multicenter clinical trials are under way.<sup>80</sup>

Other studies have investigated the immunomodulatory activity of mistletoe. A study of adjuvant therapy in glioma randomly assigned 35 patients either to receive subcutaneous injections of a standardized extract of mistletoe lectins for 3 months or to receive no therapy.<sup>81</sup> Increased lymphocyte numbers and activity were noted in the mistletoe lectin arm as was an improved quality of life determined by a standardized questionnaire.

**SPES AND PC-SPES.** SPES and PC-SPES are herbal mixtures developed by Dr. Sophie Chen, a researcher at New York Medical College, and distributed by BotanicLab in Brea, CA.<sup>82</sup> Reportedly, more than 2000 patients have used PC-SPES for the treatment of prostate cancer.<sup>83</sup>

SPES contains 14 herbs: *Agrimonia pilosa* Ledeb, *Cervus nippon* Temminck, Cheng-min chou, *Corydalis busbosa*, *Ganoderma lucidum*, *Panax ginseng* C.A. Meyer, glycyrrhiza, *Lycoris radiata*, Mou hui tou, *Phrola rotundifolia* L, *Rabdosia rubescens*, *Stephania delavayi* Diels, *Stephania sinica* Diels, *Zanthoxylum nitidum*. PC-SPES contains eight herbs: chrysanthemum, isatis, licorice, *Ganoderma lucidum*, *Panax pseudo-ginseng*, *Rabdosia rubescens*, saw palmetto, and *scutellaria* (skullcap).

Hsieh et al.<sup>84</sup> demonstrated the induction of apoptosis and down-regulation of bcl-6 in mutu I cells treated with ethanolic extracts of PC-SPES. Tumors induced in rats inoculated with a metastasizing prostate cancer cell line underwent apoptosis when the rats were fed rodent chow containing PC-SPES at levels of 0.05% and 0.045%. Neither obvious toxicity nor a significant difference in food intake was noted after 8 weeks. Dose-dependent inhibitory effects of dietary PC-SPES were observed on both tumor incidence and rate of tumor growth.<sup>85</sup>

A phase II study of PC-SPES has been performed at University of California, Los Angeles.<sup>86</sup> The results of the treatment of 34 patients (20 hormone-naïve, 14 androgen-independent) were reported. Prostatic-specific antigen (PSA) declined by more than 50% in 9 of 12 hormone-naïve patients and in 9 of 12 androgen-independent patients. Testosterone levels fell to anorchid levels by 1 month in 7 of 21 (33%). The toxicities noted were suggestive of estrogenic activity. Tender gynecomastia was seen in 71% of patients, and one patient had a thromboembolic event. Sixty percent of patients with previously normal testosterone levels lost libido and potency when present pretreatment.

Sixteen patients with advanced prostate cancer taking PC-SPES as a dietary supplement (2.7 g daily) were followed in another study.<sup>82</sup> At 3 months, 10 of 16 patients showed a decrease in PSA levels in excess of 50%. In a report of prostate cancer patients treated with PC-SPES, decreased serum testosterone levels were noted in six of six men, and drops in the PSA level were noted in eight of eight patients.<sup>87</sup>

## HYDRAZINE (OR HYDRAZINIUM) SULFATE

Hydrazine is a chemical with a variety of uses and is an important intermediate in the synthesis of some pharmaceutical drugs, such as isoniazid, hydralazine, and procarbazine.<sup>88</sup> Gold<sup>89</sup> reported that the growth of Walker 256 tumor in mice was inhibited by hydrazine sulfate. Another study found that Morris hepatoma growth in rats was inhibited when the animals were fed hydrazinium sulfate, 15 mg/kg orally twice daily for 5 days.<sup>90</sup> However, this response was associated with reduction of body weight, anorexia, and decreased nitrogen metabolism and retention. An identical group that was fed parenterally sustained body weight but suffered stimulated tumor growth and symptoms of liver toxicity.

Hydrazine sulfate is also an inhibitor of phosphoenolpyruvate carboxykinase, a key enzyme in mammalian gluconeogenesis. This metabolic pathway has been recognized to play a role in cancer cachexia.<sup>91</sup> Gold<sup>92</sup> postulated that hydrazine sulfate interrupts host energy wasting by inhibiting the conversion of lactic acid to glucose in the liver. This process is also thought to decrease the glucose available to the tumor and therefore can lead to a slowing of tumor growth.

A report of a large patient experience (740 patients) from Russia calculated that 47% of the patients had symptomatic improvement.<sup>93</sup> They also reported some patients with objective responses (4% of lung cancer patients) or stable disease (22% of lung cancer patients).

Gold<sup>94</sup> studied 84 patients with various cancers and reported that 70% had symptomatic improvement (increased appetite, weight gain, decreased pain) and 17% had prolonged tumor stabilization or some degree of tumor regression. Three small single-arm trials by other investigators failed to substantiate these findings.<sup>22,95,96</sup>

There have been four randomized, controlled clinical trials of hydrazine sulfate in cancer patients that have yielded mixed results. The first study by Chelbowski et al.<sup>97</sup> had the most promising findings but did not show a significant difference in survival between the two arms until a subgroup analysis was done.

The NCI sponsored three follow-up clinical trials. Two trials studied lung cancer patients simultaneously treated with platinum-based chemotherapy regimens with hydrazine sulfate or placebo,<sup>98,99</sup> and a third study looked at hydrazine sulfate alone versus placebo alone in patients with advanced colorectal cancer.<sup>100</sup> None of these follow-up studies showed a statistically significant improvement in survival in the hydrazine sulfate arm, and the Cancer and Leukemia Group B study<sup>98</sup> showed

a lesser quality of life in the hydrazine sulfate arm. All together, these three follow-up studies contained more than 600 patients.

There is still significant interest by the public in hydrazine sulfate and a feeling among some that the clinical trials were flawed and the results invalid. The General Accounting Office investigated the three NCI-supported randomized trials and found that they were accurate. <sup>101</sup>

## LAETRILE

Laetrile is a mixture of amygdalin, a plant glycoside, and other compounds found in the pits of some fruits, raw nuts, and other plants. <sup>102-103</sup> Although frequently called *vitamin B<sub>17</sub>* in the lay literature, amygdalin is not recognized as a vitamin by the Committee on Nomenclature of the American Institute of Nutrition. Laetrile has been given orally and intravenously, with different pharmacokinetics and toxicity profiles.

The NCI supported a trial at the Mayo Clinic using amygdalin and a "metabolic therapy" containing vitamins A, C, E, and B complex and pancreatic enzymes. <sup>104</sup> One hundred and seventy-nine patients with advanced cancer who had either failed attempts at prior standard therapy or for which no standard therapy with a curative potential was available were treated. Of the 175 assessable patients, only one met the criteria for a partial remission. There were no other responders, and all patients had progression by 7 months. The median survival from the start of therapy was 4.8 months.

Despite the fact that no new clinical trials have been reported, use of laetrile continues. <sup>105</sup> No further research appears to be under way.

## SUPPORTIVE CARE (COMPLEMENTARY MEDICINE)

### ACUPUNCTURE

Dundee et al. <sup>106</sup> found that acupuncture needling with 5 minutes of electrical stimulation at the P6 point (volar surface of the wrist) was effective in preventing chemotherapy-induced nausea and vomiting. Ten patients were studied in a randomized, crossover portion of the study in which patients received either P6 electroacupuncture or stimulation at a "dummy" point. The antiemetic effect lasted approximately 8 hours. After a systematic review of the literature, the NIH Consensus Development Panel on Acupuncture found sufficient evidence existed for efficacy in managing chemotherapy-induced nausea. <sup>107</sup>

Preliminary evidence suggests that acupuncture may also be effective in the treatment of vasomotor symptoms (i.e., hot flashes) in men receiving gonadotropin analogues for prostate cancer therapy. A pilot study used electroacupuncture to a fixed set of acupuncture points for 30 minutes, twice a week for 2 weeks followed by once a week for 10 weeks. The mean number of flushes per day for the six men who continued therapy for more than 2 weeks decreased from 7.9 during the week before therapy to 2.5 after 10 weeks. <sup>108</sup>

### PAIN MANAGEMENT

A variety of CAM modalities have been used to aid in pain management. Reiki, an "energy healing system" based on Tibetan scriptures but developed in Japan, has been tested in at least one pilot study with reportedly positive effects. <sup>109</sup>

Use of relaxation, imagery, and cognitive-behavior training for the management of oral mucositis pain has been studied in a randomized, controlled trial. <sup>110</sup> Ninety-four patients at the Fred Hutchinson Cancer Research Center undergoing their first bone marrow transplant completed the study. Oral mucositis pain levels were evaluated in four groups of patients. The two groups receiving relaxation and imagery reported significantly lower pain levels as assessed by a visual analogue scale.

A randomized controlled trial of 96 women with newly diagnosed large or locally advanced breast cancer compared standard care versus standard plus relaxation training and imagery. <sup>111</sup> A significantly improved quality of life was seen in the group receiving relaxation and imaging. Other studies have used questionnaires designed to assess general patient comfort. One such randomized study by Kolcaba and Fox <sup>112</sup> demonstrated an improved level of comfort among the patients undergoing a guided imagery intervention.

### SELF-HELP AND SUPPORT GROUPS AND HYPNOSIS

There appears to have been an increase in the number of cancer patients attending support groups. <sup>28</sup> Although patients are likely attending these groups mostly for psychosocial support, there is some evidence that these interventions may also be related to an increased survival for some groups.

Spiegel et al. <sup>113</sup> were the first to report evidence for a beneficial effect on survival of a support group intervention in a group of cancer patients. Eighty-six patients with metastatic breast cancer were randomly assigned to intervention (n = 50) or control group (n = 36). The intervention consisted of 1 year of weekly 90-minute support groups led by a therapist who had breast cancer in remission. The groups were structured to encourage discussion of how to cope with cancer and for patients to express their feelings about the illness and its effect on their lives. Also a self-hypnosis strategy was taught for pain control. The mean survival in control group was 18.9 months versus 36.6 months in the treatment group. Interestingly, a survival advantage was not seen until approximately 8 months after the completion of the group intervention (i.e., at 20 months from entry on study).

Spiegel and Spira <sup>114</sup> have written a manual explaining the details of their psychosocial intervention. Follow-up studies by Goodwin et al. <sup>115</sup> in Toronto, Canada, and Spiegel et al. <sup>160</sup> at the University of Rochester are under way.

Another study of a support group intervention with cognitive behavioral therapy in patients with metastatic breast cancer found no survival advantage for the treated group over a randomized control group. <sup>116</sup> Also a retrospective cohort study of a group of breast cancer patients with localized, regional, or distant disease found no advantage for the combination intervention of patient and family support groups with directed relaxation, imagery, and meditation. <sup>117</sup>

Fawzy et al. <sup>118</sup> reported the survival of surgically resected stage I melanoma patients randomly assigned to either six weekly 1.5-hour sessions of group support and education versus no intervention. An analysis of overall survival of the two groups, 6 years after the surgical excision of the melanoma, showed 10 of 34 dead in the control group and 3 of 34 in the treatment group. The difference was statistically significant.

## COMPLEMENTARY AND ALTERNATIVE MEDICINE CANCER RESEARCH

Many medical and surgical oncologists as well as other health care practitioners and clinical and basic science researchers have recognized the need for good quality research into CAM modalities. <sup>25,119</sup> However, concerns have been raised about the use of different standards of evidence. <sup>120</sup>

Research programs are being established to focus on alternative medicine in cancer. The Osher Center for Integrative Medicine at the University of California at San Francisco has active protocols for patients with breast cancer and prostate cancer. <sup>121</sup> Memorial Sloan-Kettering Cancer Center (MSKCC) has recently added an Integrative Medicine Service, and the University of Texas-Houston has had a center supported by the National Center for Complementary and Alternative Medicine. The National Center for Complementary and Alternative Medicine (NCCAM) and the NCI plan to support other centers for basic and clinical research in CAM and cancer.

### NATIONAL CANCER INSTITUTE OFFICE OF CANCER COMPLEMENTARY AND ALTERNATIVE MEDICINE AND THE BEST CASE SERIES PROGRAM

In 1998, the NCI established the Office of Cancer Complementary and Alternative Medicine to focus and extend the efforts of the Institute in the arena of CAM. This office seeks to promote and support research in the various disciplines and modalities associated with the field of CAM as they relate to the diagnosis, prevention, and treatment of cancer.

Since 1991, the NCI has had a process for the evaluation of data from alternative medicine practitioners of groups of patients with cancer treated with alternative medical approaches. This process, the Best Case Series Program, provides an independent review of the medical records and primary source materials (medical

imaging and pathology) and an overall assessment of the evidence for a therapeutic effect.

In 1998, the NCCAM of the National Institutes of Health in collaboration with the NCI established a Cancer Advisory Panel for Complementary and Alternative Medicine that reviews evidence about CAM modalities and advises the director of the NCCAM about promising CAM approaches that warrant further research. The NCI works closely with this new body, and Best Case Series are now presented to this panel for their review and assessment.

**EXAMPLES OF COMPLEMENTARY AND ALTERNATIVE MEDICINE TOPICS REQUIRING MORE RESEARCH**

Controversy exists about the consequences of women with or at high risk for breast cancer using soy products or other plants containing phytoestrogens. Herbs such as dong quai (angelica sinensis), black cohosh, and ginseng as well as foods such as soy contain phytoestrogens. These estrogens bind both physiologic forms of the estrogen receptor, and some induce signs and symptoms of exogenous estrogen administration.<sup>122</sup> Some of these herbs are used by cancer patients to alleviate menopausal symptoms.<sup>123</sup> Further research is needed to assess the risk-benefit ratio of these various products. Similarly, with the recent growth of interest and use of the androgen dihydroepiandrosterone, which is available as a dietary supplement, research is needed about its potential effect on men with or at high risk for prostate cancer.

Another controversy rages over the potential risks and benefits of the use of antioxidants during chemotherapy or radiation therapy.<sup>124,125</sup> With preclinical evidence on both sides of the issue, definitive clinical trials are needed. The toxicity profiles of herbs and the mechanisms of herb-drug interactions are other areas in which further research would be immediately rewarding.

**PRACTICAL ISSUES IN THE INTERFACE OF ONCOLOGY AND COMPLEMENTARY AND ALTERNATIVE MEDICINE**

**PHYSICIAN-PATIENT COMMUNICATION**

Cases have been reported of patients with potentially very curable tumors who delayed or interrupted conventional treatment to pursue unsuccessful alternative approaches and subsequently died of advanced cancer.<sup>126,127</sup> and <sup>128</sup> Therefore, the physician's relationship with his or her patient and communication with patients about CAM are of primary importance.<sup>129</sup> Eisenberg<sup>130</sup> has described an approach for the physician to take in inquiring about and exploring a patient's use of CAM.

**INTERACTIONS OF ALTERNATIVE MEDICINES WITH CONVENTIONAL MEDICINES**

Oncologists often are not aware of their patients' use of CAM.<sup>17,18,24,25,27</sup> One study found that 29% of cancer patients reported taking an herbal supplement while they were receiving chemotherapy.<sup>19</sup> The potential for interactions of alternative medicines and conventional medicines is real. One group has reported that a mixture of naturopathic remedies used by a 7-year-old child reduced the bioavailability of oral mercaptopurine used as maintenance therapy for acute lymphoblastic leukemia.<sup>131</sup> Examples of other interactions are listed in Table 61-3. There are several herbs that theoretically could interact with anticoagulants or might be contraindicated in patients with thrombocytopenia. Some of these are listed in Table 61-4.

Herb	Reported Toxicity
Chaparral (creosote bush, <i>Larrea tridentata</i> )	Hepatitis and hepatic failure <sup>132</sup>
Licorice ( <i>Glycyrrhiza glabra</i> )	Pseudohyperaldoosteronism (hypertension, and hypokalemia) <sup>133,134</sup>
Kombucha tea	Cardiac arrest <sup>135</sup>
Dong quai	Drug interaction with warfarin; increased INR <sup>136</sup>
Skullcap* ( <i>Scutellaria incarnata</i> )	Hepatotoxicity <sup>137</sup>
PC-SFES (eight herbs; see text)	Estrogenic symptoms (breast tenderness, decreased libido, thrombosis) <sup>137</sup>

INR, international normalized ratio.  
 \*Some herbal preparations purported to contain skullcap actually contain germander (*Thymus canadensis*), a known hepatotoxin. In one report of hepatotoxicity from an herbal product originally attributed to skullcap, germander had been substituted.<sup>137</sup>

**TABLE 61-3.** Reported Toxicities or Drug Interactions of Herbs Used by Cancer Patients

Herb	Activity	Source
Aztec	Contains coumarins; potential interaction with warfarin	138
Celery	Contains coumarins; potential interaction with warfarin	138
Chamomile	Contains coumarins; potential interaction with warfarin	138
Dan-shen	Increases the peak concentration of warfarin in rats	138
Dong quai	Drug interacts with warfarin; increased INR	135
Fennel	Contains coumarins; potential interaction with warfarin	138
Furcifer	Inhibits platelet activity	138
Garlic	Decreases platelet aggregation; unpublished reports of increased INR in patients taking warfarin	138,139
Ginger	Potential inhibitor of the coumarin synthesis	138
Ginkgo	Reports of spontaneous hypohematomata; inhibits adhesion of platelets; inhibits platelet-activating factor	138
Ginseng	Has antiplatelet components; can decrease INR in patients on coumarins	138

INR, international normalized ratio.

**TABLE 61-4.** Potential and Documented Dietary Supplement–Drug Interactions

**SOURCES OF INFORMATION FOR PATIENTS, PHYSICIANS, AND RESEARCHERS**

A Canadian study of cancer patients attending an outpatient pain and symptom clinic found that the top two sources of information for CAM modalities that were used were health store staff and self-help literature followed by family members, friends, and herbalists.<sup>26</sup> Even in a setting with more cultural acceptance of specific CAM therapies (i.e., Taiwan), the majority of the patients make their decisions about the use of alternative approaches based on information obtained by word of mouth or through advertisement rather than through consulting with a licensed practitioner in alternative medicine or a conventional health care practitioner.<sup>15</sup>

The Office of Technology Assessment Report of the Unconventional Cancer Treatments Panel is a valuable source of background information about many CAM modalities still in use. This report may be downloaded from the Office of Technology Assessment Web site at <http://www.ota.nap.edu/pdf/1990idx.html>.

The American Cancer Society has summaries of various CAM modalities on its Web site at <http://www.cancer.org>. The NCCAM has a Web site at <http://nccam.nih.gov> that has links to useful information about CAM research.

The NCI's Cancer Information Service has summaries about CAM modalities available through its CancerNet Web site at <http://www.cancer.net.ncl.nih.gov> or via mail.

The Office of Cancer Complementary and Alternative Research of the NCI has a Web site (<http://www.cancer.gov/cam>) with information about CAM cancer research. The Task Force on Alternative Therapeutics of the Canadian Breast Cancer Research Initiative has produced several useful reviews of CAM modalities.<sup>132,133,134,135,136</sup> and <sup>137</sup>

to immunize patients against tumors, it is possible that only transient expression of antigen genes by viral vectors such as adenovirus will be sufficient.

Viral	Gene Transfer Method						
	Gene Transfer	Efficiency	Duration	Stability	Targeting	Immunogenicity	Cost
Adenovirus	High	High	High	High	High	High	Low
Adeno-associated virus	High	High	High	High	High	High	Low
Herpesvirus	High	High	High	High	High	High	Low
Lentivirus	High	High	High	High	High	High	Low
Retrovirus	High	High	High	High	High	High	Low
Nonviral	Low	Low	Low	Low	Low	Low	High
Electroporation	High	High	High	High	High	High	Low
Microinjection	High	High	High	High	High	High	Low
Gene gun	High	High	High	High	High	High	Low

TABLE 62.1-3. A Comparison of Gene Transfer Methods

Many techniques of gene transfer make use of viruses to introduce genetic material, because viruses in most cases can deliver genes to cells with higher efficiencies compared to nonviral methods.

### RETROVIRAL VECTORS

Retroviruses are RNA viruses that are capable of stably integrating DNA within the host cell genome. The replication cycle of a retrovirus begins with viral attachment to a cell by a specific receptor (Fig. 62.1-1). The virus enters the cell, and the viral RNA is reverse transcribed to DNA by the virally encoded reverse transcriptase. The viral DNA is then transported to the nucleus, where it integrates into the host cell genome. The integrated viral DNA, termed the *provirus*, is transcribed, and then both spliced and unspliced transcripts are translated to form the viral proteins. Some of the unspliced transcripts are packaged, via a packaging signal sequence ( $\psi$ ), into viral capsids. The mature viruses then bud from the host cell membrane.

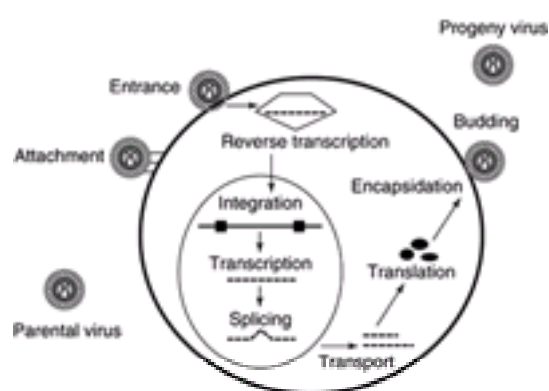

FIGURE 62.1-1. Retrovirus replication cycle. The retrovirus uses envelope glycoproteins to bind to specific receptors on the cell surface. Viral RNA then enters the cell and is reverse transcribed to DNA. The viral DNA is transported to the nucleus, where it integrates in the host chromosome and directs transcription of the provirus using the viral long terminal repeat. Viral transcripts are translated by the infected cell to form viral structural proteins. Some of the unspliced viral transcripts are packaged into the newly formed viral particles and are released by budding. (From ref. 243, with permission.)

Retroviral vectors for gene transfer have been constructed by substituting the gene of interest in place of the viral protein coding regions, thus making these vectors replication incompetent (Fig. 62.1-2). These vectors are packaged into retroviral particles using helper, or packaging, cell lines that contain the structural viral protein genes in *trans* (i.e., from another site in the packaging cell genome). Because the retroviral vector contains the  $\psi$  sequences, it is packaged into the mature virus and is capable of infecting target cells, but it is incapable of replication because of the absence of the retroviral protein coding regions. The viral structural genes, provided in *trans*, are not packaged because of the absence of the  $\psi$  sequences (Fig. 62.1-3).

FIGURE 62.1-2. Schematic diagram of the LNL6 retroviral vector. The protein-coding regions of the virus have been removed and replaced with the gene for neomycin resistance ( $Neo^R$ ). The viral packaging site ( $\psi$ ) has been left intact. The vector is a derivative of the Moloney murine leukemia virus. LTR, long terminal repeats.

FIGURE 62.1-3. Production of retroviral vectors with packaging cells. The gene of interest is cloned into a retroviral vector (see Fig. 62.1-2), and then transfected into a helper cell line, which provides the retroviral structural genes in *trans*. The retroviral structural genes cannot be packaged because of the absence of a packaging sequence ( $\psi$ ), whereas the retroviral vector can be packaged, thereby producing a replication-incompetent retrovirus. LTR, long terminal repeats. (From ref. 246, with permission.)

Retroviral vectors are one of the most common methods of gene transfer in currently approved gene therapy protocols. Their advantages include the ability to stably integrate into the host genome and the absence of viral protein expression. Current disadvantages of retroviral vectors include low titers, resulting in low levels of gene transfer efficiency, although new methods have been described to concentrate retroviral supernatants using ultracentrifugation. <sup>4</sup>

Retroviral packaging cells can use a variety of envelope genes from other viruses. Because the envelope protein is the primary determinant of the host range of the retrovirus, the particular envelope, or pseudotype, used can have a profound impact on transduction efficiencies. <sup>5</sup> Table 62.1-4 lists a number of envelope genes along with their relative host ranges. The development of packaging cell lines that use alternative envelope genes has resulted in significant advances in the ability to transduce primary lymphocytes. Retroviral vectors produced from the PG13 packaging cell line, <sup>6</sup> which uses the gibbon ape leukemia virus envelope (GALV), are capable of transducing B cells<sup>7</sup> and T cells<sup>8</sup> with significantly higher efficiencies compared with those derived from amphotropic packaging cell lines. In one study, transduction of primary T cells was 4- to 18-fold higher with PG13-packaged vectors compared with amphotropic PA317-packaged vectors. <sup>8</sup> This was found to correlate with an 8- to 19-fold higher expression of the GALV receptor (Pit-1) compared with the amphotropic receptor (Pit-2) in primary T cells, although other factors besides receptor expression have been found to play a role in transduction efficiency. <sup>9</sup> By combining the use of PG13-packaged vectors with a 1-hour centrifugation at 1000 g, Bunnell et al. <sup>10</sup> were able to obtain transduction efficiencies of primary T cells in the 40% range.

Envelope Source	Host Range
Ecotropic	Mouse, rat
Amphotropic	Human, mouse, rat, rabbit, cat, dog, monkey
Gibbon ape leukemia virus	Human, rat, rabbit, cat, dog, monkey (not mouse)
Vesicular stomatitis virus G protein	All

**TABLE 62.1-4.** Envelopes Used for Retroviral Vectors

The vesicular stomatitis virus (VSV) G glycoprotein can also be used to pseudotype retroviral vectors. <sup>11</sup> Unlike other envelope proteins, the VSV-G protein confers enhanced physical stability to retroviral particles, allowing concentration with ultracentrifugation to titers of  $10^9$  or higher. VSV-G pseudotyped retroviral vectors have a wide host range and have been used successfully to transduce primary T cells. <sup>12,13</sup>

In addition, future retroviral vectors may contain improved promoters for higher and regulatable levels of gene expression.

## LENTIVIRAL VECTORS

Stable gene transfer using vectors based on murine retroviruses is only possible in dividing cells. Human immunodeficiency virus (HIV) can infect and integrate into the genome of nonproliferating cells because of proteins that mediate the active transport of the lentiviral preintegration complex through the nucleopore. These proteins—integrase, matrix, and *vpr*—interact with the nuclear import machinery to transport the HIV preintegration complex from the cytoplasm to the nucleus.

Naldini et al. <sup>14</sup> designed lentiviral vectors based on HIV that are capable of stably infecting nondividing cells. A packaging construct was used to express HIV proteins in *trans*. To avoid production of wild-type HIV, the construct is defective for the production of viral envelope and the accessory protein Vpu, and has deletions in the 5' signal sequence. To make defective lentiviral vectors, packaging cells are transiently transfected with the packaging construct, along with a separate plasmid encoding a heterologous envelope protein, such as VSV-G protein. A third plasmid, the transfer vector, encodes the gene of interest, along with the packaging signal and other *cis*-acting sequences of HIV required for packaging, reverse transcription, and integration. <sup>14</sup> Lentiviral vectors are currently being refined to enhance safety, transduction efficiency, and convenience. <sup>15</sup> HIV-based lentiviral vectors have been shown to be efficient vehicles of gene transfer into postmitotic cells, including brain, liver, muscle, CD34+ hematopoietic cells, and retina. <sup>14,16,17,18,19</sup> and <sup>20</sup> Current efforts are focused on the use of lentiviral vectors in the transduction of hematopoietic stem cells in an attempt to enhance long-term engraftment of gene-modified cells. <sup>17,19</sup>

## ADENOVIRAL VECTORS

The adenoviral genome is divided into four early gene regions, E1 to E4, which are expressed before viral DNA replication, and late genes, which primarily encode viral structural proteins. On infection, the E1 gene products are expressed first and are responsible for transcriptionally activating other genes that begin a cascade of events ultimately leading to viral replication. Removing the E1 region therefore results in an adenoviral particle that is replication deficient. These replication-deficient adenoviruses can be used for gene transfer by cloning the gene of interest into the deleted E1 region. <sup>21</sup> The recombinant adenovirus, however, must be produced using cell lines that provide the E1 products in *trans*, such as in 293 cells, which constitutively express Ad5 E1 genes.

Adenoviral gene transfer can be performed in many cells, both dividing and nondividing, with high efficiency, and it can result in high levels of gene expression. In addition, adenoviral vectors can be produced at high titers and are capable of infecting some tissues directly *in vivo*, such as pulmonary epithelial cells. <sup>22</sup> However, because adenoviral DNA exists episomally, with little or no incorporation into the host cell genome, expression of the transgene is transient, and it is lost as the infected cell divides. For some therapeutic strategies, this high-level transient expression may be adequate, whereas other treatment approaches may require more prolonged gene expression.

One potential problem with *in vivo* administration of current adenoviral vectors is their ability to trigger a host immune response. Both neutrophilic and lymphocytic inflammatory infiltrates can be seen histologically at sites of injection of adenoviral vectors. <sup>23</sup> In addition, antibody responses to adenoviral vectors have been demonstrated in a variety of animal models, and gene expression with repeated dosing is inversely proportional to the antibody response in some systems. <sup>24</sup> Nude mice expressing adenoviral vectors in the liver exhibit transgene expression for 60 days, compared with 21 days in normal mice, implying that the absence of T cells can lead to longer gene expression. Cytotoxic T lymphocyte (CTL) responses compared with adenoviral proteins also have been reported. <sup>25</sup> It has been postulated that late gene products, such as adenoviral hexon and fiber proteins, may be the cause of the T-cell response.

The effect of neutralizing antibodies on current clinical efforts with recombinant adenovirus is not clear. In a clinical trial with recombinant adenoviruses containing tumor antigen genes, high levels of neutralizing antibody were found in the pretreatment sera of patients, which may have impaired the ability of these viruses to immunize patients. <sup>26</sup> In another study, however, intratumoral administration of an adenoviral vector expressing b-galactosidase resulted in b-galactosidase-specific T helper, CTL, and antibody responses in three of four patients. <sup>27</sup>

New generations of adenoviral vectors are attempting to limit the antiviral immune response by eliminating much of the adenoviral genome. Besides reducing immunogenicity, this also allows an increased gene carrying capacity by the adenoviral vector. Packaging of these "gutless" adenoviral vectors requires helper virus or the expression of additional adenoviral genes by the helper cell lines. In addition, adenoviral vectors are being developed that may allow targeted, regulable gene expression.

Burcin and colleagues <sup>28</sup> have reported the construction of a recombinant adenovirus containing a tissue-specific, regulable target gene. The recombinant adenoviral vector lacked all viral coding sequences to avoid immunogenicity, and it contained a transgene that could be induced *in vivo* with the antiprogestin mifepristone. Tissue specificity was conferred by coupling the regulator cassette to the liver-specific transthyretin promoter region. <sup>28</sup> Inducible expression of the transgene was

demonstrated *in vivo*, but the tissue specificity was not confirmed.

In an effort to confer targeting ability to adenoviral vectors, surface modification of the Ad fiber coat protein <sup>29,30</sup> and <sup>31</sup> or use of adenoviral/antibody complexes<sup>32,33</sup> has been attempted. Much work in vector development remains to be done for adenoviral vectors to be fully utilized in effective gene therapy strategies.

## ADENOASSOCIATED VIRUS VECTORS

Adenoassociated virus (AAV), a member of the parvovirus family, can only replicate in the presence of a helper virus, such as adenovirus. The virus is nonenveloped and consists of a single-stranded linear DNA of 4.7 kilobases, which contains two major open reading frames. The left-hand open reading frame encodes the Rep proteins, which are responsible for AAV replication. The right-hand open reading frame encodes the Cap proteins, which form the structural proteins of the viral capsid. In the absence of a helper virus, such as adenovirus, AAV cannot replicate; instead, it integrates into the host genome through the AAV-inverted terminal repeats present on each end of the AAV genome. The ability to integrate makes AAV an attractive vehicle for gene transfer.

To provide room for a transgene, the majority of the AAV genome between the inverted terminal repeats can be removed and replaced with a gene of interest driven by an appropriate promoter.<sup>34</sup> Once packaged, the replication-incompetent AAV vector has been shown to be capable of infecting and integrating into a target cell genome. However, producing recombinant AAV is cumbersome. The remainder of the AAV genome must be provided in *trans*, and a wild-type helper virus, such as adenovirus, must be present. The final recombinant AAV vector must be purified from the helper virus by heat or density centrifugation. Production of large quantities of high-titer AAV vector free of helper virus and wild-type AAV has been one of the obstacles to using AAV for clinical purposes. However, new packaging systems to produce helper virus-free recombinant AAV vectors may decrease this problem.<sup>35,36</sup>

New hybrid vector techniques are under development that may combine the advantages of two systems. For example, adenovirus/AAV hybrid vectors may allow efficient, stable gene transfer.<sup>37,38</sup>

## POX VECTORS

The poxviruses are a family of DNA viruses characterized by a large enveloped virion containing enzymes for messenger RNA (mRNA) synthesis, a genome composed of a single, linear, double-stranded DNA molecule of 130 to 300 kilobases, and the ability to replicate within the cytoplasm of the infected cell. The poxvirus genome encodes 150 to 200 genes, which can be divided into early and late genes. Early genes are expressed before viral DNA replication, and late genes are expressed after DNA replication.

Several properties of poxviruses make them attractive vectors for the introduction of foreign genes.<sup>39,40,41</sup> and <sup>42</sup> Because of the large size of the poxvirus genome, large amounts of foreign DNA can be incorporated without adversely effecting viral infectivity. Several silent or nonessential regions of the genome have been identified for the insertion of foreign DNA by homologous recombination. Plasmids that provide viral promoters and regions to facilitate homologous recombination into nonessential sites, such as the viral thymidine kinase (TK) region, have been constructed to produce recombinant vaccinia vectors. Multiple genes each can be inserted at a different site in the virus. Screening methods have been designed to isolate and expand recombinant clones containing the genes of interest.

A primary advantage of recombinant poxviruses is the large amount of gene expression that is possible because of the use of vaccinia transcription factors. Because gene expression is entirely cytoplasmic and does not rely on host-cell transcriptional machinery, it is not dependent on potential regulatory mechanisms of the host cell, and hence, large quantities of gene expression have been observed in a wide variety of cell types.

Disadvantages of poxviruses are the transient nature of gene expression and the cell lysis that results after infection. Some attenuated vaccinia strains <sup>40</sup> have been developed that result in delayed lysis of infected human target cells. Avipox viruses, such as fowlpox or canarypox, or swinepox viruses can infect human cells, but they do not result in cell lysis.<sup>43</sup> Another problem with recombinant poxviruses is that up to 200 viral gene products are expressed, many of which may be immunogenic or may adversely interact with the target cell or the gene product of interest.

## NONVIRAL METHODS OF GENE TRANSFER

Cationic lipids, complexed to DNA, have been developed that are capable of mediating high gene transfer efficiencies *in vitro* for some cell types. Cationic lipids,<sup>44</sup> such as DOTMA (1,2-dioleoyloxypropyl-3-trimethyl ammonium bromide), the prototype cationic lipid, along with a neutral lipid, such as DOPE (dioleoylphosphatidyletanolamine), can be complexed with DNA and added to cultured cells. New formulations of lipids are currently under development that may allow improved *in vitro* gene transfer as well as *in vivo* administration. Cationic lipid formulations have already been used to deliver genes to the lung *in vivo*,<sup>45</sup> as well as intratumorally.<sup>46,47</sup> and <sup>48</sup> Most recently, DNA-gelatin nanospheres have been used to allow the slow release of DNA *in vivo*. In a murine model, intramuscular injection of nanospheres containing the b-galactosidase marker gene led to higher expression levels than injection with naked DNA or DNA/lipid complexes.<sup>49</sup>

Physical methods of gene transfer include the "gene gun,"<sup>50</sup> which propels gold beads coated with DNA into cells. Although this method results in low transfection efficiencies, gene transfer to epithelial cells can be performed *in vivo*, giving it a potential role in immunization strategies.

The direct *in vivo* injection of DNA alone into selected tissues, such as muscle<sup>51</sup> and thyroid,<sup>52</sup> can result in gene transfer. This approach, termed *naked DNA*, has been used primarily for studies attempting to immunize against the products of the encoded genes.

Nonviral methods of gene delivery are more convenient and have obvious safety advantages over viral methods. However, the majority of current nonviral gene transfer methods result in transient gene expression, and the efficiency of gene transfer is lower compared with most viral methods.

## GENE MARKING STUDIES

The first gene transfer study in humans in 1989 was designed to assess the safety and feasibility of gene transfer in humans, using a marker gene, neomycin phosphotransferase (Neo<sup>R</sup>), an enzyme that inactivates neomycin and neomycin analogues.<sup>53,54</sup>

Subsequent goals of gene marking studies were to understand the biology of cancer and cancer treatments. For example, because a unique, foreign gene was introduced into cells, the fate of these cells could be followed *in vivo*. Adoptively transferred T cells could be followed for their survival *in vivo*, and patients receiving autologous bone marrow transplantations transduced with marker genes could be followed to see whether subsequent recurrences were in part due to viable tumor cells that were present in the transferred bone marrow.

