A variety of cancer antigens are available. Multiple vectors can be used to provide immunization, including peptides, proteins, DNA, and a variety of recombinant viruses such as adenovirus, fowlpox virus, and vaccinia virus. When using these immunizing vectors, the vehicle can be important as well. It is possible to inject these vectors in saline and in a variety of adjuvants, such as incomplete Freund's adjuvant, QS21, or others. Similarly, these antigens can be presented on professional antigen-presenting cells, such as mature dendritic cells. The route of immunization is also a variable that must be considered (e.g., intradermal, subcutaneous, intramuscular, or intravenous injection). Immune adjuvants may increase the immune response to these immunogens, and studies exploring the use of IL-2, IL-7, IL-10, and IL-12 have been performed. Because of the myriad of possibilities for immunization of humans, substantial effort has been placed on elucidation in animal models of the general principles for vaccination against cancer antigens. Four general principles resulting from these murine studies are presented in [Table 18-18](#) and have guided the work in humans. A detailed discussion of cancer vaccines is presented in [Chapter 63.1](#) and [Chapter 63.2](#).

Immunizations most effective in generating reactive T cells are the most therapeutically effective.
Therapeutic efficacy of immunization is enhanced by the administration of interleukin-2 and -12.
The more immunogen the better.
Repeated boost immunizations with different vehicles containing the same antigen (i.e., to avoid immunization to the vehicle itself) is optimal.

**TABLE 18-18.** General Principles for Human Vaccination against Cancer Antigens Based on Animal Models

It is possible to immunize cancer patients against antigens present on their autologous cancers and raise high levels of circulating immune lymphocytes. [304](#), [305](#) and [306](#) An example of one such series of experiments in which 11 patients with metastatic melanoma were immunized with a modification of the gp100:209–217 epitope, from the gp100 melanoma antigens, which was modified with a methionine substitution in the 210 position, is shown in [Table 18-19](#).<sup>306</sup> The introduction of this amino acid modification greatly increased the binding of this peptide to the HLA-A2 molecule and thus appeared to increase both its *in vitro* and *in vivo* immunogenicity.<sup>307</sup> Despite the ability to reproducibly generate immune reactions against this tumor epitope, little antitumor effect was seen unless IL-2 was simultaneously injected. In pilot human trials, it appeared that the response rate to immunization with the gp100 209–217 (210M) epitope plus the administration of IL-2 resulted in response rates almost three times greater than that due to IL-2 alone.<sup>308</sup> However, the confirmation of this result will require evaluation in prospective randomized trials in which patients are treated with either IL-2 alone or IL-2 plus the peptide immunogen.

Patient	Age	Sex	Pre-Immunization			Post-Immunization		
			CD4+	CD8+	HLA-DR+	CD4+	CD8+	HLA-DR+
1	42	M	1500	500	1500	1800	500	1500
2	55	F	1200	400	1200	1500	400	1200
3	68	M	1000	300	1000	1300	300	1000
4	72	F	900	250	900	1100	250	900
5	58	M	1100	350	1100	1400	350	1100
6	65	F	1300	450	1300	1600	450	1300
7	70	M	1400	550	1400	1700	550	1400
8	50	F	1100	350	1100	1400	350	1100

## ADOPTIVE IMMUNOTHERAPY

Adoptive immunotherapy—the transfer to the tumor-bearing host of cells with antitumor activity—has substantial therapeutic attractiveness as an approach to treating human cancer.<sup>308,309,310</sup> and <sup>311</sup> Early cell-transfer experiments in animals demonstrated that the cellular arm of the immune response is crucial in mediating the rejection of allogeneic grafts and syngeneic tumors. In most experimental systems, the transfer of immune cells, but not of antibody directed against cellular antigens, produces immunity to tissue transplantations.

The major obstacle to the development of successful adoptive immunotherapies for the treatment of cancer in humans has been the inability to develop immune cells with specific reactivity for human tumors that could be obtained in large enough numbers for transfer to tumor-bearing patients. However, several new approaches have been developed for generating human cells with reactivity to tumor.

Beginning in 1980, Rosenberg and colleagues<sup>312,313</sup> and <sup>314</sup> described a technique for generating lymphoid cells from mice and humans that were capable of lysing fresh tumor cells but not normal cells. The incubation of resting murine splenocytes or human peripheral blood lymphocytes with IL-2 for 3 to 4 days generates LAK cells that can lyse fresh tumor cells.

The characteristics of LAK cells have been extensively studied.<sup>314,315</sup> and <sup>316</sup> These cells represent a lytic population distinct from NK cells or CTLs, and their phenotypic surface markers are characteristic of non-MHC-restricted killer cells. LAK cells can be CD3+ or CD3–, are nonadherent, and bear NK-like markers such as CD16 and CD56. The nature of the determinants recognized on fresh tumor targets by LAK cells is unknown, although the determinants appear to be broadly expressed on fresh and cultured tumor cells and in cultured normal cells. Fresh normal cells do not appear to bear cell surface determinants recognized by LAK cells.

After the description of the LAK cell phenomenon, animal studies evaluated the use of LAK cells in the adoptive immunotherapy of established tumors. These studies demonstrated that the adoptive transfer of LAK cells in conjunction with IL-2 could mediate the regression of established pulmonary, hepatic, and subdermal metastases in a variety of animal models.<sup>317,318</sup> IL-2 stimulated *in vivo* expansion of LAK cells with maintenance of cellular function.<sup>319</sup>

Based on these *in vitro* studies and animal models, clinical protocols were developed for the systemic administration of LAK cells plus IL-2 to patients with advanced cancer.<sup>309</sup> Results from a prospective randomized trial in the National Cancer Institute's Surgery Branch comparing treatment of patients with metastatic melanoma or renal cancer using either IL-2 or LAK cells plus IL-2 revealed no difference in survival.

## TUMOR-INFILTRATING LYMPHOCYTES AND INTERLEUKIN-2

TILs are lymphocytes that infiltrate growing tumors and can be isolated by growing single-cell suspensions from the tumor in IL-2.

In animals, the adoptive transfer of TILs can be from 50 to 100 times as potent as LAK cells in mediating the regression of established micrometastases.<sup>254</sup> TILs have been isolated from virtually all types of human tumors and can recognize tumor-associated antigens.<sup>320,321,322,323,324,325,326,327,328,329,330,331,332,333,334,335,336,337,338,339,340,341,342,343,344,345</sup> and <sup>346</sup> Based on these *in vitro* and *in vivo* studies, pilot trials of TILs for the treatment of advanced cancers in humans have been conducted.<sup>290,291</sup> and <sup>292</sup> The results of a pilot trial studying patients with metastatic melanoma treated with TILs in the National Cancer Institute's Surgery Branch are presented in [Table 18-20](#).

Patient Status	NR	Objective Response		Rate (%)
		(PR + CR)	PR + CR (all)	
No previous IL-2				
IL-2 + CY	26	14	14/140	35
IL-2 (no CY)	12	6	6/18	33
Previous IL-2				
IL-2 + CY	11	6	6/17	35
IL-2 (no CY)	8	3	3/11	27

CR, complete response; CY, cyclophosphamide; IL, interleukin; NR, no response; PR, partial response.

**TABLE 18-20.** Treatment of Patients with Melanoma with Tumor-Infiltrating Lymphocytes

TILs traffic to and accumulate in tumor deposits. This finding led to attempts to genetically alter TILs to increase their antitumor activity at the tumor site. In an initial phase of this effort, TILs transduced with the gene for neomycin phosphotransferase were infused into patients with advanced melanoma, as were TILs transduced with the gene for TNF.<sup>310,347,348</sup> This study and additional efforts to develop gene therapies for patients with cancer are considered in [Chapter 62.1](#). Improved methods for developing lymphocytes with antitumor activity by *in vitro* sensitization with tumor-specific peptides, as well as the use of cloned cells, are under development and may provide valuable reagents for use in future adoptive immunotherapy studies.<sup>349,350,351</sup> and <sup>352</sup>

#### INTRODUCTION

Medical oncologists prescribe and administer those drugs with the narrowest therapeutic index in all of medicine. Thus, understanding variability in toxicity and response is of utmost importance. Such variability can be divided into two components, pharmacokinetics and pharmacodynamics. Pharmacokinetics, the relationship between time and plasma concentration ([Fig. 19.1-1](#)), is concerned with understanding issues such as metabolism and excretion. It can be simply described as “what the body does to the drug.”

**FIGURE 19.1-1.** A representative pharmacokinetic profile relating time and concentration. The area under the concentration-time curve (AUC) is shaded.

The clinical interpretation of pharmacokinetic results requires another set of information, the relationship between plasma concentrations (or dose as a surrogate) and effect, or pharmacodynamics ([Fig. 19.1-2](#)). This can be described as “what the drug does to the body.” The understanding of anticancer pharmacodynamics has increased dramatically, although most studies that have successfully correlated concentration with effect have focused on toxicity end points. <sup>1</sup>

**FIGURE 19.1-2.** A representative pharmacodynamic profile relating concentration and effect. The concentration at which there is half-maximal effect ( $EC_{50}$ ) is indicated. Note that the concentration-response curve is steepest around the  $EC_{50}$  and is relatively flat at both low and high concentrations.

It has become fashionable to conduct clinical pharmacology studies in conjunction with early clinical trials of new anticancer agents, even in multiinstitution (i.e., Cooperative Group) studies. Such studies may have as their objectives pharmacokinetic or pharmacodynamic end points, or both. In phase I trials, the primary pharmacologic objective is to define the pharmacokinetics to optimize scheduling and dosing for subsequent studies. Pharmacodynamic end points are generally secondary, unless an adequate number of patients are studied at or near the recommended phase II dose. Phase II trials offer a different opportunity, because generally all patients are treated at the same dose. Thus, variability in toxicity or response may potentially be related to variability in pharmacokinetics. <sup>2</sup> In addition, population pharmacokinetic studies can be conducted at this phase, with a relatively large patient base, sparse sampling (one to four samples per patient), and the implementation of sophisticated modeling programs.

#### PHARMACOKINETICS: FUNDAMENTAL PRINCIPLES

The study of pharmacokinetics is classically considered to consist of four aspects: absorption, distribution, metabolism, and excretion. Each of these issues is

addressed in their general aspects, and specific examples are given as appropriate.

## ABSORPTION

Because most anticancer drugs are administered intravenously, most oncologists have only infrequently dealt with those issues specific to the clinical pharmacology of orally administered agents.<sup>3</sup> The term *absorption* has historically implied transport across the intestinal mucosa, although it has been recognized that the intestinal mucosa is important in xenobiotic metabolism.<sup>4,5</sup>

The degree of absorption can be expressed as the bioavailability, which in practice is determined by comparing the area under the concentration-time curve (AUC) after oral administration to the AUC after intravenous administration. A low bioavailability can be due to either poor absorption per se, or high first-pass metabolism.<sup>6,7</sup> In addition, the presence of transport proteins in the gut, such as P glycoprotein, also impact on the oral bioavailability of anticancer agents.<sup>8</sup>

Alteration in gastrointestinal absorptive capacity can be due to a variety of factors common in patients with cancer. Recent surgery may influence absorption, as demonstrated in regard to UFT (tegafur, uracil, and 5-fluorouracil) administration in the early postoperative period after partial gastrectomy.<sup>9</sup> Prior chemotherapy can be a major issue, and diminished absorption may be present in the absence of clinical gastrointestinal toxicity.<sup>10</sup> Concomitant medications affecting gastrointestinal motility, such as opiates or metoclopramide, may also be a factor.<sup>11</sup> It also should be recognized that cytotoxic chemotherapy may alter plasma concentrations of other medications given on a chronic basis, such as phenytoin or verapamil.<sup>12,13</sup>

Absorption also must be considered in regard to subcutaneous or intramuscular dosing. Although bioavailability via these routes is usually close to 100%, there may be decreased bioavailability due to local drug degradation or other factors.<sup>14</sup>

## DISTRIBUTION

Drugs usually distribute after administration from the plasma into extracellular and intracellular fluids. If a hypothetical drug were given as a 100-mg instantaneous bolus, the initial concentration would be 100 mg divided by the volume of distribution (the higher the volume, the lower the initial concentration). Subsequent concentrations would then be determined by the drug's rate of elimination. In the simplest pharmacokinetic model, the clearance is equal to the product of the volume of distribution and the elimination rate constant.

In actuality, distribution is much more complex. A drug's pharmacokinetics can be described by one or more interconnected compartments, and distribution is then represented by drug moving from the "central" compartment to a "peripheral" compartment (Fig. 19.1-3). This description is important for several reasons.

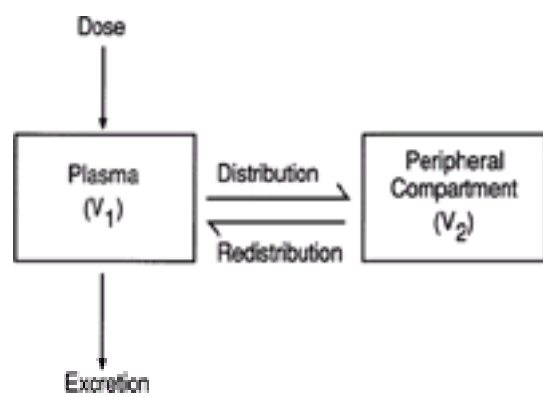

FIGURE 19.1-3. A schematic diagram of a standard two-compartment pharmacokinetic model. V, volume.

Because the central compartment is usually plasma, the site of action is probably more closely related to a peripheral compartment (i.e., intracellular fluid). Thus, plasma concentrations may be falling as the pharmacologic effect increases (Fig. 19.1-4). This inverse relationship may be compounded further for anticancer drugs by the known delay between the cytotoxic event and its clinical manifestations.

FIGURE 19.1-4. A reverse hysteresis loop representing the relationship between concentration, time, and pharmacologic effect (e.g., DNA damage). The plasma concentration rises during the period of drug administration (i.e., 24-hour infusion). The plasma concentration falls immediately after the infusion ends, but the tumor concentration continues to rise (due to distribution). Thus, the maximal effect occurs later than the end of the infusion (maximal plasma concentrations). Although the same plasma concentration occurs both during infusion and after infusion, the effect is greater when the concentration is falling.

In general, drug that distributes to the peripheral compartments eventually redistributes back to the plasma or central compartment. Drugs that are extensively distributed usually have a long terminal half-life, which can be highly dependent on the rate of redistribution. Such drugs are often highly protein-bound. This can have important clinical ramifications for highly schedule-dependent agents such as methotrexate, which distributes to "third spaces" such as pleural effusions or ascites.

## METABOLISM

Metabolism is the most critical and complex aspect of pharmacokinetics for most agents. The great majority of xenobiotic metabolism takes place in the liver, although cytochrome P-450 enzymes and uridine diphosphate–glucuronosyltransferases are present in the small bowel,<sup>5,15</sup> and both carboxylesterases<sup>16</sup> and deaminases<sup>17</sup> are present in plasma and other tissues.

Xenobiotic metabolism can be divided into phase I and phase II reactions<sup>18</sup> (Table 19.1-1). Phase I reactions are oxidative, or reductive, reactions and include the P-450 system. Phase II reactions are conjugative reactions, such as acetylation and glucuronidation. Phase I reactions usually make a drug more susceptible to phase II reactions, which generally produce molecules amenable to biliary or renal excretion. These metabolic reactions evolved for the purpose of xenobiotic detoxification, but can also result in drug activation.

Enzyme	Substrate	Polymorphic
<b>Phase I reactions</b>		
<b>Cytochrome P-450</b>		
CYP1A1	Benzocyclopentadiene	X
CYP2A6	Theophylline, caffeine	X
CYP2B6	Cyclophosphamide	
CYP2C8	Fallic acid	X
CYP2C9	Phenytoin, warfarin	X
CYP2C19	Omeprazole, esomeprazole	X
CYP2D6	Codeine, promethazine	X
CYP3A4	Etoposide, vinca alkaloids, irinotecan, docetaxel, irinotecan	X
<b>Non-cytochrome</b>		
Aldehyde dehydrogenase	Aldehyde dehydrogenase	
Carboxylesterase	Aldehyde dehydrogenase	
Dihydropyridinase dehydrogenase	5-Fluorouracil	X
<b>Phase II reactions</b>		
<b>Glucuronidation</b>		
UGT1A1	Irinotecan, SN-38	X
<b>Glucosylation</b>		
UGT2B7	Morphine, epinephrine	X
<b>Hydroxylation</b>		
CYP2C8	6-Mercaptopurine, azathioprine	X

**TABLE 19.1-1.** Selected Drug-Metabolizing Enzymes of Importance in Oncology

An area of rapidly increasing importance is genetically determined variability in drug-metabolizing enzymes.<sup>18</sup> Such genetic variability can result in enhanced toxicity because of impaired detoxification,<sup>20</sup> enhanced activation,<sup>21</sup> or lack of desired effect due to impaired activation.<sup>22</sup> Furthermore, genetically determined variability may also be a risk factor for carcinogenesis.<sup>23</sup> A number of distinct drug-metabolizing enzymes have been conclusively demonstrated to be polymorphic (see [Table 19.1-1](#)).