## T-CELL MARKING STUDIES

The first gene transfer study in humans was performed in 1989 in the Surgery Branch of the National Cancer Institute.<sup>54</sup> Tumor infiltrating lymphocytes (TILs) were genetically modified with a marker gene encoding Neo<sup>R</sup>. The goals of the study were to evaluate the safety and feasibility of using gene-modified cells in humans. In addition, because a unique, foreign gene was placed into the TIL, survival and distribution studies of the infused cells could be done using polymerase chain reaction (PCR) assays on DNA from peripheral blood lymphocytes and tumor biopsies.

Because this was the first study of its kind, safety issues pertaining to the patients and the public were a major concern by regulatory agencies, such as the Recombinant DNA Advisory Committee (RAC). Consequently, many safety studies were required before approval of this and subsequent clinical trials. Ultimately, ten patients were treated, and no safety or toxicity problems were associated with the gene transfer. Using PCR analysis, TILs were found in tumor biopsies up to 64 days and in peripheral blood up to 189 days after infusion<sup>54,55</sup> (Fig. 62.1-4). Since this initial study, more than 300 human gene transfer and therapy studies have been approved by the RAC, and research in this field throughout the world has expanded tremendously.

**FIGURE 62.1-4.** Results of polymerase chain reaction assays of peripheral blood lymphocytes (PBL, *circles*) and tumor-biopsy specimens (*squares*) obtained from patients at various intervals after the infusion of gene-transduced tumor-infiltrating lymphocytes. *Open symbols* denote negative results, and *solid symbols* indicate positive results. All results were corroborated in at least two separate Southern blot assays. The assays were performed and assessed in a blinded fashion. (From [ref. 54](#), with permission.)

T-cell marking studies have been performed using melanoma TILs,<sup>56,57</sup> renal TILs,<sup>58</sup> bone marrow stem cells,<sup>59</sup> and anti-HIV CTLs.<sup>60</sup> Using gene-marked Epstein-Barr virus (EBV)-specific CTLs in immunocompromised patients, Heslop et al.<sup>61</sup> found that EBV precursors could proliferate in response to *in vivo* or *ex vivo* viral challenge for as long as 18 months ([Fig. 62.1-5](#)).

**FIGURE 62.1-5.** Recruitment of gene-marked, Epstein-Barr virus (EBV)-specific cytotoxic T lymphocyte (CTL) by antigenic stimulation *in vivo*. DNA was obtained from peripheral blood mononuclear cells (MNC) of a patient between 0 and 108 weeks after bone marrow transplantation (BMT), and it was divided into two portions. One was analyzed by polymerase chain reaction amplification using EBV-specific primers, whereas the second was amplified using neo-specific primers. The figure shows the relationship between levels of EBV-DNA and the presence of neomycin resistance (Neo<sub>R</sub>)-marked, EBV-specific T cells. (From [ref. 61](#), with permission.)

Researchers at the University of Washington in Seattle have used Neo-marked, HIV-1, Gag-specific CD8+ CTL clones to treat HIV-infected individuals.<sup>62</sup> Using PCR amplification for the neo gene followed by *in situ* hybridization with fluorescein-labeled neo-specific oligonucleotides, the percentage of circulating transduced cells could be quantitated by flow cytometry. One day after cell infusion, 2.0% to 3.5% of CD8+ cells circulating in the periphery were neo-positive. The frequency of neo-modified CTL was found to correlate inversely with the percentage of HIV-infected cells in the peripheral blood after cell infusion. In addition, neo-positive CTLs were found to accumulate in lymph node biopsies obtained 4 days after cell infusion (2.2% to 7.9%), compared with the concurrent percentages of neo-positive CTLs circulating in the periphery (0.5% to 0.7%). Interestingly, neo-positive CTL aggregates were found in the parafollicular regions of the lymph node near cells that were productively infected with HIV. This finding illustrates the utility of cell marking to determine not only the overall traffic and survival of infused cells, but also their microanatomic localization.

## HEMATOPOIETIC STEM CELL MARKING STUDIES

The ability to label stem cells with unique, integrated DNA sequences has enabled investigators to track stem cells and their differentiated progeny,<sup>63</sup> allowing such studies as, for example, the comparison of bone marrow stem cells with peripheral blood stem cells for their ability to reconstitute the host. In addition, because microscopic tumor deposits present within the marrow also are marked by retroviral vectors, attempts have been made to assess the source of disease recurrence after autologous bone marrow transplantation therapy in patients with acute myeloid leukemia and neuroblastoma. In one study, bone marrow was harvested during complete remission and retrovirally transduced with the Neo<sup>R</sup> gene before reinfusion. Three of 12 acute myeloid leukemia patients have relapsed, and in two of these patients, tumor cells from the relapse contained the Neo<sup>R</sup> gene. Of nine neuroblastoma patients studied, three have relapsed, and in all three cases, the Neo<sup>R</sup> gene was found in the recurrent tumor cells.<sup>63,64,65</sup> and <sup>66</sup> Analysis of neuroblastoma DNA for discrete integration sites revealed that at least 200 malignant cells were introduced with the autologous marrow transplantation and contributed to the relapse.<sup>66</sup>

In a similar study using Neo<sup>R</sup> transduced autologous CD34 cells in chronic myelogenous leukemia (CML) patients, two relapsing patients were studied, and both had leukemic cells that were positive for the Neo<sup>R</sup> gene.<sup>67</sup> Thus, it is clear that remission marrow can contribute to disease relapse.

Using similar techniques, a variety of bone marrow purging regimens can be evaluated within the same patient to assess their success in eliminating tumor cells from the marrow.<sup>68</sup> This evaluation allows recurrent tumor cells to be analyzed genetically to determine if they had previously been exposed to a particular purging regimen.

Finally, gene transfer itself is being investigated as a purging technique, using antisense oligodeoxynucleotides against activated oncogenes as a means to eliminate tumor cells within the autologous marrow.<sup>69,70,71,72</sup> and <sup>73</sup>

## GENETIC MODIFICATION OF THE IMMUNE RESPONSE

Several approaches have been proposed for cancer gene therapy (see [Table 62.1-1](#)). One strategy that has been pursued is an attempt to enhance the immune response against cancer using gene transfer techniques.

### ACTIVE IMMUNIZATION

Much has been learned concerning the nature of the T-cell response to human cancers. Tumor antigens recognized by T cells have been cloned from melanoma cells.<sup>74,75,76,77,78,79,80</sup> and <sup>81</sup> These antigens have been shown to be nonmutated melanocyte differentiation antigens, nonmutated proteins expressed only in selected tissues such as testes, or mutated intracellular proteins. Despite the expression of known antigens on tumor cells, however, these tumors grow in their hosts, seemingly unopposed by any antitumor immune response. This lack of an adequate immune response could be due to a number of reasons, including deficient tumor antigen processing and presentation, lack of immune costimulation, production of inhibitory factors by the tumor cell, and insufficient helper activity from CD4 cells. In an attempt to bypass these potential deficiencies and stimulate a stronger antitumor response in the host, tumor cells have been genetically modified with a variety of cytokine genes and costimulatory molecules, and these modified tumor cells have been used as antitumor vaccines.

## Modification of Tumor Cells with Genes That Enhance Tumor Immunogenicity

**CYTOKINE GENES.** In contrast to the systemic administration of cytokines, which results in low concentrations *in vivo*, the introduction of genes encoding cytokines into tumor cells can result in the production of very high levels of cytokines in the tumor microenvironment. This approach is designed to more accurately mimic the paracrine nature by which cytokines normally interact to regulate immune responses. Tumors have been transduced with a variety of genes in an attempt to enhance immunogenicity.

**Interleukin-2.** In several murine models, tumors expressing the gene for interleukin-2 (IL-2) regress after an initial period of growth, leading to long-lasting protection from subsequent rechallenge.<sup>82,83</sup> In some cases, the immune response was shown to be dependent on CD8, but not CD4. This suggests that the IL-2 released by the tumor cells was bypassing the need for help from CD4 cells. In many studies, however, it was not clear whether systemic immunity was enhanced to levels greater than that which could be achieved using irradiated, nonmodified tumor cells.

In another study,<sup>84</sup> intraperitoneal, irradiated, IL-2-transduced murine bladder cancer cells were capable of treating 7-day parental tumors established by orthotopic implantation of tumor cells into the bladder wall. Irradiated nontransfected cells showed no antitumor response in these experiments.

Forty-five patients with renal cell cancer, melanoma, and sarcoma were treated with intratumoral injections of a DNA plasmid encoding human IL-2 complexed to the cationic lipids DMRIE/DOPE in a phase I/II study. Partial responses in uninjected tumors were observed in 2 of 14 patients with renal cell cancer and 1 of 16 patients with melanoma. On immunohistochemical evaluation of pre- and posttreatment biopsy specimens of injected tumors, an increase in IL-2 expression and CD8+ infiltration was observed in some patients.<sup>46</sup>

In another study, 23 patients with metastatic breast cancer and melanoma were treated with intratumoral injections of a recombinant adenovirus expressing IL-2. No clinical responses were seen, but IL-2 protein was detected by enzyme-linked immunoadsorbent assay in tumor at 48 hours but not at 7 days after injection. This finding demonstrated that some transgene expression could be detected, despite the presence of preexisting neutralizing antibodies against adenovirus.<sup>85</sup> Other trials have used autologous tumor or fibroblasts expressing IL-2 in melanoma<sup>86</sup> and colorectal cancer patients,<sup>87</sup> but no clinical responses have been reported.

**Granulocyte-Macrophage Colony-Stimulating Factor.** Granulocyte-macrophage colony-stimulating factor (GM-CSF) is a cytokine with the unique ability to stimulate the differentiation of hematopoietic progenitor cells into dendritic cells, a potent antigen-presenting cell. This property may allow increased presentation of tumor antigens on dendritic cells after immunization with tumors that express GM-CSF. In a comparative study,<sup>88</sup> mice were immunized with irradiated B16 melanoma cells that were transduced with either IL-2, IL-4, IL-5, IL-6, GM-CSF, interferon-g (IFN-g), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), intracellular adhesion molecule 1, or CD2. Only mice immunized with GM-CSF-transduced tumor cells were significantly protected against a subsequent tumor challenge (Fig. 62.1-6). IL-4- and IL-6-transduced tumor cells were minimally protective, but none of the other groups displayed a significant systemic antitumor response. GM-CSF-transduced B16 melanoma cells were also capable of significantly impacting on 3-day subcutaneous implants of a small inoculum of nontransduced B16 cells.<sup>88</sup> Immunization with GM-CSF-transduced tumor generated long-lasting systemic antitumor immunity that was dependent on both CD4+ and CD8+ T cells. Further studies have demonstrated that GM-CSF transduced tumor vaccines activate bone marrow-derived antigen-presenting cells to process and present tumor antigens to both CD4+ and CD8+ T cells.<sup>89</sup> Activated, tumor-specific CD4+ T cells were in turn shown to express both Th1 and Th2 cytokines that recruited other effector cells to the tumor, including eosinophils and macrophages. In addition, antitumor activity of GM-CSF-transduced vaccines were found to depend on the production of IFN-g, IL-4, and IL-5.<sup>90</sup>

**FIGURE 62.1-6.** Comparative analysis of vaccine efficacies of a poorly immunogenic murine tumor transduced with different cytokine genes. Syngeneic C57BL/6 mice were vaccinated subcutaneously with  $5 \times 10^5$  irradiated (3500 rad) B16 melanoma cells transduced with eight different cytokine genes using the MFG retroviral vector. Animals were challenged 14 days later with  $1 \times 10^6$  live nontransduced B16 cells subcutaneously. (From ref. 88, with permission.) *Open circles*, animal succumbed to tumor challenge; *solid circles*, animal protected from tumor challenge. GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN-g, interferon-g; IL, interleukin; TNF, tumor necrosis factor.

Three clinical studies have been reported that used GM-CSF-transduced tumors in renal cell cancer,<sup>91</sup> melanoma,<sup>92</sup> and prostate cancer.<sup>93</sup> In a phase I, randomized, double-blind dose-escalation study, patients with metastatic renal cell cancer were immunized with intradermal and subcutaneous injections of either nontransduced or GM-CSF-transduced autologous, irradiated renal cancer cells. Biopsy sites from patients receiving GM-CSF-transduced vaccines demonstrated infiltrates of macrophages, dendritic cells, eosinophils, neutrophils, and T cells consistent with preclinical studies. Delayed-type hypersensitivity responses using nontransduced autologous tumor cells revealed eosinophil infiltrates in only those patients who previously received GM-CSF-transduced vaccines. One partial response was seen out of nine patients treated with GM-CSF-transduced vaccines.<sup>91</sup>

In a phase I trial for patients with metastatic melanoma, 21 patients were immunized intradermally and subcutaneously with autologous melanoma cells transduced to express GM-CSF. Again, immunization sites were found to be infiltrated with T lymphocytes, dendritic cells, macrophages, and eosinophils in all 21 patients. Although only 1 of 21 patients had an objective partial response, 11 of 16 patients evaluated had T lymphocyte and plasma cell infiltrates in tumor biopsies after immunization.<sup>92</sup> In a phase I trial evaluating GM-CSF-transduced prostate cancer vaccination, delayed-type hypersensitivity reactions against nontransduced autologous tumor cells were positive in two of eight patients before vaccination and seven of eight patients after vaccination. However, no clinical responses were reported.<sup>93</sup>

**Interferon-g.** The introduction of the IFN-g gene into tumor cells can lead to the up-regulation of major histocompatibility complex (MHC) class I and class II gene products.<sup>94</sup> Although this effect can lead to decreased tumorigenicity,<sup>95</sup> it is unclear whether systemic immunity is enhanced. In some tumor systems with low class I expression or antigen processing defects, however, IFN-g-transduced tumor allowed the isolation of CD8+ lymphocytes capable of treating established pulmonary metastases from the parental, nontransduced tumor.<sup>96</sup> Thus, for some cancers, immunization with IFN-g-transduced tumor cells may allow the isolation of T cells capable of impacting on established, systemic disease.

**Other Cytokine Genes.** The introduction into tumor cells of a variety of other cytokine genes, such as TNF,<sup>88,97,98,99</sup> and 100 IL-1,<sup>101</sup> IL-4,<sup>102,103</sup> and 104 IL-6,<sup>105,106</sup> and 107 IL-7,<sup>108,109</sup> and 110 IL-13,<sup>111</sup> G-CSF,<sup>112</sup> MCP,<sup>113,114</sup> and RANTES,<sup>115</sup> can lead to decreased tumorigenicity. No evidence suggests, however, that these manipulations can increase systemic immunity above that which can be elicited from irradiated tumor cells.

Tahara et al.<sup>116</sup> introduced the IL-12 gene into murine MCA207 tumor cells (MCA207-IL-12), which resulted in decreased tumorigenicity. In addition, mice were injected with  $3 \times 10^5$  MCA207 cells in the left flank on day 0, followed by treatment on day 3 with saline, MCA207-Neo<sup>R</sup>, or MCA207-IL-12. Thirty-three percent of mice were free of tumor by day 21 when treated with MCA207-IL-12 tumor, compared to no animals free of tumor that were treated with saline or MCA207-Neo<sup>R</sup> tumor.<sup>116</sup> However, it is not clear whether these effects were due to the paracrine secretion of IL-12 or to a systemic effect of secreted IL-12.

Although the transduction of tumor cells with a variety of cytokine genes can result in decreased tumorigenicity in murine models, few studies have demonstrated that

this transduction leads to an enhanced immune response against the parental, nontransduced tumor compared to immunization with irradiated, nontransduced tumor cells. In one study, Hock et al.<sup>117</sup> demonstrated that tumor cells modified with different cytokine genes (IL-2, IL-4, IL-7, TNF, or IFN-g) were only slightly superior to irradiated parental cells as immunogens. Moreover, parental cells admixed with the classical adjuvant *Cryptosporidium parvum* were found to be superior to the cytokine-modified tumors in their ability to immunize mice against the tumor.<sup>117</sup>

## NONCYTOKINE GENES

**B7-1 (CD80).** The activation of T lymphocytes requires that they come in contact with a specific antigen and a costimulatory signal. One potential reason that some cancers develop and evade the immune system is that T lymphocytes are not adequately costimulated to become activated. The adhesion molecules B7-1 (CD80) and B7-2 (CD86) can bind to the CD28 receptor on T cells to provide costimulation.<sup>118</sup> Several groups have demonstrated that tumor cells transfected with B7-1 locally regress and lead to protection against subsequent tumor challenge with the parental tumor.<sup>119,120 and 121</sup> In one study,<sup>122</sup> regression of B7-transduced tumors was dependent on the intrinsic immunogenicity of the parental tumor.

Further studies are needed to assess the potency of B7 in the ability to stimulate an antitumor response.

**HLA-B7.** Several clinical trials based on murine models have been performed using intratumoral injection with plasmid DNA encoding HLA-B7 in HLA-B7–negative patients in the hopes of generating a stronger immune response against unmodified tumor cells.<sup>123</sup> Intratumoral injection of HLA-B7 plasmid DNA in a cationic lipid vector resulted in RNA or protein expression at the injection site in some patients,<sup>47,48</sup> but no tumor regression was seen in noninjected sites.

### Immunization with Genes Encoding Tumor Antigens

**RECOMBINANT VACCINES.** Whole tumor cells have been used as immunogens because the specific antigens recognized by T cells have been largely unknown. However, the cloning of several melanoma antigens recognized by T cells<sup>74,75,76,77 and 78</sup> has opened new possibilities for active immunization strategies for cancer. Studies in murine models have demonstrated that antigens expressed at high levels in recombinant adenoviral, fowlpox, and vaccinia vector systems can induce a significant antitumor immune response against tumors bearing the same antigen.<sup>124,125,126 and 127</sup> Recombinant viral vaccines can result in the *in vivo* production of high quantities of heterologous proteins. However, expression of native viral proteins by these vectors can also result in a host immune response against the vector itself, thereby diminishing the effectiveness of repeated immunizations.

Immunization studies with “naked DNA” given intramuscularly, or DNA administered on gold beads using the “gene gun” technique, have resulted in significant antitumor effects. Because these methods do not use viral vectors, no irrelevant viral proteins are expressed, thus allowing repeated immunizations.

Current efforts are focused on enhancing immune responses through adjuvant exogenous cytokine administration or introduction of genes encoding cytokines or costimulatory molecules into the recombinant vectors.

**DENDRITIC CELLS.** Another strategy to actively immunize a patient against cancer is to use potent antigen-presenting cells, such as dendritic cells. These cells are capable of stimulating immune responses from quiescent lymphocytes. Dendritic cells pulsed with tumor peptide or protein antigens have been shown to have significant antitumor effects in murine models<sup>128</sup> and were reported to be effective in one study of patients with lymphomas. Nestle and colleagues<sup>129</sup> treated 16 metastatic melanoma patients with intranodal injections of dendritic cells pulsed with tumor lysates or peptides derived from known tumor antigens. Eleven of 16 patients demonstrated a positive delayed-type hypersensitivity reaction to peptide-pulsed dendritic cells, and clinical responses were observed in five patients.<sup>129</sup>

Although antitumor responses can be obtained in murine models by administering dendritic cells pulsed with peptide antigens or whole proteins, this approach limits immune responses to specific, defined MHC-binding epitopes within a given antigen or requires the production of recombinant proteins. For many tumor antigens, however, multiple epitopes have been described that bind to a variety of MHC molecules. One strategy that may enable the presentation of multiple, even undefined, epitopes within a given tumor antigen is the introduction of an antigen gene into the dendritic cell. This strategy may allow multiple epitopes to be presented in the context of both class I and class II molecules as well as the constitutive expression of these antigens in transduced dendritic cells. Several strategies have been proposed to genetically modify dendritic cells with tumor antigens. One is to transduce bone marrow cells and differentiate the cells *in vitro* into dendritic cells, using GM-CSF.<sup>130,131 and 132</sup> Another is the transient transfection of dendritic cells using cationic lipids,<sup>133</sup> gene gun, adenovirus,<sup>134,135</sup> or recombinant influenza virus.<sup>136</sup>

## GENETIC MODIFICATION OF IMMUNE EFFECTOR CELLS

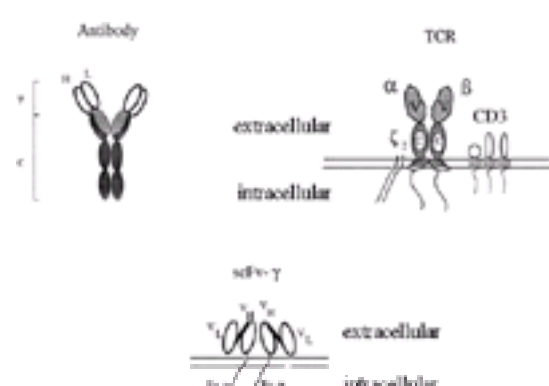

Several lines of evidence indicate that adoptively transferred T cells can be therapeutically effective. TILs have been shown to mediate significant responses in patients with melanoma, even in those who have not been successful with previous therapy with IL-2.<sup>137</sup> Adoptively transferred cytomegalovirus-specific T cells have been shown to prevent cytomegalovirus infections in patients after allogeneic bone marrow transplantation.<sup>138</sup> Infusion of donor T cells has been effective in treating the EBV-driven lymphoproliferative disease that sometimes complicates allogeneic bone marrow transplantation.<sup>64</sup> Patients with CML recurrence after allogeneic bone marrow transplantation can experience remission after transfer of donor T cells.<sup>139</sup> Several strategies for the genetic modification of transferred T cells attempt to increase their effectiveness.

### Enhancing Survival of Immune Cells

For T cells to be functional against a tumor, they must survive *in vivo*, recognize the target, and then execute an adequate antitumor effector mechanism, either by direct cell lysis or release of cytokines that may attract and stimulate other immune cells. There are several ways to potentially enhance these steps. T cells grow in response to stimulation by various cytokines, such as IL-2. On adoptive transfer of TILs in murine models, the administration of systemic IL-2 potentiates the antitumor effect, presumably by maintaining growth and viability of the administered TILs.<sup>140</sup> By inserting the gene for IL-2, TILs may become able to stimulate themselves in an autocrine fashion, as demonstrated by Yamada et al.<sup>141</sup> and Karasuyama et al.<sup>142</sup> in CTL line and murine HT-2 T cells, respectively. Treisman et al.<sup>143</sup> demonstrated that a T-cell clone transduced with the IL-2 gene could grow in an IL-2–independent fashion while maintaining antigen specificity.<sup>143</sup> However, further work must be done to obtain sufficient IL-2 secretion in primary lymphocytes for this approach to be clinically useful. In addition, insertion of the gene encoding the IL-2 receptor, which is normally up-regulated by lymphocytes after antigen stimulation, may also be required to obtain a proliferative response to IL-2.

### Increasing Tumor Recognition by Using Novel Receptor Genes

**CHIMERIC ANTIBODY/T-CELL RECEPTOR GENES.** Although adoptive immunotherapeutic strategies have been developed for some cancers, tumor-reactive T cells are difficult to isolate and expand from most types of cancer. A variety of monoclonal antibodies have been developed that bind to specific cancers. Although cancer therapy with antibodies has been largely disappointing, partially because of the lack of an adequate effector mechanism to destroy tumor cells on binding. By combining the antigen-recognition domains from antibodies with the intracellular, signaling chains of T cells, chimeric receptors can be generated that activate T cells based on antibody-like recognition ( Fig. 62.1-7). This approach, which uses the antigen-binding capabilities of antibodies with the potent antitumor activity of T cells, would allow the production of specific T cells against any antigen for which a monoclonal antibody exists. This strategy could widely generalize the use of adoptive immunotherapy for cancer and infectious diseases.

**FIGURE 62.1-7.** The chimeric immunoglobulin T-cell receptor (TCR) combines antibody-variable regions with T-cell signaling chains. In this diagram, a single-chain antibody variable (scFv) fragment derived from the variable regions of a monoclonal antibody is joined to the Fc receptor g chain, which is related to the TCR-z chain and can mediate T-cell signal transduction. <sup>149</sup>

The successful combination of antibody-variable regions with T-cell signaling chains has been established for several model antigens, such as phosphorylcholine, digoxin, and trinitrophenyl. <sup>144,145,146</sup> and <sup>147</sup> These initial approaches, however, required the use of two genes, because the antibody-variable region is encoded by a combination of light and heavy chains. This two-gene strategy, however, is impractical for use in clinical trials using primary T cells, because transduction efficiencies are relatively low for even one gene. Therefore, chimeric receptors encoded on a single gene <sup>148,149</sup> were designed by making use of single-chain antibody variable (scFv) regions in which the light- and heavy-chain variable regions are connected by a flexible linker. <sup>150,151</sup> and <sup>152</sup> These scFv fragments were joined to T-cell receptor (TCR) z or Fc receptor g chains, both of which are closely related and have been demonstrated to be capable of mediating TCR signal transduction. <sup>153,154,155,156</sup> and <sup>157</sup>

Using this single-gene approach, receptors have been constructed using the mAb MOv18, which binds to a folate-binding protein overexpressed on most ovarian adenocarcinomas. <sup>158,159</sup> T cells retrovirally transduced with these receptor genes demonstrate specific cytokine secretion and cytolysis when cultured with human ovarian cancer cells. In addition, intravenously administered murine T cells transduced with this receptor could specifically treat experimental lung metastases from tumors that express the ovarian cancer antigen. Intraperitoneal administration of these T cells could also successfully treat human ovarian cancer cells growing intraperitoneally in nude mice. <sup>160</sup> These studies demonstrate that T cells can be manipulated genetically to recognize and destroy tumor cells based on antibody-type specificity.

Besides triggering direct T-cell activation with g and z chains, antibody-variable regions can be coupled to other signaling chains, such as the intracellular portion of CD28, an important T-cell costimulatory receptor. This approach has been found to enhance T-cell survival and proliferation *in vitro*. <sup>161</sup>

Most recently, the transduction of hematopoietic stem cells with chimeric receptor genes has been under investigation, because this may not only provide a stable supply of redirected T cells, but also granulocytes, macrophages, and natural killer cells, all of which may have significant antitumor activity on expression of chimeric receptor genes. Mice that received MOv-g-transduced bone marrow cells exhibited significant antigen-specific antitumor activity *in vivo*. <sup>162</sup>

These strategies have the potential of widely generalizing the use of adoptive immunotherapy. scFv-g and -z receptors have been constructed against breast cancer using an anti-HER2 mAb, <sup>163</sup> colon cancer using an anti-GA733 mAb, <sup>164</sup> and HIV using an anti-gp41 mAb. <sup>165</sup> This strategy could be applied to a wide range of cancer histologies or infectious diseases for which appropriate mAb exist.

**NATIVE T-CELL RECEPTOR GENES.** T-cell specificity can also be altered by the introduction of genes encoding native TCRs. The TCR consists of an a and b chain heterodimer that confers the ability to specifically recognize peptide/MHC complexes on antigen-presenting cells and target cells. TCRs derived from melanoma-specific CTLs have been identified, cloned, and characterized. <sup>166</sup> Clay et al. <sup>167</sup> transduced primary lymphocytes with a TCR gene specific for the MART-1 melanoma tumor rejection antigen. Because the TCR consists of two individual chains, a retroviral vector was constructed that uses internal ribosomal entry sites (IRES sequences) that allow the translation of multiple genes from a single transcript. Primary T cells transduced with this construct were capable of specifically recognizing tumor cells expressing the MART-1 melanoma tumor antigen in the context of HLA-A2. As more TCRs recognizing specific tumor antigens are characterized and cloned, this strategy may generalize the use of adoptive immunotherapy, circumventing the need to isolate T cells with specific reactivities from each individual patient.

#### **Transduction of T Cells and Donor Lymphocytes with Suicide Genes**

Adoptively transferred T cells have been safely administered to many patients for more than 10 years. In specific situations, however, the adoptively transferred cells may be toxic to the host, such as in the treatment of immunocompromised HIV patients. In the setting of allogeneic bone marrow transplantation for hematologic malignancies, donor lymphocyte infusions can be highly effective against tumor as well as EBV-induced lymphoma but may also incite graft-versus-host disease. In an attempt to increase the therapeutic index of adoptively transferred cells in these situations, "suicide" genes can be introduced into lymphocytes to specifically delete the transduced cells should they become toxic to patients *in vivo*. The gene for herpes TK (hTK) has been used for this purpose, because it specifically sensitizes cells to the antiviral agent ganciclovir.

In one study using hTK-transduced donor lymphocytes, three of eight patients receiving donor lymphocytes after allogeneic bone marrow transplantation for hematologic malignancies developed acute or chronic graft-versus-host disease. In these patients, ganciclovir administration significantly diminished the number of circulating hTK-transduced cells within 24 hours, resulting in complete or partial remissions of the disease <sup>168</sup> (Table 62.1-5).

Patient	GVHD (Grade)	Proportion of Transduced PBL (%)		Clinical Outcome of GVHD
		Pre-ganciclovir	24 Hr after Ganciclovir	
1	Acute skin (II/III)	13.1	<0.1*	CR
2	Acute liver (III)	2.0	<0.1*	CR
3	Chronic lung, skin, gastrointestinal tract	11.9	2.8	PR

CR, complete remission of GVHD; PBL, peripheral blood lymphocytes; PR, partial remission of GVHD.  
(Adapted from ref. 168, with permission.)

**TABLE 62.1-5.** Effect of Ganciclovir Treatment on Elimination of Herpes Thymidine Kinase–Modified Donor Lymphocytes and on Graft-Versus-Host Disease (GVHD)

In another study, anti-HIV CTLs were transduced with a fusion gene encoding hTK and the selectable marker hygromycin before administration in HIV-infected patients. <sup>169</sup> Because HIV patients are immunocompromised, the CTLs could be irradiated with ganciclovir should the transduced cells become toxic. However, initial results of the trial revealed that the patients were developing cellular immune responses against the hTK-hygromycin fusion protein, thus demonstrating that foreign genes, including selectable markers, can themselves become targets of the host immune response.

#### **Increasing Antitumor Efficacy of Immune Cells**

TNF has potent antitumor activity against large tumor burdens in some murine models. <sup>170,171</sup> and <sup>172</sup> However, humans can only tolerate 2% of the systemic TNF dose (by weight) required in mice, due to dose-limiting hypotension. <sup>173,174,175,176</sup> and <sup>177</sup> High doses of TNF, administered locally via direct tumor injection <sup>178,179</sup> or isolated limb perfusion, <sup>180</sup> can result in dramatic tumor regressions in some cancer patients. At the National Cancer Institute's Surgery Branch, regressions of liver metastases have been seen in patients treated with TNF administered as a component of an isolated hepatic perfusion. <sup>181</sup> Therefore, tumor regressions seem possible in patients when adequate local concentrations of TNF can be achieved. Because TILs have been demonstrated to accumulate at sites of tumor, <sup>182,183</sup> and <sup>184</sup> the transduction of TILs with the TNF gene may allow high concentrations of TNF to be delivered locally in the absence of systemic toxicity. <sup>185</sup>

Twelve patients have been treated with TNF-transduced TILs in a phase I trial using escalating doses of TILs and IL-2. No safety problems or toxicity have been detected. Replacement of the TNF transmembrane region with the signal peptide from interferon-g, thus bypassing the transmembrane form, <sup>186,187</sup> resulted in a fivefold increase in TNF production. <sup>185</sup> Despite this improvement, however, primary lymphocytes transduced with the TNF gene probably do not produce high enough

levels of TNF constitutively to be clinically effective. To optimize this treatment strategy, current efforts are directed toward identifying promoter/enhancer regions that direct higher levels of gene expression in primary lymphocytes.

## MODIFICATION OF TUMORS WITH GENES THAT HAVE DIRECT ANTITUMOR EFFECTS

The gene therapies that have been discussed thus far have all focused on the stimulation of the immune system to react against tumor cells. Another approach to cancer gene therapy is to introduce genes into tumor cells that have direct antiproliferative or toxic effects on that cell. This approach, however, requires techniques to directly administer genes into tumor cells *in vivo* with high efficiencies, which is not technically possible at this time. However, as vector development continues, the direct administration of genes into patients may play a more important role. Some preliminary studies have been initiated that use direct *in vivo* administration of genes into tumor cells.

### TUMOR SUPPRESSOR GENES

Cancer can result from the abnormal expression of genes that control the cell cycle. Some genes, termed *tumor suppressor genes*, regulate cell growth, and their absence by mutation or deletion results in the malignant phenotype. One approach to treat tumors with deleted or mutated tumor suppressor genes is to replace these genes by *in vivo* gene transfer. Currently, gene transfer techniques do not exist that are capable of efficiently delivering these genes systemically to all tumor cells in the body, and significant technical improvements are required if this approach is to become practical.

Because of this limitation in systemic delivery, several groups have attempted local gene delivery of tumor suppressor genes. <sup>188,189</sup> Swisher and colleagues<sup>190</sup> treated 28 patients with non-small cell lung cancer with intratumoral administration of an adenovirus vector containing wild-type p53 complementary DNA.

Reverse-transcriptase PCR analysis of posttreatment biopsies were positive for the presence of vector-specific p53 mRNA in 12 of 26 patients. Partial response of the injected lesion was observed in 2 of 25 evaluable patients (8%).<sup>190</sup> Because local therapy is of limited utility in the face of metastatic disease, these studies highlight the need for improved vectors that would allow efficient, systemic gene delivery.

### ANTISENSE AND RIBOZYMES

Oncogenes are genes that cause uncontrolled cell growth when mutated or overexpressed, and neutralization of these genes can reverse the malignant phenotype. One approach to inactivate genes uses antisense oligodeoxynucleotides, <sup>191,192</sup> which are short sequences that are complementary to target RNA transcripts and can inhibit translation of the RNA into protein.

Oligonucleotides have been shown to enter cells by at least two pathways (i.e., endocytosis and pinocytosis), and significant activity of antisense constructs has been observed *in vitro* using tissue culture cell lines. *In vitro* growth suppression has been demonstrated using antisense oligonucleotides against BCL-2 <sup>193</sup> in leukemia cells, BCR-ABL<sup>194</sup> in CML cells, MYC<sup>195</sup> in lymphoma cell lines, and MYB<sup>196,197</sup> in adenocarcinoma and leukemia cell lines.

Several studies have been performed in mice demonstrating *in vivo* efficacy of antisense oligonucleotides against tumors. Antisense inhibition of c-myc mRNA increased survival of scid mice bearing human K562 leukemia cells.<sup>198</sup> In another study, antisense against the p65 subunit of nuclear factor κB inhibited the growth of the murine fibrosarcoma K-BALB and the murine melanoma B16.<sup>199</sup>

Webb and colleagues<sup>200</sup> treated nine patients with non-Hodgkin's lymphoma with daily subcutaneous BCL-2 antisense oligonucleotide for 2 weeks. BCL-2 overexpression can promote tumorigenesis by causing resistance to programmed cell death (apoptosis). A complete response was observed in one of nine patients, with resolution of left axillary lymphadenopathy.<sup>200</sup>

A current limitation to this approach is the inability to successfully deliver antisense constructs to tumor cells *in vivo* with adequate efficiency. In addition, antisense studies must be interpreted carefully, because of the possibility of nonspecific effects. For example, because charged oligonucleotides are polyanions, they can bind nonspecifically to growth factors, such as basic fibroblast growth factor (bFGF).<sup>201</sup>

Another potential method to target activated oncogenes is through the use of ribozymes. These are RNA enzymes that catalyze endoribonucleolytic cleavage of RNA.<sup>202</sup> Several investigators have reported cleavage of the bcr-abl transcript, which is involved in the pathogenesis of chronic myelogenous leukemia, by specific hammerhead ribozymes. Anti-fos and anti-ras ribozymes also have been reported.<sup>202</sup> At the present time, however, no adequate *ex vivo* or *in vivo* systems can deliver ribozymes to target cells.