An individual's metabolic capacity can also be affected by a variety of other factors, such as hepatic dysfunction, nutrition, and other medications.<sup>18</sup> These are all factors that are highly variable in patients receiving chemotherapy.<sup>24,25</sup>

Phase I metabolism (i.e., the P-450 system) appears to be more sensitive to hepatic dysfunction than phase II enzymes (i.e., glucuronidation).<sup>26,27</sup> Although oncologists generally monitor liver function tests during chemotherapy, the serum bilirubin (the most commonly used measure) is a very insensitive measure of changes in plasma drug clearance. Malnutrition, like hepatic dysfunction, may result in decreased synthesis of drug-metabolizing enzymes, decreased clearance, and enhanced toxicity.<sup>25,28,29</sup> and [30](#)

One of the most important considerations with regard to the elimination of anticancer drugs is the effect of other medications. Cancer patients receive a large number of medications that can affect metabolism (and excretion) of concomitant chemotherapy ([Table 19.1-2](#)). Given the complexity of most treatment regimens (multiple cytotoxic agents, antiemetics, analgesics, anticonvulsants, corticosteroids), relatively few specific data are available in this regard.

Inhibition of CYP3A4 by ketoconazole, itraconazole, erythromycin, clarithromycin, or grapefruit juice may result in decreased clearance of etoposide, vinca alkaloids, or irinotecan or decreased activation of ifosfamide
Inhibition of glucuronosyl transferases by valproic acid may result in decreased clearance of SN-38 (active metabolite of irinotecan)
Inhibition of xanthine oxidase by allopurinol may result in decreased clearance of 6-mercaptopurine
Induction of CYP3A4 by corticosteroids, phenytoin, phenobarbital, rifampin, cyclophosphamide, or ifosfamide may result in enhanced clearance of etoposide, vinca alkaloids, or irinotecan or enhanced activation of ifosfamide
Inhibition of biliary excretion by cyclosporine A (and other P-glycoprotein inhibitors) may result in decreased clearance of a wide range of agents
Inhibition of renal tubular secretion by probenecid, sulicylates or penicillins may result in decreased clearance of irinotecan, topotecan, or SN-38

**TABLE 19.1-2.** Potential Drug Interactions with Chemotherapy

## EXCRETION

There are two major routes of excretion, renal and biliary. Both are complex processes involving a chain of events, any of which can be modulated by disease processes or other medications.<sup>31,32,33</sup> and [34](#)

Xenobiotics may undergo filtration, secretion, and reabsorption on their journey from the glomeruli to the ureter. The creatinine clearance, either measured from a timed urine specimen or calculated based on a variety of formulas, is often used as a surrogate for the glomerular filtration rate (GFR), although these formulas have limited accuracy.<sup>35,36</sup> and [37](#) Furthermore, this surrogate may be used to describe an individual's overall renal function. Patients with reduced renal function should be considered for dose reduction if renal excretion is a major component of the agent's clearance.<sup>32</sup>

A great effort has been expended in trying to predict carboplatin pharmacokinetics.<sup>31,38,39</sup> and [40](#) The most accurate approach uses chromium-labeled EDTA (ethylenediamine-tetraacetic acid).<sup>41,42</sup> Simpler techniques, such as using a measured or calculated creatinine clearance, have inconsistently been predictive, because of the poor correlation between creatinine clearance and GFR.<sup>35,36</sup> and [37,43,44](#)

Physicians also commonly use a measured or estimated creatinine clearance to guide cisplatin dosing, primarily as a determinant of dose modifications from a standard body surface area (BSA)-adjusted dose. It is important to recognize that GFR is normally correlated with BSA, so that smaller patients appear to have poorer renal function, unless the GFR is also adjusted for the BSA (mL/min/m<sup>2</sup> or mL/min/1.73 m<sup>2</sup>).

Tubular secretion and reabsorption may also be important in drug excretion.<sup>45,46</sup> and [47](#) As an example, it has been suggested that cisplatin's reabsorption is saturable, resulting in enhanced proportional reabsorption when administered by infusion, potentially resulting in enhanced toxicity.<sup>48,49</sup> Methotrexate and topotecan<sup>50</sup> also undergo secretion and reabsorption in the renal tubules. Methotrexate's renal handling is highly influenced by the urinary pH,<sup>51</sup> and because it is a weak acid, alkalization results in enhanced excretion.

Biliary excretion involves a number of transport systems, including P glycoprotein, a known cause of multidrug resistance.<sup>33,34,52,53</sup> Another important system appears to be the more recently described multifunctional organic anion transporter, cMOAT (canalicular multispecific organic anion transporter).<sup>54</sup>

cMOAT is the primary transporter of SN-38, the active metabolite of irinotecan.<sup>55</sup> These systems can be inhibited by a variety of disease processes, as well as by other drugs (cyclosporine A, PSC-833) or formulants (Cremophor).<sup>56,57</sup>

After biliary excretion, reabsorption may take place in the small intestine, leading to an enterohepatic circulation.<sup>58,59</sup> This is particularly relevant for those drugs whose primary metabolite is a glucuronide, because of the presence of bacterial  $\beta$ -glucuronidases in the gut, which cleave off the glucuronide.<sup>60,61</sup>

The serum bilirubin is often used to determine dose modifications for hepatically cleared drugs. However, this is only a marker of impaired excretion, and it is poorly correlated with impaired metabolism. (Metabolism may be better represented by measures of synthetic function, such as serum albumin.)

## PHARMACOKINETICS: WHAT'S IMPORTANT TO THE CLINICIAN?

## CLEARANCE

The generation of pharmacokinetic data is easy, but its interpretation can be quite overwhelming, especially to a clinician attempting to apply such data to a particular patient or study. A good starting point is the assessment of total plasma clearance. Clearance can be calculated in one of two ways: either by measurement (or estimation) of the AUC after a single dose (see [Fig. 19.1-1](#)), or by determination of the steady-state concentration ( $C_{ss}$ ) during continuous infusion.

$$\text{Clearance} = \frac{\text{dose}}{\text{AUC}}$$

or

$$\text{Clearance} = \frac{\text{dose rate}}{C_{ss}}$$

Although the absolute value of the clearance may be of some interest to the pharmacologist, the clinician should be primarily concerned with variability in clearance, best represented as the coefficient of variation (CV), the ratio of the standard deviation (not standard error) to the mean. The CV may be as low as 10% to 20% for drugs with low variability, or as high as 75% to 100% for drugs with high variability. Most drugs have a CV in the 20% to 40% range.

After understanding the extent of variability, the next question is to explain it, particularly if the CV is quite large. This becomes even more relevant if patients with a low clearance have an increased risk of toxicity. Drugs with a very high CV should be closely studied for genetically determined polymorphisms of the primary metabolizing system.<sup>62,63</sup>

Another important source of variability is saturation of the major metabolic or excretory site. If saturation occurs at clinically relevant concentrations, the clearance generally decreases dramatically at higher doses, and the drug is considered to have nonlinear pharmacokinetics. Optimal administration of such drugs requires a full understanding of the complexities involved, as well as the potential effects of disease and other medications.

In assessing variability in AUC or clearance, variability in protein binding may be an important issue. The degree of protein binding may range from negligible to more than 99%. Only the free (unbound) drug is active, whereas conventional assays quantitate the total (free plus bound) drug. If significant variability in protein binding is found for a highly bound drug, it may be difficult to interpret plasma concentrations without directly measuring the free drug or extent of protein binding. For some agents, however, such as etoposide, it may be possible to estimate protein binding from simple parameters, such as serum albumin, bilirubin, and age.<sup>64,65</sup>

A potential source of variability that has been greatly exaggerated in oncology practice is variability in body size. Minimal data support the dosing of chemotherapy on the basis of BSA in adults. Because size may have no significant correlation with clearance, this practice may even increase the extent of variability in AUC.<sup>66,67,68</sup> and <sup>69</sup> Further studies of this important issue are needed, if only to decrease the complexity of oncology practice.

## HALF-LIFE

For highly schedule-dependent drugs, variability in half-life may be more important than variability in clearance. Although half-life and clearance are generally inversely correlated, an increased half-life may also be a consequence of an increased volume of distribution. This may have significant consequences, as has been well established for methotrexate's distribution into ascites or pleural effusions.<sup>70</sup>

Variability in half-life influences variability in time above any specific plasma concentration. This finding is becoming increasingly well recognized as an important factor in both toxicity and response.<sup>71,72</sup>

Knowledge of the half-life may also be important for protocol designs, because schedule-dependent drugs with short half-lives (e.g., cytarabine, 5-fluorouracil) might be best administered by continuous infusions or frequent dosing. It may also be critical to know the half-life for estimating when plasma cytotoxic activity is negligible in the context of peripheral stem cell reinfusion or colony-stimulating factor administration.<sup>73,74</sup>

## ACTIVE METABOLITES

Although metabolism generally results in detoxification, some drugs may have active circulating metabolites ([Table 19.1-3](#)). These include drugs that are true prodrugs, having no intrinsic cytotoxic activity, and drugs that have metabolites with comparable or greater cytotoxicity to the parent. It is also important to understand the pathways through which activation occurs. There may be theoretical advantages to enhancing or inhibiting formation of the active metabolites, which may have a different "therapeutic index" (ratio of beneficial to harmful effects) than the parent drug. This alteration of active metabolite formation can potentially be accomplished by the use of inhibitors (e.g., ketoconazole) or inducers (i.e., phenobarbital) of specific drug-metabolizing enzyme systems.<sup>75,76</sup> Finally, an identifiable genetic basis for differences in activation may exist, which leads to different effects in specific patient populations.<sup>22</sup>

**TABLE 19.1-3. Oncology Drugs with Active Circulating Metabolites**

## ROUTES OF ELIMINATION

Oncologists are generally well aware of the potential for drug elimination to be impaired in patients with end-organ dysfunction. However, relatively little information is available to guide dose modifications. Even if a physician knew an individual's clearance before dosing, it would be difficult to predict the extent of toxicity because of the risk of prolonged low concentrations (for schedule-dependent drugs) or concomitant pharmacodynamic factors (resulting in enhanced sensitivity, such as malnutrition).

The only generalization that can be made is that variability increases as end-organ dysfunction develops. Formal phase I studies are warranted in patients with end-organ dysfunction.<sup>77,78</sup> and <sup>79</sup>

## BASIC METHODOLOGY OF PHARMACOKINETIC STUDIES

The first pharmacokinetic studies of a new agent are almost always conducted in conjunction with phase I studies. Proper conduct of such studies requires a great deal of planning, as well as technical and logistical expertise. Data from preclinical studies are critical in the design. These generally include evaluations of *in vitro* cytotoxicity, preclinical pharmacokinetics, *in vitro* metabolism, *in vitro* toxicology (myelosuppression), and whole-animal toxicology.

Pharmacokinetic data can be collected using either intensive or sparse sampling strategies. In the first pharmacokinetic studies, intensive sampling is used to try to model each individual's pharmacokinetics. Data from all patients can be combined in two basic ways: either with a simple descriptive summary (mean  $\pm$  standard deviation) of the fundamental parameters, or by pooling all data into a single analysis. The latter approach requires a high level of statistical and computational sophistication, but may generate insights not available by other means.<sup>80</sup>

It is also useful to begin to plan subsequent pharmacologic studies in the context of the initial pharmacokinetic analysis. These subsequent studies are often primarily concerned with pharmacodynamic issues, relating toxicity or response to pharmacokinetic variables. Such studies benefit greatly from the use of optimal sampling strategies, in which only a few samples are collected on each patient.<sup>81,82,83,84,85,86 and 87</sup>

## PHARMACODYNAMICS

### FUNDAMENTAL PRINCIPLES

The fundamental objective of pharmacodynamic studies is understanding variability in effect.<sup>24</sup> In phase I trials, the primary objective is to understand variability in effect (toxicity) as a function of dose. The investigator can also begin to understand the relationship between pharmacokinetic end points (i.e., AUC) and effect.

However, because phase I trials encompass multiple doses, dose is correlated with AUC (and other end points), and relationships between AUC and effect are confounded if the dose range is wide.<sup>88</sup> Thus, phase II trials in which all patients receive a single drug at a fixed dose offer an important opportunity to correlate pharmacokinetic end points (due solely to pharmacokinetic variability) and effect (both toxicity and response).<sup>2</sup>

Since the 1980s, a progressively increasing number of studies have been published that have included pharmacodynamic end points.<sup>1,24,88,89</sup> Such studies primarily have used AUC or  $C_{ss}$  as the pharmacokinetic parameter, and blood count nadirs as the pharmacodynamic end point. More recently, several studies have demonstrated that time above a threshold concentration is an important pharmacokinetic parameter, which is consistent with the understanding that schedule is an important determinant of antineoplastic drug action.<sup>71,72,90</sup>

### METHODOLOGIC ISSUES

The methodology for pharmacodynamic studies should use generally recognized outcomes. Historically, blood count nadirs have been used, although this approach has several limitations. Nadir blood counts, by definition, measure the lowest observed blood count, which is highly dependent on the number of observations. In addition, nadir blood counts are not useful in the context of high-dose chemotherapy. Thus, it is potentially desirable to incorporate all blood counts and to use a methodology robust enough to properly analyze missing data.<sup>91,92,93 and 94</sup>

Nonhematologic toxicity is an even more difficult problem, as it is often graded rather than continuous, and subjective rather than objective. Statistical methodologies appropriate for such end points are necessary, such as logistic regression and its variants.<sup>88</sup>

The "holy grail" of antineoplastic clinical pharmacologists is to correlate pharmacologic end points with response. Although examples of plasma clearance being correlated with response are available,<sup>95,96 and 97</sup> it is likely that variability in response is primarily due to tumor factors (i.e., intrinsic drug resistance) rather than patient factors (i.e., altered clearance).<sup>98,99</sup>

Another major challenge is to expand the knowledge of anticancer pharmacodynamics from single agents to combinations. Such studies are logistically difficult, because plasma samples must be collected at times appropriate for each of the drugs in the regimen. Some work in this area has been done with regard to the effect of a second drug on carboplatin-induced thrombocytopenia.<sup>100,101 and 102</sup>

## RATIONAL USE OF PHARMACOKINETIC AND PHARMACODYNAMIC DATA IN CLINICAL ONCOLOGY

Although oncologists may have difficulty exactly defining pharmacokinetics and pharmacodynamics, many of the important principles are incorporated into oncology clinical practice. By understanding that the principles are not foreign, the oncologist can better use principles of clinical pharmacology to optimize dosing of these highly toxic agents.

### DOSE MODIFICATION FOR TOXICITY

It is common practice to reduce drug dosages for excessive toxicity. But a variety of reasons may be responsible for excessive toxicity, which can generally be categorized as either pharmacokinetic or pharmacodynamic (Table 19.1-4). It is important to understand this distinction. If one assumes that decreasing drug exposure (AUC) reduces the likelihood of response, then dose reduction may be inappropriate for patients with increased toxicity on a pharmacodynamic basis, whereas patients with altered clearance can be dose-reduced yet maintain an acceptable AUC (Fig. 19.1-5). Hypothetically, patients with normal clearance but excessive toxicity might be best served by a change in treatment (or discontinuation of treatment if no alternative is available), rather than reduction to what might be a subtherapeutic AUC.

TABLE 19.1-4. Pharmacokinetic and Pharmacodynamic Determinants of Chemotherapy Toxicity

**FIGURE 19.1-5.** Comparison of effect of altered pharmacokinetics and pharmacodynamics on toxicity and tumor concentrations. Alteration of pharmacokinetics (**B**) compared to an average patient (**A**) results in enhanced toxicity due to an increased area under the concentration-time curve (AUC), whereas altered pharmacodynamics (**C**) may result in enhanced toxicity at an average AUC. Dose reduction in the former case (**B**) results in an average tumor AUC, whereas in the latter case (**C**), the tumor AUC may be subtherapeutic.

## DOSE MODIFICATION FOR IMPAIRED CLEARANCE

It is common practice to assess hepatic and renal function (as appropriate for specific drugs) before initial (and subsequent) treatment. Such dose modifications are encouraged but are generally empiric with a few exceptions (e.g., carboplatin, topotecan, paclitaxel). For other drugs, it may be obvious that a dose reduction is necessary, but the appropriate degree of reduction may be unclear. It is also important to understand that the serum bilirubin, which is commonly used to screen for hepatic dysfunction, is insensitive, and it should be complemented by measures of synthetic function, such as albumin.

## DOSE MODIFICATION FOR ALTERED PHARMACODYNAMICS

It is well accepted that heavily pretreated patients have a lower chance of response. For the most part, this is due to altered pharmacodynamics (increased sensitivity to myelosuppressive chemotherapy coupled with tumor resistance). If one proceeds with myelosuppressive therapy in this situation, a high degree of toxicity should be expected. Thus, it is common to prospectively reduce doses to prevent such toxicity. It is also not surprising that achieving responses is very difficult in this setting, because the patient's tolerance is less while the tumor's "tolerance" has increased.

Other situations may be much less clear. In such cases, determination of the patient's pharmacokinetics may be useful (in theory) in deciding whether dose adjustment is appropriate, while aiming to avoid undertreatment (based on AUC) of the patient. Some evidence indicates that there are pharmacogenetic determinants of cellular susceptibility to cytotoxic agents. Thus, one consideration in the management of patients with unexplained toxicity is to change the treatment (hypothesizing that the patient has unique cellular susceptibility), rather than reducing the dosages.

## ADAPTIVE CONTROL OF CHEMOTHERAPY

In most fields of medicine, the dosing of drugs with a relatively narrow therapeutic index is carefully monitored and controlled.<sup>103,104 and 105</sup> Examples include antibiotics (e.g., aminoglycosides, vancomycin), psychotropic medications (e.g., lithium carbonate), anticonvulsants (e.g., phenytoin, carbamazepine, phenobarbital), cyclosporine A, and antiarrhythmics (e.g., digoxin, quinidine). Why has this approach not been widely implemented for cytotoxic chemotherapy, which inarguably has a narrow therapeutic index?

The major difference is that cytotoxic drugs are administered infrequently and usually in combination (with overlapping side effects). It is generally believed that higher doses are more effective; thus, any attempt to individualize dosing would attempt to deliver the maximal dose tolerated by each individual patient. This approach has been applied in research settings, with varying degrees of success ([Table 19.1-5](#)).

Drug	End Point	References
Etoposide	Predicted nadir WBC	118, 119
Amonafide	Predicted nadir WBC	120
Hexamethylene bisacetamide	Predicted nadir platelet count	121, 122
5-Fluorouracil	Predicted AUC	123
Methotrexate, cytarabine, teniposide	Target concentration range	97, 124
Busulfan	Target concentration range	125-127
Suramin	Target concentration range	128-132
Phenylacetate	Target concentration range	133

AUC, area under the concentration-time curve; WBC, white blood cell count.

**TABLE 19.1-5.** Studies of Therapeutic Drug Monitoring (Adaptive Control) in Oncology

Investigators have used a variety of approaches to individualize dosing of cytotoxic drugs. These include using a target concentration or AUC, a target percentile, individualization based on both concentration and pharmacodynamic factors, and individualization based on metabolism of a probe drug. These studies have yielded important insights into the understanding of the potential importance of pharmacokinetic and pharmacodynamic variability. However, adaptive control remains a research tool. Analysis of methotrexate levels after high-dose methotrexate is still the only generally accepted use of plasma level monitoring in clinical oncology.<sup>106</sup>

## MODULATING DRUGS

The use of biochemical modulators of chemotherapy has a long history. Such an approach has been used to enhance the cytotoxicity of a specific agent (e.g., leucovorin with 5-fluorouracil) or to overcome drug resistance. Such modulators have generally been used to affect the pharmacodynamics of one or more agents.<sup>107</sup>

Modulators can also be administered because of pharmacokinetic issues. Leucovorin is commonly dosed on the basis of methotrexate levels.<sup>108</sup> But drugs have not yet been routinely used in oncology to specifically affect the pharmacokinetics of another agent.

The first decade of the twenty-first century will probably bring such approaches into mainstream oncology, driven both by technological and cost issues. For example, ketoconazole is now widely used with cyclosporine to improve its bioavailability, thus reducing the overall cost of cyclosporine therapy.<sup>109,110</sup> A similar approach has been applied to oral anticancer agents, using cyclosporine (an inhibitor of CYP3A4 and P glycoprotein) to increase the oral bioavailability of paclitaxel.<sup>111</sup> The ongoing development of inhibitors of dihydropyrimidine dehydrogenase may allow 5-fluorouracil to be effectively administered orally.<sup>112,113,114 and 115</sup>

Pharmacokinetic modulators may also be beneficial to reduce toxicity, if there is more than one route of elimination. As an example, it has been suggested that cyclosporine A may ameliorate irinotecan-induced diarrhea by inhibiting biliary excretion of the toxic metabolite SN-38.<sup>116,117</sup>

## ORAL ADMINISTRATION

A resurgence of interest has been seen in oral administration of cytotoxic chemotherapy. If successful, this route of administration may be more acceptable to patients and potentially be cost effective as well.<sup>3</sup> Prolonged oral administration will allow a more detailed evaluation of specific drugs, but will introduce new complexities caused by diet, drug interactions, and compliance. Oncologists should become familiar with these issues and master a general understanding of interpatient and intrapatient variability in bioavailability.

#### INTRODUCTION

More than five decades of research effort in cancer drug discovery and development have provided approximately six dozen approved products for the treatment of malignancy.<sup>1,2</sup> Although major advances have been made in the chemotherapeutic management of some patients, particularly in hematologic malignancies, one-half of all cancer patients either do not respond to therapy or relapse from the initial response and ultimately die from their metastatic disease. Thus, the continued commitment to the arduous task of discovering new cancer therapeutic agents remains critically important.<sup>3</sup> Many of the existing antineoplastic agents share a common mechanism of action. Current research efforts are more diverse than ever, being driven by explosive discoveries in molecular biology and related areas to fully elucidate the development of the malignant process (e.g., factors controlling tumor angiogenesis and metastatic potential). The hope for improvement in treatment outcome for most patients with metastatic disease resides in continued research designed to discover novel therapeutic products that exploit differences in molecular targets between normal and tumor cells and to use them in combination with biologic agents and immune therapies to eradicate systemic disease not curable by surgery or irradiation.

Beyond the intellectual challenge of drug discovery, formidable effort, time, and expense are required for the complex development processes that move a new agent from discovery to its ultimate approval for use in the treatment of malignancy. Numerous pitfalls may threaten the progress of a promising agent (e.g., excessive early toxicity, ineffective route or schedule of administration, inappropriate formulation, long-term unpredicted toxicities, and delays in the execution of clinical trials). Although the time to drug approval for the treatment of cancer has varied considerably, depending on the specific agent (e.g., 6 to 12 years from the time of initiation of clinical trials), efforts are being made to expedite both the preclinical and clinical components of investigation. In other areas of medicine, the time to develop specific drugs may be equally long and difficult. However, the potentially fatal consequences of unsuccessful treatment of this disease continue to impart urgency in the discovery and development of novel anticancer agents.

#### DRUG DISCOVERY

##### HOW DRUGS ARE DISCOVERED

This section considers strategies for identifying new chemical entities, whether they be synthesized chemicals or compounds extracted or derived from plant, microbial, and marine animal sources. The parallel process for discovery and development of biologic agents is discussed elsewhere in this text. (See [Chapter 18.](#))

In establishing a program for drug discovery, cancer researchers must address two fundamental questions: What screening system should be used to detect a compound of interest? What compounds should be tested in this system? The answers to these questions determine whether the research effort is empiric, with few preconceived notions about where to search for compounds and what to use as the screen, or whether it focuses on a specific biologic target, such as an oncogene, and tests a specific set of materials, such as natural products and rationally synthesized inhibitors of a target enzyme. The history of cancer drug discovery reflects an evolution from highly empiric approaches, based on testing of randomly selected compounds against rapidly proliferating murine leukemia, to the current, more focused testing of natural products, rationally synthesized agents, and biologic products against well-characterized tumor cell lines or molecular targets. Even in its earliest days, however, cancer drug discovery attracted scientists who had a theoretical basis for testing certain types of compounds. Perhaps the two best examples are the antifolates, initially tested by Farber et al.,<sup>4</sup> and the fluoropyrimidines synthesized by Heidelberger and colleagues<sup>5</sup> (see [Chapter 19.5](#)).

The story of the discovery of antifolates is particularly instructive because it illustrates the important interplay between cancer biology and drug discovery. The earliest uses of an antifolate as a chemotherapeutic agent resulted from the astute observations of Farber and associates,<sup>4</sup> who observed an acceleration of the leukemic process in patients being treated with folic acid. A series of folic acid antagonists were provided to Farber and colleagues by the medicinal chemists at Lederle Laboratories. Although structure-activity relations of antifolates and the intracellular target of these compounds were unknown at that time, it was clear from laboratory studies that modified folates could inhibit tumor cell growth. The initial clinical trial involved the administration of pteroylaspartic acid (an analogue of folic acid, or pteroylglutamate) to a moribund patient with progressive acute myelogenous leukemia, which resulted in a markedly hypocellular bone marrow without actually producing clinical benefit. The investigators were sufficiently encouraged, however, to administer a more powerful folic acid antagonist, aminopterin (2,4-diaminopteroylglutamate), to children with advanced stages of acute leukemia. Substitution of an amino group at the 4 position of the folate pteridine ring created a tight-binding inhibitor of dihydrofolate reductase and yielded drugs with the potential to induce remissions. Approximately 10 of the first 16 patients treated with aminopterin demonstrated evidence of hematologic and clinical improvement. These early clinical experiences provided the foundation for medicinal chemists to synthesize a number of agents with structural similarities to naturally occurring folates. Moreover, these studies revealed that various substitutions resulted in different sites of action, in addition to inhibition of dihydrofolate reductase ( [Fig. 19.2-1](#)).

**FIGURE 19.2-1.** Structure of tetrahydrofolate and clinically useful antifolate compounds. (From Chabner BA, Collins JM, eds. *Cancer chemotherapy and biotherapy: principles and practice*. Philadelphia: Lippincott-Raven, 1996:112, with permission.)

From these relatively primitive beginnings, rational design efforts have progressed to the use of computer modeling of drug-enzyme interactions as the basis for

cancer drug discovery. Advances in x-ray crystallographic and nuclear magnetic resonance structural characterization of ligands and their target molecules have significantly enhanced the potential for rational design and, as is described later (see the section [Molecular-Targeted Screening](#)), such research efforts are now beginning to identify effective small molecules with efficacy against various human malignancies. Symmetric inhibitors of the protease of human immunodeficiency virus type 1 that were designed on the basis of the three-dimensional symmetry of the active enzyme site are currently in clinical use, thus demonstrating the feasibility and merit of such an approach.<sup>6</sup>

In most current drug discovery efforts, the rational and empiric approaches are being combined. Lead compounds are identified as inhibitors for molecular targets through molecular screening.<sup>7</sup> The lead compound can then be modified or enhanced by chemical analogue synthesis based on a variety of considerations, including a detailed study of target-inhibitor interaction. The complete characterization of the target and its interaction with the lead agent provides the basis for enhancing drug-target interaction. A key decision in this approach is the selection of a suitable target that is likely to have an impact on clinical outcome (enzyme, growth factor receptor, or oncogene product). The next challenge is the development of an appropriate and practical assay to identify the actual lead agents.

Although early efforts in cancer drug discovery tested agents either from the broad universe of synthetic chemicals or from a more targeted rational effort, attention increasingly has focused on natural products as an important, untapped source of promising lead compounds with unique sites of action as antineoplastic drugs.<sup>8</sup> The enormous diversity and complexity of chemical entities that have evolved as part of nature's chemical warfare cannot be readily duplicated by compounds synthesized in the laboratory and be made available for screening. However, the technological advances in combinatorial approaches for synthesizing large numbers of complex substances have provided an entire new source for novel antineoplastic agents.<sup>9,10</sup> Combinatorial chemistry can provide two different kinds of libraries that can then be used for further drug development.<sup>11,12</sup> and <sup>13</sup> The first is a generic library, which is used to discover a novel structural motif or feature that possesses a certain biologic activity. The goal of such an unbiased library is to identify a completely novel lead compound. The second type is a focused, biased library that serves to fine-tune the properties and biologic activity of an existing lead compound. In this case, the objective is to identify new lead compounds based on known structures that have already proven to be biologically active.

Approximately 30% of the currently effective antineoplastic agents are from natural sources or are derivatives of a natural product lead.<sup>14</sup> Certain themes run through the efforts to discover and develop natural products. Active compounds often have exceedingly complex structures that complicate efforts at total synthesis. Problems of supply and dependence on a natural resource, therefore, must be anticipated. Structure-activity relations are difficult to elucidate because of the basic problems presented by the unusual chemistry of these compounds and by the multiple chiral centers in these molecules ( [Fig. 19.2-2](#)). However, the overall contribution of these complex chemical entities to the management of patients has been extremely rewarding.

**FIGURE 19.2-2.** Structure of Taxol. (From Chabner BA, Collins JM, eds. *Cancer chemotherapy and biotherapy: principles and practice*. Philadelphia: Lippincott-Raven, 1996, with permission.)

Among the natural products, microbial antibiotics have been the most important source of cytotoxic agents. As a result of the great advances in the field of microbiology during the 1940s and the dawn of effective antibiotic therapy, potent anticancer drugs were sought in fermentation broths obtained from soil microbes, including bacteria, fungi, and related organisms. The discoveries of the actinomycins, anthracyclines, bleomycin, deoxycoformycin, and other agents have contributed valuable new entities to the repository of effective antineoplastic agents. Natural product drug discovery, however, must be complemented by efforts to improve leads through chemical modification and analogue synthesis. The discovery and subsequent clinical development of anthracyclines highlights the need for the close interplay of chemistry, biology, and clinical pharmacology in producing improved anticancer agents.

Daunorubicin, isolated from a colony of *Streptomyces* in 1957, eventually was demonstrated to have significant antileukemic activity in patients.<sup>15</sup> Additional research to induce mutant strains of the fungus *Streptomyces* resulted in the isolation of doxorubicin. Although the difference between these two anthracyclines is limited chemically to a single hydroxyl group, a marked difference exists in their spectrum of antitumor activity. Doxorubicin has been more effective than daunorubicin in the treatment of metastatic solid tumors and sarcomas. The cardiac toxicity associated with the chronic administration of both these agents, however, has provided impetus to design a new generation of anthracycline analogues. The long-term assessment of clinical outcome for children successfully treated for malignancy further substantiates the concerns regarding anthracycline-induced cardiotoxicity.<sup>16</sup> None of these anthracycline analogues is devoid of cardiac toxicity, but closely related molecules may have significant advantages. For example, the anthraquinones (e.g., mitoxantrone) demonstrate less cardiotoxicity and have remission-inducing activity in acute nonlymphocytic leukemia.<sup>17</sup> Thus, in modifying the chemical structure of a natural product in an attempt to enhance its therapeutic selectivity, the synthetic organic chemist plays a critical role in this process of drug development.

Natural product research has yielded other effective antineoplastic drugs. Although most of these agents have been identified in fermentation broths of microbial organisms, plants also have provided a number of active antineoplastic agents. One of the earliest plant-derived drugs resulted from a chance observation. In the 1950s, Noble and colleagues<sup>18</sup> were investigating interesting plant extracts used by primitive peoples. This attempt to take advantage of tribal medications, primarily natural products, represented an early entree into the discipline known as *ethnopharmacology*.

The leaves of the Jamaican periwinkle plant, *Vinca rosea*, were used to make a tea that was reported to be of benefit in diabetes.<sup>18</sup> During the initial animal investigations, the extract of these leaves was administered orally to both rats and rabbits without any observed effect on blood sugar levels. Subsequent administration of the aqueous extract of the periwinkle plant by injection to rats had a dramatic lethal effect within a week. Postmortem examination of the animals demonstrated that the rats had died of sepsis related to bone marrow suppression. Isolation and chemical characterization of the responsible chemical factors were accomplished using a bioassay-guided approach (i.e., granulocytopenia in the treated animals) for identifying the effective component of this aqueous extract of the plant. The compound was determined to be an organic base and subsequently was called *vincaloblastine*. This agent demonstrated carcinostatic activity against both a transplanted murine mammary adenocarcinoma and a rat-transplanted sarcoma.<sup>18</sup> The mechanism of action (i.e., inhibition of microtubule formation) proved to be unique and provided the basis for an entirely new area of research for cancer drug development.

In contrast to using the complicated biologic end point of the peripheral blood granulocyte count from an intact animal, simple and more rapid screens (e.g., molecular target-based or *in vitro* cell cytotoxicity assays) currently are used to guide fractionation of extracts for isolation and characterization of active components. After final chemical identification of the plant-derived chemical antineoplastic entity, validation of antitumor activity in an *in vivo* tumor model is still required. Sufficient supplies of the active agents isolated from natural product sources are needed to conduct adequate *in vivo* confirmatory studies. Adequate supply was a problem with the periwinkle extract in its early development, and it remains problematic for many natural product agents now being isolated.

Several new plant-derived natural products have proven to be of extreme interest in the treatment of cancer. Taxol was isolated from the bark of the Pacific yew tree in 1971,<sup>19</sup> and it has a unique mechanism of antitumor activity that involves stabilization of microtubule assembly with resultant inhibition of the normal dynamics of microtubule formation.<sup>20</sup> This agent has a broad spectrum of antitumor activity, and it is active against a number of human tumor xenografts, including breast cancer, ovarian cancer, and other malignancies. Subsequent clinical studies have confirmed the high degree of activity in patients with a wide range of solid tumors, including breast, ovary, head and neck, esophagus, testes, and lung malignancies.<sup>21</sup> Initially, a major obstacle to defining the role of Taxol in cancer therapy related to the difficulties encountered with drug supply.<sup>14</sup> Semisynthesis from 10-acetyl baccatin III, was eventually accomplished, and new sources of Taxol from nursery species have been identified. The supply issue has now been fully resolved with the successful total synthesis of this complex molecule.<sup>22,23</sup> Moreover, advances in the

chemistry of isoserines and taxoid anticancer agents have facilitated the synthesis of second-generation taxoid compounds with activity against drug-resistant cancer cells.<sup>24</sup> The history of the development of Taxol is important because it highlights the complexities involved with development of any cancer drug—namely challenges in supply of drug, difficulties with synthesis of drug, issues of drug formulation, and obstacles associated with the implementation of successful clinical studies.