### SUICIDE GENES

Because retroviral vectors integrate preferentially into dividing cells, replicating tumor cells might be targeted with relative specificity compared to normal tissues. To test this hypothesis, Culver et al.<sup>203</sup> implanted cell lines producing recombinant retrovirus containing the hTK gene into brain tumors in rats, then administered systemic ganciclovir therapy. Ganciclovir is a nucleotide analogue that is converted into a cytotoxic molecule by hTK, but it is a poor substrate for mammalian TK. Using this method, tumors regressed, and significant toxicity to surrounding normal tissues was not observed. Because the hTK gene can only be delivered locally *in vivo*, this treatment approach is limited to those cancers whose primary morbidity is due to local, unresectable disease. More than 30 clinical trials using suicide gene therapy have been approved by the RAC, including studies of patients with brain tumors, mesothelioma, prostate cancer, head and neck cancer, ovarian cancer, and colorectal cancer (see [Table 62.1-2](#)). These trials use retroviral and adenoviral gene transfer techniques to deliver the herpes simplex virus (HSV)-TK or cytosine deaminase suicide genes, which is followed by systemic therapy with ganciclovir (for HSV-TK) or 5-fluorocytosine (for cytosine deaminase).

Ram and colleagues<sup>204</sup> treated 15 patients with brain tumors, including malignant glioma (n = 12), metastatic melanoma (n = 2), and metastatic breast cancer (n = 1), with intratumoral implantation of up to  $1 \times 10^9$  producer cells making retroviral vectors encoding HSV-TK, followed by systemic ganciclovir therapy for 14 days. *In situ* hybridization revealed that vector producer cells survived up to 7 days *in vivo* but were associated with only a low level of gene transfer to tumors. Five of the smaller tumors ( $1.4 \pm 0.5$  mL) showed evidence of antitumor activity, but larger tumors did not respond.

Several groups have reported the local administration of recombinant adenovirus containing HSV-TK, <sup>205,206</sup> but it is not clear whether these approaches have any advantages over other methods of local therapy. In addition, the tumor specificity of this approach is a potential problem, because, in contrast to retroviral vectors, no evidence indicates that adenovirus infects dividing tumor cells preferentially over nondividing normal tissue.

In an attempt to enhance the tissue specificity of suicide gene therapy, Pandha and colleagues<sup>207</sup> treated 12 breast cancer patients with intratumoral injections of a plasmid construct encoding the *Escherichia coli* cytosine deaminase suicide gene driven by the human erbB-2 promoter, followed by systemic prodrug administration. Significant levels of expression of the suicide gene were specifically restricted to erbB-2-positive tumor cells.<sup>207</sup>

A major limitation in the current application of *in vivo* gene therapy approaches for cancer, such as suicide gene strategies, is the absence of an adequate delivery system that could transfer the suicide gene to all cancer cells within a patient's body. Despite a potential "bystander effect," which may mediate the destruction of tumor cells surrounding those expressing the suicide gene, current gene transfer technology is too inefficient to allow the application of this strategy for the treatment of disseminated metastatic cancer. A second limitation to the use of suicide genes is that of specificity. For any cancer therapy to be effective, the toxicity for the tumor cells must be greater than for normal tissues. Retroviral vectors may theoretically be more selective for tumor cells than normal tissues, because retroviruses only infect proliferating cells. However, retroviruses are suboptimal for *in vivo* administration because of their low efficiency of transduction. Adenoviral vectors, on the other hand, show no selectivity towards tumor cells.

Enhanced tumor specificity might be accomplished by using tumor-specific promoter/enhancer regions to direct transcription of the suicide genes. For example, the α-fetoprotein promoter is primarily active in hepatoma cells,<sup>208</sup> whereas the tyrosinase promoter is specifically active in melanocytes and melanoma cells.<sup>209</sup> This approach also has been suggested to target tumor vasculature, using promoters that are relatively specific for endothelial cells, such as the E-selectin, vascular cell adhesion molecule, and CD31 promoters.<sup>210</sup> The use of tumor- or tumor-vasculature-specific promoters might decrease destruction of normal cells, because they would not express the suicide gene product. For these approaches, however, the fundamental problem of inadequate gene delivery still remains.

## SELECTIVE REPLICATION OF VIRUS IN TUMORS

*In vivo* gene delivery to tumors using replication-defective viral systems are presently inadequate to obtain sufficient transduction efficiency. The design of a virus that could specifically replicate in and destroy tumor cells would be of obvious value. Some efforts <sup>211</sup> have used E1B-defective adenoviruses capable of specifically replicating and destroying tumor cells that lack p53 tumor suppressor function. The p53 protein is a transcription factor that acts as a potent tumor suppressor by its ability to induce cell-cycle arrest and apoptosis. Functional p53 is present in normal cells but is absent in more than 50% of the common solid tumors. Normally, on viral infection, p53 triggers early apoptosis of the cell, thereby limiting viral replication and spread. However, many viruses have evolved proteins, such as the adenoviral E1B 55-kD protein, that inhibit normal p53 function, thereby allowing maximal viral replication. E1B-defective adenoviruses, therefore, cannot fully replicate in normal tissues expressing p53, but they can replicate in tumor cells that lack functional p53.

Bischoff et al. <sup>211</sup> found that an E1B-deleted adenovirus (ONYX-015) could lyse p53-deficient human tumor cells but not cells with functional p53. Intratumoral injection of ONYX-015 caused regression of human cervical carcinomas grown in nude mice. Heise and colleagues <sup>212</sup> reported augmentation of antitumor effects of ONYX-015 by chemotherapy, as well as the efficacy of intravenously administered ONYX-015 in nude mice with subcutaneous human tumor xenografts. <sup>213</sup> Clinical trials are ongoing to test this approach in patients with head and neck cancer.

Studies have questioned whether the tumor specificity of ONYX-015 is strictly related to p53 expression by the tumor cells. Rothmann et al. <sup>214</sup> found that replication of ONYX-015 was independent of p53 status in tumor cells, and Hall and colleagues <sup>215</sup> reported that productive adenovirus infection was dependent on the p53 pathway. Therefore, much needs to be determined regarding the host range and mechanism of action of ONYX-015. In addition, the next generation of tumor-specific "smart viruses" must address enhanced specificity and systemic delivery of the virus, as well as methods to prevent humoral and cellular host immune responses against the virus.

## INTRODUCTION OF GENES INTO HEMATOPOIETIC STEM CELLS TO DECREASE TOXICITY FROM CHEMOTHERAPY

Expression of the MDR gene decreases the toxicity from certain chemotherapy drugs, such as Taxol, Adriamycin, vincristine, and actinomycin D, by encoding for a transmembrane molecule that actively pumps these cytotoxic agents out of the cell. <sup>216,217</sup> Expression of the MDR gene in tumor cells is commonly associated with tumor resistance to these cytotoxic agents. Sorrentino et al. <sup>218</sup> transplanted MDR-transduced bone marrow cells into mice and substantially enriched for these cells after treatment with Taxol. Several clinical trials are now under way that attempt to genetically modify bone marrow cells with the MDR gene, then reinfuse them into the patient in an attempt to decrease hematopoietic toxicity from subsequent chemotherapy. However, clinical trials with patients receiving transduced bone marrow have shown that only a small percentage of hematopoietic cells are gene modified. <sup>219,220</sup> This limitation has been confirmed by several groups attempting to decrease chemotherapy toxicity with MDR-transduced hematopoietic progenitor cells. Cowan et al. <sup>221</sup> found low levels of short-term engraftment of MDR-transduced cells in three of four patients treated, and Hersdorffer and colleagues <sup>222</sup> had similar results in two of five patients. Hanania et al. <sup>223</sup> found that the method of transduction was important. They compared a 3-day transduction method on a stromal monolayer to a 4- to 6-hour transduction procedure in a culture bag. Three to 4 weeks after transplantation, none of ten patients receiving cells transduced with the supernatant method had MDR-positive cells, whereas five of eight patients receiving cells transduced with the stromal method had MDR-positive cells. <sup>223</sup> However, the percentage of positive cells was not quantified and was presumably low because of the requirement for sensitive PCR methods for detection.

Therefore, the success of this strategy may depend on whether the levels of gene transfer are sufficient to allow the administration of higher doses of chemotherapy. If this approach is to have a significant impact in cancer therapy, an effective chemotherapeutic regimen must exist that can eradicate tumor before the development of significant nonhematopoietic toxicities, such as liver failure.

## ANTIANGIOGENIC GENE THERAPY

The discovery by Folkman <sup>224</sup> in the 1970s that tumors produce substances that stimulate the growth of their vasculature has led to intensive investigation into methods to inhibit tumor neovessel formation. Production of proangiogenic cytokines, including vascular endothelial growth factor (VEGF) and FGF, result in angiogenesis, which is required for tumor growth. <sup>225</sup> One gene therapy strategy, therefore, has focused on the inhibition of the production or function of proangiogenic cytokines. A second strategy involves the delivery of genes that encode inhibitors of angiogenesis. <sup>226</sup> A number of endogenous proteins have been described that are capable of inhibiting angiogenesis, and their expression *in vivo* may result in antitumor activity through interference with tumor blood supply.

### GENES THAT INHIBIT PROANGIOGENIC CYTOKINES

VEGF is a proangiogenic cytokine that can bind to two high-affinity receptors (VEGFR-1/FLT-1 and VEGFR-2/KDR) expressed on vascular endothelial cells. An endogenous, alternatively spliced soluble form of FLT-1 (sFLT-1) has been identified <sup>227</sup> that is capable of inhibiting the effects of VEGF on vascular endothelial cells *in vitro*. Systemic administration of recombinant adenovirus expressing sFLT-1 resulted in tumor inhibition in mice with preexisting lung or liver metastases. <sup>228</sup> In another preclinical model using GS-9L gliosarcoma cells in rats, intracerebral or subcutaneous intratumoral injection of retrovirus-producing cells encoding a dominant-negative VEGFR-2 resulted in tumor inhibition that was associated with decreased vessel density within tumors. <sup>229</sup>

Antisense approaches also are being tested as a means to inhibit VEGF. Use of a recombinant adenovirus-encoding antisense VEGF for intratumoral injection of subcutaneous human gliomas in nude mice resulted in the inhibition of tumor growth. <sup>230</sup> The von Hippel-Lindau (VHL) gene <sup>231</sup> has been shown to down-regulate VEGF production by human renal cancer cells. <sup>232</sup> Therefore, gene therapy by introducing the VHL gene into tumors is a potential strategy to down-regulate VEGF expression *in vivo*. As with other approaches that depend on *in vivo* gene delivery into tumor cells, this approach is limited by the requirement for an efficient system that allows gene transfer to a majority of cancer cells *in vivo*.

Urokinase-type plasminogen activator (u-PA) is a FGF that can result in endothelial cell proliferation. Soluble N-terminal fragments of u-PA have been used to competitively inhibit the binding of endogenous u-PA with its receptor. Systemic administration of recombinant adenovirus encoding a competitor fragment of u-PA has been shown to inhibit liver metastases in an experimental model of human colon cancer in nude mice. <sup>233</sup>

Tie2 is an endothelium-specific receptor tyrosine kinase that plays an important role in angiogenesis of embryonic vasculature through the interaction with its ligand, angiopoietin 1. <sup>234,235</sup> Systemic administration of a recombinant adenovirus expressing a soluble Tie2 receptor (sTie2) capable of blocking Tie2 activation resulted in growth inhibition of subcutaneous murine mammary (4T1) and melanoma (B16F10.9) cells. In addition, the sTie2 recombinant adenovirus inhibited the development and neovascularization of pulmonary metastases. <sup>236</sup>

### GENES WITH ANTIANGIOGENIC PROPERTIES

A number of endogenous inhibitors of angiogenesis have been described. They include antiangiogenic proteolytic fragments, ILs, IFNs, thrombospondins, and tissue inhibitors of matrix metalloproteinases (TIMPs). Angiostatin is a 38-kD internal fragment of plasminogen, and endostatin is a 20-kD fragment derived from the C-terminal noncollagenous domain of the basement membrane constituent collagen XVIII. <sup>237,238</sup> Administration of angiostatin and endostatin can lead to tumor dormancy and regression in murine models. <sup>237,238</sup> However, these proteins have been difficult to produce in large quantities for clinical use because of instability. Because it may be necessary to administer antiangiogenic agents chronically to maintain long-term tumor suppression, other strategies besides administration of recombinant protein may be required for these approaches to be effective. Gene therapy using genes encoding these proteolytic fragments may be an attractive alternative to exogenous dosing.

Systemic administration of recombinant adenovirus expressing angiostatin resulted in dose-dependent inhibition of the establishment and growth of C6 rat gliomas in nude mice. <sup>239</sup> Using intravenous delivery of complexes of cationic liposomes and plasmid DNA-encoding angiostatin, Liu et al. <sup>240</sup> demonstrated reduced B16F10 melanoma metastases in a 7-day tumor model.

Feldman et al. <sup>241</sup> demonstrated inhibition of subcutaneous MC38 murine colon adenocarcinomas using intravenous administration of recombinant adenovirus

expressing the endostatin gene. In this model, circulating levels of endostatin were as high as 2038 ng/mL in nude mice after injection of adenovirus. [241](#)

Preclinical gene therapy approaches have been investigated using genes encoding a number of other antiangiogenic agents, including IL-4, IL-10, IL-12, IFN- $\beta$ , thrombospondin-1, TIMP-1, TIMP-2, and platelet factor-4. In addition, the combination of ionizing radiation and intratumoral administration of a recombinant adenovirus expressing TNF- $\alpha$  resulted in tumor suppression in a murine xenograft model mediated by the destruction of tumor microvasculature. ## INTRODUCTION

The modern age of chemotherapy has its origins in ancient civilizations thousands of years ago, when therapists went to the forests to dig up roots, to peel the bark from trees, and to pick the leaves and flowers from plants as the first step in drug development. Through the time-consuming process of trial and error, extracts of these natural substances were identified that conferred a beneficial effect on the natural history of life-threatening diseases, such as cancer. It was not until the middle of the twentieth century that sufficient quantities of the purified active ingredients of these plant extracts were available for clinical trials.

The structure of these plant alkaloids, which were complex polycyclic hydrocarbon molecules, barely soluble in aqueous solvents and associated with very significant toxicities for the central nervous system, the kidney, and the hematopoietic and the gastrointestinal tissues, posed challenges for the therapist. Despite these limitations, plant compounds, such as the epidophyllotoxins, the periwinkle alkaloids, the taxanes, and the camptothecins, have formed the basis of the most successful cancer treatment regimens of the first 30 years of chemotherapy.

Tremendous ingenuity has been displayed by pharmacologists and cancer treatment specialists, who have designed methods for limiting and circumventing the very significant toxicities of these compounds. Chemists working with synthetic organic compounds have continuously attempted to improve on the original natural products, which have spawned synthetic derivative compounds of the original natural products, such as vinorelbine tartrate, taxotere, and irinotecan, which are now displaying exciting patterns of activity in refractory epithelial neoplasms.

The next phase of the development of chemotherapy was the cloning of the genes for naturally occurring biologically active molecules, such as interferon, interleukin-2, and the growth factors. During the last decade of the twentieth century, the enormous power of structural biology and computational chemistry was used to design totally synthetic compounds, which have no relationship to natural products but have displayed exciting activity in disease states: the protease inhibitors for human immunodeficiency virus, the kinase inhibitors for chronic myelocytic leukemia (CML), and the low-molecular-weight chemical inhibitors for virally associated cancers.

Now, at the dawn of the twenty-first century, the power of protein structure analysis, computational chemistry, combinatorial chemistry, and the engineering of biopolymers are being combined to produce an entirely new generation of antineoplastic drugs that are already reaching the clinic.

## STRATEGIES OF NEW DRUG DESIGN

### TYPES OF TARGETS

The drugs discussed here are those that will be designed to modify the assembly of subunits in a multimeric protein or to alter the assembly of complexes of multiple proteins into a receptor or a multiprotein array that is promoting the formation of a transcription initiation complex or a replication initiation complex. Thus, the ideal types of protein domains as targets for inhibition by low-molecular-weight chemicals must be considered before proceeding to the design of an inhibitor.

### ATTRIBUTES OF AN IDEAL TARGET PROTEIN FOR MOLECULAR THERAPY

The attributes of an ideal target protein are outlined in [Table 62.2-1](#). The ideal target for molecular therapy is a protein the sequence of which is unique to the tumor cell and is one that confers a selective growth advantage to the tumor cells. In addition, it is important that the target sequence be present in the tumor cells of all patients with that type of cancer and that 100% of the tumor cells in every patient have the target sequence.

<b>STRUCTURE SPECIFICITY</b>
Unique sequence by virtue of mutation, or chimeric junctional regions
Unique intracellular location
Unique pattern of expression
Origin from nonmammalian sources (DNA tumor virus oncoproteins)
<b>PROTEIN DOMAIN</b>
Receptors
Enzyme catalytic pockets
Crevices in DNA binding domains
Interdigitating subunits of a multimeric protein
G protein GTP domain
<b>PREVALENCE IN TUMOR POPULATION</b>
Confers selective advantage on tumor cell
Present in a significant percentage if not 100% of tumor cells
Tumor cell retains dependency on target protein
GTP, guanosine triphosphate

**TABLE 62.2-1.** Ideal Attributes of a Target Protein Oncoprotein Domain for Molecular Therapy

The ideal target is present in 100% of the cells of a tumor population, because the presence of this protein target confers on the cell in which it resides a selective advantage over cells that do not contain this change. This type of target has dual advantages: The inhibition of the function of this target protein will suppress the transformed phenotype and, at the very least, will halt the progression of the disease state. It may also induce cell death of the neoplastic cell.

Another attribute that is important for an ideal target is that it presents some feature unique to the regulatory environment of the tumor cell that is not shared by the normal noncancerous cell. This type of tumor-specific target enhances the probability that an inhibitor will be specifically toxic for the tumor cell and will not adversely affect the normal cells. Examples of targets that are totally unique for the tumor cell include viral oncoproteins (proteins that may not have a correlate in normal mammalian cells), a chimeric gene that produces proteins with protein junctional domains that are not present in normal cells, a mutant primary structure of a widely expressed protein, posttranslational modification of a protein that is unique to the tumor cell, and a protein that is either expressed inappropriately in a particular type of tissue or appears in an intracellular location that is unique to the tumor cell. [Table 62.2-2](#) presents a list of examples of such target oncoproteins that exhibit one or

more of these attributes.

**TABLE 62.2-2.** List of Candidate Target Oncoproteins

In terms of the types of domains in the target protein that are more or less optimal for computational analysis and for interaction with low-molecular-weight chemical inhibitors of protein action, there is general consensus in the field that protein-protein contact regions are very poor regions for modulation by chemical inhibitors. The interactions that represent the contact points for proteins often are hydrophobic areas that are binding to one another through van Der Waals forces. Such forces are at any given point extremely weak in terms of affinity. Thus, the interposition of a chemical that blocks interaction at a single point in this broad surface has very little effect on the overall assembly of a protein.

In contrast, receptors or pockets in which the catalytic site of an enzyme is located, or the crevice of a DNA binding domain, or a homodimerization domain that consists of interlocking invaginations, or stacking of flat aromatic amino acid side chains (e.g., tryptophans), which can bind to one another through sharing of electron orbitals, provide the structure within which a low-molecular-weight inhibitor can interact to disrupt a complex. Chemical inhibitors can act at multiple points with the local peptide domains to establish a very stable, high-affinity interaction that can have an impact on the entire protein.

Although receptors or enzyme pockets have a more stable conformation, all these regions of the protein are very mobile and are in continuous motion at the atomic level. Thus, interactions with low-molecular-weight chemical inhibitors may stabilize one of more of the conformations available to a protein domain. Low-molecular-weight chemicals that are designed to be inhibitors can stabilize a nonfunctional or inactive state of the protein. One example is the inactive state of a growth factor or an integrin receptor. Another example is the inactive state of the RAS proteins. A third example is a drug that can stabilize a conformal state of the protein, which limits access of a substrate, inhibits assembly of a multisubunit protein, or reduces the probability of assembly of a transcription initiation complex. Obviously, the more detailed the structural information, the more successful any design effort that is based on structure.

The alternative approach in developing drugs that stabilize one conformal state versus another is to select low-molecular-weight chemicals from a library of thousands of structural variants, each of which differs from the others by single atoms (i.e., two vs. one carbon atom in a side chain, etc.). Thus, the conformation of a chemical that best promotes the stabilization of an inactive conformal state of an enzyme or a receptor can be identified without any information about the structural details of the active and inactive states, merely by generating structural diversity, isolating relevant structures in a binding assay, and then assaying for loss of function of the protein molecules in the presence of that chemical. The same principle applies to the use of phage display libraries of random amino acid peptides. This requires the extra step of using computational and synthetic chemistry to create a chemical mimic of the peptide that produces the desired change in the protein. These two approaches can be combined by biasing the composition of the libraries on the basis of the structural information that exists about the target protein or the domain of the protein that is the contact point for the inhibitor.

Another issue is whether a domain that is in constant motion is a poor or good target as compared to a domain in which the order of the protein is so great as to reduce or restrict the excursions of the atoms and chemical functionalities. Accordingly, programs are available for simulating the possible trajectories of each atom in a biopolymer so that the dimensions of each state at very short expanses of time (nanoseconds) can be used to identify a useful target for engagement by a chemical inhibitor.

Thus, the true power of the use of structural data for drug design is revealed. Not only is there a possibility of identifying chemicals that could be selective for a particular primary amino acid sequence, but the possibility exists of identifying the chemical that is specific for the 1 in 1000 possible conformal states that can be engaged by a particular chemical structure for the purposes of stabilization or destabilization. The library approach exploits this vast expanse of possible targets by interrogating a large number of structural variants which can promote the conformal state of the target that is useful therapeutically.

## APPROACHES TO DRUG DESIGN

### STRUCTURE ANALYSIS OF TARGET

The recent example of the use of x-ray crystal structure of the human immunodeficiency virus protease for the development of successful drug treatment for the acquired immunodeficiency syndrome (AIDS) has led many researchers to apply this approach to the study of oncoproteins for drug development. The recent success in developing inhibitors of substrate-binding sites and cofactor-binding (adenosine triphosphate-binding) sites in the CML oncoprotein p210bcrabl led to the introduction into the clinic of a selective inhibitor of the p210bcrabl kinase in CML. <sup>1</sup> This new low-molecular-weight chemical inhibitor of CML was developed through the application of a structural model for the analysis of the cofactor-binding site of the p210bcrabl kinase oncoprotein of CML. <sup>1</sup>

### MIMICS OF INHIBITORS OR SUBSTRATES

The application of analysis of substrates and mimics of ligands led to the RGD mimic inhibitors of integrin receptors that contribute to the ability of tumor cells to metastasize.<sup>2</sup> Mimics of guanosine triphosphate (GTP) are also being used to develop inhibitors of the membrane RAS signal transduction proteins. <sup>3</sup>

The development of chemical inhibitors of oncoproteins may start from computational analysis of the protein domain binding the cofactor or substrate, or it can start with the screening of combinatorial libraries of chemical mimics of a substrate or naturally occurring inhibitors of an oncoprotein. Alternatively, phage display libraries of random peptides can be used to collect all the peptide sequences that bind to an oncoprotein target. <sup>4</sup> Analysis of the peptide motifs that are associated with high-affinity binding to the target can then lead to the design of mimics of the peptide inhibitors of the oncoprotein.

#### *Substrate Mimics for Tyrosine Kinase Inhibitors for Use in Chronic Myelocytic Leukemia*

CML is an ideal disease for the development of molecular therapy, since there is a single genetic change that is absolutely essential for the development of the leukemia, which is present in 100% of the patients and is present in 100% of the cells of each patient. <sup>5</sup>

The first hint that inhibition of an oncoprotein would suppress the phenotype of a neoplastic disease came from the antisense oligonucleotide field. <sup>6</sup> Because CML is a disease of genetic instability and one in which the acquisition of sequential somatic mutations leads to evolution of the clinical phenotype of the disease, it was predicted that antisense oligonucleotides would have activity only in the very earliest stages of the disease process when the genetic complexity of the mutational change within the leukemic cells was lowest. Surprisingly, the anti-p210bcrabl antisense oligonucleotides were active in blast crisis cells both at the very end of the evolution of the disease process and at the very earliest stages of the disease process. <sup>6</sup> These findings now make sense in light of our understanding of the many actions of the p210bcrabl oncoprotein. Two of these pathways are activated within the CML cell. The first is the PI3 kinase/Alt kinase/BAD pathway that results in the release of BCL-2 in the leukemic cells, prolonging survival in the absence of growth factors and extracellular matrix apoptosis rescue ligands and conferring chemotherapy resistance on these cells. <sup>7</sup> The second results in increases in BCL-2 levels inside the CML cells through the GRB-2/RAS/RAF/BAD pathway. These two

pathways are important, even at the blast crisis stage, in conferring resistance to chemotherapy on these cells.

The next stage in the evolution of molecular therapy for CML was the discovery that peptide ligands, which are parts of naturally occurring negative regulatory proteins for the *abl* kinase, could be used to suppress the transformed phenotype of CML cells.<sup>8,9</sup> This work led to the demonstration that expression vectors that carry inhibitory peptide transcription units directed to the ATP-binding sites of the tyrosine-specific protein kinases could also suppress the transformed phenotype of CML cells.<sup>10</sup>

It was a natural extension of these findings to proceed to an examination of chemical inhibitors of either the substrate-binding site or the cofactor-binding (ATP) site of the tyrosine-specific protein kinase oncoproteins in CML. A picture of the catalytic pocket of this oncoprotein is presented in [Figure 62.2-1](#). The tryphostins were the class of compounds found that inhibit tyrosine-specific protein kinases by binding to the substrate-binding site of p210bcra $\text{bl}$ .<sup>11</sup> These compounds were shown to decrease the *in vitro* proliferation of CML cells and to sensitize CML cells to the effects of chemotherapy. Interestingly, the tryphostins showed synergy when combined with cytokine therapy of chronic myelogenous leukemia cells.<sup>11</sup>

**FIGURE 62.2-1.** Adenosine triphosphate (ATP) kinase pocket of the p210bcra $\text{bl}$  oncoprotein, in which the *abl* tyrosine-specific protein kinase catalytic site is depicted. This kinase pocket contains a substrate-binding site (SBS), a catalytic site (CS), and a cofactor-binding site (ATP BS). The ATP cofactor is shown donating its gamma high-energy phosphate to the substrate.

The next stage of development of chemical inhibitors was to engineer competitive inhibitors for the cofactor-binding (ATP) site of the tyrosine-specific protein kinase-binding site of p210bcra $\text{bl}$ . This class of inhibitors is structurally distinct from the tryphostins. These compounds have been refined by Druker et al.,<sup>12</sup> who have introduced STI 571, a low-molecular-weight inhibitor of ATP binding, into the therapy of CML.

Druker et al.<sup>12</sup> have already shown that these compounds *in vitro* are remarkably selective for the *abl* kinase and are able to reduce the circulating level of the white blood cell count in chronic-phase CML. Although the evaluation of these compounds is still at its early stage, cytogenetic remissions have already been achieved in some chronic-phase patients. In addition, the level of circulating leukemic cells is reduced even in myeloid blast crisis patients. These compounds exhibit inhibitory activity for the *abl* kinase at micromolar concentrations and are remarkably specific for the *abl* kinase, showing cross-inhibitory activity only for the platelet-derived growth factor kinase. These compounds are already producing great interest on the part of therapists as a vindication of the use of structural analysis of biopolymers and computational chemistry. The duration of these remissions and the extent to which all chronic-phase patients will exhibit such remissions are the subject of current clinical trials.

Building on this advance, other workers are attempting produce low-molecular-weight inhibitors that are more selective and more effective than the compounds of Druker. At Yale, Austin has proposed (D. J. Austin, personal communication, 1998) that a chemical mimic of ATP can be constructed by attaching adenosine to a bicyclic scaffold molecule, which is a mimic of the triphosphate of ATP ([Fig. 62.2-2](#)).

**FIGURE 62.2-2.** Adenosine-scaffold mimic in the adenosine triphosphate kinase pocket of the p210bcra $\text{bl}$  oncoprotein. The interaction of the side chains of the adenosine scaffold with the local peptide domains of the kinase pocket is depicted. ATP BS, cofactor-binding site; CS, catalytic site; SBS, substrate-binding site.

The bicyclic scaffold molecule contains five ligands that can interact with local protein domains in the *abl* kinase pocket. As shown in [Figure 62.2-2](#), these chemical functionalities can engage multiple local protein domains in the kinase pocket and can be projected into a spherical three-dimensional space through the use of the bicyclic scaffold. In the example presented in [Figure 62.2-2](#), adenosine, the natural ligand for ATP to the cofactor kinase-binding site of *abl*, is attached to the scaffold, leaving four other positions where chemical functionalities can be attached.

Automated, convergent, synthetic, combinatorial chemical synthesis can be used to generate low-complexity libraries of compound, all of which have the scaffold and the adenosine but in which the structure of the other chemical functionalities can be varied automatically to generate diversity. Recombinant clones of the kinase pocket are used for screening the libraries for the high-affinity binders, which may identify molecules that display therapeutic activity that is greater than existing compounds.

### **RAS Oncoproteins (Farnesylation Inhibitors and G Pocket Inhibitors)**

The RAS family of membrane-bound G proteins usually is activated in response to growth factor stimulation and trigger activation of at least two types of pathways within the cell: the MAP kinase pathway that ends in the nucleus at the level of transcription factor activation and the RAF/BAD pathway that results in the release of BCL-2 within the cell. In cancer, the acquisition of point mutations in RAS leads to continuous activation of these proteins, contributes to the dual phenotypes of chemotherapy resistance, and increases proliferation. This combination has the resultant effect of increasing the genetic instability of populations of cancer cells. These point mutations often are acquired as secondary mutations in a broad spectrum of epithelial neoplastic cells. In fact, very few neoplastic diseases exist in which RAS mutations do not occur. CML is an example of a disease in which the acquisition of RAS-activating point mutations is very rare, in part, perhaps, owing to the fact that the p210bcra $\text{bl}$  kinase of CML results in activation of the RAS proteins.

The connections made by RAS, which are essential for it to be linked to its interacting pathways that link growth factor stimulation with gene expression of survival, depends on its localization to the plasma membrane. This localization depends on the action of a number of enzymes, which mediate posttranslational modifications of the RAS protein.<sup>14</sup> Inhibitors of one of these posttranslational enzymes—protein farnesyltransferase—showed activity in animal models with respect to the suppression of human tumor xenografts. Interestingly, although the spectrum of clinical activity of the farnesylation inhibitors has been somewhat of a disappointment,

the interesting surprise is that these agents appear to display activity even in tumor populations in which farnesylation of RAS is not playing a role in the natural history of the disease.<sup>14</sup>

Despite the initially disappointing spectrum of activity in trials of the farnesylation inhibitors, the inhibition of RAS activity is still an important goal. Every time a transdominant negative inhibitor of RAS activation has been tested in animal models or cell lines, a dramatic effect on the phenotype of the cancer cells has been observed in a spectrum of malignancies, including CML,<sup>14</sup> melanoma,<sup>15</sup> and gastrointestinal cancer.<sup>17</sup> Thus, many groups have been attempting to analyze the structure of RAS so as to design low-molecular inhibitors of RAS.

At the center of these new molecular approaches to the development of inhibitory agents for RAS is the GTP/GDP exchange role of RAS. As outlined previously, RAS acts as a molecular switch for cell growth. In its off state, p21RAS is bound to guanosine diphosphate (GDP), whereas on activation, GDP is exchanged for GTP ( [Fig. 62.2-3](#)).

**FIGURE 62.2-3.** Guanosine triphosphate (GTP) pocket of the RAS G protein.

When GTP occupies the guanine nucleotide pocket of RAS, cell growth is promoted. In fact, many of the point mutations acquired in tumor cells by RAS prevent the hydrolysis of GTP. This maintains the activated state of RAS and prevents a return to its off state. The Karplus group at Harvard<sup>17</sup> has designed molecules that would recognize the dimensions and charge of the guanine nucleotide pocket of RAS in its activated state. Such molecules would bind to activated RAS, not to RAS proteins in their nonactivated state. This group is undertaking a computational analysis of the molecular switch regions of RAS (residues 30–38 and residues 60–75).

Karplus and his coworkers studied the bicyclic scaffold shown in [Figure 62.2-2](#), now attached to a guanosine molecule ([Fig. 62.2-4](#)) and found that the guanosine scaffold was energetically a good mimic of the GTP and engaged the same amino acid side chains in the RAS guanine nucleotide-binding pocket as does GTP. These computational models have suggested that the designing of chemical mimics of GTP such that they will bind more tightly and selectively to the inner protein domains lining the GTP pocket of RAS is feasible. The guanosine scaffold shown in [Figure 62.2-5](#) may engage multiple domains in the RAS-binding pocket and, therefore, produce inhibitors that can override even an excess of GTP and, owing to the multiple sites of interaction, can produce inhibitors that are selective and, therefore, nontoxic as well (M. Karplus, personal communication, 1996).

**FIGURE 62.2-4.** Austin bicyclic molecular scaffold as a mimic for the triphosphate domain of guanosine triphosphate (GTP). The natural cofactor of the abl kinase, GTP, is compared to the guanosine-scaffold mimic.

**FIGURE 62.2-5.** Guanosine-scaffold mimic in the guanosine triphosphate (GTP) pocket of the RAS G protein. The interaction of the side chains of the guanosine scaffold with the local peptide domains of the GTP pocket is depicted.

### **Metastasis Inhibitors**

The integrin receptors constitute a complex class of surface cytoadhesion molecules that mediate apoptosis rescue signals from extracellular matrix proteins and stromal cells or supporting cell ligands into the cell, with connections to cytoskeletal structures and transcriptional regulation pathways within the cell.<sup>18</sup> The integrin receptors can exhibit changes in the number of receptors on the membrane and changes in the composition of the available subunits that contribute to the heterodimeric arrays of integrin receptors, and they can undergo changes in conformation, sometimes associated with posttranslational modification, which define differing states of functionality. Integrin receptors can also be activated to functionally active conformal states from signals arising from within the cell. Thus, the integrin receptors, which are apoptosis rescue signal transduction elements, can be activated from “inside out” and from “outside in.”<sup>18</sup>

Several researchers have reported that the transfection of integrin expression vectors carrying specific integrin subunits, such as the  $\beta_3$  integrin, can direct cells to metastasize to specific organs. Indeed, the  $\alpha V\beta_3$  integrin receptor is commonly encountered in cancer cells that are metastatic and rapidly proliferating, whereas the  $\alpha V\beta_5$  integrin receptor is often found in differentiating cells.

Extensive testing of the ligands and antibodies that can engage various integrin receptors have shown that the inhibitors of integrin receptors can be effective in

suppressing particular patterns of metastatic spread in preclinical animal models. Some groups have used phage display libraries in which thousands of phage clones, each with a different peptide, are injected into the tail vein of a mouse. This is followed by analysis of the endothelial cells from the vessels of different tissues. These studies have shown that peptide sequences exist that are characteristic of the vessels of different tissues. This knowledge has led to the speculation that chemical mimics of trafficking molecules on the endothelial surface of different tissues could be used to prevent metastases to a particular target organ. An example would be the treatment of individuals with stage III colon cancer with chemical mimics of peptides, which would bind to the cytoadhesion molecules characteristic of vasculatures of hepatic tissues.

Several groups have reported the isolation of chemical mimics of the RGD peptide, which binds to the integrin receptor. The use of phage display peptide libraries led to the collection of peptide motifs, including RGD, that bind to integrin receptors. Now, combinatorial chemical libraries are being used to refine the structure of low-molecular chemical inhibitors of integrin receptors that appear to reduce the metastatic potential of a cell. These types of drugs should be highly exciting therapeutically when they are brought into the clinic.

### LOW-MOLECULAR-WEIGHT INHIBITORS FOR THE ANGIOGENESIS RECEPTOR

One of the most exciting paradigm shifts has been the attempt to target drug development to normal tissues. Angiogenesis is a process that takes place during tumor growth. Now, inhibitors of this process are being tested in the therapy of solid tumor malignancies. This approach was stimulated by the correlation between the density of the neovasculature in histopathologic specimens and the aggressiveness of the natural history of the disease in a given patient. Also stimulating interest in this area was the demonstration in animal models that a number of naturally occurring modulators of angiogenesis also displayed activity in modulating the rate of tumor growth in animal models. This has led to the isolation of a large number of agents (synthetic chemicals as well as naturally occurring biologically active proteins) that are known to affect angiogenesis in the treatment of solid tumors and hematopoietic neoplasms. There is immense interest in the current clinical trials of these natural products and naturally occurring proteins to determine whether they are selective for tumor neovasculature or whether they affect the formation of vasculature in normal tissues as well.

Computational and combinatorial chemistry is being used to test whether it is possible to develop synthetic inhibitors of angiogenesis that are specific for tumor cell neovasculature. The first step was to test whether computational analysis of the normal angiogenesis receptor could be used to design and synthesize low-molecular-weight chemical inhibitors of the angiogenesis receptor; this has been accomplished (C. Crews, personal communication, 1999). Two approaches are being used now to develop chemical therapy that is antiangiogenic. The first is to engineer low-molecular-weight inhibitors of the angiogenesis receptor. At Yale, Hu et al.<sup>19</sup> have taken a second approach: chimeric immunoconjugate molecules that are composed of an amino-terminal targeting domain that binds specifically to tumor endothelial cells, and a carboxyl-terminal end that carries the Fc fragment of IgG. The latter molecule is known to bind to natural killer cells. Hu et al.<sup>19</sup> have reported that the release of such chimeric immunoconjugate molecules into the systemic circulation of human tumor xenografts in nude mice results in regression of established tumor nodules. This reaction has been shown to depend on the binding of natural killer cells to the Fc fragment of the immunoconjugate molecules.

### CHEMICAL INHIBITORS FOR ONCOPROTEINS OF DNA TUMOR VIRUSES

The oncoprotein products of DNA tumor viruses provide almost ideal targets for the development of low-molecular-weight chemical inhibitors for cancer treatment or prevention. As in many of the other targets we have discussed, the continued expression of these proteins is essential to the maintenance of the neoplastic phenotype. Moreover, since they are viral proteins, those proteins are unique targets that are not essential to the survival or proliferation of normal cells. Thus, drugs developed against these proteins may be highly selective for the tumor tissue and not toxic to the uninfected normal tissue.

The diseases associated with the DNA tumor viruses, human papilloma virus (HPV), and Epstein-Barr virus (EBV) are significant world health problems.<sup>20</sup> HPV-associated malignancies represent the second leading cause of cancer death in the world among women.<sup>20</sup> In addition, it is estimated that 40% of all AIDS patients alive today will eventually develop an EBV-associated non-Hodgkin's lymphoma.<sup>21</sup>

Again, the use of antisense oligonucleotides first showed convincingly that the continued expression of the protein products of the episomal DNA of these viruses was essential for the continued replication of tumor cell lines and growth of these cells in human tumor xenografts in severe combined immunodeficiency mice.<sup>22</sup> HPV E6/E7 antisense oligonucleotide transcription units were shown to suppress the growth of cervical cancer cell lines in severe combined immunodeficiency mice.<sup>23</sup> Antisense oligonucleotides to the EBNA 1 and LMP2 proteins of the EBV were shown to induce replication arrest of EBV-associated tumor cell lines and induction of apoptosis of these cells. Additionally, use of the antisense oligonucleotides to these unique targets produces sensitization of these cells to chemotherapy.

Most surprising is that cervical cancer cell lines harboring HPV-transforming proteins E6 and E7 still retained dependency on these oncoproteins for the continued proliferation and survival of these cells *in vitro* as well as in animal models.<sup>24</sup> Thus, drug development is being targeted to these two proteins and their associated proteins, with the aims of stopping progression of disease as well as sensitizing the cervical cancer cells to the effects of chemotherapy.

The E2 protein of HPV is also an interesting target for prevention of cervical cancer. Very commonly, the chronic infection of HPV in the cervical mucus, which is associated with dysplasia and chromosomal translocations, persists for years before the development of invasive cancer. In the United States, such dysplastic states of the cervical mucosa can be identified by repetitive Papanicolaou smear, and appropriate surgical action can be taken if the dysplasia is severe or persists. In contrast, in most areas of the world, the infrastructure necessary to screen women for HPV-associated dysplasia does not exist. Thus, the development of chemicals that will inhibit the formation of viral protein complexes necessary for the assembly of the replication initiation complex could be useful for the development of preventive therapy for cervical cancer.

Two of the viral proteins—E1, a helicase, and E2, a chaperone protein—are important for assembly of a functional replication initiation complex in HPV-infected cells. Once infected, the germinal epithelial cells of the cervical mucosa contain approximately 50 copies of HPV DNA per cell.<sup>25</sup> These copies of HPV are retained at a stable copy number because the replication of the HPV DNA episome is coupled to the replication of the host cells. This is probably owing to the need for host DNA polymerase for the replication of the HPV DNA.

E2 must form a homodimer before binding to the E2-binding sites in the HPV origin of replication. E2 also connects with E1, which also binds to HPV DNA. Thus, many virus-specific protein contact domains, which are virus-specific and not shared by the host mammalian cell, are available as targets for inhibition: the E2 homodimerization domain, the E2 DNA-binding domain, the E2/E1 contact domain, and the E1 DNA-binding domain. Computational analysis of these surfaces led to predictions about the structure of potential inhibitory compounds, which in turn led to a prospectively randomized, double-blind, placebo-controlled trial of drugs in a multiinstitutional setting, sponsored by the National Cancer Institute.

### GROWTH FACTOR RECEPTOR INHIBITORS

The use of monoclonal antibodies has already shown that blocking of growth factor receptors can act to suppress the proliferation of tumor cells, enhance their chemotherapeutic sensitivity, and extend the duration of the progression-free interval in cancer patients. The Her2/neu receptor antibody Herceptin and the epidermal growth factor receptor (EGFR) inhibitory antibody C221 have been shown to sensitize tumor cells to chemotherapy.<sup>26</sup> These clinical examples have shown that blocking of the appropriate domain on the growth factor receptor is sufficient to suppress the transformed phenotype of the cell.

Computational analysis of these two closely related receptors (EGFR and Her2/neu) is being directed to the development of low-molecular-weight chemical inhibitors of these receptors in such cancers as breast, gastric, and esophageal cancer, squamous cell carcinoma of the head and neck, and ovarian and lung cancer, which are associated with amplification of these receptors' genes.

### SUMMARY AND FUTURE DIRECTIONS

In the twenty-first century, drug development will no longer depend on going to the forests to dig up roots, to pick flowers and leaves, or to strip the bark from the trees to discover new drugs for cancer treatment. It is now possible for a laboratory scientist to recapitulate in a few months what once required millions of years of evolution to produce. The ability to analyze protein structure, to decipher the dynamic array of conformational states of oncoproteins (both activating and inactive), and to characterize the genetic changes that may exert a dominant effect on the natural history of solid tumors and hematopoietic neoplasms ( [Table 62.2-3](#)) has opened the door to selecting for drug development the best domains on target oncoproteins.

**TABLE 62.2-3.** Genetic Changes in Solid Tumor and Hematopoietic Neoplasms That Are Suitable Targets for Drug Development

The availability of computational chemistry and the ability to generate diversity in chemical structure have enabled scientists to reach beyond the limits of available data about structure and activity relationships and to probe deeply in the unknown repository of untapped chemical structures for molecules that may exhibit favorable binding and specificity properties. It is apparent that the explosion of information about genetic changes in tumor cells will provide the necessary clues with which the chemist can direct structural diversification and screening to isolate newer and more effective compounds. Recent successes in the development of drugs for AIDS and CML on the basis of protein structure is a dramatic validation of this new approach to drug design. It is possible that this paradigm will be reiterated many times in the development of an entirely new generation of cancer treatment drugs based on inhibitors of receptors, transcription factors, adaptor molecules, viral and somatic cell oncoproteins, and apoptosis rescue proteins. The dividends for cancer patients and society may be substantial in terms of reducing the cost of therapy and enhancing its efficacy.

#### INTRODUCTION

The high rate of morbidity and mortality attributable to cancer has stimulated concerted efforts to prevent malignancies from developing. The recognition that environmental factors may account for the majority of cancers has encouraged researchers to identify the exogenous factors that trigger the carcinogenic process and to define their role in tumorigenesis. Infectious agents make up one important class of environmental factors implicated in tumor development. <sup>1,2</sup> and <sup>3</sup>

Although the oncogenic potential of some infectious agents, such as hepatitis B virus (HBV), was recognized more than two decades ago, many of the infectious agents now believed to be oncogenic were discovered after 1975 ([Table 63.1-1](#)).<sup>2</sup> These latter include the oncogenic papillomaviruses, hepatitis C virus, herpesvirus type 8, and *Helicobacter pylori*. It seems likely that further research will result in additional forms of cancer being attributed to infectious agents. The expanded list will arise via the demonstration that infectious agents already recognized as oncogenic may be causally involved with additional forms of cancer, by attributing these additional cancers to other infectious agents not yet recognized as oncogenic, or both.

Identification of an infectious agent in the etiology of a malignant process implies that timely interference with the infection could prevent the tumor from arising. <sup>4,5</sup> The development of effective vaccines against infectious carcinogenic agents represents a potentially powerful approach and is the main focus of this chapter. The prototype for this approach is the HBV vaccine, which can protect immunized individuals against both acute disease and the malignant consequences attributable to this virus.<sup>6,7</sup>

This chapter briefly considers how infectious oncogenic agents lead to cancer, discusses general issues related to developing vaccines against these agents, and presents individual sections devoted to the three agents that account for the most cancers worldwide. Vaccines against other infectious oncogenic agents are also in various stages of development.<sup>8,9</sup> and <sup>10</sup>

#### INFECTIOUS AGENTS AND CANCER

Reducing exposure to an identified carcinogen represents the principal approach to reducing the carcinogenic effects of many environmental carcinogens. For carcinogens such as cigarette smoke, entrenched human behavior and conflicting economic interests may present considerable obstacles to reducing or eliminating exposure. By contrast, a vaccine against an infectious carcinogen does not require modification of the behavior that leads to exposure because the vaccine attenuates the oncogenic activity of the infectious agent by reducing or preventing infection of target tissue. <sup>4,5,11</sup> Furthermore, the induction of *herd immunity* via the widespread use of an effective vaccine, offers the possibility of reducing the risk of nonimmunized individuals to exposure to the infectious agent. Vaccination also offers the long-term possibility of eliminating the agent from the environment.

Before considering vaccination itself, it is worthwhile reviewing some features of oncogenic infectious agents, as their characteristics may have implications for vaccine development, testing, and implementation. Viruses, bacteria, and parasites have all been implicated in the pathogenesis of human cancer (see [Table 63.1-1](#)). Investigators at the International Agency for Research on Cancer estimated that in 1990 approximately 15% of cancers worldwide could be attributed to infectious agents ([Table 63.1-2](#)).<sup>2</sup> In the United States and other developed countries, a smaller proportion of cancers (approximately 9%) are associated with these agents, while they account for a higher proportion (approximately 20%) in developing countries.

Agent	Tumor Types	Annual Cases Worldwide (Estimate)
<b>BACTERIA</b>		
<i>Helicobacter pylori</i>	Stomach cancer, gastric lymphomas	500,000
<b>VIROUSES</b>		
Human papillomavirus	Cervical, anal, vaginal, oropharyngeal cancers	447,000
Hepatitis B virus	Liver cancer	285,000
Hepatitis C virus	Liver cancer	113,000
Human immunodeficiency virus	Kaposi's sarcoma, non-Hodgkin's lymphomas	50,000
Human herpes type 8	Kaposi's sarcoma	44,000
Eggs of <i>Schistosoma</i> spp.	Lymphomas (Hodgkin's, non-Hodgkin's, Burkitt's)	30,000
Human T-cell lymphotropic virus I	Adult T-cell leukemia	3000
<b>PARASITES</b>		
<i>Schistosoma</i> spp.	Bladder cancer	11,000
Liver flukes	Cholangiocarcinoma	400

(Adapted from ref. 2.)

TABLE 63.1-1. Oncogenic Infectious Agents

Tumor Type	Developing Countries	Developing Countries	Total	Percentage of Total Type Attributable to Infection
Stomach cancer	202	204	406	36
Cervical cancer	46	20	66	81
Liver cancer	42	22	64	43
Kaposi's sarcoma in acquired immunodeficiency syndrome	16	28	44	—
Vaginal cancer	11	11	22	88
Hodgkin's disease	11	10	21	33
Bladder cancer	9	10	19	3
Non-Hodgkin's lymphoma in acquired immunodeficiency syndrome	4	4	8	—
Gastric lymphoma	3	3	6	36
Burkitt's lymphoma	3	3	6	83
Leukemia	2	1	3	—
Cholangiocarcinoma	1	1	2	—

Figures in each column represent the estimated number of cases of the tumor type attributed to infection, except for the column on the right, which represents the percentage of all cases of the type worldwide attributed to an infectious cause.  
(Adapted from ref. 1.)

TABLE 63.1-2. Cancers Attributable to Infection: Estimate of Worldwide Distribution According to Type (Annual Number of Cases in Thousands) <sup>a</sup>

Several factors probably account for these differences. Some of the infectious agents, such as parasites with oncogenic potential, are extremely uncommon in the United States, or the rate of infection may vary greatly, as with HBV. <sup>12</sup> For others, such as human papillomaviruses (HPV), infection in the United States is common, but Pap smear screening for premalignant lesions in the cervix leads to effective treatment before carcinomas develop. <sup>13</sup> In still other instances, strain differences or the interaction between the infectious agent and environmental, host factors, or both might help determine the rate of carcinogenic progression. <sup>14</sup>

The identified oncogenic infectious agents share at least four characteristics: the ability to establish chronic infection, the actual establishment of chronic infection in those individuals destined to develop malignancy attributable to the infection, an interval of many years between the initial infection and the development of malignancy, and a benign (i.e., nonmalignant) outcome for most infected individuals. These characteristics imply that cancer attributable to infectious agents develops only after prolonged infection and that a malignant outcome arises only after the development of infection-dependent changes in the host.

Consistent with current concepts of the multistep nature of carcinogenesis, the changes in the host probably involve genetic alterations in potential target cells, impairment of the immune system, or both. Since not all infectious agents that establish a chronic infection are carcinogenic, chronic infection with agents not implicated in carcinogenesis must be much less efficient in inducing the types of changes that lead to cancer than are those agents that are implicated in carcinogenesis.

Infection seems to induce tumors by three main mechanisms, either singly or in combination, depending on the agent.<sup>5</sup> In some instances, such as with the papillomaviruses, the agent infects the potential target cell population and induces a series of changes from within those cells that lead to cancer.<sup>15</sup> Some of the changes include alterations in the agent, so that only a subset of its genetic information is expressed. The viral genes that continue to be expressed contribute directly to the tumorigenic phenotype by, for example, inactivating the activity of tumor suppressor genes. Other genes from the virus are presumably silenced to lower the likelihood of the tumor cells being recognized and destroyed by the immune system.

In a second scenario, as occurs with *H pylori*, the infectious agent is present in the target tissue and induces cancer by local effects, usually chronic inflammation, but the agent remains outside the tumor cells.<sup>16,17</sup> By the time the tumor is capable of distant metastasis, if not sooner, its growth becomes independent of the infectious agent.

The third mechanism, which is more indirect, results in increased tumor risk secondary to suppression of the host immune system. This process has been identified in tumors that arise as a consequence of infection with the human immunodeficiency virus (HIV), which predisposes infected individuals to a variety of tumors.<sup>18,19</sup> As the immunosuppression associated with HIV renders patients much more susceptible to chronic infection with other agents, including some with oncogenic potential, many of the tumors result from the combined effects of coinfection with HIV and these other agents.

## PROPHYLACTIC VERSUS THERAPEUTIC VACCINATION

Vaccination against an infectious oncogenic agent can be contemplated in three possible clinical settings: as a prophylactic vaccine to prevent infection or acute disease, as a therapeutic vaccine to treat an established infection before a malignancy has been induced, and as a therapeutic vaccine to treat the infection after the malignant tumor has developed, provided the growth, viability, or both growth and viability of the tumor still depend on the presence of the infectious agent. The use of vaccines in the treatment of cancer, which is the subject of intense investigation, is covered later in this chapter. This section examines the potential utility, complexity, and challenges for vaccines whose goals are to prevent established infection or to eradicate established infection before tumor development.

Ideally, a vaccine should be effective in both prevention and treatment. However, it has proven easier to develop prophylactic vaccines against infectious agents than therapeutic ones. Of the more than 20 approved vaccines in the United States, all are approved for prevention, rather than treatment, of established infection.<sup>20</sup>

The cellular and humoral arms of the immune system generally function together to interfere either with the initial phases of infection or the eradication of established infection. Antibodies capable of neutralizing the infectious agent appear to be the prime effectors in preventing infection, while CD8+ T cells appear to serve more critical roles in the resolution of established infection.<sup>11,21,22</sup> The success of prophylactic vaccines in inducing long-term protection against infection probably lies primarily in their ability to induce neutralizing antibodies, although other immune components probably also contribute to their overall effectiveness.

For infections that induce serious acute disease, such as polio, the main theoretical goal of vaccination is the prevention or modification of the acute disease. Since it is easier to reduce the incidence of acute disease by inducing widespread immunity with a prophylactic vaccine than by treating established infection, a prophylactic vaccine approach has an important theoretical advantage in this setting over a therapeutic one.

However, for cancer-causing microbes that induce benign primary infection, such as papillomaviruses, the long interval between infection and cancer, combined with the apparently necessary role played by the infectious agent during much of this period, provides a relatively long opportunity to identify and treat the infected population. Situations in which premalignant lesions attributable to the microbe are frequently identified, as in the case of Pap smear screening for cervical cancer, present an opportunity to intervene with a therapeutic vaccine.

The comparative ease with which prophylactic vaccines can be developed, relative to the continuing challenge posed by therapeutic vaccine development, makes prophylactic vaccination an important approach for cancer vaccines. Another advantage of prophylactic vaccines is that they do not depend on effective progress in identifying individuals with premalignant disease. Furthermore, worldwide public health vaccine efforts are designed primarily for the administration of prophylactic vaccines, and this vaccine approach has been extremely successful and highly cost-effective in combating many infectious disease. In addition, the primary disease induced by many oncogenic infectious agents can provide sufficient rationale for development of a prophylactic vaccine, in addition to the long-term prevention of cancer.

Numerous theoretical and practical concerns arise when considering development of a prophylactic vaccine against cancer. Safety is especially important for a vaccine whose primary goal is to prevent cancer, as many individuals will never be infected by the agent, the majority of infected individuals will never develop malignancy, and malignancy only develops many years after infection. In addition, it requires many years to determine whether a candidate prophylactic vaccine can prevent cancer. The minimum theoretical duration of efficacy trials whose end point was prevention of malignancy would be the length of the latent period between infection and malignancy. Thus, while vaccination against HBV was found more than 20 years ago to prevent primary infection, data showing this vaccination can actually reduce the frequency of hepatocellular carcinoma are only beginning to accumulate.<sup>7</sup>

Although cancer prevention might appear to be a necessary end point for establishing vaccine efficacy, there can be serious ethical obstacles to using this clinical end point. For those clinical situations in which the standard of care involves the treatment of premalignant lesions to prevent the development of malignancy, as with cervical abnormalities related to Pap smear screening, it may be unethical to delay treatment until cancer develops. In addition, once a vaccine has been shown to be effective in preventing infection, it might be considered unethical to withhold the vaccine from the control group, despite the possible ambiguities such vaccination might create for efforts to determine directly whether the vaccine could reduce cancer frequency.

The most critical information for vaccine development lies in determining which antigens can induce protective immunity. For HBV, many aspects of its immunology and its role in carcinogenesis remain incompletely understood, but identification of a *protective* viral antigen was able to lead to development of an effective vaccine.<sup>6,12,23</sup>

Many of the infectious agents with recognized oncogenic activity (see [Table 63.1-1](#)) induce nonmalignant diseases that carry significant morbidity and economic cost long before they cause cancer, although oncogenic HPV infection may be a notable exception. It may be more practical to use a nonmalignant end point in efforts to demonstrate efficacy, with the effect on cancer being determined, directly or indirectly, by follow-up studies. This was the approach taken with the hepatitis B vaccine, which has been approved for use in the United States because of its ability to prevent acute hepatitis. However, the presumption that the vaccine would prevent many liver cancers attributable to hepatitis B infection was also considered in recommending widespread use of the vaccine.

Some issues surrounding a therapeutic vaccine differ from those of a prophylactic one. As the individual is already infected, it is usually much easier to carry out therapeutic clinical trials that determine efficacy, compared with prophylactic trials. A therapeutic vaccine trial can limit its enrollment to infected individuals at a particular stage of disease, and the response to vaccine can be evaluated, usually within a short period, by suppression of infection and of the disease.

Another major theoretical advantage of an effective therapeutic vaccine is that it can have an effect on the incidence of malignant disease much sooner than a prophylactic vaccine. For cervical cancer, where the interval between HPV infection and cancer typically takes more than 20 years, it would take at least this length of time before a prophylactic vaccine, even if it were completely effective and were given to all at-risk individuals, would have any effect in the incidence of malignancy. By contrast, an effective therapeutic vaccine could reduce the incidence of cervical cancer after a much shorter interval. These considerations underscore the potential utility of determining whether successes with therapeutic vaccines in experimental animal systems, such as *H pylori*,<sup>17,24</sup> and papillomaviruses,<sup>25</sup> can be

achieved in people.

## HEPATITIS B VIRUS

The identification of HBV in the 1960s led to epidemiologic studies that have clarified its worldwide role in hepatocellular cancer. <sup>6,12,26,27</sup> Although infection with this DNA virus can cause acute hepatitis, its most serious global consequences are chronic hepatitis, cirrhosis, and hepatocellular carcinoma, all of which are associated with chronic HBV infection. It is estimated that there are more than 1 million chronic HBV carriers in the United States and more than 300 million carriers throughout the world. The virus is believed to account for approximately 1 million deaths per year worldwide, approximately one-half of them secondary to hepatocellular carcinoma.

In highly endemic areas, the lifetime risk of exposure may exceed 50%, and most HBV infections occur perinatally or in early childhood. In areas of low endemicity, HBV transmission occurs mainly in adults, often via sexual exposure or parenteral exposure from infected shared needles used with illicit drugs. The risk of medical exposure to infected blood products has been greatly reduced by systematic screening of these materials for HBV.

The HBV carrier state, which is a measure of persistent infection, is a critical determinant of the long-term risk for hepatocellular carcinoma. HBV carrier rates vary dramatically in different populations, being less than 0.5% in the United States and many other countries with high standards of living, to rates of 10% to 20% in parts of Africa, Asia, and the South Pacific. The relative incidence of cancer attributable to HBV follows a similar geographic distribution, with many studies consistently showing chronic HBV infection is an important risk factor for hepatocellular carcinoma.

The frequency with which persistent HBV infection is established varies inversely with the age of exposure. The highest risk by far occurs during the perinatal period and the first year of life. More than 70% of neonates born to infected mothers become chronic carriers, compared with around 8% of those exposed at 3 years of age and an even lower proportion in immunocompetent adults. <sup>26</sup>

Conversely, HBV is much more likely to induce acute hepatitis in older age groups, while acute infection is usually asymptomatic when exposure occurs in the perinatal period. This difference occurs because the acute hepatic disease results from the immune response to infection, as HBV does not directly induce hepatocellular damage. Thus, the relative immunoincompetence of infants probably accounts for their lack of symptoms and for the high frequency with which the virus establishes persistent infection in this age group.

The precise role of the virus in the development of hepatocellular carcinoma has not been fully determined. Persistent infection appears to lead to cancer mainly as the result of chronic inflammation and repeated cellular regeneration, and some evidence implicates the viral X gene, which encodes a transcription factor, in this process. <sup>26</sup> Most cases of liver cancer associated with HBV infection arise after chronic hepatitis has led to cirrhosis. Hepatocellular carcinoma may develop in as little as 5 to 10 years of infection, but it does not usually occur until an individual has been infected for at least 20 to 30 years. Ongoing infection continues to be a risk factor for carcinoma, with an estimated cumulative risk of 15% for an individual who has had persistent infection for 50 years. <sup>12</sup>

The rate of hepatocellular carcinoma attributable to HBV is at least three times higher in male than in female subjects, even when a similar proportion of male and female subjects are exposed to HBV. The difference is explained in part by the higher frequency with which the HBV carrier state is established in male subjects (close to 2:1) and the greater likelihood of female subjects to eliminate the carrier state.

The HBV vaccine is the prototype prophylactic vaccine against an oncogenic infectious agent. <sup>6,12,29,30</sup> A key to HBV vaccine development was the recognition that the neutralizing antibodies were directed against the hepatitis B surface antigen (HBsAg), and that there is only one HBV serotype. The HBsAg is expressed in relatively pure form as circulating enveloped virus-like particles (VLPs) in the blood of infected HBV carriers. The HBsAg particles do not carry the viral genome and are not infectious. It was possible to purify the particles, inactivate possibly contaminating infectious virus with formalin (which should also have inactivated other viruses), and to test the particles as a subunit vaccine in human clinical trials that were initiated in 1975.

The HBsAg vaccine was found to be well tolerated, to induce an immune response in almost all vaccinees, and to reduce the infection rate in adults by at least 95% and in neonates by at least 85%. The protection rates in neonates may be further increased by giving hepatitis B immune globulin in addition to the vaccine. The vaccine was licensed in the United States in 1981.

An analogous HBsAg particle vaccine has been produced in yeast by recombinant DNA technology, and it was licensed in the United States in 1986. The recombinant vaccine has replaced the blood-derived vaccine, although the immunogenic properties of the latter product are somewhat superior to the recombinant material. Efficacy trials have shown that the recombinant vaccine confers a similar rate of protection against HBV as the blood-derived vaccine. <sup>12,29,30</sup> In addition, the recombinant vaccine is less expensive to manufacture and does not have the theoretical concern of contaminating infectious material, although extensive analysis of the blood-derived vaccine recipients failed to document excess exposure to infectious agents.

The initial series of immunizations, with either vaccine preparation, confers protection against infection for at least several years. In instances in which breakthrough infection has occurred several years after immunization, it has not been associated with development of a chronic carrier state. Routine revaccination is not recommended at this time by vaccine advisory groups in the United States. Further studies, in progress, should determine whether this policy should remain in place or be modified.

The long interval between HBV infection and the development of hepatocellular carcinoma means that only limited data thus far indicate directly that vaccination can actually decrease the incidence of cancer attributable to HBV. Data from an HBV vaccination program in Taiwan, an area with high HBV endemicity where universal vaccination was instituted in 1984, do show such a reduction in children. <sup>7</sup> From 1990 through 1994, the incidence of cancer in children aged 6 to 14 was one-half the rate before implementing vaccination, and that for children aged 6 to 9 was only one-fourth the rate of the earlier period.

These results indicate that HBV vaccination can achieve the long-term goal of cancer reduction. However, such a reduction will occur only if the populations most at risk are given the vaccine in a timely manner. Even in such a setting, reduction in cancer among adults, in whom the incidence is greatest, would not be expected to be seen until these children achieve adulthood.

## HUMAN PAPILLOMAVIRUS

Papillomaviruses are epitheliotropic agents that induce benign papillomas of the skin and mucous membranes. <sup>31,32</sup> In contrast to HBV, there are more than 100 HPV genotypes (types). <sup>33</sup> A subset of HPV types, which are almost always transmitted sexually, are the main cause of human cervical cancer. Infection with these HPV types is a strong risk factor for cervical cancer, and HPV DNA from one or more of these types is found in virtually all cervical tumors. <sup>31,34,35</sup> and <sup>36</sup> The virus encodes oncoproteins that appear to be required both for the induction and the maintenance of the cancer. <sup>32</sup>

HPV infection has also been linked to the majority of anal cancers, in which the molecular pathogenesis seems to be similar to that of the cervix, as well as to other anogenital malignancies and to tumors of the upper aerodigestive tract. The precise relationship between HPV infection and the development of some of these cancers is not as firmly established as that with cervical cancer.

As with HBV, cancer attributable to HPV develops only after many years of persistent HPV infection and is an infrequent outcome of infection. Cervical HPV infection is remarkably common, with sensitive polymerase chain reaction assays indicating prevalence rates of 20% to 40% among young sexually active women. Most infections are self-limited, and clinical cures are associated with resistance to reinfection. The antigenic divergence between HPV types is such that protection appears to be largely type specific.

The HPVs associated with cervical and anal cancer are usually designated high-risk types, as contrasted with the low-risk types, which also participate in anogenital infection but are almost never found in cervical or anal cancers. <sup>15,32</sup> Although there are several high-risk HPV types, HPV-16 is the most common type, being present in more than one-half of cervical cancers worldwide. The viral E6 and E7 genes are preferentially retained and expressed in the tumors, where they inactivate the p53 and Rb tumor suppressor proteins, respectively.

In principle, cervical cancer is already a largely preventable disease. In countries in which Pap smear screening reaches most women, the incidence of cervical cancer has decreased markedly. In the United States, for example, the rate of cervical cancer has decreased several-fold since the 1950s, from more than 50 in 100,000 to less than 10 in 100,000. This decrease in cancer rates is even more impressive because it has occurred during a period in which increased sexual promiscuity has been associated with an increased frequency of genital HPV infection.

However, the cost of Pap smear screening and follow-up is high (estimated to be more than \$5 billion annually in the United States), and Pap smear screening is not routinely available in many less well-developed countries. This situation has made cervical cancer the leading cancer among women in many developing countries, and it remains the third most common female cancer worldwide.<sup>39</sup>

Establishing the etiologic link between HPV infection and cervical cancer (and other tumors) has focused interest on developing an HPV vaccine.<sup>35,40,41</sup> The main goal would be to protect against cervical cancer, which accounts for approximately 75% of the cancers worldwide attributable to HPV infection (see [Table 63.1-1](#)).<sup>2</sup> Since cervical cancer is especially prevalent in developing countries, such a vaccine would potentially have its greatest public health effect in these populations. However, in the United States, an effective HPV vaccine might further reduce the current incidence of cervical cancer by reaching populations that currently do not receive adequate Pap screening. In addition, by decreasing the frequency of genital HPV infection, a vaccine could decrease the anxiety and morbidity associated with cervical dysplasia and its treatment and reduce the social stigma associated with genital HPV infection. If widely used, a vaccine might reduce the frequency and overall cost of cervical cancer screening. The overall effectiveness of a vaccine, even for prevention of cervical cancer, would be greater if it were given to male subjects as well as to female subjects.

As papillomaviruses contain oncogenes, and a prophylactic vaccine would be directed toward healthy young individuals, efforts to develop a prophylactic vaccine have emphasized a subunit approach, analogous to that used for HBV.<sup>40,41 and 42</sup> Indeed, constitutive high-level expression of the L1 major structural viral protein, even in nonmammalian cells, will lead to its efficient self-assembly into VLPs that resemble authentic viral capsids structurally and antigenically. Preparative amounts of VLPs can be synthesized in insect cells or yeast. Such VLPs are suitable immunogens that, as is true of authentic virions, possess the immunodominant conformational epitopes capable of raising high titer neutralizing antibodies.

Since papillomaviruses are species specific, animal papillomavirus models have been used preclinically to evaluate VLPs as a candidate subunit prophylactic vaccine.<sup>40,41 and 42</sup> Excellent results (90% to 100% protection, even without adjuvant, against high-dose virus challenge) have been obtained with systemic immunization in three models, one cutaneous and two oral mucosal. The neutralizing antibodies appear to be largely responsible for the protection, which can last at least 1 year. Excellent protection has also been reported in the cutaneous animal model when a vaccinia vector was used to express L1 or when the L1 gene was injected as naked DNA. However, administration of protein seems more likely to be readily accepted by regulatory authorities in developed countries.

Alternative approaches are also being considered.<sup>40,41 and 42</sup> These include mucosal immunization via purified VLPs or via nonpathogenic enteric bacteria or the use of nonstructural viral proteins either alone or as incorporated into VLPs. Nonstructural viral proteins have been shown to prevent and, in some cases treat, animal papillomavirus infection,<sup>25,43</sup> in addition to working in tumorigenic models with cells that express a papillomavirus protein.<sup>42</sup> The utility of a vaccine that might treat established infection, especially if it were also effective prophylactically, makes it highly worthwhile to pursue the development of therapeutic HPV vaccines.

HPV-11 and HPV-16 L1 VLPs have been tested in early safety and immunogenicity trials of intramuscular injection of healthy human volunteers.<sup>44,45</sup> The vaccines were well tolerated and induced serum antibody titers, with or without adjuvant, comparable with the protective levels induced in animals. Large-scale efficacy trials will be needed to determine if this approach, which is not specifically directed toward the mucosal immune system, will confer protection against cervical HPV infection.

As noted in the [Prophylactic versus Therapeutic Vaccination](#) section, it would take many years to establish unequivocally if a vaccine actually had an effect on cervical cancer, since cervical HPV infection usually precedes the development of malignancy by more than 20 years. In addition, ethical considerations would argue against allowing cervical lesions arising in women in a vaccine study population to progress to malignancy. However, since infection with high-risk HPV is highly associated with the development of Pap smear cytologic abnormalities, which in turn place women at increased risk of progression,<sup>34</sup> it is likely that surrogate intermediate end points of infection will be used to determine vaccine efficacy in prospective trials.

If prophylactic vaccination with VLPs proves efficacious, the type specificity of neutralizing antibodies makes it likely that protection will also be type specific. Since multiple HPV types are found in cervical cancer, the type-specific nature of the immune protection implies that a polyvalent vaccine would be required to inhibit the majority of cervical cancers. For example, a vaccine that contained VLPs against HPV-16, 18, 31, and 45, might theoretically prevent close to 80% of cervical cancers.

### ***Helicobacter pylori***

*H pylori*, which was discovered in 1982, induces chronic gastric infection of almost one-half the world population. Infection with *H pylori* is associated with a variable proportion of several disorders, including duodenal ulcer, gastric ulcer, carcinoma of the gastric antrum and fundus, which is the second most common cancer worldwide, and gastric mucosa-associated lymphoid tissue lymphomas.<sup>2,16,24,46</sup>

*H pylori* is usually acquired in childhood. It disproportionately affects people of lower socioeconomic status, and the majority of adults from developing countries are infected. The bacterium is found less frequently among individuals in developed countries such as the United States, and the low rate of infection in children from developed countries suggests the proportion in adults will continue to fall.<sup>24</sup>

Most *H pylori* infections are asymptomatic and have a benign outcome. When infection does lead to stomach cancer, it usually takes decades.<sup>46</sup> In this process, bacterially induced chronic gastritis is believed to progress to atrophic gastritis and metaplasia, and then to cancer. The bacterium appears to be required only until atrophic gastritis develops, at which stage it frequently can no longer be cultured from the stomach. Experimental *H pylori* infection of Mongolian gerbils can induce these sequential pathologic changes, including gastric adenocarcinoma.<sup>47</sup>

Gastric mucosa-associated lymphoid tissue lymphoma is much less common than gastric carcinoma and has a distinct pathogenesis.<sup>16</sup> This B-cell lymphoma arises from *H pylori*-dependent chronic stimulation of the Peyer's patches in the gastric mucosa. Localized mucosa-associated lymphoid tissue tumors often remain dependent on continued stimulation by bacterial antigens, and eradication of the bacteria with antibiotic treatment may frequently be associated with lymphoma regression at this stage. However, the growth of more invasive tumors, which may become widely disseminated, is usually autonomous, and these tumors typically do not respond to antibacterial therapy.

Several bacterial virulence factors account for the ability of *H pylori* to colonize and persist in the gastric mucosa.<sup>17,24</sup> Although different isolates of *H pylori* are closely related antigenically, type I isolates, which are associated with carcinoma, contain a cassette of genes that are designated a pathogenicity-associated island called *cag*.

In principle, *H pylori* infection can be eradicated by combined treatment with several antimicrobial agents plus proton pump inhibitors. However, the high cost and the emergence of antibiotic resistance make this approach poorly suited for bacterial eradication from whole populations. These limitations have fostered efforts to develop *H pylori* vaccines.<sup>17,24</sup> Encouraging preclinical studies have been obtained with a variety of animal models. Mucosal immunization with bacterial lysates, purified bacterial antigens, or with attenuated salmonellae encoding *H pylori* antigen can all prevent experimental infection. Some of these vaccines have also been used successfully to eradicate established infection in the animal models. It remains to be determined which of these approaches will prove efficacious in human vaccine trials. The most desirable outcome would be a cost-effective vaccine that could eradicate established infection while also protecting against new infections. Such a vaccine would have the long-term benefits of a purely prophylactic vaccine while reducing the incidence of gastric cancer after a much shorter interval.

## INTRODUCTION

The term *vaccine* originally referred to use of live cowpox virus inoculated in the skin as prophylaxis against smallpox, and hence is derived from the Latin *vacca*, which means cow. This meaning was extended to include the use of live, attenuated, or killed microbes or derivatives of microbes given by virtually any route to prevent the development of an infectious disease. The most recent incarnations of this term include the use of any antigen or fragment of an antigen, or any collection of antigens used alone, or together with an adjuvant, to modulate an immune response.