Another natural product that has been under investigation for many years, but only now found to have broad activity against various human malignancies, is derived from the bark of *Camptotheca accuminata*, a tree prized for its medicinal properties in traditional Chinese medicine.<sup>25</sup> The camptothecin derivatives are unique because they inhibit topoisomerase I, a key enzyme that maintains DNA in a torsionally relaxed state.<sup>26,27</sup> Both topotecan and CPT-11, which are derivatives of camptothecin, have significant activity in patients with advanced malignancies, including colorectal cancer, esophageal cancer, non-small cell and small cell lung cancer, and cervical cancer.<sup>28,29</sup> and <sup>30</sup> Significant efforts continue to focus on developing novel analogues of camptothecin with enhanced biophysical and biologic activity. 9-Nitroaminocamptothecin and 9-aminocamptothecin are currently in advanced stages of clinical testing.<sup>31</sup>

Marine organisms represent a largely unexplored and untapped source of unique toxic chemicals. These toxins are elaborated by sponges and other sessile saltwater organisms as defenses against their predators. Several highly potent agents demonstrate interesting antitumor activity against unique molecular targets in preclinical models, and some examples include the bryostatins (which inhibit protein kinase C), the dolastatins and halichondrins (which bind to microtubules), and the tunicate-derived ecteinascidins (which bind in the minor groove of DNA).<sup>8,14,32,33,34,35</sup> and <sup>36</sup> Although the marine environment represents an untapped potential source for interesting new chemical entities, certain unique problems affect this biosphere. Scale-up procurement of bulk material from marine sources presents a special challenge in biomass collection. The potency of many of these agents may ameliorate this supply problem, but selectivity against the tumor (and not the normal host) must first be demonstrated. In addition, the highly potent natural products present additional challenges for clinical investigators conducting phase I studies. For example, clinical pharmacologic studies may be impossible if the active species is present in such low levels that detection by even very sensitive analytic methods is not feasible at clinically tolerated doses. The rich diversity of chemical structures found in nature provides the impetus for continued research in this area. Moreover, the use of combinatorial chemistry technology may be incorporated into the process once novel therapeutic leads are identified from these natural products.

Cancer drug discovery may also result from a totally fortuitous experimental observation. The discovery of platinum complexes as antiproliferative agents with remarkable clinical activity demonstrates the importance of enlightened empiricism combined with dogged persistence in clinical testing and development. In 1965, Rosenberg<sup>37</sup> observed that an electric current passing through platinum electrodes could inhibit *Escherichia coli* bacterial cell division. This discovery was confirmed by the subsequent testing of platinum complexes in murine tumor model systems. Cisplatin inhibited the development of sarcomas, and other platinum complexes also were found to be effective in the preclinical models. The early clinical trials demonstrated antitumor activity in patients with advanced malignancies, but the excessive initial toxicity (nephrotoxicity) raised serious concern among the clinical investigators. The demonstration that adequate hydration and slow infusion reduce the degree of renal toxicity permitted further evaluation of the agent. The responses observed in testicular cancer and ovarian cancer led to approval of the drug approximately 6 years after the initial clinical trial. This excellent anticancer drug might have been discarded in error without the foresight of both preclinical and clinical investigators who were convinced of the drug's potential, were committed to the systematic testing of the drug, and were clever enough to find ways to deal with its toxicity. Most of the antineoplastic agents have been discovered through empiric screening efforts or represent chemical modifications of lead compounds discovered in cancer screenings.

Screening methods can either be simple, such as a well-characterized cell line or a defined enzymatic target, or complex, such as an *in vivo* animal tumor. In general, current efforts favor simple systems that accommodate high volumes of unknown compounds. The end point of the cancer screen may be a biologic target (e.g., tumor cell cytotoxicity, growth inhibition, differentiation) or a biochemical-molecular target that is known to be important for the survival of cancer cells. The advantages and disadvantages of each of these approaches is presented in [Table 19.2-1](#). Both the cell line and molecular approach may be combined through the use of genetically engineered cell lines that express a specific molecular target.

Assay	Advantages	Disadvantages
Screen of low-molecular-weight agents	High-throughput Can identify new cancer-causing drugs Defines agents with effects on tumor cell and displays the pattern of cellular response Defines agents that cross cell membrane and without the need for receptors	Mechanism of action not defined by the approach May define agents that are specifically toxic to cells Does not determine the cellular target responsible for the observed effect
Molecular or molecular target assays	High-throughput Has a rational basis for drug discovery May provide agents specifically aimed at a critical part in the tumor cell Potential selective antitumor activity May provide novel classes of antitumor agents	Despite scientific appeal, approach only more recently implemented No guarantee that agents will enter the cell or without intracellular action No guarantee that agents will be effective

**TABLE 19.2-1.** Comparison of Cancer Screening Devices

The evolution of strategies at the National Cancer Institute (NCI) illustrates the changes in screening that have resulted from the advances in cancer biology and cancer genetics. The early NCI cancer screening efforts used murine leukemias (L1210 and P388) as the index tumors in an *in vivo* screening effort.<sup>38</sup> The screen identified agents that had efficacy in humans in the treatment of leukemias and lymphoproliferative malignancies, such as hydroxyurea and the nitrosoureas. However, the failure of this screen to identify active drugs for the major solid tumors resulted in a significant change in 1975 in the approach of the NCI when animal solid tumor and human tumor xenografts were added as a secondary *in vivo* tumor panel.<sup>38</sup> In 1985, a second major change was made.<sup>38,39</sup> The increasing availability of a growing number of cell lines derived from human solid tumors and well characterized with respect to drug response patterns, growth factor dependence, oncogene expression, and other biochemical and molecular features presented an opportunity to focus screening efforts on the unique biology of human solid tumors.

A number of human solid tumor cell lines were selected to provide a disease-oriented approach to drug discovery in contrast with the previous compound-oriented drug discovery methods. A total of 60 human tumor cell lines derived from seven cancer types (e.g., lung, colon, melanoma, kidney, ovary, brain, leukemia) formed the original cell line panel. Breast cancer cell lines were subsequently added. The initial concept proposed that leads demonstrating disease specificity would be identified, and activity could be further examined by *in vivo* testing in nude mice, using the most sensitive *in vitro* index tumor cell lines.

In the current NCI anticancer screen, each candidate agent is tested over a broad concentration range against every cell line in the panel.<sup>2,3,38,39</sup> and <sup>40</sup> Active compounds are selected for further testing based on several different criteria: disease-type specificity in the *in vitro* assay, unique structure, potency, and demonstration of a unique pattern of cellular cytotoxicity or cytostasis, indicating a unique mechanism of action or intracellular target. The agents selected for further investigation are then subjected to additional testing to assess their *in vivo* therapeutic index.<sup>3,41</sup> The current version of the cancer drug screening program of the NCI has been in operation since 1990, and a number of novel chemical entities have been identified for further evaluation. This high-capacity screen was designed to accommodate approximately 10,000 individual chemicals tested annually, with additional capacity for screening natural product extracts. Approximately 5% of the compounds tested in the initial screen show sufficient activity to warrant further evaluation in *in vivo* screens or biochemical-molecular assays. More than 60,000 agents have been screened against a panel of 60 human cancer cell lines. The tumors that are represented in this cell line panel include melanomas; leukemias; and cancers of the breast, prostate, colon, ovary, kidney, and central nervous system. To date, this approach has identified five novel agents (e.g., a tyrosine kinase inhibitor, a protein kinase C inhibitor, and several disease-specific agents) for further testing in clinical trials. It is hoped that an overall assessment of the clinical usefulness of this novel cell line screening approach will be feasible in the near future.

The concept of cancer drug discovery that is based on high-volume screens, whether oriented toward a cell line-based or molecular target, relies on the acquisition of a large source of diverse materials for examination. In the case of the NCI, an extensive program for acquiring both defined chemical entities and diverse natural products has been pursued. Enormous effort was initially invested to standardize the *in vitro* assay, and sufficient time should be provided to fully evaluate the clinical utility of its early findings.

The pharmaceutical industry is also actively engaged in the procurement of large numbers of interesting chemical structures and natural products for testing in their respective cancer screens, many of which focus on specific molecular targets. Difficult decisions must be made to choose among the large number of unknown entities for initial testing and to aid in the prioritization of known active compounds for further development. Computer programs have been developed to assist in this

prioritization and to enhance the diversity of potential chemical entries and crude natural products introduced into the screening process. <sup>40,42</sup> For example, there are significant challenges in representing, analyzing, and storing the vast amount of experimental data generated by the substances tested in the *in vitro* screen of the NCI. In [Figure 19.2-3](#), drug testing data are represented as a mean graph presenting growth inhibition in a standard bar graph. <sup>38</sup> The mean graph is constructed by projecting bars to the right or left of the mean, depending on whether an individual cell line is more or less sensitive than the average line in the panel. Furthermore, the length of each bar is proportional to the relative sensitivity of the cell lines. Thus, each agent can be represented by a characteristic fingerprint of cell line responsiveness.

**FIGURE 19.2-3.** Mean graph representation of antitumor effects in the National Cancer Institute's (NCI) cancer screen. The effects of a specific agent on the tumor cell lines in the NCI cancer screen are shown by the construction of a mean graph presentation of the data. Screening results for two anthracyclines are charted. A mean concentration of the agent that produces the same level of response for all the cell lines in the screen forms an anchor point for this graphic presentation. The individual response of each cell line to the agent is then depicted by a bar graph extending to the right or left of the mean, depending on whether the cell line was either more or less sensitive than the average response, respectively. The length of each bar is proportional to the relative sensitivity when compared with the mean determination. CNS, central nervous system; Leuk, leukemia; NSCLC, non-small cell lung carcinoma; Misc, miscellaneous; SCLC, small cell lung carcinoma.

After an agent has been tested in the cancer screen, its unique response pattern can be compared with the results from all other agents within the database. A computer program called *COMPARE* uses a simple algorithm for aligning and contrasting the patterns for each compound with the patterns of other compounds in the database. <sup>43,44</sup> A compound is entered into the program as a seed, and the computer database elicits a list of those agents that have similar patterns of tumor cellular responsiveness. In [Table 19.2-2](#), an example is presented for the introduction of a seed compound and the resulting list of agents that had similar patterns of cellular cytotoxicity. A correlation coefficient is also expressed, relating the closeness of the seed to those agents listed by the computer program. Close correlations between agents appear to have biologic and pharmacologic importance, implying a common intracellular target despite a dissimilarity in structure (e.g., tubulin-binding agents, topoisomerase-interactive agents). The *COMPARE* program has several important features. <sup>44</sup> It can identify the intracellular target or mechanism of action of a new compound through a comparison of its fingerprint with known agents. It can search for compounds previously tested in the cancer screen that have a fingerprint similar to that of a lead compound known to inhibit a unique target. It also has the power to detect inhibition of integrated biochemical and molecular pathways that are not adequately represented by a single molecule or molecular interaction. The comparison also allows recognition of a new agent that does not match with compounds of known mechanisms of action. Given the critical roles of an intact cell-cycle checkpoint and apoptotic pathways in determining chemosensitivity, it is clear that such an algorithmic approach may help identify candidate anticancer drugs that are not dependent on an intact checkpoint and apoptosis function. Finally, this strategy provides the rational basis for future pharmacophore development.

NSC Number	Parent + Seed		Chemical Name
	High Concentration	Correlation Coefficient	
152050	1.00E-09	0.912	Maprotiline
49842	2.50E-06	0.787	Valproic acid
352199	1.00E-06	0.745	Ribavirin
408199	1.00E-06	0.733	Haloperidol H
715	6.25E-06	0.691	Calcitriol
62574	1.00E-05	0.628	Valproic acid
378229	1.00E-05	0.628	Delamanid

The extensive database has been generated from the many agents used in the National Cancer Institute's cancer screen. The unique patterns of cellular responses can be used to characterize an agent by its "signature" of cytotoxicity or cytotoxicity. Agents that have common cellular targets can be identified by the use of the COMPARE database. For example, introduction of a seed or parent compound into the COMPARE program elicits a list of those agents that exhibit similar patterns of cellular cell response. In the example in this table, the agents listed are known to be tubulin-interacting agents. The correlation coefficient for the relation of each agent to the seed or parent compound is provided. High concentration refers to the highest concentration of the agent used during the screening experiment. NSC number refers to the National Cancer Institute number assigned to each agent submitted to the National Cancer Institute.

**TABLE 19.2-2.** The COMPARE Program<sup>a</sup>

Computer approaches to data analysis similar to that described by the NCI are being developed by industry to search for agents interacting with specific molecular targets. In addition, the NCI has conducted an elaborate characterization of specific molecular targets expressed by the existing tumor cell lines within its screen. For example, because certain cell lines are known to contain a mutated or overexpressed oncogene, such as k-ras or HER-2/neu, it is possible to search the existing database for agents active against only those particular cell lines. This process may ultimately combine the advantages of both cell line-based and molecular screens, but will require separate validation to confirm that identified leads do indeed interact with the purported molecular target in specific assays directed at that entity. Although the NCI cell line screen represents a carefully constructed system for obtaining and analyzing voluminous data on diverse compounds, alternative screening systems in academic centers and industry increasingly rely on high throughput assays based on specific molecular targets, against which combinatorial chemistry inventories are tested. A good example of this approach is the potent antimetabolic agent monastrol, isolated by Mayer et al. <sup>45</sup> This agent targets kinesin Eg5, a mitotic protein required for spindle bipolarity and, thus, acts to inhibit the process of mitosis.

## MOLECULAR-TARGETED SCREENING

From a scientific perspective, a compelling argument can be made for focusing on a well-defined molecular target and for using computer-based approaches to design small molecules that would specifically interact with this target.

With the rapid advances being made in defining the molecular pathology of neoplastic cells, specific oncogenes have been identified that are expressed uniquely in malignant tissue. The discovery of inappropriately expressed or mutated genes has provided an impetus for the establishment of numerous screens designed to detect specific inhibitors or modulators of the products of these abnormal genes. Intracellular signaling pathways that mediate the actions of growth factors and oncogenes on cell proliferation, such as protein kinases, G proteins, and transcription activators, provide additional novel targets for anticancer drugs. However, given the considerable overlap of access to various growth-factor signaling pathways (many signals use the same distal steps), signal transduction inhibitors may lack specificity for the neoplastic cells. <sup>46</sup>

As an alternative to targeting these intracellular pathways, significant attention has focused on strategies to inhibit the process of angiogenesis. <sup>47</sup> This concept stems from the seminal work of Folkman and colleagues <sup>47a</sup> who proposed that the growth of a tumor mass is dependent on the formation of a vascular network that supplies the tumor with essential nutrients. The targeting of the tumor vasculature has two potential advantages over conventional biochemical and molecular targets. The first is that this approach does not require tailoring of therapy to the unique genetic makeup of the tumor, because it appears that all solid tumors are dependent, to some extent, on angiogenesis for growth. In addition, the target of this approach is the normal vascular endothelial cells that are genetically stable and, thus, less likely to become drug-resistant.

Advocates for the use of mechanistic-based approaches to novel drug discovery have emphasized the potential for selectivity that may result from the use of molecular targeting. <sup>7,48,49</sup> and <sup>50</sup> The expression of identical or closely related molecular or biochemical targets in normal tissue must always be considered. Mutant

oncogenes and their corresponding protein products appear to be the most attractive targets for drug design. Two examples include the fusion protein that results from the BCR-ABL translocation in chronic myelogenous leukemia (CML) and the interference with tumor suppression resulting from the binding of papillomavirus proteins to the RB (retinoblastoma) gene in cervical carcinoma.

In CML and in approximately 20% of adult patients with acute lymphocytic leukemia (ALL), a characteristic reciprocal translocation between chromosomes 9 and 22 is observed. The protooncogene (ABL) from chromosome 9 is translocated at the breakpoint cluster region (BCR) on chromosome 22. This translocation encodes the Bcr-Abl protein, which expresses constitutively activated tyrosine kinase function. It is a 210-kD oncoprotein, and expression of p210 BCR-Abl induces a disease in mice resembling CML, confirming the critical role of this oncoprotein in the development of CML.<sup>51,52</sup> The p210 Bcr-Abl protein is present in 95% of patients with CML and in 5% to 10% of adults with ALL for whom there is no evidence of CML. A second fusion protein of 185 kD is found in 10% of adult cases and 5% to 10% of pediatric cases of ALL, but not in CML.

It is clear that expression of this genetic rearrangement is essential for maintaining the malignant phenotype.<sup>53</sup> In addition, transfection of the specific DNA for the BCR-ABL–encoded protein kinase into the hematopoietic stem cells of mice results in the induction of a malignant disorder *in vivo* with similarities to the clinical illness in humans.<sup>54</sup> Modification of these murine models could provide a potential opportunity to test promising new therapeutic products *in vivo*. Moreover, the aberrant tyrosine kinase resulting from these abnormal genetic rearrangements (BCR-ABL) within the hematopoietic stem cells does not exist in normal host cells. This abnormal gene provides an ideal molecular target for therapeutic intervention. The crystal structure of several protein kinases has been solved, and a number of compounds have been designed based on the structure of the adenosine triphosphate (ATP) binding site or the active site of the enzyme. In screening against the recombinant BCR-ABL kinase protein, the 2-phenylaminopyrimidine derivative known as CGP 57148 (STI 571) proved to be a potent and selective inhibitor, targeting the ATP binding pocket.<sup>55</sup> This compound inhibits all ABL tyrosine kinases at submicromolar concentrations *in vitro*, and it has minimal to no inhibitory effect on the colony-forming potential of normal bone marrow cells. CGP 57148 appears to be selectively toxic to cells expressing the BCR-ABL tyrosine kinase.<sup>56,57</sup> A phase I clinical trial has been completed in CML patients who were unsuccessful with interferon therapy.<sup>58,59</sup> CGP 57148 was given orally on a daily basis, and treatment was well tolerated, with the most common toxicities being only mild nausea (grade 1), muscle cramps, and arthralgias. With regard to its clinical activity, significant hematologic responses have been observed, with 100% clinical complete response at daily doses greater than 300 mg and a 40% to 50% cytogenetic response. Clinical investigations are in progress to validate the clinical efficacy of this novel agent. Studies have shown that the drug also has potent activity against the platelet-derived growth factor receptor, and in experimental studies, it inhibits tumors that overexpress this receptor. Thus, this compound may have broader application than just for CML.

Another potential target for therapeutic intervention has evolved from an enhanced understanding of the role of aberrant tumor suppressor protein function in the malignant process. It is appreciated that more than 80% of cervical carcinomas have evidence of integrated DNA sequences from papillomaviruses.<sup>60</sup> Human papillomavirus-16 has been implicated frequently as a causal role of this malignancy. Extensive molecular investigation of the association of human papillomavirus with cervical carcinoma has identified specific nuclear proteins that interact with the tumor suppressor gene RB.<sup>61</sup> In fact, the complex protein-protein interaction between the E7 protein from human papillomavirus-16 and the retinoblastoma suppressor protein (pRB) is believed to be important in the cellular transformation that leads to cervical carcinoma. Expression of the E7 protein apparently occurs both within cells from patients with cervical carcinoma and from cell lines derived from this malignancy. The inactivation of the RB tumor suppressor gene by this protein appears to be reversible. There is significant interest in identifying agents that could selectively interfere with this deleterious E7-RB interaction.

## DRUG DEVELOPMENT

There is an urgent need to move promising new therapies into clinical trials. However, important and clinically relevant information may be lost by proceeding immediately from a primary *in vitro* screen to a clinical trial without defining the *in vivo* activity of an agent, its pharmacokinetics and schedule dependency in animals, and its profile of toxicity for normal and malignant cells and tissues. Each of these issues is important and must be addressed in a timely manner to provide safe and reasonable starting doses for implementing phase I trials in patients. The steps required in the development of a cancer agent for clinical practice are complex, and as outlined in Figure 19.2-4, they are both time- and resource-intensive.

FIGURE 19.2-4. Steps in cancer drug development. FDA, U.S. Food and Drug Administration.

Secondary *in vitro* studies to optimize the exposure time to an agent and to define mechanisms of resistance are useful for the investigators planning *in vivo* studies. Examination of the dose-response data for several tumor cell lines should permit a selection of the optimal tumor system for subsequently evaluating *in vivo* efficacy. Furthermore, preliminary pharmacologic studies in non-tumor-bearing animals provide useful information about the plasma concentrations achievable and an estimate of the acute toxicity after systemic administration of a new agent. Success in identifying new therapies relies on the expeditious, yet careful, conduct of those studies pertinent to developing a promising *in vitro* observation (derived from either the cell line screen or the molecular models) into an actual drug candidate.<sup>62,63,64</sup> and<sup>65</sup>

## IN VIVO ANTITUMOR ASSAYS CURRENTLY IN USE

In the current NCI development schema, the human tumor cell line most sensitive to an active candidate *in vitro* is selected for testing as a xenograft in a subcutaneous implant site in a nude mouse. Compounds identified in molecular screens are usually tested against human or murine tumors engineered to overexpress the specific drug target.

Failure to demonstrate *in vivo* efficacy for agents that display strong *in vitro* evidence of antitumor activity should prompt additional studies to determine whether a pharmacokinetic or metabolic explanation exists for the loss of activity. The initial lead, either discovered by an empiric screen or as a result of rational chemical design, is usually not the optimal chemical entity for clinical investigation. Lead optimization and an iterative process between chemists and tumor biologists may be required to enhance the *in vivo* therapeutic index. Factors such as poor solubility and rapid *in vivo* metabolism may be corrected by analogue development. More potent and less toxic derivatives can often be subsequently developed (i.e., provided the molecule is amenable to modification).

## PRECLINICAL PHARMACOLOGY

Preclinical studies in mice, rats, and dogs provide essential information about pharmacokinetics and provide a basis for rational schedule development for the new drugs in humans. Factors such as bioavailability (for agents administered by the oral route), metabolism, renal excretion, and penetration into the central nervous system contribute to the understanding of how best to test a new drug in humans. Although there is no guarantee that human subjects will handle a new drug in the same way as the animal species, in most instances the major pathways for drug metabolism and excretion are qualitatively, if not quantitatively, the same across species.

Pharmacokinetic information in animals can also provide a rational basis for dose escalation in humans. Collins and associates<sup>66</sup> have hypothesized that dose-limiting toxicity in mice and humans is a function of drug exposure, as measured by the area under the drug concentration in plasma  $\times$  time curve ( $C \times T$ ). They predict that

animals and humans encounter dose-limiting toxicity at the same  $C \times T$  for any given drug and that the experimentally determined dose-limiting  $C \times T$  can be used as a target for dose escalation in humans. An analysis of experience with phase I drug trials suggested that for most, but not all, drugs, the relationship of  $C \times T$  to toxicity holds across species. This work potentially allows the clinical investigator to base initial dose escalation steps on measurements of  $C \times T$ . Dose escalation can proceed in a more rapid fashion than formerly possible using empiric schemes, and wasteful multiple steps in dose escalation can be avoided. This approach, although apparently valid in retrospective studies, still requires broader validation in a prospective manner.

Drugs that demonstrate substantial interspecies variation in patterns of target tissue activation are not good candidates for this approach. For example, drugs activated by deoxycytidine kinase, such as fludarabine phosphate, are much more toxic to human marrow cells than to mouse bone marrow, presumably as a result of the higher levels of this activating enzyme in human cells.<sup>67</sup> In this instance, toxicity in humans would not be accurately predicted by the  $C \times T$  approach. Furthermore, drug candidates that are excessively potent (e.g., several of the marine natural products) may have biologic effects at plasma concentrations lower than the level of reproducible detection. Consequently, such agents are not acceptable candidates for pharmacologically guided dose escalation.

## FORMULATION STUDIES

Although the preliminary pharmacologic and toxicologic studies may begin before a decision on the final formulation of a product, the Investigational New Drug (IND)-directed toxicology should be performed with the final formulation. In addition, other critical studies may be influenced by the formulation (e.g., bioavailability of an oral formulation, insolubility of an agent demonstrating interesting antitumor activity in the cancer screen). Three important factors that have an impact on formulation studies include solubility, stability, and dosage requirements.<sup>68</sup>

Because the route of drug administration for antineoplastic agents has primarily been through the intravenous approach, the issue of solubility has provided a substantial challenge for a number of agents with limited aqueous solubility. Efforts to improve the solubility of an agent have primarily involved physical measures, including the use of various mixed solvent systems. Novel approaches, including the use of micronization, liposomal encapsulation, and other unique delivery systems (e.g., cyclodextrins and coacervate systems), have been investigated in an effort to improve methods of drug delivery to tissues. Major efforts are needed to expand the vehicles that are available for intravenous drug delivery of agents with limited aqueous solubility and stability.

The prodrug approach uses chemical modification to solve the difficulty associated with drug insolubility. The most recent example of a simple prodrug approach is the synthesis of the monophosphate of 2-fluoro-adenine arabinoside (fludarabine).<sup>69</sup> In essence, the halogenated nucleoside was poorly soluble in aqueous solution. In contrast, the monophosphate (fludarabine) was more soluble and readily cleaved enzymatically *in vivo* to the 2-fluoro-adenine arabinoside. The nucleoside is rapidly rephosphorylated after transport to the intracellular compartment and, thus, can be effective as an anticancer agent.

Unique opportunities exist to use monoclonal antibodies to selectively deliver antineoplastic agents to targeted tumor cells. New methods of prodrug administration (e.g., ADEPT) are being evaluated that couple the administration of an anthracycline glucuronide and the use of a human  $\beta$ -glucuronidase conjugated to a monoclonal antibody for selected delivery to a tumor-bearing animal. It is hoped that this novel approach will enhance the selectivity of anticancer agents, and it may have particular utility in the case of highly potent compounds.

## TOXICOLOGIC INVESTIGATION

Preclinical toxicology is frequently the final step in the progression of a new chemotherapeutic drug from discovery to initial phase I testing in humans (see [Fig. 19.2-4](#)). The major objectives of the preclinical toxicologic studies include (1) the definition of the qualitative and quantitative organ toxicities (including dose and schedule dependencies), (2) the reversibility of these effects, and (3) the initial safe starting dose proposed for humans. In general, the ideal approach is to ensure that the preclinical toxicologic studies accurately reflect the intended clinical investigations in humans (i.e., identical formulation, schedules, and routes of drug administration, and dose levels anticipated to reflect the likely experience in patients).

The protocols for performing the preclinical toxicology at the NCI have changed dramatically since the late 1970s.<sup>70,71</sup> Numerous schedules of drug administration were examined in a variety of animal species in the era before 1980. The emphasis later focused on mouse lethality studies for the initial dose-range-finding studies [i.e., lethal dose in 10% of mice ( $LD_{10}$ ),  $LD_{50}$ , and  $LD_{90}$ ]. The subsequent toxicologic studies were performed on fixed schedules to refine the doses associated with lethal and nonlethal toxicities. The preclinical toxicities reported correlated reasonably well with the subsequent clinical observations.<sup>72,73</sup> and <sup>74</sup> However, the extent of useless information relating to highly lethal murine doses ( $LD_{50}$  and  $LD_{90}$ ) led to a redesign of the toxicologic studies.

The current toxicologic investigations accepted by the U.S. Food and Drug Administration involve a simplified two-step approach. The initial step focuses on acute toxicity in small animals (e.g., mice), and the major end point is a determination of the  $LD_{10}$  level. The second phase of preclinical toxicologic investigation is more extensive. In this case, emphasis is placed on a careful qualitative and quantitative characterization of the organ-specific toxicities in rodents associated with the schedule and route of administration that is to be used in the initial clinical trial. Attention is given to defining accurately those toxicities that are likely to be observed at doses slightly higher than the highest nontoxic dose. Careful investigation of the doses in the animals that approximate the highest projected tolerable dose in the model should provide data that are more relevant to the anticipated clinical experience in patients.

In the past, most new antineoplastic agents were tested clinically on two relatively fixed schedules of drug administration—that is, single-bolus intravenous dose once every 3 to 4 weeks, and 5 consecutive days of treatment repeated at 3- to 4-week intervals. The most frequently used toxicologic protocols reflect each of these schedules. Some newer agents entering preclinical evaluation for cancer therapy are being proposed for weekly intravenous administration, continuous intravenous infusion, or oral dosing. It is critically important that the preclinical toxicologic protocol simulates the planned therapeutic approach in patients.

Because substantial variation may exist between species in their tolerance to a given drug, the safety of a projected starting dose in humans is confirmed by examining the preclinical toxicities in at least two species. Both the qualitative and the quantitative toxicities are usually well defined after investigation of a small animal model (e.g., mouse) and a larger animal (e.g., dog). Only occasionally is testing needed in an additional large animal (e.g., monkey), although this species has been shown to be especially useful for defining central nervous system pharmacokinetics.

Certain organ-specific toxicities are reliably detected with the current toxicologic models (e.g., myelosuppression and gastrointestinal toxicity). In contrast, hepatic and renal toxicities are often missed or falsely positive in animal testing. Toxicities involving the heart, lung, nervous system, pancreas, and integument are even less reliably appreciated. At best, the preclinical evaluation can establish a safe starting dose for humans and predict acute organ toxicity. A complete definition of the toxicologic profile of a new agent usually emerges only after extensive clinical experimentation.

## CONCLUSION

The discovery and development of novel anticancer agents involves substantial time, effort, and resources. The strategies used for drug discovery range from empiric screening (the source of most of the current active drugs) to rational drug design based on an enhanced understanding of the various biochemical and molecular targets. As outlined in this chapter, an extensive series of preclinical investigations are necessary before the decision to enter clinical trials is made. Significant efforts are then required for the successful completion of clinical studies, in which an individual agent is taken from the initial phase I testing through to the randomized phase III and IV settings ([Table 19.2-3](#)). The effective development of new cancer agents demands the close cooperation of a multidisciplinary team that includes basic research scientists, clinical pharmacologists, clinical research nurses, data managers, and clinical investigators. The combined resources of government, academic centers, and the pharmaceutical industry are needed for successfully dealing with the formidable task of identifying effective new therapeutic agents for cancer patients.

Phase	Objective	Primary Population Studied
Phase I	Determine whether a new drug is safe and effective in humans. Establish a safe dose range and determine the maximum tolerated dose.	Healthy adult volunteers
Phase II	Determine whether a new drug is effective in treating a specific cancer. Establish a safe dose range and determine the maximum tolerated dose.	Cancer patients
Phase III	Determine whether a new drug is effective in treating a specific cancer. Establish a safe dose range and determine the maximum tolerated dose.	Cancer patients
Phase IV	Determine whether a new drug is effective in treating a specific cancer. Establish a safe dose range and determine the maximum tolerated dose.	Cancer patients

#### PRINCIPLES OF COMBINATORIAL CHEMISTRY

##### REVOLUTION IN SYNTHETIC AND MEDICINAL CHEMISTRY

The field of combinatorial chemistry represents a revolution in both the concepts and construction of chemical entities. This revolution has not only changed the fields of chemical catalysis, materials science, and methods development, but also has impacted the field of drug development. The impact of combinatorial chemistry is likely to be as significant to drug development as the polymerase chain reaction was in advancing cloning techniques for molecular biology. The postgenomic era is predicted to present us with between 50,000 and 150,000 unique genes, each encoding a protein product that is potentially a therapeutic target. <sup>1</sup> Between 1000 and 3000 unique members are predicted to exist within the protein kinase family, which is an important class of therapeutic targets. <sup>2</sup> Because the average medicinal chemist can synthesize approximately 100 molecules per year, it is difficult to envision the identification of unique inhibitors for thousands of proteins using traditional techniques.

This chapter introduces the field of combinatorial chemistry and describes how it has impacted drug development and how it will likely impact future drug development. The aim of this introduction is to serve as a primer for researchers wishing to incorporate chemical diversity into their research program.

##### WHAT IS COMBINATORIAL CHEMISTRY AND HOW DOES IT RELATE TO CHEMICAL DIVERSITY?

To properly understand what combinatorial chemistry is, the concept of chemical diversity must first be addressed. If diversity is defined as that which represents all possible permutations of a given set, then chemical diversity can be described as the atomic representation of all possible permutations of molecular structure or functional space. The concept of chemical diversity has been recognized since the early days of drug development, when natural products (biologically active chemical entities found in nature) were the main focus of the pharmaceutical industry. At that point, the methods of achieving chemical diversity—in other words, the techniques required to synthesize  $10^3$  to  $10^6$  molecules—were unknown, and researchers depended on nature for diversity. *Combinatorial chemistry* is a collective term referring to those techniques that are used to achieve chemical diversity. A collection of diverse molecules is referred to as a *chemical library* or, often, a *combinatorial library*.

##### THE HISTORY OF COMBINATORIAL CHEMISTRY

##### TECHNICAL ADVANCES THAT ENABLED COMBINATORIAL SYNTHESIS

The chemical techniques for generating diversity have their origin in the solid-phase synthesis of peptides and nucleotides, both of which had a major impact on the growing field of molecular biology and biotechnology. These technical developments in combinatorial chemistry can be grouped into three major categories: the development of solid-phase chemical synthesis techniques, the development of deconvolution and encoding strategies for combinatorial library construction, and the development of arrayed technologies and chemical synthesizers for the rapid synthesis of molecules. A search of literature reference databases for the keywords *combinatorial chemistry* or *solid-phase organic synthesis* provides interesting insight into the rapidity of growth in the field of combinatorial chemistry. By plotting the number of literature citations as a function of year, an almost logarithmic growth is seen in the number of references between the years 1993 and 1996. Most of the major technical achievements in combinatorial chemistry were made before 1990 and were largely influenced by the demands of the pharmaceutical industry.

It should also be noted that the decrease in references to combinatorial chemistry that begins in 1997 is most likely not a function of the field slowing down, but rather a function of the acceptance of combinatorial chemistry in science as a whole. This can be thought of as *keyword disappearance*. In an analogous fashion, every paper mentioning the polymerase chain reaction technique shortly after its development would contain the phrase in the title or abstract. After its acceptance as a common technique, however, it was relegated to the experimental section of papers. As the technique of combinatorial chemistry becomes more widespread in the literature, it will cease to be the main focus of papers, becoming merely the technique used to solve much greater research problems. This is likely the trend that is taking place now, as illustrated in [Figure 19.2-5](#).

**FIGURE 19.2-5.** Graphic representation of the number of literature articles containing the keywords *combinatorial chemistry* or *solid-phase organic synthesis*, from 1979 to 1999.