Vaccines are traditionally thought of as *preventing* infectious diseases, but they may have new uses in the *treatment* of malignancies. In the case of cancer, it is now clear that the immune system can recognize and destroy even large quantities of established tumor. Evidence for this immune-mediated destruction comes primarily from clinical trials using interleukin-2 (IL-2), which is now approved by the U.S. Food and Drug Administration for treatment for melanoma and renal cell carcinoma.<sup>1</sup> Although data are limited, experimental therapeutic vaccines have also been demonstrated to cause regression of cancer in a small percentage of patients.<sup>2,3</sup> and <sup>4</sup>

The goal of designing vaccines to prevent cancer may be appealing, but a variety of practical and theoretical problems arise in creating a prophylactic vaccine. Predicting which patients will develop cancer remains difficult, although assessment of risk becomes more accurate with the expansion in knowledge of genetic and environmental factors that contribute to carcinogenesis. There are also theoretical reasons why prophylactic vaccination against defined antigens may not be feasible. For example, the difficulty in predicting which of myriad mutations may occur in any one of a large number of genes makes vaccination against mutated tumor antigens unlikely to be successful. Similarly, vaccination against self-antigens may be subject to chronic immunologic tolerization, or may produce untoward side effects resulting from the destruction of normal tissues that express the same antigen.

The only truly preventive cancer vaccines that are under serious consideration are vaccines designed to prevent infectious diseases linked to the development of cancer.<sup>5</sup> For example, vaccines that prevent human papillomavirus or hepatitis B virus infections should also prevent cervical cancer and liver cancer, respectively. However, most cancers affecting individuals in developed countries have not been associated with viruses. Thus, prophylactic vaccines for cancer are likely to be the exception rather than the rule. Most research in the field of cancer vaccines is devoted to vaccines designed to activate the immune system to destroy established cancer cells.

The notion that cancer cells could be recognized by the immune system has been the subject of scientific investigation for over 100 years. The nineteenth-century physician William Coley attempted to treat tumor-bearing patients by injecting fluid cultures of living *Streptococcus erysipelas* and reported an apparent decrease in tumor burden in some of his patients.<sup>6</sup> Since then, results from experiments first done by Gross, then by Prehn and Main, and finally expanded on by Klein and colleagues, indicated that mice could be immunized against subsequent challenge with methylcholanthrene-induced sarcomas.<sup>7,8</sup> Advances in molecular biology and immunology have since led to the identification of prospective tumor antigens and improved methods of immunization. Clinical studies of human immunotherapies and work done in experimental animal tumor systems have been mutually enhancing efforts. A number of broad categories of anticancer vaccine approaches have emerged from this research ([Table 63.2-1](#)).

WHOLE TUMOR CELL VACCINES MODIFIED IN VIVO OR EX VIVO
Adjuvanted with adjuvant (chemical, bacterial, or viral)
Physical alteration (gamma irradiation)
Gene modification (with interleukin-2, tumor necrosis factor, interferon- $\gamma$ , granulocyte-macrophage colony-stimulating factor, B7-1/B7-2)
TUMOR-DERIVED HEAT SHOCK PROTEINS
RECOMBINANT AND SYNTHETIC VACCINES
Peptides and proteins (given with adjuvants such as IFA)
Plasmid DNA (intramuscular injection, gene gun)
Self-replicating DNA or RNA (intramuscular injection, gene gun)
Recombinant viruses (herpes, vaccinia, adenovirus)
Recombinant bacteria ( <i>Bacillus Calmette-Guérin</i> , <i>Listeria</i> , <i>Salmonella</i> )
DENDRITIC CELL-BASED VACCINES
Pulsed with recombinant or protein or tumor cell lysate
Pulsed with synthetic or tumor-derived peptides
Transfected with recombinant or tumor-derived DNA or RNA
Infected with recombinant viruses or bacteria
Fused to whole tumor cells
IFA: incomplete Freund's adjuvant.

TABLE 63.2-1. Candidate Vaccines for the Treatment of Established Cancer

## IMMUNE MECHANISMS UNDERLYING VACCINE FUNCTION

### CRITICAL ROLE OF T CELLS IN THE ANTITUMOR IMMUNE RESPONSE

The principle that T cells were critically important in the immune response against cancer was derived originally in mice with methylcholanthrene-induced tumors.<sup>9,10,11,12 and 13</sup> In both animal tumors and some human malignancies, T cells that accumulate within the mass of a tumor have been shown to specifically recognize autologous tumor cells *in vitro*, and to proliferate and specifically secrete cytokines, such as IL-2, interferon-g (IFN-g), granulocyte-macrophage colony-stimulating factor (GM-CSF), and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), in response to stimulation with autologous tumor cells.<sup>14,15 and 16</sup> The adoptive transfer of these antitumor T cells can treat substantial tumor burdens in both humans and mice.<sup>17,18</sup> Furthermore, the antitumor activity observed with systemic administration of the T-cell growth factor IL-2 in animal models, and perhaps also in patients, appears to be mediated in large part by tumor antigen-specific T lymphocytes.<sup>19,20</sup>

Several mouse studies have suggested that tumor rejection is largely dependent on CD8+, cytolytic T cells, with little if any role for CD4+ T cells.<sup>21</sup> In addition, adoptive transfer of pure populations of CD8+ T lymphocytes was shown to mediate tumor regression in mice.<sup>22,23 and 24</sup> Thus, many efforts to develop therapeutic anticancer vaccines have focused on CD8+ T lymphocytes, and the molecular targets of these cells have been identified in human and mouse systems.<sup>25,26</sup>

Compared with the comprehensive studies using CD8+ T cells in tumor models, relatively little is known about how CD4+ T cells influence antitumor immunity. Early work demonstrated that disseminated murine leukemia could be eradicated by a combination of cyclophosphamide and adoptive transfer of CD4+ T cells.<sup>27,28</sup>

We now understand some aspects of how CD4+ T lymphocytes help initiate and maintain the antitumor immune response.<sup>29,30</sup> CD4+ T cells regulate antigen-specific immune responses by regulating the functions of other components of the immune system, including B lymphocytes and CD8+ T lymphocytes. In the B16 murine melanoma system, CD4+ T cells appear crucial for the induction of both antitumor and autoimmunity that is mediated by B lymphocytes, as well as eosinophils and macrophages.<sup>31,32,33,34,35,36 and 37</sup>

Activated CD4+ T cells express CD40 ligand (gp39), which can engage the CD40 receptor on antigen-presenting cells (APCs) such as dendritic cells (DCs). These DCs can secrete proinflammatory cytokines such as IL-12, which in turn trigger the activation of CD8+ T cells and their production of IFN-g and IL-2, resulting in the attraction of a host of other immune cells to the site.<sup>38,39</sup>

One potentially important experimental thrust in the use of adoptively transferred T cells may be the intentional addition of helper CD4+ T cells to adoptively transferred CD8+ T cells. Walter and colleagues found that the cytotoxic activity of adoptively transferred cytomegalovirus-specific CD8+ T-cell clones declined in patients deficient in cytomegalovirus-specific helper CD4+ T cells.<sup>40</sup>

Perhaps the most dramatic examples of the power of CD4+ T cells in the immune response to self proteins can be found in murine models of autoimmune diseases such as experimental allergic encephalomyelitis, systemic lupus erythematosus, and diabetes. In these models, disease can often be transferred to naive mice with purified, self-reactive CD4+ splenocytes or specific CD4+ T lymphocyte clones.<sup>41,42</sup> These studies suggest that the full activation of autoreactive CD4+ T cells may be a key element missing from many current clinical cancer vaccine trials. Attempts to identify the molecular targets of antitumor CD4+ T cells have already been successful.<sup>43,44,45,46,47 and 48</sup> Thus, current work focuses on efforts to harness the potential capabilities of tumor-specific CD4+ T cells.

## TUMOR-ASSOCIATED ANTIGENS

Now that many tumor antigens have been identified ([Table 63.2-2](#)), how does one go about choosing an antigen appropriate for use in the design of a cancer vaccine? Some workers have picked target antigens because they are frequently mutated in tumors, as in the case of p53<sup>49</sup> or ras,<sup>50,51</sup> are at the site of joining of a translocation such as bcr-abl,<sup>52</sup> or are aberrantly glycosylated and thus the subject of recognition by antibodies as is the case for MUC-1.<sup>53,54</sup>

**TABLE 63.2-2.** Examples of Defined Tumor-Associated Antigens in Cancer Vaccine Clinical Trials

It is clear that not every peptide that can be generated from a protein will be presented in a major histocompatibility complex (MHC) class I-restricted fashion. The chances that any given peptide will be presented on the tumor cell surface are in the range of 1%, although this number is approximate. Because not every MHC-binding tumor-derived peptide will be naturally presented on the tumor cell surface, it is possible to induce a cytotoxic T lymphocyte (CTL) that can kill peptide-pulsed targets but not actual tumors.<sup>56</sup>

### Identifying Tumor Antigens Recognized by T Lymphocytes

Because of the difficulty in predicting what peptides from a given potential antigen will be present on the cell surface, one of the most successful approaches to identifying tumor-associated antigens suitable for the development of cancer vaccines starts with the antitumor immune response. In many cases, the antitumor T cells were derived from cultures of tumor-infiltrating lymphocyte. Our own group [the Surgery Branch of the National Cancer Institute (NCI)] has focused on the T-cell reactivities that were associated with objective regressions of metastatic melanoma lesions after their adoptive transfer.<sup>57</sup> cDNA libraries of expressed melanoma genes were screened by transfecting these genes, along with the gene for the restricting MHC molecule, into an antigen-negative cell line that was then admixed with T lymphocytes that have antitumor activity. If the T cells recognize the transfected cell line, they lyse it and release cytokines such as GM-CSF, TNF- $\alpha$ , and IFN-g, any of which can be measured.<sup>2,14</sup> This process of cloning genes encoding tumor antigens is under constant improvement and has become considerably faster and more streamlined.<sup>58</sup>

### Targeting Self-Antigens

The identification of self-antigens as potential targets in the immunotherapy of cancer has been an important factor driving interest in cancer vaccine development. Many of the tumor antigens that have been identified, in the case of melanoma, are tissue differentiation antigens in melanocytes and include gp100,<sup>59,60,61,62,63,64 and 65</sup> MART-1/MelanA,<sup>66,67,68,69 and 70</sup> tyrosinase,<sup>61,71,72,73 and 74</sup> and tyrosinase-related protein-1/gp75<sup>75</sup> and tyrosinase-related protein-2.<sup>76,77 and 78</sup> Interestingly, these antigens are involved in the synthesis of melanin that gives both melanocytes and deposits of melanoma tumor their dark pigment. CEA expressed in gastrointestinal and some other malignancies, and prostate-specific antigen (PSA), are other examples of differentiation antigens that have relatively restricted expression in normal tissues and could be targeted by cancer vaccines.<sup>79</sup>

A second group of self-antigens are expressed by a diversity of tumor histologies but are not expressed by normal tissues other than testis. Cloned in large part by Dr. Thierry Boon and his colleagues, these antigens are encoded by genes with family names like MAGE, BAGE, GAGE, RAGE, LAGE, and CAMEL.<sup>80,81 and 82</sup> NY-ESO-1 also falls into this group and is expressed in a significant proportion of human melanoma cells as well as tumors arising from breast, ovary, bladder, prostate, and liver.<sup>83,84,85,86,87 and 88</sup>

The fact that differentiation antigens are nonmutated in most tumors has two important implications. First, expression of these antigens would be expected in subsets of patients with a defined tumor histology, thus an *off-the-shelf* vaccine strategy targeting these antigens is possible (a strategy that targets a mutated antigen may have to be individualized for every mutation). Second, the nonmutated nature of these antigens suggests that immunotherapies that target these antigens could elicit autoreactivity. One consequence of this autoreactivity may be vitiligo, the patchy and permanent loss of pigment from the skin and hair thought to result from the autoimmune destruction of pigment cells.<sup>31</sup> Vitiligo has been correlated with objective shrinkage of deposits of metastatic melanoma in patients receiving high-dose IL-2, a cytokine known to activate and expand T lymphocytes.<sup>89</sup> This correlation is among the strongest evidence that the antitumor effects of IL-2 are mediated by antigen-specific immune responses and supports the notion that targeting immune responses to recognize self-antigens expressed by tumor can lead to tumor regression.

### **Are Mutated Tumor Antigens Better Targets for Immune Recognition?**

Besides shared antigens, human tumors also express mutated antigens that can be processed and presented for recognition by T cells. Neoantigens produced as a result of mutation often are found to originate in ubiquitously expressed proteins. Examples include epitopes from b-catenin,<sup>90</sup> CDK4,<sup>91</sup> MUM1,<sup>92</sup> FLICE (caspase 8),<sup>93</sup> HLA-A2,<sup>94</sup> and a mutant gene from a bladder carcinoma that is recorded in databases under the name KIAA0205, whose function is unknown.<sup>93,95</sup> Interestingly, some of these antigens are also oncogenic, including the mutations described for b-catenin and CDK4.<sup>90,91</sup>

Mutated antigens may not lend themselves easily to off-the-shelf vaccines consisting of purely recombinant and synthetic components, because each neoantigen for each patient must be checked for sequence and that sequence must be verified to be present on the surface of a tumor cell. Some workers have asserted that mutated tumor antigens are superior targets for vaccine design because immune cells will not be tolerized to these antigens.<sup>96</sup> However, work has shown that even the most immunogenic *foreign* antigen, such as the hemagglutinin antigen from the influenza A virus, can be tolerizing when expressed peripherally (i.e., outside the thymus) either in normal cells<sup>97</sup> or tumor cells.<sup>98</sup> Thus, mutated or otherwise foreign antigens may also induce peripheral tolerance when expressed by tumor cells.

### **ROLE OF DENDRITIC CELLS IN VACCINE FUNCTION**

It is likely that DCs are a key mediator of vaccine function.<sup>99,100</sup> and <sup>101</sup> DCs activate T-cell responses by capturing, processing, and presenting antigens in the context of MHC molecules to T lymphocytes. In addition, DCs express the costimulatory molecules B7-1 (CD80) and B7-2 (CD86), which provide a second signal on interaction with their receptors on the surface of T cells known as CD28 and CTLA-4.<sup>102,103</sup> Engagement of CD28 is associated with proliferation and differentiation whereas CTLA-4 may trigger functional unresponsiveness.<sup>104,105</sup> Blocking CTLA-4 engagement has been reported to enhance immune responses to tumor cells.<sup>106</sup> Activating T cells by DC is thus accomplished by presenting antigen/MHC complexes in the context of a variety of other activating signals.<sup>107</sup>

DCs can undergo maturation or *super activation* through the activity of GM-CSF and TNF- $\alpha$  and other macrophage-derived cytokines, greatly enhancing their ability to activate naive T cells. In addition, CD40 and its ligand have been shown to be important in B-cell activation, in the production of type 1 cytokines by T-helper cells, and in the generation of cytotoxic T-cell memory responses. We and others have found that the addition of CD40L trimer to DNA vaccination can significantly increase antitumor efficacy.<sup>108</sup> Another molecule called FLT3 ligand can induce the apparent growth and differentiation of functional DC and has been reported to have antitumor effects,<sup>109,110</sup> and its effect on the function of recombinant and synthetic anticancer vaccines is the subject of a great deal of investigation in experimental mouse models.

### **ROLE OF ANTIBODIES IN IMMUNE-MEDIATED ANTITUMOR RESPONSES**

Much of the experimental data generated with cancer vaccines in animal models suggests that immune-mediated antitumor activity is attributable to T cells. Nevertheless, adoptive transfer of antibodies directed against surface tumor antigens can cause regression of cancer in animal models, and vaccine-induced antibody responses have been demonstrated to reject a tumor challenge and to cause regression of small-volume established cancer.<sup>111</sup> Antibodies mediate antitumor effects by complement-dependent lysis or by antibody-dependent cellular cytotoxicity. In addition, antibodies directed against growth factor receptors or other cell surface molecules have demonstrated antitumor activity in animal models and in human clinical trials, by mechanisms that appear to involve blocking or stimulating a cell signal. For example, trastuzumab (Herceptin) is a humanized monoclonal antibody that blocks the function of the HER-2/neu protooncogene, which is overexpressed in 25% to 30% of breast cancers, and causes objective tumor responses in approximately 15% of breast cancer patients with metastatic disease. It also significantly enhances the therapeutic effect of paclitaxel in these patients. Although the mechanism of action is thought to involve the inhibition of stimulatory signals provided by multiple neuregulins and epidermal growth factor–like molecules,<sup>112,113,114,115</sup> and <sup>116</sup> there is some evidence that the therapeutic effect may also have an immunologic component through direct killing of antibody-coated tumor cells by natural killer cells.<sup>117</sup>

Antibody responses are generally directed toward cell surface components of tumor cells. Similar to T-cell responses, several factors may influence the antitumor activity of an antibody response, including the density of the target on the cell surface; the type of target; the type of antibody response; the affinity of the antibody for its target; the magnitude of the response (titer); the amount of circulating antigen; the presence of antigen on normal cells; and perhaps the availability at the tumor site of effector immune cells bearing the appropriate Fc receptors. Entry of antibodies into tumors can be limited by physiologic barriers, for example, by high tumor pressure, and the presence of complement inhibitors has been documented on various tumor cell lines,<sup>118,119</sup> perhaps limiting the activity of antibodies that require complement activation for antitumor activity.

### **MONITORING OF CANCER VACCINE TRIALS**

A major challenge for cancer vaccine trials is determination of efficacy, as measured by immune response and patient benefit. Techniques for measuring antibody response have become relatively well established, although it is important to verify that the antibody responses actually recognize tumor cells bearing the antigen, and that affinity, titer, and biologic activity are sufficiently high to expect antitumor activity *in vivo*.

T-cell responses can be measured through a biologic assay, for example, a skin test of delayed-type hypersensitivity (DTH), by assessment of number and function of antigen-specific T cells in peripheral blood, and by assessment of histologic changes and antigen-specific T-cell number and function within the tumor. DTH is commonly used to measure responses to autologous and allogeneic cell vaccines. Application of appropriate controls for DTH testing is often difficult, and it is often not possible to be certain that a positive reaction truly indicates response to a relevant tumor antigen and not, for example, serum or other components of the tumoral growth medium.

Detection of antigen-specific T cells in blood or tumor can be accomplished by a physical characteristic (presence of a particular T-cell receptor) or function (production of cytokine in response to the binding of a peptide-MHC complex with the T-cell receptor). If the peptide to which the immune response is directed is known, peptide-MHC complexes can be joined to form a tetramer, which can be used to detect T cells bearing the appropriate T-cell receptor in a flow cytometer.<sup>120</sup> By this technique, the number of peptide-specific T cells in a bulk population can be enumerated, and after sorting, the functional capacity of the T cells can be characterized.<sup>121,122</sup> The tetramer technique is promising but is still limited by the sensitivity of the flow cytometer.

Perhaps the most sensitive techniques for assessing a T-cell response to immunization are based on detecting a particular function of a T cell when exposed to its antigen, most commonly secretion of cytokines, cytotoxicity toward antigen pulsed cells, tumor expressing the antigen, or all these. Ultimately, it is important to demonstrate induction of immune responses that recognizes tumor cells and not just antigen presented by a target cell, since efficacy is based on the immune response recognizing naturally processed and presented antigen. If immunization results in an increased frequency of T cells against the immunizing antigen, posttreatment bulk cultures of T cells exposed to the appropriate target should produce greater amounts of cytokines than pretreatment bulk cultures. Indeed, the latter has been shown after immunization with various peptides including MART-1 and modified gp100 melanoma peptides, although the posttreatment cultures still require some expansion of precursors *in vitro* before measuring cytokine release.<sup>123</sup> Limiting dilution assays allow a more accurate enumeration of T-cell precursors that are ultimately detected based on function such as cytokine release or cytotoxicity.<sup>2</sup>

The enzyme-linked immunosorbent assay–spot (ELISPOT) technique involves plating T cells with targets and fixed antibodies to a particular cytokine. The plate is developed by a second antibody to the cytokine, so that a spot appears wherever a T cell has recognized a target and has been stimulated to produce the indicator cytokine. By counting the number of spots and dividing by the number of T cells plated, an estimate of the frequency of antigen-specific T cells can be made. The

ELISPOT technique also has sensitivity limitations, but may become a useful tool in monitoring of some cancer vaccine trials. <sup>124</sup>

The Surgery Branch of the NCI has explored the use of quantitative reverse transcriptase polymerase chain reaction techniques to detect evidence of immunization to a peptide vaccine directly from peripheral blood and from tumor. The technique involves measurement of mRNA message for a particular cytokine normalized to a standard curve. Measurements can be made on fine-needle aspirates of tumor. Since the mechanism of vaccine antitumor response likely involves infiltration of tumor by T cells, and activity is dependent on cytokine production by the infiltrating T cells, an efficient measure of vaccine biologic activity is an increase in mRNA for a particular cytokine at the tumor site. <sup>125</sup>

## ANTICANCER VACCINE APPROACHES DERIVED FROM AUTOLOGOUS AND ALLOGENEIC TUMOR CELLS

Many cancer vaccines in current development use autologous or allogeneic tumor cells as the source of antigen for immunizing patients. Autologous tumor cell vaccines must be prepared individually for each patient, but offer the potential to immunize against antigens generated by patient- and tumor-specific gene mutations. Allogeneic tumor cells provide a more reliable and uniform source of antigen for preparation of vaccines, but target only antigens that are shared between the cell lines in the vaccine and the patient's tumor.

Final preparations of autologous or allogeneic tumor cell vaccines contain either whole cells, lysates, or extracts from the cells. Some attempts have been made to immunize with live autologous cancer cells, but to avoid the concern that live cells might implant or metastasize, whole tumor cells are irradiated or otherwise killed before reinjection. To ensure adequate presentation of antigens to the immune system, adjuvants such as bacille Calmette-Guérin (BCG), <sup>126,127</sup> *Corynebacterium parvum*, <sup>128,129</sup> DETOX, and alum must be added to the cells or cell extracts. Attempts to increase immunogenicity have also included the infection of allogeneic tumor cells with vaccinia virus, <sup>130,131</sup> vesicular stomatitis virus, <sup>132</sup> as well as other viruses to create *oncolysates* that contain both viral and tumor antigens. The strong foreign viral antigens serve as an immunologic adjuvant that enhances immune responses to the tumor antigens.

A significant body of work in experimental animals has shown that transfection of genes into tumor cells is capable of increasing their immunogenicity. <sup>133,134</sup> and <sup>135</sup> Based on these results, patients have been treated with tumor cells genetically modified *ex vivo* or *in vivo* to express several different classes of genes, including cytokines, T-cell costimulatory molecules, or foreign genes encoding allogeneic or xenogeneic MHC class I molecules. The substantial work with gene-modified tumor cells is described in greater detail in [Chapter 62.1](#).

More recent efforts to improve the immunogenicity of autologous and allogeneic cancer cell vaccines have involved the direct transfer to, or expression of, potential antigens in host APC. Methods under investigation in animal models, and either ongoing or planned for clinical trials, include expressing whole tumor cell RNA in host APC, <sup>136</sup> pulsing APC with peptides extracted by acid elution from the surface of tumor cells, <sup>137,138</sup> and creating DC-tumor cell fusions. <sup>139,140</sup>

An alternative to the use of whole tumor cells in vaccines has been to enrich the relevant and immune-activating components of tumor cells while excluding the irrelevant and immune-suppressing substances that may be present. Partially purified fractions of allogeneic tumor cell lines, in this instance shed tumor antigens into the culture media, have been shown to yield preparations that are capable of stimulating immune responses in experimental murine models. <sup>141</sup> This method of preparing a tumor vaccine has been extended into the clinic, <sup>142,143</sup> in combination with adjuvants such as alum <sup>144</sup> or DETOX. <sup>145</sup> Srivastava and colleagues have shown that heat shock proteins carry antigenic peptide determinants of cellular proteins, including tumor antigens, to the MHC molecules in the endoplasmic reticulum. <sup>146,147</sup> When isolated from tumor cells and administered as a vaccine, the heat shock proteins can apparently gain access to both the class I and class II antigen-processing pathways of certain APCs, including macrophages, and can induce both tumor-antigen specific helper and cytotoxic T-lymphocyte responses. <sup>147</sup> The heat shock protein preparations have generated protective and therapeutic antitumor activity in animal models, and on this basis, have entered clinical trials. <sup>148,149,150,151</sup> and <sup>152</sup>

## CLINICAL EXPERIENCE

Some of the vaccines that have progressed to randomized trials are listed in [Table 63.2-3](#). Most of the clinical experience has been in patients with melanoma. A large number of clinical trials have been conducted including vaccinia-induced lysates of allogeneic melanoma cell lines <sup>131</sup>; shed antigens from cultures of allogeneic melanoma cell lines (admixed with alum) <sup>142,143</sup>; Melacine, lysates from two allogeneic melanoma cell lines (administered with DETOX) <sup>145,153</sup>; CancerVax, a combination of three allogeneic melanoma cell lines (with BCG as adjuvant) <sup>154,155</sup>; and autologous melanoma cells chemically modified with dinitrophenyl (DNP). <sup>156,157</sup> and <sup>158</sup> For several of the vaccines, including Melacine, CancerVax, and the DNP-modified autologous melanoma cells, low rates of objective responses were observed in patients with metastatic disease, although usually not in patients with large tumor burdens or visceral involvement. A striking observation in trials of the DNP-modified autologous melanoma cells was the induction of inflammation and lymphocytic infiltrates in distant metastatic lesions. For all the vaccines, single-arm studies suggested that the vaccine improved disease-free survival of stage III patients (in general, patients following resection of their primary or regional nodes, or both, and at high risk for recurrence), and for some of the vaccines improved survival was also suggested for patients with metastatic disease. Comparisons were made with historical controls, or within the study, immune responders were compared with patients who had poor or no immunologic response to the vaccine.

Vaccine	Adjuvant	Stage/Type	Year	Results	Reference
Melanoma vaccine (vaccinia)	Yes	Stage III-IV (large tumor)	1981-1977	No survival improvement compared with control (vaccinia alone)	131
Melanoma vaccine (shed antigens)	Yes	Stage III-IV (large tumor)	1981	Feasible	142,143
Melanoma vaccine (Melacine)	DETOX, Alum	Stage III-IV (large tumor)	1981	No survival improvement compared with control (DETOX, Alum)	145
Melanoma vaccine (CancerVax)	BCG	Stage III-IV (large tumor)	1981-1982	Feasible, objective response rate 10%	154,155
Melanoma vaccine (DNP-modified autologous cells)	None	Stage III-IV (large tumor)	1981-1982	Feasible, objective response rate 10%	156,157,158
Colorectal cancer vaccine (autologous cells)	None	Stage III-IV (large tumor)	1981-1982	Feasible, objective response rate 10%	159
Colorectal cancer vaccine (allogeneic cells)	None	Stage III-IV (large tumor)	1981-1982	Feasible, objective response rate 10%	160
Renal cell cancer vaccine (autologous cells)	None	Stage III-IV (large tumor)	1981-1982	Feasible, objective response rate 10%	161

TABLE 63.2-3. Moderate and Large Randomized Trials of Cancer Vaccines

Based on these data, several of the vaccines were tested or are currently in phase III randomized trials (see [Table 63.2-3](#)). The vaccinia melanoma oncolysate showed no benefit for patients with stage III disease in one trial, although another larger study of a vaccinia melanoma oncolysate is pending analysis. Melacine, a vaccine composed of lysates from two allogeneic melanoma cells lines admixed with DETOX, did not improve survival of patients with metastatic melanoma compared with chemotherapy. Two randomized trials of an autologous colon cancer vaccine admixed with BCG adjuvant involving stage II/III patients have been published. <sup>159</sup> One of the studies indicated an improvement in disease-free survival for stage II patients only. The difference in outcome between the two trials was attributed to improved quality control in vaccine preparation and administration of an additional dose for late boosting of the immune response in the positive trial. Additional studies may be required to assess the true efficacy of the vaccine when administered optimally.

Various autologous tumor cell vaccine approaches have been explored in patients with advanced renal cell cancer. Among 20 evaluable patients immunized with autologous tumor cells and a bacterial (*Corynebacterium parvum*) adjuvant, one complete and four partial responses were observed, all in lung metastases. <sup>160</sup> Positive DTH responses to the autologous tumor cells correlated with response and survival. <sup>161</sup> Kugler et al. reported on 17 metastatic renal cell cancer patients immunized with a vaccine composed of autologous tumor cells fused to allogeneic monocyte-derived DCs. <sup>140</sup> Theoretically, the tumor self-MHC molecules are presenting unique cancer antigens to the host immune system, and the allogeneic DC fusion partner is providing the necessary costimulation to T cells to ensure optimal activation. Four complete and two partial responses were observed. Regression was noted primarily in metastases of lung, bone, lymph node, and local recurrences and appeared durable in some patients, although median follow-up was only 13 months at the time of the report. DTH responses to autologous tumor developed in 11 of the 17 patients, which included all the objective antitumor responses.

The clinical experience obtained with tumor cells modified with genes encoding cytokines or other immune-stimulatory molecules is covered in [Chapter 62.1](#). Whether gene modification of tumor cells enhances their immunogenicity and therapeutic outcome in comparison with a simple admixture of tumor cells with nonspecific

adjuvants remains a subject of debate and further study in preclinical models and clinical trials. Nevertheless, a large number of clinical trials involving gene-modified tumor cells have been initiated. An occasional antitumor response has been reported, but in general the vaccines have had minimal activity against advanced disease. Of note, in a trial of GM-CSF–transfected autologous melanoma cells, the vaccine appeared to induce T-cell infiltrates in distant metastatic lesions, similar to results reported for the DNP-modified autologous tumor cell vaccine. Despite the biologic activity, systemic antitumor response as measured by standard criteria was observed in only a few patients.<sup>162</sup>

## APPROACHES USING RECOMBINANT AND SYNTHETIC ANTICANCER VACCINES

Because cancer cells are notoriously poor immunogens, workers in a number of laboratories have attempted to isolate tumor antigens and present them to the immune system in more immunogenic formulations. This has led to the development of recombinant and synthetic cancer vaccines, which are predicated on the identification of tumor-associated antigens.

Among the most effective immunization strategies for defined antigens in animal models has been to insert the gene for the antigen in recombinant vectors. A partial list of recombinant viral immunogens includes vaccinia, fowlpox, canarypox, adenovirus, influenza, polio, and sindbis.<sup>163</sup> Recombinant organisms include *Listeria*, *Salmonella*, and BCG.<sup>164,165</sup> In addition, *naked* nucleic acid–based vectors include the administration of DNA by intramuscular or intradermal injection or by *gene gun* and most recently, the administration of *self-replicating* nucleic acid-based immunogens.<sup>166,167</sup>

### RECOMBINANT VIRUS–BASED VACCINES

Recombinant virus–based cancer vaccines are created by inserting genes encoding tumor antigens into the viral genome. The safety of these recombinant viruses can be ensured in a number of ways. Some of the recombinant vaccines are composed of viruses incapable of replicating in mammalian cells because of their host range (e.g., the avian poxviruses),<sup>168</sup> whereas others are highly attenuated (such as certain influenza A viruses<sup>169</sup> or the Wyeth and MVA strains of vaccinia virus<sup>170</sup>), and still others are made safe by the removal of viral genes that are critical to viral replication and virulence (such as adenoviruses).<sup>171</sup>

Vaccines based on live, attenuated, or killed viruses can be highly effective in preventing human viral diseases such as polio, smallpox, and even influenza A. However, recombinant viruses encoding tumor antigens have an important shortcoming: The only component of the immune response that can be tumor specific is the response elicited by the expression of the transgene(s) encoding the tumor antigen(s). Although viral elements might help boost immune reactivity through their activity as helper epitopes, they will not contribute any specificity of immune reactivity for tumors, with the exception of recombinant virus-based immunogens used to vaccinate against a virally induced cancer (e.g., the use of recombinant human papillomavirus to treat cervical cancer).

#### Problem of Preexisting Immunity to Viral Immunogens

Although viral vaccines are potent inducers of antitumor immunity in animal models, the obstacle of preexisting immunity remains an important problem in the translation of these strategies to the clinic. We have learned in the conduct of our own clinical trials that humans have high neutralizing titers to recombinant viral vaccines based on adenoviruses, likely due to the ubiquitous presence of adenovirus in the environment of the upper respiratory systems.<sup>172,173,174</sup> and <sup>175</sup>

Vaccinia virus was widely used in the campaign to eradicate smallpox.<sup>176</sup> Thus, anyone born in the United States before approximately 1970 (the majority of patients who currently have cancer) have already been immunized to vaccinia.<sup>177</sup> Elsewhere in the world, immunization with vaccinia was continued well after the early 1970s.<sup>178</sup> Indeed, most patients appear to be able to rapidly clear these viruses, making it difficult or impossible to effectively use cancer vaccines based on these viruses. One way of circumventing the problem of preexisting immunity is the use of viruses whose natural hosts are nonmammalian, such as the avian poxviruses.<sup>168</sup>

#### Clinical Experience

Viruses engineered to express some tumor antigens induce potent immune responses in murine models, which serve as the basis for initiating human clinical studies. However, the animal models may overestimate the efficacy of the recombinant viral vaccines in clinical trials. In addition to the problem of preexisting immunity to several of the viral vectors, patients also are likely to have preexisting immunologic tolerance to the tumor antigen, which is often a self-antigen in the human trials. The results of clinical studies to date seem to bear out these concerns (Table 63.2-4). Limited data from a trial of vaccinia-CEA, and separately ALVAC-CEA, the latter a nonreplicating poxvirus in humans, suggest that weak cellular responses to CEA can be induced *in vivo*, as measured by T-cell responses to an HLA-A201 restricted peptide from CEA.<sup>179</sup> Antibody responses to the CEA protein were not detected in a separate study.<sup>180</sup> The Surgery Branch, NCI, has conducted clinical trials of adenovirus, vaccinia, and fowlpox separately carrying the MART-1 and gp100 melanoma genes<sup>172</sup> (S. A. Rosenberg, personal communication, 2000). One patient treated with the adenovirus-MART-1 vector experienced a durable complete regression, but otherwise, no clinical responses were observed with any of the vaccines used alone in patients with metastatic melanoma. Furthermore, the viral vaccines were not able to elicit immune responses to the viral-encoded tumor antigens, as measured against known HLA-A201 restricted peptide epitopes of the antigen. Because of the methodologies used to detect immune responses in the latter trials, it is not possible to exclude weak immune responses to known or unknown epitopes of the tumor antigens. Clinical trials of recombinant vaccinia and fowlpox vectors containing PSA and MUC-1 are in progress. Preliminary results of the vaccinia-PSA trial, in patients with rising PSA levels postsurgery, suggest that some patients may remain progression-free for an extended period, although actual benefit from the vaccine must be proven in randomized trials.

TABLE 63.2-4. Clinical Trials Using Vaccines Based on Recombinant Viruses<sup>a</sup>

Table 63.2-4 demonstrates that trials of recombinant viral vaccines have employed different routes of administration including scarification (multiple punctures of the vaccine solution into the skin), intradermal, subcutaneous, and intramuscular injection. Some patients also received the nonreplicating fowlpox-gp100 vaccine intravenously (S. A. Rosenberg et al., personal communication, 2000). A large range of doses has been explored in the phase I trials. Immunizations were repeated monthly in most trials for a maximum of three to four doses. Using immune responses to the viral vector antigens as a guide, no route of administration has proven to be superior, and a relationship between dose and immune response has not been established, although higher doses are predicted to be more effective for the nonreplicating vectors. Exploration of schedule issues (e.g., a longer interval between doses) has been difficult in the selected patient populations with progressing metastatic disease. For the vaccinia vectors, a *take* (formation of an inflammatory response and a bleb at the injection site) has occurred in most patients receiving the vaccine by scarification or intradermal injection despite preexisting immunity to vaccinia. However, second and third doses of vaccinia are usually not associated with a significant local reaction, suggesting that the vaccinia is cleared too quickly to allow boosting of immune responses to the encoded tumor antigen.

In order to improve the effects of these vectors, current studies are combining different viral vectors that are non–cross-reactive in patients, or viral vectors combined with the corresponding peptide epitopes of the antigen gene, administered sequentially. These heterologous boost strategies were superior to repeated immunizations with single vectors in animal models.<sup>181,182</sup> Examples of ongoing trials include sequential immunizations with vaccinia-CEA and ALVAC-CEA in patients with CEA-expressing malignancies, and vaccinia-tyrosinase sequenced with fowlpox-tyrosinase in metastatic melanoma patients. Investigators are also combining genes for T-cell costimulatory signals with the antigen gene within a single viral vector, or combining viral vectors that respectively express the antigen gene and genes for cytokines or one or more T-cell costimulatory signals. Clinical trials of vaccinia containing genes for both CEA and B7-1 (CD80) have been initiated, but

results are pending. Several of the recombinant viral vaccines encoding tumor antigens have also been administered in combination with systemic or local administration of GM-CSF, and with systemic IL-2. The Surgery Branch, NCI, administered high-dose IL-2 following immunization with adenovirus, fowlpox, and vaccinia vectors containing either the MART-1 or gp100 genes in patients with metastatic melanoma<sup>172</sup> (S. A. Rosenberg, personal communication, 2000). Although some clinical response were observed, the response rates did not appear higher than expected with IL-2 alone, and no enhancement of immunologic responses to the tumor antigens was observed. Results of studies employing lower doses of IL-2 with other recombinant viral vaccines have not been completed.