## HIGH-THROUGHPUT SCREENING AND COMBINATORIAL CHEMISTRY

Since its inception, high-throughput screening has become a major source of novel drug leads in the pharmaceutical industry. After the existing pharmaceutical chemical stocks had been processed, however, a need for more screening materials emerged. This need far outweighed the potential efforts of the medicinal and natural product isolation chemists. The initial technical advances required for combinatorial chemistry were already in place (see [Figure 19.2-5](#)) and promised to be a potential source for large quantities of new chemical entities. Initial libraries were composed mainly of natural peptides. Later, as newer and more general coupling techniques became available, libraries of peptides with unnatural amino acids became commonplace. In general, peptides and peptide-like molecules are usually not a direct source of drugs because of their susceptibility to proteases, poor pharmacodynamics, and potential for antigenic response; therefore, they require extensive chemical development. This fact prompted a large effort in the development of novel chemistry that would be compatible with solid-phase resins. The growth of solid-phase organic synthesis began with the development of solid-phase protocols of known solution-phase reactions. As solid-phase synthetic efforts became more sophisticated, the emergence of complex, even pharmacologically proven, molecules (such as the benzodiazepine core) became commonplace.<sup>3</sup>

### THE BENEFIT OF SOLID-PHASE SYNTHESIS

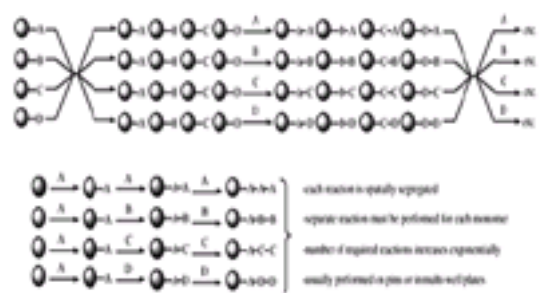

The development of solid-phase techniques for the manipulation of peptides and nucleotides preceded the development of combinatorial library techniques and thus paved the way for automation by allowing the synthesis of biopolymers in a reproducible format.<sup>4</sup> As mentioned earlier, solid-phase synthesis was an important factor in the development of consistent, high-yielding syntheses of polynucleotides and polypeptides. The concept of solid-phase synthesis is summarized in [Figure 19.2-6](#). A solid-phase resin is a beaded form of polystyrene, or any polymeric material, that is chemically functionalized to allow the synthesis of molecules while they are attached to the bead. As is shown in [Figure 19.2-6A](#), each new component can be attached to the previous one in a processive manner, allowing both the automation of the synthesis procedure and a reduced need for chemical purification. Because reagents can be used in large excess, then simply washed away, the only purification step that is required is the last one, after resin cleavage. Developments in solid-phase chemistry involve the development of new resins, more advanced chemistry, and improvement in linking strategies. More advanced approaches to solid-phase synthesis involve improvements in the cleavage step (see [Fig. 19.2-6B](#)), in which the final transformation in a synthesis alters the nature of the connection to the solid support. In this manner, a selective resin cleavage is achieved, thereby removing the need for purification altogether. This has been demonstrated in many cases, including cyclic peptides,<sup>5,6</sup> metathesis reactions,<sup>7,8</sup> and cycloaddition-cycloreversion reactions.<sup>10,11</sup>

**FIGURE 19.2-6.** Solid-phase synthesis and selective resin cleavage. **A:** The major benefit of solid-phase synthesis is a reduced need for chromatographic separation, because only the last step requires purification. **B:** Through synthetic design, some solid-phase synthesis techniques eliminate chromatography altogether.

### PARALLEL VERSUS COMBINATORIAL SYNTHESIS

It should be pointed out that the term *combinatorial*, which is often used as a general term for the entire field, has a specific meaning in terms of library synthesis. The field is collectively known as *chemical diversity*; however, the term *combinatorial chemistry* is still largely ingrained in the literature. Two types of synthetic procedures are used in chemical diversity: parallel and combinatorial synthesis. [Figure 19.2-7A](#) shows an example of a combinatorial synthesis. In this method, each reaction takes place in a separate reaction vessel. After the first step, the beads are combined and split apart again. Each mixture is then subjected to a second chemical reaction, pooled, and then split apart again. This process is commonly referred to as the *split-pool technique*. Each bead travels through a different path in the overall scheme, and ultimately, each possible combination is made. In parallel synthesis ([Fig. 19.2-7B](#)), the pools are never recombined and the syntheses proceed independently. The benefits, drawbacks, and required technical advances for each of these synthetic protocols are discussed in the next two sections, [Combinatorial Chemical Libraries](#) and [Parallel Chemical Libraries](#).

**FIGURE 19.2-7.** Combinatorial versus parallel library synthesis. **A:** Combinatorial synthesis involves the combination of library components during the synthetic sequence. **B:** Parallel synthesis involves the spatial segregation of library members during each reaction scheme.

### Combinatorial Chemical Libraries

The major difficulty with the implementation of a combinatorial synthesis strategy is the identification of active molecules. Because the strategy involves the pooling of beads, all of the molecules are mixed together in solution, and individual library members must somehow be characterized once they are identified as having biologic activity. For this reason, early developments in combinatorial synthesis focused on deconvolution strategies. Later, methods were developed that involved the encoding of individual beads. The combinatorial deconvolution procedure involves a split-pool synthesis, as seen in [Figure 19.2-7A](#). However, the last set of mixtures are not pooled together, but rather are tested as a mixture. The active “pool” is then resynthesized, but during the resynthesis, the final mixtures are not pooled. This method is called *serial deconvolution*.<sup>12</sup> A related method, referred to as *recursive deconvolution*, has been developed, in which a fraction of each reaction mixture is saved at each stage of synthesis.<sup>13</sup> In this manner, resynthesis involves only adding the last monomer at each stage of deconvolution. This method works best when evaluating a combinatorial library in cell-based assays, because the mixtures can be cleaved off the resin and tested as a whole.

Another type of combinatorial synthesis is referred to as the “one bead, one molecule” approach.<sup>14</sup> This procedure also uses the split-pool technique; however, instead of relying on a deconvolution strategy, each bead is chemically tagged after it has been chemically modified. These tags are chemically orthogonal to the growing chemistry chain and have proven useful for the on-bead analysis of protein affinity<sup>15</sup> and in off-bead strategies using spatial arrays of beads.<sup>16</sup> Once a bead has been identified to contain an active component, the tag is removed and “read” to determine the identity of the molecule. Some of the tagging strategies that have been used include nucleotides,<sup>16,17</sup> gas-chromatography (GC)–detectable electrophoretic molecules,<sup>18</sup> and high pressure liquid chromatography (HPLC)–detectable

secondary amines.<sup>19</sup> Modern mass spectrometry methods are becoming powerful enough to allow the direct detection of the molecules attached to the solid-phase resin.<sup>20</sup> The split-mix technology remains the best method for the construction of libraries of more than  $10^3$  members.<sup>21</sup>

### Parallel Chemical Libraries

The need for technical advances in the development of parallel synthetic techniques is much less than for combinatorial approaches, because the major requirement involves the spatial arraying of each molecule. Two early developments in this field involve the pin<sup>22</sup> and teabag methods.<sup>23</sup> In pin-based library synthesis, the molecules are synthesized on the head of functionalized pins, which serve as probes that can be inserted into any number of solvent or reagent wells. The randomization process takes place by the nature of the fact that each pin is exposed to a different set of reagents or monomers. The teabag approach is similar, in that each separate bag is moved from one reagent or reaction mixture to another. In this case, the molecules are spatially arrayed in the individual bags. A popular advance on this technique involves the use of radiolabels to tag each bead, thus allowing a rapid handling of each bag.<sup>24</sup> Microarray chip technology also allows the spatial arraying of a combinatorial library and has proven useful in library synthesis. More recent developments involve synthesis in multiwell plates on automated synthesizers. In general, the pharmaceutical industry has turned to this technique, using discrete molecules in a high-throughput format. This technique has been facilitated by the development of large-scale machine-based organic synthesizers.

## THE PRACTICE OF COMBINATORIAL CHEMISTRY

### IDENTIFYING AN INHIBITOR FOR A SPECIFIC RECEPTOR

Once a protein is identified as a potential therapeutic target, the major goal is to evaluate a biologic system in the absence of the protein activity. Gene technology has been developed to generate knockout mice that lack a specific protein of interest; however, the mouse must reach development without the aid of this protein and often this gene is required for proper development. Furthermore, it is often more desirable to study the biologic effect in a cell line before proceeding to an animal model.

A number of methods have been developed for identifying inhibitors of receptors. The most common, often used in the pharmaceutical industry, is high-throughput screening. This method often involves an automated assay based on affinity or some related *in vitro* cell-based or cell-free phenotype and a large library of chemical compounds. These chemicals may originate from a natural product isolation, combinatorial synthesis, or an in-house library grown over many years of chemical development. Such a library can be a great place to start to determine whether a molecule or class of molecules with affinity for either the receptor of interest or a closely related receptor from the same family has already been identified.

In the case in which no known inhibitor exists for the class of receptor of study, or for identifying a novel inhibitor for a specific receptor, then access to chemical diversity is essential. There are two ways of obtaining chemical diversity: It can be made or bought. Because this chapter is intended for a nonchemical audience, we discuss methods of buying chemical diversity.

### NATURAL PEPTIDES AS A STARTING POINT FOR CHEMICAL DIVERSITY

The presentation of peptides on the surface of bacteriophage particles is known as *phage display*.<sup>25</sup> Phage display of peptide libraries has become a common method for quickly obtaining large libraries of natural peptides.<sup>26</sup> The benefit of a natural peptide is that it can elucidate the type of functionality that binds to the receptor of interest, and many peptide phage display libraries are commercially available. Once a natural peptide inhibitor is identified, peptidomimetic strategies can be used to identify nonpeptide inhibitors. The development of nonpeptide inhibitors is usually performed by the further analysis of molecules that mimic the functional nature of the peptide, yet eliminate the poor drug-like qualities of the peptides. One popular and potentially very powerful modification of peptides to improve function and biologic activity is the cyclization of the peptide, which results in a cyclic peptide with a limited number of ground-state conformations and a reduced susceptibility to proteases. However, the cyclization may result in locking the peptide in an inactive conformation, limiting the success of the method. For this reason, many individuals begin screening with cyclized libraries rather than cyclizing a linear peptide. This can even be achieved in phage display by using a randomized peptide sequence that is flanked by cysteine residues. Once the phage is secreted from the cell, the flanking cysteine residues form a disulfide bond and create a cyclic structure. Peptidomimetics has become one of the most studied areas of molecular recognition.<sup>27</sup> Indeed, many natural products themselves are mimics of biologically active peptides.<sup>28</sup>

### NATURAL PRODUCTS AS A STARTING POINT FOR CHEMICAL DIVERSITY

Natural products have a rich history in the elucidation of biologic processes and in drug development.<sup>29</sup> Even in those cases in which the natural product itself is not a potential drug, it can offer a glimpse as to what kinds of molecules will be effective in drug development. It is often found that the product of nature lacks the specificity that is desired for therapeutic activity. Combinatorial chemistry offers the possibility of developing a more specific inhibitor using the chemical nature of the natural product as a good starting point for diversity. However, the modification of a natural product or the construction of a novel library based on a natural product is chemically intensive and usually requires collaboration with a chemistry laboratory or pharmaceutical company.

### THE MATHEMATICS OF DIVERSITY

One issue that must be addressed when designing a chemical library or evaluating a combinatorial phage peptide library is the total number of individual molecules in that library. Table 19.2-4 shows the diversity that one might expect from different chemical and biologic libraries. The formula for diversity, in any library, can be described as the number of monomer units raised to the power of the number of variable positions. For example, if we chemically synthesize a heptapeptide library using all 20 natural amino acids, our library will contain  $20^7$  or 1.28 billion different molecules. If we use phage display to create the same heptapeptide library, we must account for the redundancy of the genetic code and consider each codon as a monomer unit. In this case, the diversity increases to  $64^7$ , or  $4.4 \times 10^{12}$ , library members, which is an unmanageable number of clones. Proper design of the library and use of the wobble position can reduce the required number of codons to 32, reducing the diversity to  $32^7$ , or  $3.4 \times 10^{10}$ , library members. This is still a very large number but is slightly more realistic.

TABLE 19.2-4. The Mathematics of Chemical Diversity<sup>a</sup>

It is important to consider the size and chemical diversity of the library. There is increasing data to suggest that it is more important for a library to be diverse than to be large. Permutational libraries, such as peptides, do not have to cover their diversity. In all likelihood, the epitope is likely to be smaller than the total positions varied. For example, a peptide sequence such as RGD, a common motif in integrin recognition, would come up many times in a heptapeptide library. Some phage display libraries contain 12 randomized amino acids, with no hope of containing that diversity. Yet these libraries are very useful for the identification of discontinuous epitopes within the same peptide. In summary, phage display offers the most accessible first entry into chemical diversity, but often it must be followed up with a synthetic library.

## COMBINATORIAL CHEMISTRY IN PHARMACEUTICAL DRUG DEVELOPMENT

### “HIT” GENERATION AND “HIT TO LEAD” DEVELOPMENT

Modern drug development often begins with the screening of thousands of molecules to generate chemical “hits” against a therapeutic target or cell line. A *hit* is defined as a molecule that shows activity in an assay below a certain activity level. High-throughput screening of chemical compounds emerged in the early 1990s to aid the rapid evaluation of the large chemical stocks that were being amassed in the pharmaceutical industry. The high-throughput assay is usually an *in vitro* assay, although it is not necessarily cell-free. Once a molecule has been identified as a hit, it is evaluated by a medicinal chemist who begins a synthetic effort to obtain a structure activity relationship for the molecule. If the activity of the initial hit can be optimized for *in vitro* activity, the molecule becomes a “lead” molecule. This process is known as “*hit to lead*” development. Although each pharmaceutical company and, indeed, each therapeutic target has different criteria for the categorization of a lead molecule, the development process is basically the same. Once a lead is identified, a series of *in vivo* tests and further development take place to determine whether the chemical lead has the proper pharmacologic properties and *in vivo* efficacy to become an actual drug.

### COMBINATORIAL CHEMISTRY AND LEAD DEVELOPMENT

Although the desire for large numbers of compounds led to the rapid growth of combinatorial chemistry and solid-phase synthetic techniques, it was quickly recognized that a combinatorial approach to lead generation could also be developed. This approach involves the synthesis of secondary libraries, synthesized in a manner that allow the randomization of chemical functionality that was not, or could not be, addressed in the first library. In this manner, an entire library is not synthesized, but rather a small sample of the library is synthesized, and that hit is used as a starting point for a subsequent library generation. This is a convenient method of evaluating a library that has more diversity than can be synthesized. Consider, for example, a library with six potential sites of randomization (see [Figure 19.2-6](#)). If twenty monomers were chosen to construct this library, 64 million molecules would have to be synthesized. This diversity is much higher than that which could ever be achieved with a parallel synthesis approach, and it is even outside the limit of a combinatorial synthesis. The premise of this approach is that an actual drug resides within the design of the library and that an activity-driven search of diversity space will pick it out. This is analogous to the needle in the haystack dilemma.

### CANCER-RELATED TARGETS

Combinatorial chemistry is still in its adolescent stage with regard to drug development. However, many cancer-related targets have been discovered with combinatorial approaches. Farnesyl transferase, responsible for targeting the oncoprotein p21ras to the cellular membrane, was one of the first targets explored with combinatorial chemistry because of the well-defined CAAX nature of the farnesylation site.<sup>30</sup> Cell surface receptors such as vitronectin, implicated in the complex mechanism of cellular metastasis, have been the target of attempts to inhibit tumor cell adhesion.<sup>31</sup> The receptor tyrosine kinases and cellular kinases have been implicated as therapeutic cancer targets, and the development of kinase inhibitors is a very active area with many combinatorial library approaches.<sup>32</sup> In addition to the active site of kinases, the SH2 recognition and SH3 regulation domains, also involved in kinase activation, are targets of cancer intervention.<sup>33,34</sup> Their peptide nature makes them excellent targets for combinatorial development.

### COMBINATORIAL BIOLOGY: NATURE'S BIOLOGIC DIVERSITY

Herceptin,<sup>35</sup> an antibody targeted against the her-2/neu/erb-B2 receptor, is an example of biologic products developed for cancer treatment. Peptide phage display is an efficient and convenient method of obtaining a self-encoded combinatorial library of natural peptides, both linear and cyclic. It is also a convenient method for obtaining combinatorial mixtures of randomized proteins. Although *in vivo* techniques are still the primary source for antibody production, phage display offers the potential for accessing nonantibody proteins for the development of biologic cancer chemotherapeutics. Although this technique has been used mainly for the investigation of basic biology, combinatorial antibodies against a malignant melanoma have been reported.<sup>36</sup> An interesting combination of biologic techniques for the construction of chemical libraries involves polyketide synthase gene swapping. It has been demonstrated that small-molecule diversity can be achieved by randomizing the order of polyketide synthase genes in bacterial systems. This method is unique, because it offers the promise of a biologic synthesis format once an active molecule is identified.

### THE FUTURE OF CHEMICAL DIVERSITY IN DRUG DEVELOPMENT

The need for a large numbers of molecules for high-throughput screening has led to the rapid growth of combinatorial chemistry; however, only now are scientists recognizing the need for the development of chemical diversity.<sup>37</sup> As the field of combinatorial chemistry matures, it is becoming more apparent that library design is more important than library size. Although large chemical libraries may provide the potential for hit generation, it is not yet established that such libraries will replace the use of natural products for hit generation. At a minimum, it should be expected that natural products, peptides, and signaling molecules will continue to be a source of inspiration for the design of chemical libraries.

In addition to natural product leads, structural biology is continually providing insight into the structural nature of biologic macromolecules. The combination of chemical diversity with structural and molecular biology and computational chemistry will undoubtedly provide the greatest advance in modern drug development.<sup>37</sup>

The use of chemical diversity to address genomic diversity is likely to be the single most important effort for chemical diversity in the postgenomic era.<sup>38</sup> Proteomics has already emerged as a field in need of small-molecule probes. Biologic techniques, such as expression cloning, complementary DNA phage display, and cellular display systems, offer the opportunity to probe protein function with small molecule diversity. Indeed, if the potential of combinatorial diversity can be realized, we envision a small-molecule inhibitor for every protein encoded by the human genome.

### HISTORY OF THE ALKYLATING AGENTS

A nitrogen mustard alkylating agent was the first nonhormonal chemical that demonstrated significant clinical antitumor activity. The clinical evaluation of nitrogen mustards as antitumor agents evolved from the observed clinical effects of sulfur mustard gas used as a weapon in World War I. This gas was used because of its vesicant effect on the skin and mucous membranes, especially the eyes and respiratory tract.<sup>1</sup> However, in addition to this deadly effect, depression of the hematopoietic and lymphoid systems was observed in victims and experimental animals.<sup>2</sup> These observations led to further studies that used the less volatile nitrogen mustards (Fig. 19.3-1). Studies published in 1946 demonstrated regression of tumors, especially lymphomas<sup>3,4</sup> and led to the introduction of the compound nitrogen mustard (mechlorethamine, Mustargen) into clinical practice. Subsequently, less toxic and more clinically effective nitrogen mustard derivatives and other types of alkylating agents have been developed.

FIGURE 19.3-1. Structures and alkylation mechanisms for sulfur mustard and the nitrogen mustard, Mustargen (mechlorethamine).

### CHEMISTRY AND CYTOTOXICITY OF ALKYLATING AGENTS

The alkylating agents react with (or “alkylate”) many electron-rich atoms in cells to form covalent bonds. The most important reactions with regard to their antitumor activities are reactions with DNA bases. Some alkylating agents are monofunctional and react with only one strand of DNA. Others are bifunctional and react with an atom on each of the two strands of DNA to produce a “cross-link” that covalently links the two strands of the DNA double helix. Unless repaired, this lesion will prevent the cell from replicating effectively. The lethality of the monofunctional alkylating agents results from the recognition of the DNA lesion by the cell and the response of the cell to that lesion. Analogous cellular reactions may occur to the interstrand cross-links, but such reactions have not been definitively established.

### CLASSES OF ALKYLATING AGENTS AND THEIR PROPERTIES

#### NITROGEN MUSTARDS

##### *Mustargen*

Mustargen is currently used in the MOPP [Mustargen, vincristine (Oncovin), procarbazine, prednisone] regimen for the treatment of Hodgkin's disease<sup>6</sup> but rarely for other purposes. The other nitrogen mustards in significant clinical use are cyclophosphamide, ifosfamide, melphalan, and chlorambucil ( Fig. 19.3-2). All these compounds produce cytotoxicity by forming covalent interstrand cross-links in DNA (as shown in Fig. 19.3-3 for Mustargen). The nitrogen mustard cross-link has been demonstrated to occur in the G-X-C/C-Y-G configuration,<sup>7</sup> as opposed to the G-C/C-G cross-link that had previously been predicted.<sup>8</sup> The formation of the G-X-C/C-X-G cross-link has been postulated to occur on the basis of the greater frequency of approximation of the N7 atoms of the two guanylates in the G-X-C/C-X-G configuration, as opposed to the G-C/C-G configuration.<sup>9</sup>

FIGURE 19.3-2. Nitrogen mustards in frequent clinical use.

FIGURE 19.3-3. Alkylation of DNA and formation of interstrand cross-link by nitrogen mustard.

Mustargen is available only as an intravenous preparation that can also be used topically for cutaneous malignancies. In the MOPP regimen, Mustargen is used at a dose of 6 mg/m<sup>2</sup> on days 1 and 8 of the monthly schedule. Toxicities unique to the agent are topical irritation and pain on injection if given too rapidly. The clearance of the drug is very rapid, but pharmacokinetics have not been performed with modern techniques.

### Cyclophosphamide

The most frequently used alkylating agent, cyclophosphamide, is used for the treatment of breast cancer in combination with doxorubicin (Adriamycin) <sup>10</sup> or with methotrexate and 5-fluorouracil<sup>11</sup> and for the treatment of lymphomas,<sup>12,13</sup> childhood tumors,<sup>14,15</sup> and many solid tumors.<sup>16</sup> High doses of cyclophosphamide are frequently used in conjunction with bone marrow transplantation<sup>17,18</sup> and 19 and for the treatment of autoimmune diseases.<sup>20,21</sup>

Cyclophosphamide is inactive *in vitro* and is metabolized by P-450 enzymes in the liver to active species, as shown in Figure 19.3-4. The initial product is 4-hydroxycyclophosphamide (4-HC), which is released from the liver into the circulation.<sup>22</sup> This compound is in equilibrium with an open-ring tautomer, aldophosphamide. Aldophosphamide spontaneously eliminates acrolein to produce phosphoramidate mustard,<sup>23</sup> which is an active bifunctional alkylating species.<sup>24</sup> Phosphoramidate mustard is zwitterionic at physiologic pH<sup>25</sup> and enters cells poorly. 4-HC-aldophosphamide is not charged and enters cells readily. While phosphoramidate mustard is toxic to cells *in vitro* at concentrations of 100 μM and higher, 4-HC is cytotoxic in the range of 10 μM.<sup>26</sup> Thus, 4-HC-aldophosphamide serves as an efficient delivery system for phosphoramidate mustard, which has been demonstrated to produce an interstrand DNA cross-link analogous to the cross-link produced by mechlorethamine.<sup>7</sup> Recent studies by Shulman-Roskes et al.<sup>27</sup> have demonstrated that phosphoramidate mustard readily eliminates chloroethylaziridine,<sup>27</sup> which probably also plays a role in the cross-linking of DNA in cells exposed to 4-HC.

FIGURE 19.3-4. Metabolism of cyclophosphamide.

As shown in Figure 19.3-4, 4-HC is a substrate for the enzyme aldehyde dehydrogenase.<sup>28</sup> In cells that contain this enzyme, the bulk of the 4-HC is oxidized to carboxyphosphamide, which is not an active alkylating agent. Consequently, cells with high aldehyde dehydrogenase (ALDH) content are resistant to the metabolites of cyclophosphamide.<sup>29,30</sup> Early hematopoietic stem cells and megakaryocytes contain high levels, as do the epithelial stem cells in the small intestine and mucous membranes.<sup>30,31</sup> These observations explain why cyclophosphamide administration produces a shorter period of hematopoietic depression,<sup>32</sup> is relatively sparing of platelets, and is associated with less gastrointestinal toxicity and mucositis than other alkylating agents.<sup>33</sup>

4-HC is too unstable to be used as a reagent, but the compound 4-hydroperoxycyclophosphamide (see Fig. 19.3-4) is spontaneously converted in aqueous solution to 4-HC and can be used for *in vitro* studies of cell sensitivity.<sup>34,35</sup> This compound has also been used for the *in vitro* treatment of autologous bone marrow to reduce the number of tumor cells returned to the patient.<sup>36</sup>

Cyclophosphamide is available as tablets for oral administration or as an intravenous preparation. The drug is used at a variety of doses and schedules. Oral administration is particularly used for autoimmune diseases at a daily dose of approximately 100 mg. Because of its rapid absorption and high bioavailability, even very high doses can be given orally, but high intermittent doses are usually given intravenously. In moderate-dose combination chemotherapy, doses of cyclophosphamide in the range of 750 mg are usually used. For high-dose therapy in conjunction with hematopoietic cell transplantation, doses of up to 50 mg/kg for 2 or 4 days in combination with other agents are used.

The bulk (nearly 70%) of a dose of cyclophosphamide is excreted in the urine as the inactive carboxyphosphamide.<sup>37,38</sup> At high doses (approximately 50 mg/kg), plasma concentrations of up to 400 μM of cyclophosphamide are achieved,<sup>38</sup> and clearance depends on the renal clearance and the rate of microsomal metabolism in the liver. With improved and more facile techniques to measure 4-HC concentrations accurately, the clinical pharmacology of cyclophosphamide and this critical transport intermediate are being more carefully defined. Studies in patients receiving high-dose therapy have demonstrated considerable variation in the rates of clearance of cyclophosphamide between patients, with consequent differences in the peak concentrations (1 to 15 μM) and total exposure of the patient to 4-HC (60

to 140  $\mu\text{M}\cdot\text{hours}$ ).<sup>39,40</sup> The total exposure to 4-HC is probably the major determinant of therapeutic effect. Currently, several programs are evaluating dose adjustment regimens based on the initial pharmacokinetics of cyclophosphamide and 4-HC. While it is known that substantial concentrations of phosphoramidate mustard are present in plasma (up to 10  $\mu\text{M}$  after 60 mg/kg of cyclophosphamide<sup>38</sup>), this concentration is well below the concentrations needed for *in vitro* cytotoxicity of phosphoramidate mustard.<sup>26</sup>

A unique toxicity of cyclophosphamide and other oxazophosphorines is a characteristic hemorrhagic cystitis<sup>41,42</sup> due to irritation of the bladder mucosa from urinary metabolites. Acrolein has been identified as the metabolite most responsible for this effect,<sup>43</sup> but phosphoramidate mustard and chloroacetaldehyde may contribute to this toxicity. Careful hydration and emptying of the bladder are crucial to avoiding this toxicity, which has produced massive and even fatal hemorrhage. Another toxicity that has been associated with cyclophosphamide is an antidiuretic effect, especially at high doses.<sup>44</sup> This effect may produce marked fluid retention and electrolyte abnormalities, particularly low sodium, and seizures and fatalities have been seen.<sup>45</sup> It is important to avoid low-sodium-containing fluids after high-dose cyclophosphamide, and the fluid retention syndrome has been treated with furosemide to promote free water clearance.<sup>46</sup> The most severe dose-limiting toxicity of cyclophosphamide is a fulminant cardiac toxicity,<sup>47</sup> which is often fatal when seen clinically. This toxicity is seen only after the high doses used in bone marrow transplantation. It was initially seen in patients receiving 60 mg/kg/d of cyclophosphamide for 4 days, and the incidence has decreased since lower doses have been used. The syndrome usually presents with severe cardiac failure, beginning approximately 10 days after drug administration, with a dilated heart and low electrocardiogram voltage. There is a characteristic pathologic picture of edema, interstitial hemorrhage, and cardiac necrosis.<sup>47</sup>

### Ifosfamide

Ifosfamide is a structural isomer of cyclophosphamide that is often used in the treatment of sarcomas and pediatric tumors (see Fig. 19.3-2). There is more chloroethyl side chain oxidation of ifosfamide (up to 50%) than of cyclophosphamide (<10%), and the degree of such metabolism is more variable than with cyclophosphamide.<sup>48</sup> Oxidation of the chloroethyl groups produces chloroacetaldehyde, which is probably responsible for the neurotoxicity<sup>49</sup> and renal toxicity<sup>50</sup> that have been seen with ifosfamide therapy. Since the oxidation of a chloroethyl side chain produces a much less toxic monofunctional agent, higher doses of ifosfamide than cyclophosphamide must be used clinically. The studies of the clinical pharmacology of ifosfamide have been more limited than those of cyclophosphamide but have demonstrated large inpatient variability in the pharmacokinetics and metabolism of the agent during repeated administrations.<sup>51,52</sup>

### Melphalan

Melphalan is now used principally for the treatment of multiple myeloma,<sup>53</sup> for high-dose myeloablative therapy in conjunction with bone marrow transplantation,<sup>54</sup> and for the isolated limb perfusion of localized tumors,<sup>55</sup> especially malignant melanoma and sarcomas (see Fig. 19.3-2). Melphalan is an amino acid analogue and is actively transported into cells by amino acid transport systems.<sup>56,57</sup> It has been demonstrated that cellular uptake<sup>58</sup> and transport into the central nervous system (CNS)<sup>59</sup> of melphalan can be modulated by the amino acid content in the extracellular fluid.

Melphalan is available both as tablets and as an intravenous preparation. For the treatment of multiple myeloma, melphalan is usually used orally at a dose of 0.25 mg/kg for 4 days, with prednisone on the same schedule every 4 to 6 weeks. At these doses, peak plasma concentrations of 0.625  $\mu\text{M}$  are found, but absorption is variable.<sup>60</sup> For bone marrow transplantation, doses of melphalan of 100 to 140 mg/m<sup>2</sup> are used.<sup>61</sup> At these doses, peak concentrations of melphalan of 40 to 50  $\mu\text{M}$  are reached.<sup>61,62</sup>

### Chlorambucil

Chlorambucil is used for the treatment of B-cell chronic lymphocytic leukemia<sup>63</sup> and lymphomas<sup>64</sup> and for the immunosuppressive therapy of autoimmune diseases.<sup>65</sup> It is administered orally and is well tolerated when given either by daily administration or intermittent high-pulse doses.<sup>64</sup> Chlorambucil is well tolerated by most patients and can be used successfully for patients who have severe nausea and vomiting with cyclophosphamide or melphalan.

Chlorambucil is available only in an oral formulation. For chronic leukemia and immunosuppression, daily doses of 3 to 6 mg are given for a number of weeks, or 12 mg/m<sup>2</sup> may be given monthly. Pulsed dose pulse chlorambucil for lymphoma is given orally at a dose of 16 mg/m<sup>2</sup> daily for 5 consecutive days each month.<sup>64</sup> Chlorambucil is metabolized to a less active derivative—phenylacetic acid mustard—and the clinical pharmacology of chlorambucil is very similar to that of melphalan.<sup>66</sup>

## AZIRIDINES AND EPOXIDES

The aziridine agents are related to the nitrogen mustards but contain uncharged aziridine rings that are less reactive than the aziridinium rings formed by most of the nitrogen mustards. The two aziridine agents that are frequently used clinically are thiotepa and mitomycin C (Fig. 19.3-5). The diepoxide dianhydrogalactitol reacts with DNA in a similar fashion to the aziridines but has been succeeded in clinical use by dibromodulcitol, which spontaneously generates dianhydrogalactitol *in situ* (Fig. 19.3-6).

FIGURE 19.3-5. Aziridine agents.

FIGURE 19.3-6. Structures of dianhydrogalactitol and its prodrug, dibromodulcitol.

## Thiotepa

Thiotepa is now used most frequently in combination with other alkylating agents in high-dose therapy with stem cell support.<sup>39,67</sup> Thiotepa has been demonstrated to react with the N7 position of guanylic acid in DNA<sup>68</sup> and to cross-link DNA,<sup>69</sup> indicating that it is acting similarly to the nitrogen mustards. Thiotepa is desulfurated by cytochrome P-450 enzymes<sup>70</sup> to produce tepa. Tepa is less toxic than thiotepa and has been demonstrated to produce alkali-labile sites in DNA, rather than cross-links.<sup>69</sup> These findings suggest that tepa reacts differently from thiotepa and produces monofunctional alkylation of DNA.

In combination with cyclophosphamide for high-dose therapy, thiotepa has been given as a continuous infusion for 4 days, at a daily dose of 200 mg/m<sup>2</sup>. Under these conditions, steady-state levels of 2 to 6 μM of thiotepa are rapidly achieved.<sup>71</sup> Thiotepa is also used at a dose of 900 mg/m<sup>2</sup> in combination with high-dose cyclophosphamide and cisplatin.<sup>72</sup>

## Mitomycin C

Mitomycin C is an antibiotic extracted from a *Streptomyces* species and is used for the treatment of breast cancer,<sup>73</sup> esophageal cancer,<sup>74</sup> and gastrointestinal tumors.<sup>75</sup> As seen in [Figure 19.3-5](#), this compound contains an aziridine ring. Particularly under hypoxic conditions, mitomycin C is reduced, with activation of the C1 position of the aziridine ring. This carbon then reacts in the minor groove with the extracyclic N2 amino group of a guanylic acid,<sup>76,77</sup> positioning the 10 carbon of the carbamate moiety to react with the N2 of a guanylic acid residue in an adjacent base pair in the complementary DNA strand. Mitomycin C and its reduced metabolites can also produce intrastrand guanylic acid–guanylic acid cross-links that produce bending of the DNA.<sup>78</sup>

In combination regimens, mitomycin C is given at doses of 10 to 15 mg/m<sup>2</sup> every 4 to 6 weeks. After a dose of 15 mg/m<sup>2</sup>, peak plasma concentrations of 3 μM are seen.<sup>79</sup>

## Dianhydrogalactitol

Dianhydrogalactitol (see [Fig. 19.3-6](#)) is a hexitol derivative that contains two epoxide groups and cross-links DNA through the N7 atoms of guanylic acid,<sup>80</sup> presumably through the nucleophilic attack of the N7 atoms on the strained-ring epoxide groups. This compound was evaluated in clinical trials and demonstrated modest antitumor activity.<sup>81,82</sup> However, the structurally related dibromodulcitol (see [Fig. 19.3-6](#)) has demonstrated more antitumor activity<sup>83,84</sup> and is still being used in combination chemotherapy of breast cancer, cervical cancer, and brain tumors. Dibromodulcitol is hydrolyzed to dianhydrogalactitol, and its better antitumor activity is presumably due to more effective localization of the reactive agent in tumor cells.<sup>85</sup> Dibromodulcitol is usually administered at a dose of 1 g/m<sup>2</sup>, which produces a maximum plasma concentration of approximately 50 μM.<sup>86</sup>

## ALKYL SULFONATES: BUSULFAN

Busulfan (Myeleran), other alkyl sulfonates, and the related sulfamates react with DNA by a direct displacement reaction (as shown in [Fig. 19.3-7](#)). Busulfan has been demonstrated to cross-link DNA,<sup>87</sup> but the structure of the cross-link has not been established. A chemically related agent, hepsulfam, with seven methylene units between the reactive groups, has been demonstrated to form a DNA G-X-C/C-X-G interstrand cross-link analogous to those formed by the nitrogen mustards.<sup>88</sup> Haddow and Timmis<sup>89</sup> reported in 1953 that busulfan was active against chronic myelogenous leukemia. Busulfan was for many years the principal agent used to treat this disease, before being replaced by the use of hydroxyurea<sup>90</sup> and interferon-α,<sup>91</sup> both of which have proved to be more effective than busulfan. The most frequent use of busulfan in cancer therapy today is in high-dose therapy for many tumors, including chronic myelogenous leukemia, in conjunction with bone marrow or stem cell transplantation. For this application, high doses of busulfan are combined with cyclophosphamide, total body irradiation, or other agents.<sup>18,92,93 and 94</sup> The effectiveness of busulfan for this purpose is undoubtedly related to its marked myeloablative properties,<sup>95</sup> the mechanistic bases of which are not understood.