## RECOMBINANT VACCINES BASED ON NAKED NUCLEIC ACID

Reports dating from the early 1990s indicated the surprising finding that the intramuscular injection of *naked* plasmid DNA (i.e., DNA without a viral coat) could result in an immune response.<sup>183</sup> Like viral vaccines, the activity of DNA vaccines appears to be mediated through DCs and other *professional* APCs.<sup>100</sup>

In the case of gene-gun delivery, nucleic acid is precipitated onto an inert particle (generally gold beads) and forced into the cells with a helium blast. Transfected cells then express the antigen encoded on the plasmid, resulting in an immune response. Like live or attenuated viruses, DNA vaccines effectively engage both MHC I and MHC II pathways, allowing for the induction of CD8+ and CD4+ T cells.

DNA-based vaccines are relatively safe and easy to engineer and produce. In animal models, they are generally not as potent as recombinant viruses at eliciting immune responses capable of destroying tumors. Important innovations in the design of DNA vaccines include promoter optimization, enhancement of polyadenylation sequences, the removal of 5' and 3' untranslated regions from the inserted gene, and the use of intronic sequences to improve nuclear export.

Clinical trials using naked DNA vaccines encoding tumor antigens have begun. One of the first of these trials was launched at the Surgery Branch, NCI. It uses a plasmid encoding a modified form of the human gp100 melanoma antigen first alone then in combination with IL-2, previously shown in murine studies to enhance vaccination with plasmid.<sup>166</sup> Preliminary results indicate no clear signs of immunization and no objective tumor regressions.

One promising new approach to the development of nucleic acid vaccines may be strategies designed to make them self-replicating. Self-replication can be accomplished by using a gene encoding an RNA replicase polyprotein derived from alphaviruses, a family of viruses that includes Semliki Forest virus, Sindbis virus, and the Venezuelan encephalitis virus. A gene encoding a tumor antigen can be added to such a construct under the control of a viral promoter. Such constructs can elicit antigen-specific antibody and CD8+ T-cell responses at doses as low as 0.1 µg.<sup>166</sup>

## PEPTIDE VACCINES

Table 63.2-5 describes the clinical results of selected trials conducted with peptide vaccines. Peptides have been derived from various antigens, including melanoma antigens MART-1, gp100, tyrosinase, and tyrosinase-related protein-1; cancer testis antigen MAGE-3; PSA and prostate-specific membrane antigen; CEA; the mucin MUC-1; the hormone human chorionic gonadotropin- $\alpha$ ; the oncogene HER-2/neu; mutated ras and p53; and human papillomavirus E6 and E7 proteins. Several conclusions can be drawn from the series of studies conducted with MHC class I (HLA-A201 in most trials) restricted peptides derived from the melanoma antigens. In those trials, doses of 1 mg administered in an emulsion with a type of incomplete Freund's adjuvant were adequate to induce immune responses, and within the range of doses studied (100 µg to 10 mg), the immune response did not appear to be dose related. While scheduling was not examined in detail, the studies revealed that administration of the vaccine every 3 to 4 weeks was effective in inducing immune responses. Cytotoxic T-cell responses to the peptide and to HLA-A201+, antigen-positive tumor cells could be detected by several techniques, and the strength of the immune response was dependent on the peptide. The ability to induce detectable T-cell responses to peptides in patients, using current immune monitoring techniques, was found to be dependent on coadministration of an adjuvant (S. A. Rosenberg et al., personal communication, 2000).

**TABLE 63.2-5.** Clinical Trials Using Vaccines Based on Synthetic Peptides or Purified Proteins

Occasional mixed and true objective antitumor responses have been observed in a small minority of patients receiving melanoma peptide vaccines. However, no correlation has been made between detection of immune response and clinical outcome in these trials. In a study of an HLA-A1 restricted peptide from the cancer testis antigen MAGE-3, administered without an adjuvant to 39 patients with metastatic melanoma, three complete responses and four other patients with objective regression were reported, despite the inability to detect immune responses to the peptide.<sup>184</sup>

A substantial experience has been developed in studies of a synthetic peptide immunogen corresponding to an epitope from the gp100 melanoma antigen. The epitope, consisting of amino acids 209 to 217 and restricted by HLA-A\*0201, was identified by determining reactivities of tumor-infiltrating lymphocytes from patients with metastatic melanoma. When the second amino acid from the amino terminus was modified from a threonine to a methionine to create a peptide called g209-2M, binding to the HLA-A\*0201 molecule could be increased ninefold compared with the native peptide in an *in vitro* competitive binding assay.<sup>185</sup> *In vivo*, 91% of patients vaccinated with this peptide were successfully immunized on the basis of immunologic assays in peripheral blood, a substantial improvement over the immunization rate observed with the native peptide. CD8+ T-cell responses to the modified peptide recognized the native peptide as well as tumor cells expressing the gp100 protein. Despite the increased immunogenicity of the peptide in patients, antitumor responses were not observed. Clinical trials of immunization with a combination of several HLA-A201 restricted peptides from different melanoma antigens including gp100, MART-1, and tyrosinase have been initiated, but preliminary results do not indicate a marked improvement in activity against metastatic disease (S. A. Rosenberg et al., personal communication, 2000). However, a randomized trial of immunization with the combined g209-2M, MART-1, and tyrosinase peptides in HLA-A201 stage IV melanoma patients who have had resection of all metastatic disease, compared with placebo, is ongoing, and is designed to test whether immunization against these antigens will have greater effect in patients with minimal tumor burdens.

The clinical experience with other peptides selected to induce only CD8+ lymphocyte responses remains limited. Results of studies involving peptide-pulsed DCs are discussed in the section on DC tumor vaccines [see [Vaccination Using Host Antigen-Presenting Cells \(Dendritic Cell Vaccines\)](#), later in this chapter]. HLA-A201 restricted peptides from the E7 human papillomavirus-16 have been administered in adjuvant or attached to a lipidated peptide designed to elicit broad nonspecific T-cell helper responses.<sup>186,187</sup> Human papillomavirus-16 E7 peptide-specific T-cell responses were observed in several patients without evidence of antitumor activity. A small experience with an HLA-A201 restricted peptide from the her2 protein illustrates an important principle in selection of peptides for clinical trials. The her2 peptide was shown to bind to HLA-A201 *in vitro*, and CTL raised to the peptide and some tumor-infiltrating lymphocyte preparations could kill peptide-pulsed target cells. On this basis, a clinical trial was initiated administering the peptide in Montanide ISA 51 similar to the melanoma trials.<sup>56</sup> While the HER-2/neu peptide could be demonstrated to induce peptide-specific T-cell responses in patients, the CTL did not recognize HER-2/neu+ HLA-A201+ tumors, suggesting that the peptide is not naturally processed and presented on HLA-A201 molecules sufficiently by most tumor cells to allow T-cell activation. Therefore, it is possible to generate potent T-cell responses to various MHC class I binding peptides in patients, but these immune responses do not necessarily recognize tumor, and therefore would not be expected to have antitumor effects.

Various peptides of longer length, usually greater than 10 to 12 amino acids, have also been studied in clinical trials. Longer peptides are most often intended to induce CD4+ T-helper cell responses, although long peptides are capable of inducing CD8+ lymphocyte responses if they are trimmed or processed *in vivo* to a peptide of correct length that can bind to the patient's class I MHC molecules. Disis et al. demonstrated that immunization with peptides 15 to 18 amino acids in length

and selected from the HER-2/neu protein could induce T-cell proliferative responses to the her2 protein in six of eight patients with HER-2/neu+ tumors. <sup>188</sup> Demonstration of responses to the protein, rather than just the peptide itself, suggests that the immune responses are relevant and could recognize antigen presented by tumor cells or picked up by host APC. The investigators also reported evidence of epitope spreading, manifest as the induction of proliferative responses to her2 peptide epitopes not in the vaccine. Clinical antitumor responses could not be assessed as most patients had minimal or no disease at the start of vaccination. Immunization with a 105 aa *peptide* composed of five tandem repeats derived from MUC-1 did not produce antitumor activity among 63 patients with advanced adenocarcinomas, although T-cell infiltrates were observed in the peptide delayed-type hypersensitivity skin test sites of 44 of 55 patients. <sup>189</sup> Immunization of 25 metastatic adenocarcinoma patients with a MUC-1 mannan fusion protein produced high antibody titers in 13, but T-cell responses were limited. <sup>190</sup> Low-level antibody and T-cell proliferative responses, as well as regression of liver lesions in two patients, were reported among 21 patients immunized against a carboxy-terminal peptide of human chorionic gonadotropin-b, conjugated to diphtheria toxoid. <sup>191</sup> The results have been extended to a randomized controlled trial in advanced colon cancer.

Cytokines have been administered together with peptide vaccines to enhance presentation, for example, by recruiting and activating host APC, or to affect the developing T-cell response by directly interacting with the T cells. When the T-cell growth and differentiation cytokine IL-2 was added to the g209-2M melanoma peptide treatment regimen, 13 of 31 patients (42%) had objective clinical responses and four additional patients had mixed or minor responses ( [Table 63.2-5](#)).<sup>2</sup> These results are significantly different from results obtained in clinical trials using high-dose IL-2 alone, in which objective response rates are in the range of 15%, and a randomized trial comparing IL-2 plus peptide with IL-2 alone is due to start in 2000. Of note, high-dose IL-2 diminished the CTL response to peptide as measured in peripheral blood. Coadministration of IL-12 or GM-CSF with the g209-2M peptide in adjuvant also diminished CTL reactivity to the peptide, and among the 14 patients treated with peptide and IL-12 and 13 treated with peptide and GM-CSF, there were no objective antitumor responses. <sup>192</sup> GM-CSF has been an effective adjuvant in studies of the her2 peptides, which were not admixed with a nonspecific adjuvant. <sup>188</sup> The cytokine flt3, which increases the number of circulating and tissue APC, has generated substantial interest and is being administered before peptide vaccination in a number of clinical studies, although results are not yet available.

Future directions in the development of synthetic peptide vaccines may include the use of modified peptides embedded into microspheres or coated onto microbeads, a maneuver that can target antigen for uptake and MHC class I restricted presentation by professional APCs. <sup>193,194</sup> Other novel strategies developed in experimental animal systems use toxin-linked peptides <sup>195,196</sup> and peptides linked to endoplasmic reticulum insertion signal sequences covalently attached to the amino terminus of a peptide immunogen. <sup>197</sup>

### VACCINATION USING PURIFIED OR SYNTHETIC DEFINED PROTEINS

In relative terms, only a few vaccines are in development that are composed of synthetic or purified proteins. Proteins provide the opportunity for immunization against multiple epitopes, and also have the potential for inducing both CD4+ and CD8+ T-cell responses. However, for some self-antigens, immunization with proteins may be limited by tolerance to its dominant epitopes. Animal models have shown that immunization with xenogeneic proteins may be superior to the syngeneic self-protein, due to amino acid differences that induce helper CD4+ T-cell responses, and the chance occurrence that the xenogeneic protein will contain a peptide epitope just different enough from the native epitope to be highly immunogenic, but still induce T-cell responses to the native epitope. <sup>198,199</sup> An alternative to immunization with a purified or recombinant protein is to insert the gene into a viral vector, which theoretically enters the cytoplasmic compartment of an APC to produce large amounts of the protein for processing and antigen presentation.

Clinical experience with vaccines containing defined proteins is limited, with the exception of idiotype lymphoma vaccines (see [Vaccination Using Idiotypes or Antiidiotypes](#), later in this chapter). Results of trials of liposome-encapsulated PSA protein vaccines have been presented in abstract form.

### VACCINATION USING HOST ANTIGEN-PRESENTING CELLS (DENDRITIC CELL VACCINES)

In order to improve the immunogenicity of antigens, investigators have increasingly adopted the approach of placing the antigen directly into host APCs, which when fully differentiated present surface molecules and produce cytokines that result in optimal activation of T cells. Interpretation of the many clinical trials is confounded by the different approaches to generating APC *in vivo* and *in vitro*; by the different types and functions of APC; by difficulty in fully defining the characteristics of APC that result in optimal antigen presentation; by the many different approaches to place antigen into or onto APC; and by the variety in dose, route of administration, and use of concurrent cytokines in the clinical studies. Few if any studies have compared APC-based vaccines with other immunization approaches, for example, peptide pulsed on APC to peptide in adjuvant. A representative sample of tumor vaccines employing host APC is presented in [Table 63.2-6](#). APC used to deliver antigens derived from autologous tumor cells, for example, tumor cell-DC fusions, is discussed earlier (see [Anticancer Vaccine Approaches Derived from Autologous and Allogeneic Tumor Cells](#), earlier in this chapter).

**TABLE 63.2-6.** Clinical Trials Using Vaccines Based on Antigen-Presenting Cells

The majority of clinical studies have produced APC by *ex vivo* culture of nonadherent peripheral blood mononuclear cells (PBMC) in the presence of the cytokines IL-4 and GM-CSF (monocyte-derived APC). After several days of culture, the APC are incubated with the antigen, and then administered to the patient. In some cases an additional signal to mature APC is provided before the final harvest for injection, for example, addition of TNF or monocyte-conditioned media. Some clinical studies use as the APC preparation all PBMC obtained from a pheresis with minimal *ex vivo* manipulation, or apply centrifugation and elutriation techniques to isolate circulating APC from blood, which are then directly cultured *in vitro* with antigen only. The optimal route of administration for APC has not been determined, but clinical protocols have employed intravenous, intradermal, subcutaneous, and intralymphatic routes, as well as direct injection into lymph nodes.

Preliminary data from immunization with monocyte-derived APC pulsed with melanoma peptides suggest that the approach is less effective than administering peptide in adjuvant for generating CTL responses in peripheral blood (F. M. Marincola, personal communication, 2000). Nevertheless, some antitumor responses have been observed in the clinical trials. Nestle et al. reported two complete and three partial responses among 16 melanoma patients treated with melanoma peptides or tumor lysates pulsed onto monocyte-derived APC and injected directly into lymph nodes. <sup>3</sup> Immune response was assessed by delayed-type hypersensitivity reactions to APC alone versus APC plus antigen, and 15 of the 16 patients appeared to have increased delayed-type hypersensitivity responses to the antigen-pulsed APC.

Declines in the PSA levels of prostate cancer patients have been observed following administration of APC-based vaccines. Approximately 25% of 70 patients, including 33 with hormone-refractory disease, were reported to achieve complete or partial responses when treated with monocyte-derived APC pulsed with two HLA-A2 restricted peptides from prostate-specific membrane antigen. <sup>200</sup>

### VACCINATION USING IDIOTYPES OR ANTIIDIOTYPES

The antigen-binding region of an antibody (the idiotype), which is formed from recombination of genes within the B cells, can theoretically be processed by the B cells to peptides that bind self-MHC molecules and are presented on the surface of the cell, thus forming a unique antigen that can be recognized by T cells. Antigen-binding regions of antibodies can also be recognized by other antibodies; therefore, it is possible to raise antibodies to the idiotype present on the surface of malignant B cells. The specific antibody idiotype to be used in a vaccine must be prepared individually from each patient using hybridoma or recombinant DNA

techniques, processes that can take several weeks to months to generate a clinical product. Nevertheless, a substantial clinical experience is now available with these unique lymphoma idiotype vaccines.<sup>201,202</sup> and <sup>203</sup> Optimal induction of immune responses requires conjugation of the idiotype protein to KLH and administration with a strong nonspecific adjuvant. The Stanford group demonstrated induction of antibody responses to the idiotype in 20 of 41 immunized patients with follicular lymphoma.<sup>202</sup> Fifteen of the immune responders were among the 20 patients who were in complete remission at the beginning of vaccine treatment. There was a marked increase in progression-free survival and overall survival in immune responders versus nonresponders. Two of 21 patients had regression of residual disease with the vaccine treatment. A similar vaccine was studied at the NCI in follicular lymphoma patients in their first complete remission.<sup>203</sup> T-cell responses, including proliferation to the idiotype and cytotoxicity toward autologous tumor, were reported in 19 of the 20 patients, and antibody responses to the idiotype in 15 of 20. Eight of 11 patients with detectable bcl-2 translocations in peripheral blood following chemotherapy developed molecular complete remissions with vaccination. Furthermore, 18 of 20 patients were relapse-free from 28+ to 53+ months from initiation of initial chemotherapy. Although the results of the two series are promising, the data must be interpreted with caution since the beneficial clinical effects are occurring primarily in complete remission patients whose natural history of disease is already quite favorable. A phase III randomized trial of the lymphoma idiotype vaccine is expected to begin in 2000.

The antibodies directed to the antigen-binding regions of other antibodies carry within their own antigen-binding region a physical resemblance to the original antigen. For example, if CEA is the intended tumor antigen, an antibody is first raised to CEA. That antibody (termed Ab1) is itself used as an immunogen in mice to raise a second group of antibodies (Ab2), some of which recognize the CEA-binding site of the Ab1. The antigen-binding site of Ab2 physically resembles CEA, and when used to immunize animals or patients, can generate antibodies (Ab3) that recognize CEA. The Ab2 is capable of generating more potent immune responses to the original antigen than the antigen itself in some circumstances, since the antigenic epitope is being presented outside of immune-tolerizing influences.

Clinical results of representative antiidiotype vaccines are presented in [Table 63.2-7](#).<sup>156,204,205,206,207,208,209,210</sup> and <sup>211</sup> The antiidiotype antibodies are most often of murine origin and are administered together with a nonspecific immunologic adjuvant. Several antiidiotypes have been developed to immunize against melanoma cell surface antigens. An antiidiotype developed to mimic the melanoma high-molecular-weight antigen generated antibody responses that recognized melanoma cells expressing the antigen and was also associated with regression of metastatic disease in 3 of 52 patients.<sup>212</sup> Only a subset of the 52 patients received the antiidiotype conjugated to KLH and administered with BCG, which appeared to be necessary to induce the antimelanoma antibodies. An antiidiotype mimicking the ganglioside GD2 produced antibody responses to GD2 in 40 of 47 patients and was associated with one complete response and 12 patients who had stable disease for greater than 14 months.<sup>213</sup> Another antiidiotype mimicking the ganglioside GD3 has been examined in patients with melanoma and small cell lung cancer.<sup>214,215</sup> Approximately one-third of the patients receiving the GD3 antiidiotype developed antibodies to GD3, some despite having completed intensive chemotherapy. In the 15 patients with small cell lung cancer who were immunized while in partial or complete remission from chemotherapy, disease-free survival appeared to be prolonged compared with historical controls. The latter results formed the basis for an ongoing randomized phase III trial in the same patient population.

**TABLE 63.2-7.** Clinical Trials Using Vaccines Based on Idiotypes and Antiidiotypes

Antiidiotypes mimicking colorectal cancer antigens are also in clinical trials. A polyclonal goat antiidiotype mimicking the 17-1A antigen was the subject of a small randomized trial in advanced colon cancer, and despite inducing antibodies to 17-1A in 12 of the 21 patients in the treatment arm, no survival benefit was observed compared with the control (immunization with nonspecific goat polyclonal antibody).<sup>216</sup> An antiidiotype mimicking CEA was reported to induce high titer anti-CEA antibodies in all 32 immunized patients.<sup>217</sup> Furthermore, because the antiidiotype contained sequences that were similar to the protein sequence of CEA, some patients developed CD4+ T-cell proliferative responses to CEA. No antitumor responses were observed, but 18 of 23 patients with no evidence of disease, including eight of nine with completely resected metastatic disease, were progression free at the time of the publication. Combination with 5-fluorouracil-containing regimens did not appear to reduce the immunogenicity of the antiidiotype, and a phase III trial in the adjuvant setting is planned.

### VACCINES USING CARBOHYDRATE AND GANGLIOSIDE CELL SURFACE ANTIGENS

Certain tumors, particularly melanoma and small cell lung cancer, are known to express gangliosides that can be recognized by antibodies. Induction of antibody responses against the ganglioside antigens can have therapeutic value in animal models, particularly in micrometastatic settings. A vaccine composed of purified GM2 combined with BCG was administered subcutaneously in a randomized controlled trial in patients with stage IIb/III melanoma. Patients received low-dose cyclophosphamide before immunization. The GM2/BCG vaccine was shown to induce low to moderate titers of IgM anti-GM2 antibodies in the majority of patients, and produced a trend toward improved disease-free survival.<sup>218</sup> When patients with preexisting anti-GM2 responses, which are associated with a better prognosis, were excluded from the analysis of both arms, the differences between arms became statistically significant. Pilot studies of GM2 conjugated to the protein KLH and admixed with QS-21 produced higher titers of IgM antibodies to GM2 compared with the GM2/BCG vaccine, and also high titers of IgG antibodies to GM2, although the IgG anti-GM2 antibodies did not appear recognize cell surface GM2 in the majority of patients.<sup>219,220</sup> Among the patients who develop IgM anti-GM2 antibodies, only approximately 40% to 50% have antibody responses that are cytotoxic for GM2-expressing melanoma cells. A phase III trial of the GM2-KLH/QS-21 vaccine compared with high-dose IFN for patients with stage IIb/III melanoma completed accrual in 1999 and is awaiting analysis.

A vaccine containing both GM2 and GD2 gangliosides has been developed and appears to induce IgM and IgG antibody responses to both gangliosides.<sup>221</sup> Another ganglioside, Fucosyl-GM1, which is expressed on small cell lung cancer, has been conjugated to KLH and administered with QS-21 to ten patients with small cell lung cancer in partial or complete remission following chemotherapy.<sup>215</sup> The vaccine induced cytotoxic antibody responses in the majority of patients.

STn is a carbohydrate antigen from the MUC-1 glycoprotein, expressed on various adenocarcinomas including breast, ovarian, and colon cancer.<sup>53,222,223</sup> The carbohydrate epitopes are revealed due to abnormal glycosylation patterns in tumors. A synthetic STn was conjugated to KLH and administered with the DETOX adjuvant in several trials involving patients with metastatic breast, ovarian, and colon cancer. High-titer IgG responses to natural mucin STn epitopes were demonstrated, and a correlation was found between survival and development of IgM (colon cancer) or IgG (breast cancer) titers above the median.<sup>224,225</sup> and <sup>226</sup> Of note, there was no correlation in these same studies between survival and anti-KLH antibody responses. The STn-KLH/QS-21 vaccine is the subject of a large randomized phase III trial in metastatic breast cancer patients who are stable or have a partial or complete response after initial chemotherapy.

### ENHANCING VACCINE-INDUCED IMMUNE RESPONSES

#### OPTIMIZING DOSE, BOOSTING, AND ROUTE OF THE IMMUNIZATION

There are a bewildering number of choices that the immunotherapist must make when designing an anticancer vaccine, including choice of antigen, immunogen, and adjuvant. In addition, it becomes important to consider the appropriate dose, route of administration, and the length of intervals between boosting. The answers to these questions require an understanding of the immunophysiology of vaccination *in vivo*. *In vitro* work with human cells is of limited benefit, while work in human subjects must necessarily be limited in its scope. Thus, in practice, questions regarding dose, route, and boosting are generally addressed in mouse models.

Based on the idea that more antigen is better, most viral and DNA vaccines are geared toward maximum expression and use the strongest available promoters. In our own preclinical trials using immunogens based on vaccinia viruses, as well as DNA given by blasts with the gene gun, efficacy improves as the dose of immunogen

increases.<sup>166,227</sup>

It has long been known that boosting an immune response can increase its intensity. When primary and booster immunization using a single vector (i.e., homologous boosting) is compared with a regimen that uses two different vectors (i.e., heterologous boosting), the heterologous boosting generally resulted in significantly more potent antigen-specific cytotoxic T-lymphocyte responses.<sup>181,182</sup> This is likely due to absence of a neutralizing antivector immune response during the booster immunization.

The route of immunization can determine its efficacy; for example, administration of a synthetic peptide by the intraperitoneal route can lead to tolerization, whereas administration of the same peptide immunogen subcutaneously leads to activation.<sup>228</sup> For poxviral vectors, the intravenous route of immunization is optimal in mice.<sup>229</sup> For any given immunogen, we surmise that the optimal route of immunization is likely to be dictated by the route that leads to the presence of the antigen on the maximal number of activated DCs, perhaps with the least amount of antigen presentation by normal, potentially tolerizing cells.

## CYTOKINES, CHEMOKINES, AND COSTIMULATORY MOLECULES AS MOLECULARLY DEFINED ADJUVANTS

From the vaccinologist's point of view, cytokines, chemokines, and costimulatory molecules can be used as molecularly defined adjuvants, significantly improving vaccine-induced immune responses. They can be administered systemically as protein or through insertion of their genes into recombinant vaccines.<sup>166,230,231</sup> and <sup>232</sup> We have found that gene gun delivery of a model antigen was protective by itself, but was only therapeutic when delivered with IL-2, IL-6, IL-7, or especially IL-12.<sup>166</sup> Other useful cytokine adjuvants include GM-CSF, a cytokine thought to play an important role in the recruitment and maturation of DCs.<sup>162,233,234</sup> Studies using vaccinia virus-based immunogens have revealed that IL-2 and IL-12<sup>166,230,231</sup> are extremely potent in their ability to increase the efficacy of cancer vaccines. In addition, the costimulatory molecules B7-1, B7-2, and CD40L have a beneficial effect on vaccination.<sup>108,231,232,235</sup> Less studied as vaccine adjuvants, chemokines induce the activation and directional migration in a variety of immune cells.<sup>236,237,238</sup> and <sup>239</sup> They are produced locally in the tissues, often as a result of the presence of pathogens, and act on leukocytes through a family of at least a dozen receptors.

Importantly, not all of the findings in murine models were confirmed in human clinical trials. When patients with metastatic melanoma were immunized with a modified immunodominant peptide derived from gp100, no increase in efficacy as measured by objective clinical response was observed using GM-CSF or IL-12.<sup>2,192</sup> Only IL-2 was found to have a beneficial effect as an adjuvant for peptide immunization.<sup>2</sup>

Bacterial DNA sequences called *immunostimulatory sequences* have been reported to be potent adjuvants. Nonmethylated, palindromic DNA sequences containing CpG-oligonucleotides can activate an innate immune response by activating monocytes, natural killer cells, DCs, and B cells in an antigen-independent manner.<sup>240</sup> Thus, the use of large amounts of plasmid for immunization may not only overcome the low transfection efficiency *in vivo*, but may also serve as an adjuvant, driving a Th1 response.<sup>241</sup>

## FUTURE CHALLENGES: TUMOR ESCAPE FROM IMMUNE RECOGNITION

Every cancer that kills a person is a cancer that has not been destroyed by the immune system, and many mechanisms have been hypothesized for this apparent lack of immunogenicity (Table 63.2-8).

Category	Impediment
BARRIERS TO CANCER-CELLS PRESENTING ANTIGENS FOR RESPONSE	Lack of antigen expression <sup>242,243</sup>
	Lack of molecules of costimulatory molecules <sup>244</sup>
POSSIBLE MECHANISMS OF SUPPRESSION OF ANTIGEN PRESENTATION OR T-CELL REACTION	Suppression of costimulatory molecules <sup>245</sup>
	Suppression of the ligand or other costimulatory ligands that bind to receptors on T cells and costimulatory receptors <sup>246</sup>
	Suppression of costimulatory receptors <sup>247</sup>
	Suppression of costimulatory receptors <sup>248</sup>
OBSTACLES TO GENERATING EFFECTIVE IMMUNE RESPONSES BASED ON LIMITATIONS TO HELPER T CELLS	Suppression of costimulatory molecules <sup>249</sup>
	Suppression of costimulatory receptors <sup>250</sup>
	Suppression of costimulatory receptors <sup>251</sup>
	Suppression of costimulatory receptors <sup>252</sup>
OBSTACLES TO MAINTAINING AND AMPLIFYING ANTITUMOR IMMUNE RESPONSES	Suppression of costimulatory molecules <sup>253</sup>
	Suppression of costimulatory receptors <sup>254</sup>
	Suppression of costimulatory receptors <sup>255</sup>
	Suppression of costimulatory receptors <sup>256</sup>

TABLE 63.2-8. Potential Impediments to Immunization against Tumor Antigens and Development of Effective Antitumor Immune Responses

## LACK OF INFLAMMATION

One mechanism that may explain why patients with cancer usually do not reject their tumors involves the lack of inflammation at the tumor site. There are important differences between the site of a tumor deposit and a site of infection. Tumors produce few, if any, immunologic danger signals to stimulate the immune response.<sup>242,243</sup> In contrast, at a site of infection, the innate immune response is triggered because of tissue destruction. Inflammatory cells, such as monocytes, macrophages, and DCs, are activated as a result of this tissue destruction, and by components of the infectious agents themselves, such as lipopolysaccharide, nonmethylated CpG sequences, and double-stranded RNA, each of which are components of invading microbes that are not shared by either normal host cells or growing cancer cells. In the absence of these danger signals, the immune system may not become fully activated.<sup>107,244</sup>

## INDUCTION OF TOLERANCE BY TUMOR CELLS

Despite cancer cells' expression of clearly immunogenic molecules, the host usually does not mount an effective immune response to these antigens. One reason could be the lack of expression of costimulatory molecules necessary for efficient T-cell activation by tumor cells. In the absence of costimulation, T cells tend to become anergic, a process thought to protect against autoimmune disease. The costimulatory molecules CD80 (B7-1) and CD80 (B7-2) are expressed on professional APC and on a variety of other tissues after exposure to inflammatory cytokines.<sup>245</sup> Transfection of tumor cells with both B7 isoforms has been used successfully to trigger their immune-mediated rejection of experimental mouse tumors, which have some inherent immunogenicity.<sup>246</sup> However, this strategy is insufficient for nonimmunogenic tumors, a category into which most, if not all, human tumors would likely fall.<sup>247</sup>

A number of groups have conducted experiments in which highly immunogenic foreign antigens, such as the hemagglutinin protein from influenza,<sup>98</sup> the b-galactosidase enzyme from *Escherichia coli*,<sup>168</sup> and the ovalbumin protein from chicken are expressed in tumor cells.<sup>248</sup> The results are fairly uniform: Tumors tend to grow progressively, retaining their lethality despite the expression of a foreign and highly immunogenic protein by the tumor cell.

Alternative immune mechanisms designated *tolerance* and *ignorance* have been used to explain why the immune system fails to recognize tumors expressing even these normally highly immunogenic antigens. Tolerance generally refers to the lack of a destructive immune reaction to a given antigen. In the tumor context, we might distinguish an active state of tolerance, in which the immune system undergoes a functional and phenotypic change after encounter with antigen, from ignorance, a passive process in which immune cells do not have any contact with the antigen that alters their phenotype or function.<sup>249,250</sup> Both mechanisms likely play a role in the immune system's unresponsiveness to tumor cells.

## PRODUCTION OF IMMUNOSUPPRESSIVE FACTORS

Tumor cells may ectopically employ normal immunosuppressive mechanisms, such as the production of transforming growth factor- $\beta$ , normally produced by certain immune and other somatic cells, but potentially antiproliferative for CTL, natural killer, and lymphokine-activated killer cells.<sup>251</sup> Another example, IL-10, produced by activated T cells, B cells, monocytes, and keratinocytes may be produced by certain solid tumors and may interfere with macrophage-mediated antigen presentation

and other immune functions.<sup>251</sup>

It has been reported that expression of Fas ligand (FasL/CD95L) by melanoma cells was responsible for their escape from immune recognition.<sup>252</sup> Because FasL was reportedly expressed in areas of immune privilege such as the eye and testis, it was reasoned that expression of FasL by melanoma cells indicated that the tumor bed was also an "immune privileged" site. In our own study, however, we found no FasL expressed by a panel of 26 human melanoma lines we tested.<sup>253,254</sup> and <sup>255</sup> Thus, our data do not support a role for FasL expression in the escape of melanoma cells from immune destruction.

## TUMOR AS A MOVING TARGET

Tumor cells can be a *moving target* when it comes to immune recognition. The field of chemotherapy has produced a number of well-known examples of tumor escape from treatment including the induction of the expression of the multidrug resistance (MDR) gene. As recombinant and synthetic vaccines become more effective, the selective pressure on the loss of particular target antigens may increase. Indeed, there is some evidence that tumor cells may preferentially lose the gp100 tumor antigen as a result of treatment with the gp100 209 to 217 (2M) peptide plus IL-2.<sup>256,257</sup>

Tumors have unstable genomes that lead them to be heterogenous for the expression of tumor-associated antigens. Further, their unstable genomes may enable them to escape immune recognition because they lose or mutate key elements of the antigen processing machinery such as the TAP [transporter associated with antigen processing] transporters,  $\beta_2$ -microglobulin, or the MHC class I a chain molecules.<sup>258,259,260,261</sup> and <sup>262</sup> Other mechanisms underlying the poor immunogenicity of tumors includes the down-regulation of two IFN- $\gamma$ -inducible proteasomal components called LMP2 and LMP7 in certain human tumors.<sup>258</sup> The proteasome is a large multicatalytic complex involved in the degradation of many of the peptides that later find their way into the MHC class I pathway.

## CONCLUSION

The field of cancer vaccines has been greatly advanced by a wave of technological innovation as well as a deeper understanding of the immunologic response to both cancer cells and potential vaccines. Vaccines using whole tumor cells have been optimized by transfection or addition of costimulatory molecules, cytokines, and chemokines. In addition, target antigens that can mediate tumor cell recognition by immune cells have been cloned and are currently used in a variety of vaccine approaches. The antigens that are most practical for application in vaccines are the self-antigens shared among cancer patients. Encoded in recombinant viruses and bacteria, naked nucleic acids, or delivered as minimal peptide epitopes, these antigens can induce immune responses that can destroy established tumors in animal models and in some instances even in cancer patients. The great genomic plasticity and poor inherent immunogenicity of tumor cells make them difficult targets for complete eradication by the immune system. Yet our growing understanding of the important roles of CD4+ and CD8+ T cells and APC, as well as the importance of dosing and the frequency and route of vaccine administration, will further improve on these initial attempts at therapeutic cancer vaccines.

## INTRODUCTION

With the introduction of the x-ray at the turn of the twentieth century heralding the advent of modern medical imaging, the surgeon's eye has been supplemented with indirect imaging data that better defines local disease. Conventional x-ray techniques have been supplemented, or even supplanted, by radiographic contrast agents, nuclear imaging techniques, ultrasound (US), computed tomography (CT), and magnetic resonance (MR) imaging. There is no reason to believe that even more powerful imaging techniques will not follow. These increasingly sophisticated imaging techniques have steadily improved the identification of local disease, and this development, in combination with concomitant improvements in surgical techniques, has resulted in dramatic improvements in surgical outcomes. Newer imaging techniques now allow disease that cannot easily be visualized with the naked eye to be "seen." Furthermore, the diseased tissue can be better visualized in relationship to adjacent normal tissue, allowing for more precise anatomic treatment. In contemporary practice, fewer and fewer diseases are treated on the basis of direct observation alone. Such is the heritage of twentieth-century medicine.

Until relatively recently, however, the surgeon was still personally responsible for transferring the imaging data to the patient. That is, the surgeon usually reviewed the various imaging studies before surgery and then mentally, but indirectly, incorporated this information into the actual surgical procedure. The future of image-guided surgery (IGS) rests with the development of techniques that allow the operator to more directly incorporate the images into delivery of the therapy. The goal is to enable more precise and less invasive access to a tumor and to monitor its resection, ablation, or other form of local therapy.

## MEDICAL IMAGING TECHNIQUES

Any type of image (medical or other) has two intrinsic properties: spatial and signal.<sup>1</sup> The former defines the location and geometric features of a structure or lesion. The latter, generally reflected by gray tone or color, is important for lesion detection and the definition of tissue type. Spatial features of an image include the number of dimensions represented and the resolution. Most medical images are either two-dimensional (2D) projections, such as with a chest film, or three-dimensional (3D), such as with thin section CT or MR. Obviously, 3D images provide more data for guiding a therapeutic device (including a scalpel) into a 3D object (a patient). High spatial resolution, although generally desirable, is often impractical, being associated with longer examination times or poorer image quality. There is also no reason to have higher resolution images than is necessary to detect a lesion or guide therapy. In general, "high-resolution" medical images have 0.5 to 1.0 mm<sup>3</sup> resolution. The biophysical interactions of the imaging technique and the tissues of the body determine the "signal" properties of medical images. Different imaging techniques report different features of tissues. The following are general characteristics of current medical imaging techniques.<sup>2</sup>

### X-RAY IMAGES

The measurements of x-ray emitted by a point source and transmitted through the human body depends on the integral of the electron density along rays projected through the body, which is a function of the mean atomic number of the tissue. These measurements of "radiodensity" have traditionally been made on films or by image intensifiers, both of which are devices that create analog images that can then be digitized. Digital images are required for most IGS applications. More recently, x-ray-sensitive solid state detector systems in linear or planar arrays are being used to directly generate digital x-ray images.<sup>3</sup> The spatial resolution of most 2D x-ray images is less than 0.5 mm. Conventional x-ray images are used primarily to image bony structures, but also to image the distribution and temporal evolution of contrast agents such as iodine in soft tissues (e.g., blood vessels). Soft tissue contrast is very poor on conventional x-ray studies.

Rotation of the x-ray source and detector around the longitudinal axis of a patient produces projections that can be used for tomographic reconstruction of slices, with typical series of parallel 1- to 10-mm thick sections of 512 × 512 pixels, each 0.25 to 1.0 mm<sup>2</sup> in size. Because this reconstruction process provides a correct approximation of tissue densities and not integrals of tissue densities as in x-ray projections, CT images accurately differentiate bony and soft tissues. Since the advent of CT in the 1970s, the technology has rapidly evolved. Now a common technique, the spiral CT uses a continuous rotation of the x-ray source and a 2D-detector array synchronized with a linear continuous motion of the patient.<sup>4</sup> This technique provides individual slices in approximately 1 second. On the horizon is the use of planar detectors for real 3D volumetric acquisitions instead of reconstruction of 3D images from 2D sections. These x-ray volume imagers will become increasingly important for IGS.

### MAGNETIC RESONANCE IMAGING

MR imaging (MRI) provides information about molecular properties of tissues.<sup>5</sup> A body first is set into an intense constant magnetic field (ranging from 0.1 T to a few Teslas). MRI studies the way tissues behave when they are submitted to a weak, transient perturbation of this strong magnetic field. Radiofrequency (RF) pulses induce spinning motions of nuclei that come back to an equilibrium. Using a select sequence of perturbations, information is provided about the concentration (often called *density*) of atoms (mainly hydrogen in H<sub>2</sub>O) and about their physicochemical environment. Several components of the received signals, which relate to intrinsic MR parameters (proton density, relaxation times *T*<sub>1</sub> and *T*<sub>2</sub>) are used to create images. Although each of these MR tissue parameters reflects a unique aspect of the biophysical milieu of tissue water, they remain poorly understood from a biologic perspective. However, they have been empirically shown to provide great contrast between different types of normal and abnormal tissues, including benign and malignant neoplasms. MRI is a true 3D-imaging technique, because the application of magnetic field gradients can define any point of the volume studied. Whereas most standard devices provide series of parallel sections in sagittal, coronal, or axial planes, it is possible to obtain homogeneous 3D volumes of 256 × 256 × 256 voxels having a spatial resolution of 1 mm<sup>3</sup>. A valuable modification of MRI is MR angiography, which produces clear images of blood vessels noninvasively.<sup>6</sup>

MR spectroscopy allows for metabolic studies of complex biologic systems: Spectra in the frequency domain correspond to the composition of molecules of a region.<sup>7</sup> Clinical applications of MR spectroscopy are increasing, with protons being the main nuclei that are observed. Chemical shift imaging techniques (multivoxel spectroscopy) have been developed,<sup>8</sup> but more work still is necessary before these will be ready for routine clinical use. Miniaturization of RF coils for

ultra-high-resolution imaging of small regions is another interesting trend in MRI research, which may be important for IGS applications.<sup>9</sup>

## ULTRASOUND

US is a relatively inexpensive, portable, real-time imaging system with a typical spatial resolution of 1 mm.<sup>10</sup> These features make US a major imaging tool for IGS. After the emission of an US wave from a piezoelectric element, the sound signal reflected by the discontinuities of acoustic impedances of tissues is analyzed. Time of flight measurements of the reflected echoes gives spatial information of acoustical interfaces. Acoustic impedances of tissues are primarily related to physical features rather than to their biologic properties. Selection of US frequency depends on a trade-off of resolution versus attenuation. High-resolution, 12-MHz US images of the thyroid gland have 0.5 mm<sup>3</sup> resolution, but the depth of view is only a few centimeters. Mechanically or electronically moving the direction of US allows one to obtain a 2D or 3D image. Images may be corrupted by a rather strong texture noise and by distortions due to such things as bone and air.

The analysis of blood velocities is achievable through the use of Doppler US probes, some of which have been miniaturized and mounted at the tip of a needle. Newer US imaging modalities include color and power Doppler sonography, which produce 2D or 3D color images of blood velocities superimposed on a standard grayscale US image.<sup>11</sup>

## NUCLEAR MEDICINE

In contrast to the imaging techniques already described, which are primarily dependent on physical, morphologic properties of tissue, nuclear imaging is usually directly dependent on biochemical or physiologic properties. In nuclear medicine imaging, or scintigraphy, a source of photons (gamma) or positrons (beta) is attached to a specific radiopharmaceutical and injected into the body. External detectors observe the emission of such radioactive elements. A typical image corresponds to an orthogonal projection of the density of radioactive elements, which is related to the metabolism of the radiopharmaceutical in the studied region.<sup>12</sup> Rotation of the gamma camera around the patient provides a set of projections that is fed onto tomographic algorithms similar to those used for x-ray CT. The result is a 3D volume of datatomoscintigraphy, or single photon emission CT (SPECT).<sup>13</sup> A more complex strategy studies the emission of positrons (negative electrons). Each emitted positron collides with an electron of the environment and gives rise to two high-energy photons that go in opposite directions. A ring of detectors set around the patient detects these two photons at very near instants. Thus, the associated events lie on a straight line between these two corresponding detectors. The intersection of such lines gives rise to a 3D region of emission from which a 3D image can be reconstructed. Such is the technique of positron emission tomography (PET).<sup>14</sup> Both SPECT and PET have relatively poor spatial resolution when compared with CT or MRI (typically a set of 64<sup>3</sup> or 128<sup>3</sup> voxels, each 2 to 10 mm<sup>3</sup>, is obtained), but these methods provide functional information that is not available with other techniques.

## IMAGE GUIDANCE

These various modalities provide images of anatomic or pathologic structures that can form the basis for surgical planning and subsequent image guidance of a procedure. In contrast to traditional surgery that depends heavily on physician inferences and qualitative decisions based on human perception of these images (and other data), IGS depends on quantitative decisions (e.g., direction and depth of a needle) based on digital image data processed by computers that are directly linked to surgical devices. The engineering requirements of such a system are extraordinarily demanding; system fidelity and reliability must be superb. Even with the most sophisticated system, however, the physician operator remains the critical unit.

Generally, five important elements make up IGS: (1) high-quality digital images, (2) advanced computer image processing that includes tissue classification or segmentation algorithms and 2D and 3D visualization tools, (3) a computer modeling system for simulation, (4) a registration system that links the medical images with the real patient, and (5) digital interfaces to therapeutic devices.<sup>15</sup>

## DATA ACQUISITION

In most cases, image information is provided by preoperative or intraoperative studies. Medical *a priori* knowledge (e.g., an anatomic atlas) as well as video images or different types of signals (e.g., Doppler, electrophysiology) can also be used.

## IMAGE PROCESSING

The "raw" image data must be processed to allow the surgeon to intuitively perceive the pertinent image information and relate it to the planned surgical procedure. Often, this process requires that images be reformatted into 3D or pseudo-3D images and that key structures or tissues be identified, either implicitly or explicitly. The former step requires state of the art computer visualization tools, whereas the latter step requires accurate tissue classification or segmentation algorithms. Although current segmentation techniques can quickly and accurately classify spatially well-defined and high-contrast tissues, such as bone on x-ray CT, much more work is necessary for the accurate segmentation of subtle soft tissue differences, such as those related to infiltrating neoplasms.

## REGISTRATION

The problem of matching all of the image data available for a patient into a unique coordinate system is commonly referred to as *registration*. Registration is a crucial technology in IGS for three reasons. First, the coregistration of medical data allows the surgeon to plan an operation using all of the available information. Second, registration of preoperative and postoperative data is crucial for individual patient follow-up and statistical analysis of results. Third, registration of preoperative and intraoperative data provides the crucial step required to relate the "virtual patient" created from the medical images to the actual patient on the operating table. Ideally, all patient data should be correlated with the physical space of the real surgery and made available to the surgeon. A variety of registration techniques have been developed, some of which use external markers or fiducials placed on the patient, whereas other methods use intrinsic anatomic structures to register images and physical spaces.<sup>16</sup> This latter capability is important because it is more direct, logistically easier, and potentially more robust. Although accurate rigid registration is now routinely performed, a continuing challenge is still the elastic registration of nonrigid tissues for instance, tracking deformations due to surgery, respiration, and temporal changes of structures.

## SURGICAL PLANNING

A 3D model of the patient and pathology is created into which all the relevant image data has been incorporated. The operator (surgeon or physician) can then manipulate the model in a virtual reality mode. This permits the surgeon to define the surgical strategy, which can then be simulated and modified.

## PERFORMING THE SURGERY

Different types of guiding systems can be used to execute the surgical plan. Passive systems enable the surgeon to compare the actual intervention with the planned one. This is the case with systems such as the ISG Wand (ISG Technologies, Mississauga, Ontario, Canada),<sup>17</sup> in which previously obtained images have been registered to the patient using a computer system with a digital articulated arm. Surgical instruments are then attached to the articulated arm and manipulated by the surgeon who can observe the tool in real, patient space as well as on the workstation in image, or virtual, space. Semiactive systems enable the physical guiding of the instrument that is still controlled by the operator, which is the case, for example, with the stereotactic neurosurgical system described by Lavallee and Troccaz.<sup>18</sup> Finally, active systems execute part of the intervention. Kellygg developed a system in which a laser is used for brain microsurgery. The laser is directed toward a tumor that has been localized by MRI. The laser is digitally manipulated until a synthesized image built from MRI data can be superimposed on an intraoperative video image.

The use of active robots, perhaps the ultimate IGS, remains rare and experimental. However, there are some potential advantages to the use of robots in surgery, including (1) repeatable tool position and trajectory; (2) steady motion; (3) ability to react rapidly to changes in force level; (4) remote operation; and (5) ability to remain poised in a fixed position.<sup>19</sup> Because of such attributes, the use of robots could lead to more effective treatment. In the case of contagious diseases, reducing human contact might lower the risk of infection. In other cases, robots might reduce risks to the patient by offering the potential of less invasive surgery.

However, a number of points should be considered before a suitably autonomous device is implemented, not least of which is the role of "expert systems" for high-level system control. It is not reasonable that a robot system should operate without continuous backup from a surgeon who is in a position to define and check the step-by-step progress of the task and to override the system in case of unforeseen difficulties. The robotic device would be driven to an acceptable start under

position control by the surgeon and, on instruction, would perform the defined task, prompted by the surgeon at each stage. The system would be required to react to given situations in real time by comparison of actual behavior with sophisticated reference models, few of which exist.

## SPECIFIC APPLICATIONS OF IMAGE-GUIDED SURGERY

A variety of imaging techniques have become an integral part of the surgeon's approach to managing tumors, both benign and malignant. Many can be used for both preoperative and intraoperative localization. Several surgical specialties have incorporated IGS into their approach to patient management.

### NEUROSURGERY

IGS has its origins in the development of techniques for stereotactic brain biopsy.<sup>20,21,22</sup> and<sup>23</sup> These early studies used CT to localize lesions in the brain through coordinates provided by a device fixed to the patient's skull. In one study, RF ablation was applied to a deep brain lesion with symptomatic relief for the patient.<sup>20</sup> This may represent one of the earliest applications of IGS.

The techniques and equipment used for image-guided neurosurgery have evolved substantially since the late 1970s. Improvements in biopsy techniques paved the way for therapeutic interventions using a variety of ablative procedures, culminating in dedicated operating suites with real-time imaging from CT and MRI.<sup>24</sup> The success of these techniques is predicated on their ability to allow surgeons to perform their procedures more safely and efficiently.<sup>25</sup> The approach to lesions that are located deep in the brain presents challenges that help to illustrate where image guidance may prove its utility.

Microsurgery of deep brain lesions is often complicated by the close proximity of major vessels, eloquent brain, and the need to work in a confined space where standard microscopic visualization may be limited. By combining images from CT, MRI, and digital angiography, a 3D rendering of the surgical field has been successfully applied to guide microsurgical resections of deep-seated cerebral lesions.<sup>26</sup> The information obtained allows the surgeon to visualize the relationship between the lesion and cerebral vessels as well as brain structures of high functional significance. 3D rendering allows the surgeon to overlay the position of surgical instruments and to predict and simulate the trajectory of the approach.<sup>26</sup>

Similar guidance systems have been used to allow for the ablation of brain tumors using heat generated by RF devices. In this setting, the accurate position of the RF ablation probe is critical to minimizing the potential for collateral thermal injury of adjacent structures. In a study of 12 patients (14 lesions treated) with primary or metastatic brain tumors, an MR-guided stereotactic RF procedure was evaluated.<sup>27</sup> Using MRI, the stereotactic coordinates of the tumor and the angle of the RF ablation probe were calculated. Once the probe was properly positioned, the tissue was heated to the target temperature, and full ablation of the tumor was confirmed by real-time MRI. All procedures were performed in awake patients, and patients were followed for up to 10 months. MRI was successful in demonstrating well-defined lesions in all cases, documenting accurate placement of the RF probe. Characteristic changes in the appearance of the lesions during treatment on T2-weighted images allowed for confirmation of focal energy delivery during the procedure.<sup>27</sup>

In addition to providing for accurate localization and real-time anatomic feedback, newer computer-guided imaging systems also have been designed to give functional information during the surgical procedure. Using real-time MR images in conjunction with superimposed functional data from somatosensory evoked potentials derived from dipole tracings, investigators have been able to localize the central sulcus in 12 patients with intracranial disorders.<sup>28</sup> In six of the patients, 3D computer graphics were reconstructed from MRIs, which allowed for the visualization of lesions deep in the brain. The 3D functional images were then superimposed on the anatomic images. This technique allowed the surgeons to see the 3D relationship between the lesion and the functional sensorimotor cortex. This type of data can potentially allow for greater preservation of normal brain function during surgery.

A significant advance for intraoperative IGS has been the open-bore MR unit ( Fig. 64-1). This is an open MR device, which allows for optimal vertical access of the surgeon and assistant to the patient. Using such a system, surgeons at the Brigham and Women's Hospital in Boston published their experience with 110 cases, which included 47 biopsies, six catheter placements, four cyst drainage procedures, 47 craniotomies for resection, three spinal cases, and three laser tumor ablations.<sup>29</sup> This intraoperative MR surgery unit was especially useful in guiding biopsies and resections near cysts, ventricles, and critical vascular structures. Standard approaches using prior image data with framed and frameless techniques would be inadequate to show anatomic changes during the procedure. The acquisition of real-time images of the biopsy needle within the lesion were found to be very useful. The information obtained from this system allowed for more complete resection of infiltrative tumors. Image fusion of SPECT and neurofunctional data into the imaging space enabled the surgeons to better visualize tumor invasion or neural function with real-time imaging during resection.<sup>29</sup>

**FIGURE 64-1.** Open magnetic resonance imaging for image-guided surgery as implemented at the Brigham and Women's Hospital, Boston.

The true test of whether image-guided techniques are of benefit in neurosurgery is whether an impact on outcome is the result. Studies focusing on outcome analysis are beginning to emerge.<sup>30,31,32</sup> and<sup>33</sup> Early data indicate that the addition of image-guided techniques can reduce operative time, patient morbidity, and the need for repeat procedures. Further prospective studies of cost analysis are necessary to definitively demonstrate these benefits.

### HEAD AND NECK SURGERY

Because of anatomic similarities, IGS techniques developed for neurosurgery have found several applications in the management of patients with both benign and malignant tumors of the head and neck. For patients with skull base tumors, an intraoperative guidance system has been used to provide nearly instantaneous CT and MRI images with computer reconstruction to the surgeons. The ISG viewing wand can correlate any point within the operative field to its corresponding locus on the reformatted images.<sup>34,35</sup> and<sup>36</sup> The use of this wand in 14 patients with skull base, cerebellopontine angle, or temporal bone lesions has allowed for minimally invasive incisions, intraoperative navigation, and identification of important anatomic structures. This precision allowed for a greater margin of safety and a more precise assessment of the extent of lesion resection.<sup>34</sup>

Endoscopic techniques have revolutionized the approach to nasal and sinus surgery. A computer-assisted surgery system has been applied to help in intraoperative localization during endoscopic surgery of the paranasal sinus region.<sup>37</sup> This system allows for the continuous orientation of the scope by using a 3D reconstruction of the preoperative CT scan with superimposed positioning of the endoscope. By using a dual display on the endoscopic monitor, the surgeon can see the video-endoscopic picture and the information from the localizer simultaneously. This allows for positional adjustments of the scope without the need for the surgeon to look away from his or her operative field. This system also has been used for complex skull base and head and neck resections.<sup>38</sup>

3D intraoperative navigational systems have been used to assist in craniofacial procedures ranging from corrections of craniofacial asymmetry to tumor resections. A study of 17 patients undergoing craniofacial procedures demonstrated the utility of the ISG navigation system in precisely orienting the surgeon to his exact location throughout the procedure.<sup>35</sup> The system was particularly useful in defining intraorbital anatomy, in determining ocular globe position, and in delineating tumor margins.

No additional operative time or adverse events were attributed to the use of the system.

The development of virtual endoscopy is another useful application of real-time imaging. A virtual otoscope has been designed that provides a precise view of the structures of the inner ear.<sup>40</sup> The precision of the images derived from this device may replace the more invasive endoscopes in current use.

## SURGICAL ONCOLOGY

The application of IGS to the management of malignancies of soft tissues in the abdominal cavity has required imagination as well as modifications of the approaches used in neurosurgery. Unlike the brain, which is fixed in its position, the abdominal contents, such as small bowel, are more fluid and present certain difficulties in making use of imaging techniques for “target” acquisition. The liver, however, represents a relatively fixed anatomic structure for which image-guided therapies have been used.

A variety of ablation techniques have been applied to the treatment of liver tumors in situations in which surgical resection may not be appropriate. These techniques, such as RF ablation, cryotherapy, and interstitial laser thermoablation are discussed in greater detail elsewhere in this text. These techniques share in common the need to not only localize the target lesion, but also to monitor the effects of the therapy during the time it is being applied.

Several imaging modalities, including US, CT, and MRI, have been used to accurately position the ablation probes into the lesion and to monitor the effects of the therapy. Using an Nd-YAG (neodymium:yttrium-aluminum garnet) laser system and real-time MRI, a group of 12 patients had a total of 27 lesions in the liver treated under local or general anesthesia.<sup>41</sup> An MR colorization sequence was used to monitor changes in the tissue temperature during therapy. The patients tolerated the procedure well, with 8 of the 12 being discharged home on the day after the procedure. Thermal zones of ablation up to 5 cm were achieved with two patients with 3-cm lesions, achieving complete ablation with a single procedure. Seven of the patients required multiple procedures to successfully ablate their lesions. Similar procedures also have been performed laparoscopically.<sup>42</sup>

Using intraoperative US and a laparoscopic approach, RF ablation has been applied to the treatment of liver metastases from neuroendocrine tumors.<sup>43</sup> In six patients (13 lesions treated) no intraoperative complications were reported. US was used successfully to position the thermal ablation probe and to monitor the treatment effect in the operating room to determine when an adequate zone of necrosis was achieved. US is able to detect the “outgassing,” which occurs as the tissue is heated and gas is released into the surrounding parenchyma.

A trial at the National Cancer Institute is currently under way to evaluate US, CT, and MRI to determine the best modality for positioning the probes and monitoring the effects of RF ablation in the liver. [Figure 64-2](#) demonstrates a real-time CT image of a lesion in the liver before and after RF ablation. Patients are imaged with dynamic enhanced MRI preoperatively and in follow-up as a means of following response.

**FIGURE 64-2.** A tumor (*arrow*) located in the right lobe of the liver in a patient with metastatic adrenal cancer as seen on computed tomographic (CT) scan. Panel **A** shows the lesion before radiofrequency (RF) ablation on a noncontrast scan. Panel **B** shows a three-dimensional rendering of the lesion, illustrating the path of the needle. This image was obtained while the patient was on the table, as a means of directing the therapy. Panel **C** demonstrates the lesion post-RF ablation on an arterial phase postcontrast CT scan. Note that the lesion appears larger than at preablation. This is because of the 1-cm zone of necrosis achieved around the lesion.

Nuclear imaging has been applied to the preoperative and intraoperative detection of malignancy in the abdominal cavity. This approach has been most extensively evaluated with respect to colon and rectal cancer. Two strategies have been pursued, one using anti-carcinoembryonic antigen (CEA) antibody immunoscintigraphy and the other using PET and the radiopharmaceutical [<sup>18</sup>F]fluorodeoxyglucose (FDG).

Radioimmunoguided surgery (RIGS) has relied on the ability of radiolabeled monoclonal antibodies or antibody fragments to bind specifically to markers expressed on tumor tissue. The sensitivity and specificity of these antibodies is based to a large degree on the tumor marker itself and how restricted its expression is to neoplastic tissue. CEA has been extensively studied as a target for this approach.<sup>44,45,46,47,48,49,50,51 and 52</sup>

Radioimmunoguided surgery using an intraoperative probe to detect radioactivity has been evaluated as an adjunct to second-look laparotomy in the evaluation of colorectal cancer patients with rising serum CEA levels.<sup>44</sup> Sixteen asymptomatic patients with a history of colorectal cancer surgery and a rising serum CEA level underwent second-look surgery using the RIGS approach. Patients received the anti-tumor-associated glycoprotein iodine 125-labeled monoclonal antibody (MoAb) B72.3 preoperatively. RIGS exploration was combined with a standard exploratory laparotomy. Recurrent disease was observed in 14 of the 16 patients as the result of this combined exploration. Standard exploration alone demonstrated recurrent disease in 9 of 16 patients (56.2%). In five patients (31.2%), RIGS detected disease that would otherwise have been overlooked. The additional RIGS-detected tumor sites were resectable for cure. In this study, RIGS improved the results of colorectal cancer, CEA-guided, second-look procedures in asymptomatic patients by recruiting one-third of patients to curative resections.<sup>44</sup>

Preoperative SPECT imaging studies can be obtained using a gamma camera in addition to the use of the intraoperative probe. This combined approach was used in a study evaluating *in vivo* posttargeting of tumor by means of anti-CEA monoclonal antibodies and the avidin-biotin three-step system.<sup>52</sup> Six patients with primary or recurrent rectal cancer were preoperatively injected with 1 mg of FO23C5 (anti-CEA) and/or B72.3 anti-tumor-associated glycoprotein (TAG-72) biotinylated monoclonal antibody. At 24 hours after injection, 1 mg of avidin was administered and, after a further 24 hours, biotin-labeled indium 111 was also injected. Eight tumor sites were localized in the six patients. Four of the eight lesions were identified preoperatively by the gamma camera; and six intraoperatively using a nuclear probe. An advantage of this method was the ability to perform preoperative scintigraphy and intraoperative radioimmunodetection with a single radioactive compound injection of biotin labeled with <sup>111</sup>In within a few days before surgery.<sup>52</sup>

Radioguided surgery using antibody-directed immunoscintigraphy relies on the ability of the antibody to bind efficiently to the target tissue and to be imaged above background. It also requires multiple antibodies to be derived against a number of tumor markers, depending on the histology of the target lesion. Many of these limitations could be overcome by using a more universal reagent that would be taken up by tumor tissue selectively, regardless of the tumor histology and independent of the need for antibody-antigen interactions. The radiopharmaceutical FDG has many of these properties.

Several studies have shown that malignant lesions demonstrate elevated glycolysis when compared to normal tissues.<sup>53,54</sup> By using the radiolabeled glucose analog FDG, investigators have documented increased uptake of FDG in cancer tissues.<sup>55,56</sup> PET scanning with FDG has been used to image a variety of malignant neoplasms, including breast cancer, head and neck tumors, lung cancer, lymphoma, melanoma, ovarian tumors, bone cancers, and colorectal carcinomas.

The mechanism whereby FDG is selectively accumulated in neoplastic tissue is based primarily on increased uptake of FDG and conversion to FDG-6-phosphate. The inability of cells to further metabolize FDG-6-phosphate causes the molecule to be trapped in the cells, facilitating accurate imaging. [Figure 64-3](#) shows a representative PET image using FDG. The intensity in this image is proportional to the amount of FDG that has entered the cells, begun the first steps of the metabolic conversion of sugar to energy, and then been trapped. The reasons why so many tumors avidly accumulate glucose are only partly understood. The energy

needs of rapidly dividing cells obviously plays a role.

**FIGURE 64-3.** Positron emission tomographic image obtained using [ $^{18}\text{F}$ ]fluorodeoxyglucose in a patient with rising serum carcinoembryonic antigen in the setting of metastatic colon cancer. The lesion is seen in the right lobe of the liver in all three views.

Currently, a study is under way at the National Cancer Institute evaluating the use of FDG-PET scanning and anti-CEA antibody immunoscintigraphy in the preoperative and intraoperative detection of recurrent colon and rectal cancers. Patients are recruited based on a rising serum CEA value in the absence of imageable disease, or with a single site of otherwise resectable disease. Patients are explored, and in some cases, a probe designed to detect FDG is used intraoperatively. This study is ongoing and is designed to evaluate the sensitivity, specificity, and predictive value of these scans as well as second-look laparotomy for the detection of recurrent tumor.

IGS has made possible a more minimally invasive approach to the diagnosis and management of breast lesions. The use of mammography and breast US has resulted in successful localization of lesions. Percutaneous core sampling of lesions, guided by specialized, computerized, stereotactic radiographic equipment is less painful and can be done under local anesthesia.<sup>57,58</sup> Tissue cores obtained are adequate to make the diagnosis in most cases.

Using an open MRI scanner, excisional biopsies of breast lesions have been successfully performed.<sup>59</sup> Intraoperative real-time scanning assisted in determining adequacy of resection margin and in positioning and minimizing the size of the incision. In a study of women undergoing excision of benign lesions, the MR demonstrated that all lesions were adequately excised with pathologic confirmation of clean margins.<sup>59</sup>

During an exploratory laparotomy, the surgeon is limited in the examination of the hollow viscera by the inability to adequately assess the mucosal surfaces. Although intraoperative endoscopy can be performed, this procedure is often difficult logistically and complicates the exploration because of the need to insufflate gas into the bowel. Furthermore, the small bowel is virtually inaccessible. Virtual endoscopy may help to overcome these limitations.

Virtual colonoscopy, for example, is a method of colon examination in which computer-aided 3D visualization of spiral CT simulates fiberoptic colonoscopy. In one study, a colon phantom containing spheres of various sizes was used to determine the influence of CT acquisition parameters on lesion detectability and sizing.<sup>60</sup> Results demonstrated that detection of beads of 4 mm or more was 100%. Detection decreased to 78% to 94% for 2.5 mm beads. The authors concluded that CT scanning at 5 mm collimation and up to pitch 2 is adequate for detection of high-contrast lesions as small as 4 mm in their model. As the imaging algorithms are improved, virtual colonoscopy may be used as a screening modality both preoperatively and intraoperatively in a CT-equipped operating suite.

Virtual endoscopic techniques also have been applied to the examination of the biliary and pancreatic ducts. MR cholangiography is a noninvasive technique that allows one to image the biliary system without the need for a contrast agent. Depending on the MR sequence chosen and the image processing, the ductal anatomy can be highlighted as a light or dark image.<sup>61</sup> Because this is an MRI-based approach, there is no radiation exposure. Images can be rendered in three dimensions to give an accurate representation of the ductal anatomy. Studies have demonstrated that the image quality compares favorably to endoscopic retrograde cholangiopancreatography of pancreatic (duct).<sup>61</sup>

A similar approach has been used to image the pancreatic duct in patients with mucin-producing pancreatic tumors. In a group of 13 patients with a total of 18 lesions, a computer-based virtual endoscopy system was used to render 3D reconstructions of the pancreatic ductal anatomy.<sup>62</sup> The virtual pancreatoscopy was successful in demonstrating the surfaces of the bile and pancreatic duct and could distinguish cystic from solid tumors. The surfaces of the malignant mucin-producing tumors were shown to be more irregular than those of the benign lesions. The data were useful for surgical planning with regard to extent of resection.

## ENDOCRINE SURGERY

Nuclear imaging, making use of radioisotopes that target specific tissue types, has made significant contributions to IGS, allowing for more minimally invasive procedures. The application of technetium Tc 99m sestamibi scanning to the preoperative and intraoperative localization of parathyroid adenomas has improved detection and allowed for less morbid surgical procedures. For the majority of patients, routine preoperative imaging may not be necessary.<sup>63</sup> In experienced hands, 95% of patients with primary hyperparathyroidism (HPT) are cured after a careful bilateral neck exploration.<sup>64</sup>

Imaging becomes critical for those patients who have persistent or recurrent HPT. In this patient population, reexploration is complicated by scarring, which not only makes it difficult to identify the parathyroid glands, but also increases the risk of injury to the recurrent laryngeal nerves.<sup>65,66</sup> Furthermore, in patients who are not cured at the first operation, it is possible that the abnormal parathyroid gland is located in an ectopic site, such as the pharynx or mediastinum.<sup>67,68,69 and 70</sup>

Compared to other noninvasive imaging studies, such as CT, US, and MRI, the sestamibi scan has been shown to be superior, with a positive predictive value as high as 90%.<sup>65,71</sup> Sestamibi scans can localize the parathyroid adenoma to the correct side of the neck and to the position within the neck relative to other structures ( Fig. 64-4). The accuracy of sestamibi has led to the introduction of a minimally invasive approach to parathyroid surgery.

**FIGURE 64-4. A:** Technetium Tc 99m sestamibi scan demonstrating a parathyroid adenoma on the left in a patient with primary hyperparathyroidism. **B:** A large left inferior parathyroid adenoma was found at operation.

The standard approach of bilateral neck exploration for the patient with primary hyperparathyroidism has been questioned. In a retrospective study, a group of 68

patients was reviewed with respect to localization studies and the need for bilateral neck exploration.<sup>72</sup> Forty-four patients were treated with localization study-aided unilateral neck exploration, whereas 24 patients were treated with the standard bilateral approach without localization studies. In 15 patients, the preoperative localization study was a sestamibi scan, which correctly localized the adenoma in all cases. All 15 patients with unilateral neck exploration guided by sestamibi results were cured, as were all 24 patients who underwent a bilateral neck exploration. Based on their results, the authors recommend a preoperative sestamibi scan for patients with primary hyperparathyroidism who have not undergone previous neck exploration, followed by a unilateral approach if the scan demonstrates a single lesion. They suggest that the second gland on the explored side be identified and biopsied. They conclude that bilateral exploration should be reserved for patients with multiple glands seen on sestamibi, or an abnormal biopsy of the second gland. This approach has been further supported by the use of an intraoperative probe for the detection of sestamibi during the procedure.<sup>73,74</sup>

However, caution should still be exercised in pursuing less than a bilateral neck exploration at the time of primary surgery for HPT. In a study using preoperative sestamibi and intraoperative measurements of parathyroid hormone levels, a success rate of unilateral exploration of 67% at 3 months was reported.<sup>75</sup> Failed unilateral exploration was due to multigland disease (31%), erroneous localization (31%), slow metabolism of parathyroid hormone (13%), and need for improved exposure (25%). The authors suggest that, at best, the success rate of unilateral exploration using intraoperative parathyroid hormone measurements can be expected to be 85%.<sup>75</sup> Although these strategies are a good example of how image guidance can change surgical management, the ultimate utility of this approach compared with standard bilateral neck exploration with a historical success rate of 95% awaits more definitive prospective studies.

## CONCLUSIONS

The ultimate goal of any medical therapy is obvious: precisely define the site and nature of disease and deliver the most effective therapy to the diseased tissue while doing no harm to normal tissue. Two main therapeutic approaches have been followed: systemic (generally medicinal) and surgical. The fundamental basis of surgery, for cancer or any other disease, is the concept of "local treatment of local disease." This presumes that the disease, or a major component of the disease to be treated, is (1) confined to a local region, (2) can be accurately defined, (3) is accessible, and (4) can be treated locally by resection or other ablative techniques.

Simplistically, this means that the surgeon is directly responsible for targeting the therapy. Systemic therapy, on the other hand, is based on the assumption that the therapy (i.e., antibiotic or chemotherapy) will self-target the disease, which can be local or disseminated. Given these precepts, IGS is a redundant term. Some type of "imaging" of the local disease must guide surgery and other forms of local therapy. Traditionally, the imaging has been performed by the surgeon's naked eye, supplemented by other, cruder sensory facilities, such as palpation. As advanced imaging techniques and technology become available, the surgeon will be able to expand the repertoire of available information and deliver local therapy in a more precise fashion.

### INTRODUCTION

There is a growing interest in developing techniques that produce extremely conformal x-ray dose distributions. Several means of reducing treatment volumes are under active development and clinical testing. These new techniques include three-dimensional treatment planning, stereotactic patient positioning, and conformal delivery technology, such as intensity-modulated radiation therapy. The results of these efforts support the concept that higher doses of radiation can be delivered with equal or reduced normal tissue complications. The ability to deliver higher doses of radiation using proton radiation therapy should lead to improved local control and survival rates.

### PHYSICAL ASPECTS OF PROTONS

Protons have comparable biologic effects in tissue relative to high-energy x-rays used in conventional radiation therapy. Evidence of this comes from the fact that the relative biologic effectiveness (RBE) of protons is approximately 1.1. The RBE of a proton beam is the ratio of the dose required to produce a specified effect using a reference radiation, usually cobalt 60 photons, to the proton dose required to produce the same effect. Most recent studies have reported RBE values for clinical protons in the range of 1.0 to 1.25.<sup>1,2 and 3</sup> Therefore, the advantage of proton radiation therapy is because of the superiority of the physical dose distributions compared with those for conventional therapy beams, rather than a biologic advantage.

A proton loses its energy in tissue through coulombic interactions with electrons, although a small fraction of energy is transferred through nuclear collisions. The energy loss per unit path length is relatively small and constant until near the end of the proton range, where the residual energy is lost over a short distance, resulting in a steep rise in the absorbed dose (energy absorbed per unit mass). This portion of the particle track, where energy is rapidly lost over a short distance, is known as the *Bragg peak* (see the curve labeled "Unmodulated Proton Beam" in [Fig. 65-1](#)). In physical terms, the magnitude of the transfer of energy to tissue per unit path length traversed by the protons is inversely proportional to the square of the proton velocity. The initial low-dose region in the depth-dose curve, before the Bragg peak, is referred to as the *plateau of the dose distribution* and is 30% to 40% of the maximum dose.

**FIGURE 65-1.** Depth dose curves (relative percent dose vs. depth in tissue) for an unmodulated proton beam (Bragg peak), a modulated proton peak (spread-out Bragg peak; SOBP), and 10-MV x-rays.

The Bragg peak is too narrow to treat any but the smallest of targets. For irradiation of larger targets, the beam energy is modulated to widen the Bragg peak, which is accomplished by superimposing several beams of closely spaced energies (ranges) to create a region of uniform dose over the depth of the target; these extended regions of uniform dose are called *spread-out Bragg peaks*. This is illustrated in [Figure 65-1](#). For comparison, [Figure 65-1](#) also shows the depth-dose curve for a 10-MV x-ray beam, an energy commonly used to treat deep-seated tumors. Note that the x-ray beam dose rises to a maximum value at relatively shallow depths, then falls off exponentially as depth increases. This fundamental difference in energy loss in tissue leads to superior dose distributions with protons.

The physical superiority of proton dose distributions is illustrated for the treatment of a paranasal sinus cancer ([Fig. 65-2](#)) and a large Ewing's sarcoma of the pelvis ([Fig. 65-3](#)). In this comparison, intensity-modulated x-ray therapy and intensity-modulated proton therapy are used. Both x-ray and proton treatment plans of the paranasal sinus make use of multiple beam portals and identical constraints. The two treatment plans are designed to provide equal doses of 76 Gy to the target volume. The differences in the two plans are shown in the lower panels of [Figure 65-2](#). This illustration reveals that x-rays deliver an additional 5 to 15 Gy throughout the brain. In the region of the right eye, which is magnified, the x-ray plan delivers up to 40 Gy more than the proton plan. The constraint on the right eye retina was 50 Gy. Had this been reduced, the x-ray dose would have been lower in this region, but at the expense of increased dose elsewhere or greater dose inhomogeneity in the target. This comparison illustrates that protons can be made to stop sharply beyond a target volume, sparing a critical structure distal to the target.

**FIGURE 65-2.** Paranasal sinus tumor treated with intensity-modulated proton therapy (upper left) and intensity-modulated x-ray therapy (upper right). The difference in the two plans is shown in the lower right panel and magnified in the lower left panel. Note the additional 5 to 15 Gy that the brain receives and the increased dose to the right eye. The plans were developed by one of the authors (A. L.) at the Paul Scherrer Institute in Villigen, Switzerland.

**FIGURE 65-3.** Ewing's sarcoma of the right pelvis treated with intensity-modulated proton therapy (upper left) and intensity-modulated x-ray therapy (upper right). The lower panel shows the difference in the two plans. Note the additional 8 to 28 Gy that the small bowel, midline structures, and contralateral sacrum receive. The plans were developed by one of the authors (A. L.) at the Paul Scherrer Institute in Villigen, Switzerland.

The second example is a Ewing's sarcoma of the ilium in an 18-year-old man as shown in the transverse computed tomography images in [Figure 65-3](#). The x-ray plan delivers greater dose to the anterior small bowel and midline structures, such as the bladder, prostate, and large bowel. This plan also dispels the commonly held misconception that protons only offer significant advantages over x-rays for small treatment volumes. The effects of excess dose outside of the target volume are not well understood, although late effects of radiation do not occur in unirradiated tissues. Such excess radiation may also be important in the acute tolerance to treatment as well as the tolerance to combined treatment with chemotherapy and radiation. These two examples illustrate the superiority of protons in treating both small and large targets.

## PROTON BEAM RADIATION TREATMENT: HISTORICAL NOTE

In 1946, Robert Wilson proposed that proton beams would provide superior dose distributions and should be considered for clinical radiation treatment. Initial efforts were directed at intracranial targets and used single-dose protocols. The first treatments using proton or helium ion beams were at the University of California at Berkeley (1955), University of Uppsala, Sweden (1957), Massachusetts General Hospital (MGH; 1961), Physics Research Institute, Dubna, Russia (1964), and the Institute for Experimental and Theoretical Physics, Moscow (1969). As of 1999, approximately 24,500 patients have received part or all of their radiation treatment by proton beams (for a historical review, see [ref. 4](#)). Today 19 proton treatment centers are established worldwide. Only one prospective randomized trial reporting on the efficacy of proton beam radiation therapy versus photon therapy has been published. <sup>5</sup>

The proton treatment program at MGH began in 1961. It was led by the neurosurgical group of W. Sweet and R. Kjellberg using the 160-MeV cyclotron in the department of physics at Harvard University. Their targets were principally pituitary adenomas, arteriovenous malformations, and other benign intracranial neoplasms and were treated by single-dose protocol. In January 1974, the MGH department of radiation oncology began a program of fractionated proton treatment. This clinical research program represents an active collaboration between the Harvard Cyclotron Laboratory (HCL), the Massachusetts Eye and Ear Infirmary, the Harvard Medical School, and MGH.

## CLINICAL RESULTS

### PROSTATE CARCINOMA

Investigators at MGH completed a phase III trial comparing 67.2 Gy of photons versus 75.6 Cobalt Grey Equivalent (CGE) using a conformal perineal proton boost. <sup>5</sup> From 1982 through 1992, 202 patients with T3–T4 prostate cancer received 50.4 Gy by four-field photons. Patients then received either 25.2 CGE with conformal protons or a 16.8 Gy photon boost. No differences were found in overall survival, total recurrence-free survival, or local recurrence-free survival in the two groups. The local recurrence-free survival rate at 7 years for patients with poorly differentiated (Gleason 9 and 10) tumors was 85% on the proton arm and 37% on the photon arm. Grade 1 and 2 rectal bleeding was higher in the proton arm (32% vs. 12%), as was urethral stricture (19% vs. 8%). In conclusion, dose escalation to 75.6 CGE by conformal proton boost led to increased late radiation sequelae, but not to increased total survival in any subgroup. However, there was an improved local recurrence-free survival in patients with poorly differentiated tumors.

Based on the results of this trial, the Proton Radiation Oncology Group (PROG) 95-09 was initiated. Participants in the trial were MGH and Loma Linda University (LLU) Medical Center. PROG 95-09 is a randomized phase III trial using conformal photons with proton boost in early-stage prostate cancer. The study was proposed because long-term follow-up of T1–T2 irradiated patients demonstrated biochemical disease-free survival rates of 50%, 35%, and 20% for well, moderate, and poorly differentiated tumors, respectively. This study randomized patients to two different proton boost dose levels, with patients receiving a total dose of either 79.2 Gy or 70.2 Gy. Patients deemed to be a low risk for local failure (prostate-specific antigen less than 4 ng/ml) and patients with high risk for distant disease (prostate-specific antigen greater than 15 ng/ml and/or positive lymph nodes) are not likely to benefit from this dose escalation and thus were excluded. This randomized trial was designed to detect a 20% increase in freedom from local failure and biochemical relapse at 5 years. With 390 patients entered, this trial is now closed and is awaiting analysis.

The results of the LLU experience in early-stage prostate cancer have been published. <sup>6</sup> Three hundred and nineteen men with T1–T2b tumors were treated with 74 to 75 CGE protons, or combined protons and x-rays. The overall 5-year biochemical disease-free survival rate was 88%. No severe treatment-related morbidity was observed.

### UVEAL MELANOMA

As of October 1998, a total of 2586 patients have been treated for uveal melanoma at MGH with protons in collaboration with the Massachusetts Eye and Ear Infirmary. <sup>7</sup> Patients were treated with 70 CGE in five fractions over 7 to 9 days. The 5-year actuarial local control rate is 96% for all sites within the globe, with an 80% survival. The probability of eye retention at 5 years was estimated to be 90% for the entire group and 97%, 93%, and 78% for patients with small, intermediate, and large tumors, respectively. Independent risk factors for enucleation were involvement of the ciliary body, tumor height more than 8 mm, and distance between the

posterior tumor edge and the fovea. These results compare favorably with local control rates of 89% reported with protons in Nice, France. <sup>8</sup>

Because some patients have experienced deteriorating vision after doses of 70 CGE, a randomized trial compared 50 and 70 CGE for small- and intermediate-size lesions located within 6 mm of the optic disc or macula. This dose-reduction study was completed in June 1994 with accrual of 188 patients. Interim analysis based on patients followed through September 1997 (median follow-up 60 months) suggested no reduction in either local control or survival rate. No marked improvement in visual outcome or complications has been observed. However, visual field analysis does show a smaller mean defect in the patients randomized to 50 CGE. <sup>7</sup>

A study has been completed comparing iodine 125 plaques to helium ions by the group at University of California, San Francisco (UCSF) and Lawrence Berkeley Laboratories (LBL).<sup>9</sup> Patients with melanomas less than 10 mm in height and less than 15 mm in diameter were randomized by the UCSF/LBL group to receive either 70 CGE in five treatments with helium ions, or 70 Gy to the tumor apex with <sup>125</sup>Iodine plaque brachytherapy. Local control was 100% in those patients treated with helium ions compared with 87% in those patients treated with <sup>125</sup>I plaques.

## **SARCOMAS OF THE SKULL BASE AND CERVICAL SPINE**

Treatment of patients with a sarcoma of the skull base is challenging because of the large number of critical structures penetrating the skull base and the proximity of these tumors to the brain stem and optic pathways. These factors have limited the success of conventional photon radiation therapy and surgery. The results of the MGH series has been analyzed.<sup>10</sup> One hundred and sixty-nine patients with chordoma and 165 patients with chondrosarcoma were treated with protons between 1975 and 1998. The 5-year actuarial local control rates for skull-base chondrosarcomas was 98% and was 73% for chordoma patients. For cervical spine patients, local control rates were 54% and 48% for chondrosarcoma and chordoma patients, respectively. The LLU proton experience for skull-base tumors showed 5-year actuarial local control rates of 75% for chondrosarcoma and 59% for chordoma.<sup>11</sup> The MGH results compare favorably with the experience (median dose 50 Gy) from Princess Margaret Hospital in Toronto of 55%.<sup>12</sup>

## **OPTIC PATHWAY GLIOMA**

Seven patients with optic pathway glioma were treated at LLU between 1992 and 1997.<sup>13</sup> Tumor volumes ranged from 3.9 cm<sup>3</sup> to 127 cm<sup>3</sup>. At a median follow-up of 37 months, all patients were locally controlled. A reduction in tumor volume was seen in three patients, and tumor volumes remained stable in four patients. Visual acuity remained stable in patients who presented with useful vision. Proton radiation therapy was shown to reduce the dose to the contralateral optic nerve by 47%, compared with three-dimensional photon techniques.

## **ASTROCYTOMA**

Between 1993 and 1998, 48 patients were treated for nonresectable grade II and III intracranial tumors at the Center for Proton Therapy in d'Orsay, France.<sup>14</sup> Mean tumor doses ranged from 63 to 67 Gy at 1.8 Gy per fraction. With a median follow-up of 18 months, local control was 97% (33 of 34 cases) and 43% (6 of 14 cases) for nonparenchymal and parenchymal lesions, respectively.

Twenty-three patients with the diagnosis of glioblastoma multiforme were treated to 90 CGE with twice-daily protons.<sup>15</sup> Median survival time was 20 months from the date of surgery and 18.6 months from the start of radiation treatment. Actuarial survival at 2 and 3 years was 34% and 18%, respectively. Sixteen of the 23 patients were judged to have had tumor progression. Of these 16, 15 had progression in tissues that received 60 to 70 CGE (or less). In only one patient was there evidence of failure within the 90-CGE volume. All patients developed new areas of gadolinium enhancement during the follow-up period. Pathologic material was examined in 15 patients. Radiation necrosis only was demonstrated in seven patients. The survival rate for this group of 23 patients is comparable to that of the best brachytherapy or radiosurgery series. However, a trend towards larger and less accessible tumors was seen in this patient population. This regimen has achieved an apparent high frequency of tumor eradication in the 90-CGE volume, although toxicity has been significant.

## **BENIGN MENINGIOMA**

Between 1981 and 1996, 46 patients with incompletely resected or recurrent benign meningioma were treated at the HCL with a combined proton-photon technique. The median dose to the tumor volume was 59.0 CGE. Overall survival at 5 and 10 years was 93% and 77%, respectively, and recurrence-free survival at 5 and 10 years was 100% and 88%. Three patients developed local tumor recurrence at 61, 95, and 125 months, although no patient died from recurrent disease. Complications have included focal brain stem necrosis in two patients and grade 3 memory loss in another patient. In four patients who developed ophthalmologic toxicity, the maximum dose to the optic structures was 58.4, 59.2, 59.3, and 63.0 CGE. Unilateral sensorineural hearing loss developed in two patients and endocrinopathy in 11 patients.

Nineteen patients with inoperable skull-base meningiomas were treated at the Svedberg Laboratory in Uppsala, Sweden, with 24 Gy in four fractions. With a minimum follow-up time of 36 months, no patients have experienced disease progression.<sup>16</sup>

## **PARANASAL SINUS CARCINOMA**

Between 1991 and 1996, 32 patients with carcinomas of the paranasal sinuses were treated on an accelerated-dose proton-photon protocol.<sup>17</sup> The stage distribution was T3 in two cases and T4 in 30 cases, and all were N0 and M0. Four patients had had a gross total resection, whereas the others had had only a biopsy (7) or subtotal resection (19). The median observation period was 2.7 years. Actuarial disease-specific survival at 3 years was 62%. Ten deaths with intercurrent disease and seven with metastatic tumor have been reported. Three patients developed local failure. The 3-year actuarial local control rate was 89%. Late toxicity has included temporal lobe necrosis in three patients, although all have regressed with steroid treatment. Three patients have required surgical soft tissue repair. These local-control results appear to constitute a substantial gain over conventional surgery and photon treatment techniques.

## **HEPATOCELLULAR CARCINOMA**

Investigators at Tsukuba University, Japan, have reported impressive long-term control and survival results in patients with primary hepatocellular carcinoma treated with proton radiation therapy.<sup>18</sup> The dose per fraction was 4 Gy and the mean total dose was 72 Gy. The 7-year local control and survival results in this series of 122 patients were reported as 94% and 27%. Proton therapy did not cause clinically symptomatic changes in liver function.<sup>19</sup> The only notable change observed was a transient increase in liver transaminases.

## **LUNG CARCINOMA**

Between 1994 and 1998, 37 patients with medically inoperable stage I–IIIa lung cancer were treated at LLU with conformal photons and protons.<sup>20</sup> Patients received either photons and protons or protons alone to 73.8 CGE over 5 weeks. Patients with poor lung function received 51 CGE in ten fractions over 2 weeks to the gross tumor volume. With a median follow-up time of 14 months, disease-free survival at 2 years was 63% for all patients and 86% for stage I patients.

## **PROTON RADIOSURGERY**

Between 1961 and 1993, 2987 patients were treated with single-fraction proton therapy (proton radiosurgery). This effort was led by the late Dr. Raymond Kjellberg, a neurosurgeon at MGH. The majority of patients were treated for inoperable arteriovenous malformations and pituitary adenomas.<sup>21</sup> Beginning in 1991, a second proton radiosurgery technique was developed using a patient positioning system capable of stereotactic alignment for radiosurgery (STAR).<sup>22</sup> This system was developed because of the inherent restrictions of the fixed horizontal beam at the HCL. The STAR unit was based on target coordinates obtained directly from computed tomography, magnetic resonance imaging, or angiography. Early results with arteriovenous malformations, acoustic neuromas, and brain metastases are comparable with those produced by other stereotactic technologies (Gamma Knife, linear accelerator, Elektra Corporation, Stockholm, Sweden).

## **DESIGN OF CLINICAL TRIALS USING PROTON BEAMS**

The fixed horizontal, 160-MeV HCL proton beam, with an effective treatment depth of 15.9 cm, constrained the number of sites that could effectively be treated. For

this reason, past efforts have focused on intracranial targets, skull-base tumors, head and neck tumors, eye tumors, and prostatic carcinoma. The Northeast Proton Therapy Center (NPTC) at MGH will have a more energetic beam (220 MeV) capable of treating to depths of 32 cm, a gantry-based delivery system, and state-of-the-art patient positioners. These improvements will increase the numbers of patients that can be treated and will facilitate treatment at a number of new sites, including lung, rectum, and liver. In addition, a major effort will be placed on developing protocols for the treatment of pediatric malignancies.

Several examples of the potential advantages of the NPTC proton beam have been documented. Medulloblastoma is a pediatric malignancy that occurs in the posterior fossa and can spread through the cerebrospinal fluid to seed in the cranial cavity and the spinal axis, requiring radiation treatment to the cranial contents as well as the spinal axis. As a result, these patients frequently experience hearing, neurologic, neuropsychological, endocrine, musculoskeletal, cardiac, and fertility deficits because of the combined chemotherapy and radiation treatment. [Figure 65-4](#) illustrates the dramatic reduction in the volume of normal tissue irradiated in the thorax (heart, lung, and esophagus) seen with protons. In addition, similar reductions would be seen in the abdomen (stomach, small bowel, pancreas, and liver) and pelvis (ovaries, bladder, and bowel). Also, not illustrated here, the dose to the middle ear can be reduced by 50% using photon techniques. Another example for which protons would reduce treatment-related morbidity is the treatment of rectal carcinoma. Current treatment of patients with stage II and III rectal carcinoma includes surgical resection, pelvic radiation, and infusional 5-fluorouracil. Significant treatment-related morbidity results from this regimen because of the irradiation of large volumes of normal bowel and bladder with conventional photon radiation techniques. Proton beam treatment allows for irradiation of the target lymph nodes with minimal dose to the small bowel and the bladder ([Fig. 65-5](#)).

**FIGURE 65-4.** Comparison of x-ray and proton single posterior portals for craniospinal irradiation in medulloblastoma. The x-ray plan results in exit irradiation of the heart, lung, carina, esophagus (not visualized), and anterior soft tissues.

**FIGURE 65-5.** Posterior proton portal for the treatment of rectal carcinoma. The tumor bed and internal iliac lymph nodes are targeted, whereas the small bowel and anterior soft tissues are not treated.

The reduction in normal tissue irradiation with protons has significant implications for combined radiation and chemotherapy protocols. Even when modest doses of radiation are prescribed, as in the case of rectal carcinoma, proton radiation should improve tolerance to the combined regimen. This should result in fewer dose-limiting toxicities and improved treatment intensity and treatment compliance, which may allow for higher chemotherapy doses and, ultimately, lead to higher cancer control rates.

## CONCLUSIONS AND FUTURE DIRECTIONS

The history of radiation oncology has demonstrated that major improvements in local control have occurred because of improvements in dose distributions. Proton radiation therapy represents one of the most precise and sophisticated treatment delivery systems in radiation oncology. Proton therapy will also make use of some of the same improvements that have developed in conformal x-ray therapy (intensity modulation, rotational delivery, multileaf collimation, stereotactic localization) to further improve the dose distribution of protons. Such improvements will allow for continued escalation in tumor doses while minimizing dose to normal, nontarget tissues. With the installation of a high-energy (220 MeV) hospital-based proton therapy facility at the NPTC at MGH and the existing facility at LLU Medical Center, the technology exists for continuing clinical research in proton radiation therapy. Efforts for the first decade of the twenty-first century will include: (1) comparing intensity-modulated x-ray therapy and intensity-modulated proton therapy, (2) assessing the gains in treatment intensity in combined modality therapy with protons, and (3) assessing the impact of proton therapy on improving cure rates in pediatric cancer and reducing late effects.

**BCC-1.** Nodular basal cell carcinoma on nasal tip. Note pearly, translucent appearance with telangiectasias.

**BCC-2.** Nodular basal cell carcinoma on right cheek. Note confluence of multiple nodular lesions with telangiectasias.

**BCC-3.** Nodular basal cell carcinoma of the left glabella with central depression. Note classic rolled borders and pearly appearance. There is also a large violaceous nodule in the left medial canthus. This long-standing lesion is an eccrine acrospiroma.

**BCC-4.** Large nodular basal cell carcinoma of the forehead with classic rolled border.

**BCC-5A.** Nodular basal cell carcinoma of the forehead at the site of a previous automobile injury. The patient states that she had multiple fragments of glass removed over a long period of time. Basal cell carcinoma and squamous cell carcinoma are known to develop at the site of chronic scar.

**BCC-5B.** Microscopic example of nodular basal cell carcinoma demonstrating peripheral palisading of basal cells, retraction of tumor masses from dermis, and hyperchromatic cells.

**BCC-5C.** Defect following Mohs micrographic excision, demonstrating extension of cancer to the periosteum. The patient subsequently underwent skin flap repair.

**BCC-6.** Superficial basal cell cancer on the left upper lip of a 27-year-old woman. The patient, an aspiring actress, did not want treatment with surgery or radiation therapy. A course of intralesional interferon was successful at eliminating the cancer. It should be noted that this approach should only be used in superficial, easy to monitor basal cell cancer and has a recurrence rate of 20%.

**BCC-7.** Superficial basal cell cancer on an extremity. This lesion had been treated for many years as eczema and psoriasis. Topical corticosteroids provided no benefit. Any persistent rash that does not respond to topical treatment or is not otherwise diagnosed should be promptly biopsied.

**BCC-8.** Superficial basal cell carcinoma on trunk.

**BCC-9.** Pigmented basal cell carcinoma with nodular morphology.

**BCC-10.** Large pigmented basal cell carcinoma. The differential diagnosis includes melanoma.

**BCC-11.** Ulcerating basal cell carcinoma of the angle of the jaw.

**BCC-12.** Extensive basal cell carcinoma of the medial eyebrow and nasal root. Proximity to the supraorbital nerve raises the possibility of perineural extension of cancer in this long-standing carcinoma.

**BCC-13A.** Large nodular basal cell carcinoma in the medial canthus. Deep extension of the cancer in this area can involve the lacrimal duct.

**BCC-13B.** Defect following Mohs micrographic surgery indicates complete elimination of cancer. The lacrimal duct was not involved.

**BCC-14.** Extensive basal cell carcinoma of the right medial canthus, nasal sidewall, and distal nose. Basal cell cancer is typically a slow-growing tumor, but neglect can result in extensive destruction sometimes requiring removal of the orbital contents.

**BCC-15.** Cystic basal cell carcinoma of the glabella. This tumor was misdiagnosed as a cyst until a biopsy confirmed that it was a basal cell carcinoma, cystic type.

**BCC-16.** Morpheaform basal cell carcinoma of the left chin. Note light coloration and smooth texture. Although it appears to be well demarcated, the infiltrative histologic nature of this cancer can be expected to result in a larger defect upon complete extirpation.

**BCC-17.** Long-standing morpheaform basal cell carcinoma of the left cheek. Note smooth, white appearance, slightly elevated from the surrounding tissue. Crust in the center is an indication of tumor necrosis. Patients who have this type of cancer diagnosed histologically must be prepared for the large extent of the defect.

**BCC-18.** Morpheaform basal cell carcinoma, a form of aggressive growth basal cell cancer, is noted on the right cheek of a 30-year-old woman. It had been long-standing and was noted to grow very slowly. Especially in young patients, the true extent of the cancer must be discussed in advance and proper preparation must be made so that optimal reconstruction results in the best aesthetic outcome. This cancer, located in the embryonic fusion plain, must be removed with Mohs micrographic surgery to minimize the chance of recurrence. Recurrent basal cell cancer, especially in this region, is at high risk for extension deep in the facial planes.

**BCC-19.** Poorly defined morpheaform basal cell carcinoma of the right upper eyebrow in a 55-year-old woman. The patient had this lesion for some time before noting that it had changed. The extent of the cancer is larger than it appears clinically. It is best treated with the Mohs micrographic surgery method.

**BCC-20.** Morpheaform basal cell carcinoma of the right upper eyebrow. The patient believed that she had a scar at the site for many years but could not identify an episode of related trauma. This is the classic appearance of a morpheaform basal cell cancer, the true extent of which is significantly greater than appears clinically.

**BCC-21.** Large basal cell cancer of the left upper outer arm. The cancer had been present for approximately three years before the patient sought treatment.

**BCC-22.** Extensive basal cell carcinoma of the left face. Although this is an extreme example, it highlights the potentially aggressive nature of basal cell carcinoma. Despite the very low risk of metastasis, the cancer can be extremely locally destructive and, if present near vital organs, lethal.

**BCC-23.** Young patient with a nevus sebaceus on the left cheek. This is a benign tumor of sebaceous glands but is associated with basal cell carcinoma. Current recommendations are that a nevus sebaceus be removed in young adulthood to minimize the risk of basal cell cancer.

**BCC-24A.** Multiple small papules in the periorbital region. Patients may present concerned that these represent cancer. In fact, they are syringomas, or benign tumors of the sweat glands. No treatment is necessary.

**BCC-24B.** This patient was referred because of concern that the red patch on the cheek, of long-standing duration, represented basal cell cancer. This is the classic appearance of rosacea, an adult form of acne. The condition responds promptly to topical therapy.

**BCC-25.** Severe solar damage of left face. This is the classic setting for the development of nonmelanoma skin cancer. Note fair skin, mottled pigmentation, and telangiectasias.

**BCC-26.** Close-up of patient in [Figure BCC-25](#). This patient has skin type I. When exposed to ultraviolet radiation from the sun, he always burns and never tans. The absence of the tanning response probably increases the risk for epidermal mutations from solar radiation. Actinic keratoses, hypopigmentation from previous cryotherapy, and telangiectasias are noted.

**BCC-27.** This patient has had lifelong problems with basal cell carcinoma. Some patients who received radiation therapy for acne later developed multiple basal cell cancers. Despite multiple surgeries, topical chemotherapy, and cryotherapy, the patient continues to develop new basal cell carcinomas.

**BCC-28A.** This patient worked for many years in his youth as a lifeguard. Evidence of basal cell cancer and solar damage, as well as scar related to previous surgery, are noted.

**BCC-28B.** The same patient 10 years later with progressive basal cell cancer and areas of scar associated with basal cell cancer recurrence. Although we refer to these lesions as recurrences, histologic evaluation of the patient's facial skin indicates widespread basaloid budding in the epidermis, consistent with a field defect.

**BCC-29.** Elderly patient with multiple basal cell cancers. This patient has a history of arsenic exposure, which is associated with the development of basal cell carcinomas.

**BCC-30.** Nodular basal cell carcinoma on the nasal sidewall of a 40-year-old woman. Although most likely to be basal cell carcinoma, all such lesions must be biopsied. Melanoma and other forms of nonmelanoma skin cancer are in the differential diagnosis, although they are less likely.

**BCC-31.** Ulcerated nodular basal cell carcinoma of the nose.

**BCC-32.** Nodular basal cell carcinoma of the left upper lip and alar groove. Basal cell cancer is thought to double in size over approximately 1 year. The size of this lesion suggests it has been present for many years. It is at risk for deep infiltration into the nasolabial groove.

**BCC-33.** Basal cell carcinoma of the tip of the nose. Because of the ill-defined margins of this cancer and its technically challenging location, Mohs micrographic surgery is indicated.

**BCC-34.** Basal cell carcinoma of the right nose. Patients must be advised of the likely size of the cancer, which is often larger than appears clinically. The final wound and reconstruction may be unsettling to the patient if he or she has not been properly prepared.

**BCC-35.** Small basal cell carcinoma of the left upper lip.

**BCC-36.** Basal cell carcinoma of the nose. Note the extensive nodularity under the surface of the skin. This cancer is likely to be at least 50% larger than it appears on the surface.

**BCC-37.** Nodular basal cell carcinoma of the left ala. This lesion is easily treated by Mohs micrographic surgery. Because of its presence in the alar groove, healing by second intention is often an acceptable alternative to plastic reconstruction.

**BCC-38A.** Recurrent basal cell carcinoma on the left nose of an individual who works outdoors. Although very little scar tissue is noted on clinical exam, the cancer proved to be approximately twice the clinical size because of the extension of cancer cells within and under scar tissue.

**BCC-38B.** The defect following Mohs micrographic surgery.

**BCC-38C.** Immediately after Mohs micrographic surgery, the defect was repaired in a linear fashion, which will result in a fine-line scar. Patients must be advised that the complete healing process takes approximately twelve months. Maturation and fading of the scar continues during this whole period.

**BCC-39.** Ulcerating nodular basal cell carcinoma of the left alar rim. Because of its proximity to the alar rim as well as to the embryonic fusion plain, Mohs micrographic excision is indicated. A shallow defect in this area can be allowed to heal by second intention with excellent results. Alternatively, plastic reconstruction may be required to preserve normal anatomic and functional relationships.

**BCC-40.** Linear erosions on the right alar rim of a patient with a history of squamous cell cancer of the cheek. The patient also has a history of prurigo. The area was biopsied and failed to reveal any cancer. The patient admits to scratching. If topical treatment with corticosteroids fails to resolve the problem, a deeper biopsy may be indicated.

**BCC-41.** Nodular basal cell carcinoma on the left ala, similar to [Figure BCC-39](#).

**BCC-42.** Extensive basal cell carcinoma of the left nose. Mohs micrographic treatment surgery is the treatment of choice. The reconstruction technique depends on the final defect.

**BCC-43.** Large eroding basal cell carcinoma of the nasal bridge. This patient, of northern European ancestry, had worked outdoors his whole life. Several other basal cell carcinomas are noted on the cheek and lip.

**BCC-44A.** Large basal cell carcinoma of the left ala. Note elevation and retraction of the alar rim. This is an indication of extensive deep infiltration by basal cell carcinoma.

**BCC-44B.** Defect following Mohs micrographic surgery. The patient was referred for complex flap reconstruction.

**BCC-45A.** Large nodular basal cell carcinoma of the left upper lip and left nostril.

**BCC-45B.** Defect following Mohs micrographic surgery. It is essential to minimize the recurrence of cancer in this location, as recurrent tumor is likely to invade deeply. The patient was referred for plastic reconstruction. Recurrence of cancer under complex flaps may be concealed, so careful examination including bimanual palpation of the region is necessary.

**BCC-46A.** Extensive basal cell carcinoma of the left upper lip. Excision with conventional margins may not have adequately removed the cancer. Mohs micrographic surgery was performed.

**BCC-46B.** Following Mohs micrographic excision with preservation of the orbicularis oris.

**BCC-46C.** After reconstruction using an Abbe flap. (Figure BCC-46C courtesy of Dr. Stephan Ariyan).

**BCC-47.** Nodular basal cell carcinoma of the right upper lip.

**BCC-48A.** Morpheaform basal cell carcinoma of the left cheek with indistinct margins. Excision by the Mohs micrographic surgery technique resulted in a 5-cm defect. The wound was repaired under local anesthesia at the time of Mohs surgery.

**BCC-48B.** Three months following reconstruction with cheek advancement flap.

**BCC-49A.** Long-standing basal cell carcinoma of the left cheek. Note areas of nodularity, hypopigmentation, and crusting resulting from bleeding from the surface of the cancer.

**BCC-49B.** Extensive defect following Mohs micrographic excision demonstrates histologic extent of cancer. Incomplete excision of cancer is an important cause of recurrence. Proper preparation of the patient for the extent of this defect was essential. Repair was performed without complication.

**BCC-50.** Ill-defined extensive basal cell carcinoma of the left temporal region.

**BCC-51A.** Neglected basal cell carcinoma of the right temporal region and ear. Cancer in this area, especially when long-standing, has the potential for deep invasion.

**BCC-51B.** Defect following Mohs micrographic surgery reveals temporalis muscle.

**BCC-51C.** Despite the very high cure rates associated with Mohs micrographic surgery, risk of recurrence is proportional to the size of the cancer. Because of concern about concealing any recurrence, the wound was allowed to heal by second intention. The wound is pictured here at approximately 4 weeks status post excision.

**BCC-51D.** Completely healed wound at 3 months. The patient did not wish to have reconstructive surgery done on the helix of the ear.

**BCC-52.** Basal cell cancer within the triangular fossa of the ear. Basal cell cancer on the antihelix is not uncommon, and the recommended treatment is Mohs micrographic excision.

**BCC-53.** Ill-defined nodular basal cell carcinoma of the forehead.

**BCC-54.** Large basal cell carcinoma of the right lower eyelid. Retraction of surrounding tissue indicates deeply infiltrative nature of the cancer. The patient was treated with Mohs micrographic surgery and referred for reconstruction to minimize the risk of ectropion.

**BCC-55.** Very large ulcerated basal cell carcinoma of the glabella.

**BCC-56.** Basal cell carcinoma of right lower eyelid in an African-American. Although basal cell carcinoma is most common in light-skinned people, it can occur in more darkly pigmented individuals.

**BCC-57.** Ulcerated basal cell carcinoma on the root of the nose. The majority of facial basal cell carcinomas occur on the nose.

**BCC-58.** Extensive basal cell carcinoma of the left nose extending into the medial canthus and along the lower eyelid. Treatment of this cancer requires an interdisciplinary approach. Following Mohs micrographic surgery, the patient was referred for plastic reconstruction. Because of the large size of the lesion, the patient must be monitored for recurrence.

**BCC-59A.** Extensive basal cell carcinoma in a young man. The location in the medial canthus, the long-standing nature of the cancer, and its size create a high risk that if the lesion recurs it will extend into the orbit. The patient was treated with Mohs micrographic surgery.

**BCC-59B.** Defect following Mohs micrographic surgery demonstrating the canthal ligament.

**BCC-60.** Basal cell cancer of the nasal root extending into the medial canthus.

**BCC-61.** Large nodular basal cell cancer of the lower eyelid. Mohs micrographic excision was performed followed by plastic reconstruction. Based on its size, this lesion had been present for many years.

**BCC-62.** Extensive basal cell carcinoma with retraction of the medial canthus. This clinical appearance suggests that the cancer likely extends deeply and may be at risk for involving the infraorbital nerve.

**BCC-63.** Recurrent nodular basal cell carcinoma of the post-auricular sulcus. Basal cell cancer in this region can extend widely along the cartilage and posterior scalp before it is diagnosed. Mohs micrographic excision is indicated.

**BCC-64.** Nodular basal cell carcinoma within an area of previous excision consistent with recurrent cancer.

**BCC-65.** Extensive basal cell carcinoma of the ear and temple. Because of the extensive nature of this cancer, radiation therapy was used with a good result. The therapeutic plan was to use Mohs micrographic surgery if the cancer recurred.

**BCC-66.** Multiple nodular and papular lesions on the scalp in an individual with severe solar damage. Although the clinical diagnosis of the large lesion on the right is basal cell cancer, the red nodular lesions are concerning and require biopsy as well to obtain a definitive diagnosis.

**BCC-67.** Large superficial basal cell carcinoma on the right breast. This was successfully treated with radiation therapy, although Mohs micrographic surgery and reconstruction would have been an equally acceptable alternative.

**BCC-68.** Large nodular basal cell carcinoma on the chest. The differential diagnosis includes squamous cell carcinoma.

**BCC-69.** Basal cell carcinoma on the shin of a 60-year-old woman. Basal cell carcinoma on the lower extremity is more common in women than in men. This highlights the likely association between solar exposure, secondary to clothing styles, and basal cell cancer.

**BCC-70.** Additional basal cell cancer on the lower extremity in the same patient as in [Figure BCC-69](#).

**BCC-71.** Multiple basal cell carcinomas of the lower extremity with evidence of venous stasis changes. Treatment of cancer in this area is extremely difficult because of the dependent location and the resultant slow healing in older patients. Treatment by Mohs micrographic excision with healing by second intention provides excellent results. While skin grafting creates secondary wounds in the patient that require additional healing, new biologic dressings and allograft permit excellent healing while minimizing limitations on activity.

**BCC-72.** Large nodular basal cell carcinoma on the upper extremity.

**BCC-73.** Nodular basal cell carcinoma on the upper extremity, side view, indicating the exophytic nature. The differential diagnosis includes squamous cell cancer and melanoma.

**BCC-74.** Superficial basal cell carcinoma on the shoulder of a 45-year-old male. This lesion can be treated easily with electrodesiccation and curettage.

**BCC-75.** Basal cell carcinoma on the instep of an elderly woman.

**BCC-76A.** Basal cell carcinoma with ill-defined clinical margins on the nasal tip of a 50-year-old man. The lesion had been treated for several years as rosacea. Biopsy confirmed the presence of rosacea but also revealed a few foci of superficial basal cell carcinoma.

**BCC-76B.** Defect following Mohs micrographic surgery.

**BCC-77.** Basal cell carcinoma on the philtrum complicated by an outbreak of herpes labialis. Surgery was deferred until the lesion resolved. Prophylactic antiviral medication was used. This case highlights the occasional misdiagnosis of basal cell carcinoma for herpes labialis. The chronic, recurring nature of both, in certain circumstances, may be responsible for the confusion. Basal cell cancer is not associated with a prodrome.

**BCC-78A.** Basal cell carcinoma of the right medial canthus. This red, scaling lesion had been treated for many years as a form of eczema. Biopsy was eventually performed when the patient was seen by his dermatologist, and it revealed basal cell cancer.

**BCC-78B.** Defect following Mohs micrographic surgery.

**BCC-78C.** Two weeks after placement of a full-thickness skin graft.

**BCC-78D.** After complete healing of skin graft.

**BCC-78E.** Recurrent basal cell carcinoma at upper edge of graft 10 years after original surgery.

**BCC-79.** Multiple basal cell carcinomas in a severely sun-damaged patient. Compare this clinical presentation with that in [Figure BCC-25](#), [Figure BCC-26](#), [Figure BCC-27](#), [Figure BCC-28](#), and [Figure BCC-29](#). Surgery and radiation therapy are generally the only treatments currently available. Photodynamic therapy, incorporating the use of topical aminolevulinic acid, which avoids systemic adverse effects, holds promise for treatment of large numbers of lesions. The long-term benefit of this approach remains to be determined.

**BCC-80.** Multiple basal cell carcinomas in a patient who received radiation therapy for acne 50 years earlier. Any new therapeutic modality that is practiced on the skin today may yield unanticipated complications decades later. In most cases, it is difficult to anticipate what those effects might be, and the need for effective current management typically outweighs unknown delayed risks.