**FIGURE 19.3-7.** Alkylation of guanylate in DNA by busulfan through S<sub>N</sub>2 alkylation. A second displacement reaction with the N7 of a guanylate in the complementary strand creates a G-X-C/C-X-G interstrand cross-link.

Until recently, busulfan was available only as an oral preparation, but intravenous preparations are now available. For hematopoietic transplantation, busulfan is usually given as 1 mg/kg every 6 hours for 4 days, for a total dose of 16 mg/kg. Peak concentrations of busulfan after each dose are approximately 10 μM.<sup>96</sup> High doses of busulfan have been associated with venoocclusive disease of the liver. This syndrome consists of hepatomegaly, jaundice, ascites, and hepatic failure with a high mortality rate.<sup>97</sup> Grochow et al.<sup>96</sup> have demonstrated that pharmacokinetic monitoring and dose adjustment of the busulfan can markedly reduce the incidence of venoocclusive disease.

## NITROSOUREAS

The members of the nitrosourea group of therapeutic alkylating agents are related to the alkylnitrosoamines and similar compounds that have long been known to be carcinogenic. Methylnitrosoguanidine and methylnitrosourea are monofunctional alkylating agents and were found to have modest antitumor activity.<sup>98,99</sup> Montgomery<sup>100</sup> and others<sup>101,102</sup> evaluated a number of analogues of these compounds and demonstrated remarkable antitumor effects of bischloroethylnitrosourea (BCNU; [Fig. 19.3-8](#)) against mouse tumors, and particularly against intracerebral tumors, which had been refractory to most agents because of the blood–brain barrier.<sup>100,101 and 102</sup> BCNU was found to produce interstrand cross-linking of DNA,<sup>103</sup> which has been demonstrated to occur through the spontaneous generation of a chloroethyldiazonium species<sup>104</sup> and the series of reactions illustrated in [Figure 19.3-9](#).<sup>105</sup> As illustrated, this interstrand cross-link occurs between a guanylate in DNA and the base-paired cytidylate in the other strand of the DNA.<sup>106</sup>

FIGURE 19.3-8. Nitrosoureas.

FIGURE 19.3-9. Reaction of BCNU with DNA to produce a G-C interstrand cross-link.

### Bischloroethylnitrosourea

BCNU (carmustine; see Fig. 19.3-8) demonstrated activity against brain tumors clinically<sup>107</sup> and has continued to be used in the treatment of gliomas and other brain tumors. BCNU has also been used in the treatment of multiple myeloma<sup>108</sup> and in high-dose therapy in conjunction with bone marrow and stem cell transplantation.<sup>109</sup> BCNU can also be administered to brain tumors by direct injection<sup>110</sup> and by the implantation of biodegradable polymers containing BCNU into the brain.<sup>111</sup>

### Cyclohexylchloroethylnitrosourea

Cyclohexylchloroethylnitrosourea (CCNU, lomustine; see Fig. 19.3-8) is a more lipid-soluble nitrosourea. It is administered orally and is used in the treatment of brain tumors.<sup>112,113</sup>

### Methylcyclohexylchloroethylnitrosourea

Methylcyclohexylchloroethylnitrosourea (semustine; see Fig. 19.3-8) is an oral investigational drug that has been used in the treatment of gastrointestinal tumors.<sup>114</sup>

### N'-[(4-amino-2-methyl-5-pyrimidinyl)methyl]-N-(2-chloroethyl)-N-nitrosourea

N'-[(4-amino-2-methyl-5-pyrimidinyl)methyl]-N-(2-chloroethyl)-N-nitrosourea (nimustine; see Fig. 19.3-8) is more water-soluble than the other chloroethylnitrosoureas and has been used for the treatment of CNS tumors by the intraarterial<sup>115</sup> and intrathecal routes.<sup>116</sup>

### Clinical Pharmacology

As a single agent, BCNU is usually used in a dose of 125 to 200 mg/m<sup>2</sup> every 6 to 8 weeks. In combination with doxorubicin for multiple myeloma, a dose of 30 mg/m<sup>2</sup> every 3 to 4 weeks has been used.<sup>117</sup> After doses in the range of 100 mg/m<sup>2</sup>, peak plasma concentrations are in the range of 5 μM.<sup>118</sup> For high-dose therapy of breast cancer, BCNU is given at a dose of 600 mg/m<sup>2</sup> in combination with cyclophosphamide and cisplatin.<sup>119</sup> After this dose of BCNU, the peak plasma levels of BCNU have been shown to be approximately 5 μM.<sup>120</sup> Phenobarbital has been demonstrated to increase the clearance of BCNU<sup>121</sup> and to decrease the toxic and therapeutic effects. CCNU is administered in doses similar to those of BCNU. The parent CCNU has not been detected, but the peak concentrations of the ring hydroxylated metabolites are approximately 3 μM after doses of 130 mg/m<sup>2</sup>.<sup>122</sup>

### Specific Toxicities

Hematopoietic toxicity of the nitrosoureas is severe and is delayed, with the nadir of the granulocytes occurring approximately 5 to 6 weeks after administration.<sup>123</sup> This finding indicates that these agents selectively damage a very primitive hematopoietic precursor.

### HYDRAZINE AND TRIAZINE DERIVATIVES

The hydrazine and triazine derivative compounds are analogous to the nitrosoureas in that they decompose spontaneously or are metabolized to produce an alkyl carbonium ion, which alkylates DNA. Hydrazine and its substituted analogues are known carcinogens<sup>124</sup> that inhibit gluconeogenesis in cells<sup>125</sup> and have been promoted as antitumor agents.<sup>126</sup> However, objective preclinical and clinical studies have not supported a significant antitumor effect<sup>127,128</sup> for hydrazine analogues in general.

### Procarbazine

Procarbazine is a phenylhydrazine derivative that was initially developed as an inhibitor of monoamine oxidase but was found to have significant antitumor activity in preclinical models and clinically (Fig. 19.3-10).<sup>129</sup> Procarbazine was one of the components of the first effective combination chemotherapy regimen, MOPP, for Hodgkin's disease.<sup>6</sup> The agent is currently used for the treatment of Hodgkin's disease<sup>6,130</sup> and for the treatment of primary brain tumors.<sup>113,131</sup> Procarbazine has been demonstrated to be metabolized to a DNA-methylating agent,<sup>132,133 and 134</sup> which is most likely methylazoxiprocarbazine.<sup>135,136</sup> Since procarbazine is a monoamine oxidase inhibitor, patients can experience CNS depression<sup>137</sup> or stimulation<sup>138</sup> and acute hypertension, especially after the ingestion of tyramine-rich foods.

Procarbazine

FIGURE 19.3-10. Procarbazine .

## Dacarbazine

Dacarbazine, or DTIC [(dimethyltriazeno)imidazole-carboxamide], is a triazene derivative that is metabolized by microsomal N-demethylation, predominantly in the liver, to an intermediate that spontaneously decomposes to release a methyl diazonium that methylates DNA ( Fig. 19.3-11).<sup>139,140</sup> and <sup>141</sup> Dacarbazine is used in the regimen of doxorubicin, bleomycin, vinblastine, and dacarbazine for the treatment of Hodgkin's disease <sup>130,142</sup> and for the treatment of malignant melanoma.<sup>119,143</sup>

FIGURE 19.3-11. Generation of methyl diazonium from the triazenes dacarbazine and temozolomide.

## Temozolomide

Temozolomide is a triazene analogue that spontaneously decomposes to produce a methyl diazonium ion, as illustrated in Figure 19.3-11.<sup>144,145</sup> This compound may produce a more homogeneous distribution of the short-lived MITC [(methyltriazeno)-imidazole-carboxamide], which is spontaneously generated from temozolomide at all sites, than does dacarbazine, which is metabolized to MITC in the liver. The principal toxicities seen in phase I trials have been neutropenia and thrombocytopenia, and tumor responses were seen in those trials<sup>146,147</sup> in patients with glioma and melanoma. Phase II trials in patients with gliomas have shown response rates of 20% to 30%,<sup>148,149</sup> but phase II trials in patients with sarcomas<sup>150</sup> and pancreatic cancer<sup>151</sup> did not demonstrate significant responses.

These agents exert their toxicity predominantly through the methylation of the O<sup>6</sup> position of guanylic acid in DNA. Therefore, cells that contain significant O<sup>6</sup>-alkyltransferase or are deficient in mismatch repair will be resistant to them (as discussed in the section [Mechanisms of Toxicity and Drug Resistance](#)).

Procarbazine is an oral preparation and used in the MOPP regimen for Hodgkin's disease at a dose of 100 mg/m<sup>2</sup>/d for 14 days.<sup>142</sup> Because of its complex metabolism, pharmacokinetic studies have been limited. Dacarbazine is an intravenous preparation and is used in the regimen of doxorubicin, bleomycin, vinblastine, and dacarbazine for Hodgkin's disease at a dose of 375 mg/m<sup>2</sup>/d for 15 days.<sup>142</sup> For the treatment of malignant melanoma, a dose of 200 to 250 mg/m<sup>2</sup>/d for 5 days is used and, at this dose, peak plasma concentrations of dacarbazine are approximately 30 μM.<sup>152</sup> This agent has been used as a single agent with bone marrow transplantation at a dose of 2000 mg/m<sup>2</sup>.<sup>153</sup> At this dose, the maximum plasma concentration of dacarbazine was 800 μM.<sup>153</sup> Temozolomide is usually given orally at 150 to 250 mg/m<sup>2</sup>/d for 5 days. Reid et al.<sup>154</sup> measured peak concentrations of MITC of 0.5 to 5 μM after administration of these doses of temozolomide.<sup>154</sup> Baker et al.<sup>155</sup> studied the pharmacokinetics of <sup>14</sup>C-labeled temozolomide and found peak concentrations of temozolomide of approximately 30 μM and peak concentrations of MITC of approximately 1 μM.

## MECHANISMS OF TOXICITY AND DRUG RESISTANCE

### REACTION WITH CELLULAR MOLECULES

The alkylating agents are potent electrophiles and react with many electron-rich molecules within the cell to be inactivated. The principal such molecule is glutathione (GSH), a tripeptide with a free cysteine sulfhydryl that is present at millimolar concentrations in cells ( Fig. 19.3-12). This small nucleophile is known to react with and inactivate virtually all the therapeutic alkylating agents, and a correlation between elevated cellular GSH concentrations and resistance to nitrogen mustards has been demonstrated.<sup>156,157</sup> The GSH S-transferase enzymes catalyze the conjugation of GSH with electrophiles, and increased activity of this class of enzymes enhances GSH-mediated resistance.<sup>158,159</sup> and <sup>160</sup> The GSH conjugates of specific alkylating agents have been characterized,<sup>161,162</sup> and <sup>163</sup> and the specific isoenzymes of GST that catalyze their formation have been characterized.<sup>164,165,166,167</sup> and <sup>168</sup>

FIGURE 19.3-12. Structure of glutathione.

Buthionine sulfoximine is an inhibitor of gamma-glutamylcysteine synthetase, the rate-limiting enzyme in the GSH synthesis pathway, and decreases the GSH concentration in cells.<sup>169</sup> Exposure to this compound sensitizes both normal and tumor cells to alkylating agents.<sup>156,170,171</sup> In a phase I clinical trial, buthionine sulfoximine has been shown to increase the hematologic toxicity of melphalan<sup>172</sup> and is currently in further clinical trials to determine whether this agent can increase the clinical antitumor efficacy of melphalan.

Cells can also be sensitized to alkylating agents by exposure to inhibitors of GSH S-transferases,<sup>173,174</sup> and a clinical trial of the GSH S-transferase inhibitor sulfasalazine with melphalan demonstrated increased nausea and vomiting but no increase in hematopoietic toxicity.<sup>175</sup> The membrane transporter multidrug resistance protein is known to mediate the efflux of GSH conjugates from the cell,<sup>176</sup> and Barnouin et al.<sup>177</sup> have demonstrated that this system can transport the GSH conjugates of chlorambucil and melphalan from cells. The observations suggest that modulation of these systems could enhance the efficacy of alkylating agents.

Kelley et al.<sup>178</sup> demonstrated that transfection of metallothionein into cells produced increased resistance to chlorambucil and melphalan. Subsequently, Yu et al.<sup>179</sup> have demonstrated that the thiol groups of metallothionein will bind melphalan and phosphoramidate mustard.<sup>180</sup> It has also been demonstrated that exposure of cells to zinc will increase metallothionein concentration in the cell and increase resistance of the cells to melphalan, doxorubicin, and cisplatin.<sup>181</sup>

## ENHANCED DNA REPAIR: O<sup>6</sup> ALKYLATION

Another mechanism of cellular resistance to alkylating agents is repair of the DNA damage that the agents produce. The most defined mechanism of cellular repair of alkylating agent damage is that of the enzyme O<sup>6</sup>-alkylguanine-alkyltransferase. As illustrated in [Figure 19.3-13](#), this enzyme can remove an alkyl group from the O<sup>6</sup> position of guanine, and the alkylated enzyme is then rapidly degraded. <sup>182</sup> This mechanism has been shown to be effective in protecting normal and tumor cells from the carcinogenic and toxic effects of DNA methylating agents, such as temozolomide and procarbazine. <sup>183</sup> Erickson et al. <sup>184</sup> demonstrated that this enzyme would also remove the 6-chloroethyl lesion produced by the alkylation of guanine by the chloroethylnitrosoureas and produce resistance to these compounds, and this observation has been confirmed and extended. <sup>185</sup>

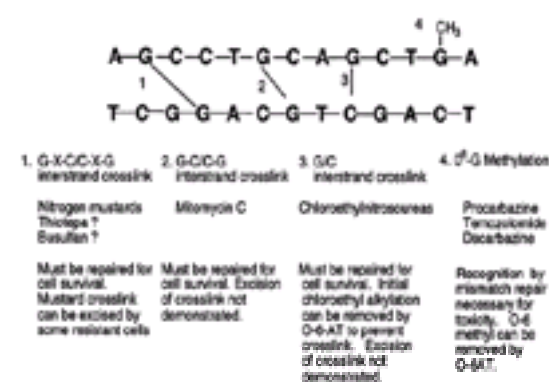

**FIGURE 19.3-13.** Interactions of O<sup>6</sup>-alkylguanine-DNA alkyltransferase. Pathway A: Repair of O<sup>6</sup> alkylation by O<sup>6</sup>AT. Pathway B: Inactivation of O<sup>6</sup>AT by benzylguanine.

It has been shown that such compounds as O<sup>6</sup>-benzylguanine will be acted on by O<sup>6</sup>-alkylguanine-DNA alkyltransferase (see [Fig. 19.3-13](#)) to remove the benzyl group <sup>186</sup> and that the enzyme will be rapidly degraded and depleted. Such compounds have been demonstrated to reverse tumor resistance due to O<sup>6</sup>AT to the O<sup>6</sup> alkylating agents *invitro* and *invivo*, <sup>187,188</sup> and clinical trials of the combination of such agents and O<sup>6</sup>-methylguanine are currently in progress. <sup>189,190</sup>

However, inhibitors of O<sup>6</sup>AT enhance the hematopoietic toxicity of O<sup>6</sup> alkylating therapeutic agents. Hematopoietic stem cells have been successfully transfected with O<sup>6</sup>AT variants that are resistant to O<sup>6</sup>-benzylguanine and related compounds. <sup>191</sup> The hematopoietic systems of animals populated with these cells are resistant to the combination of O<sup>6</sup>-benzylguanine and BCNU, <sup>192</sup> and clinical trials of this approach to improve the efficacy of chloroethylnitrosoureas and methylating agents are planned.

## CROSS-LINK REPAIR

The use of alkaline elution and other techniques ([Fig. 19.3-14](#)) has demonstrated that DNA interstrand cross-links produced by nitrogen mustards can be removed in bacteria <sup>193</sup> and mammalian cells. <sup>194</sup> The mechanism of such repair has not been elucidated, but nucleotide excision repair <sup>195</sup> and poly(adenosine diphosphate-ribose) polymerase <sup>196</sup> appear to play a role.

**FIGURE 19.3-14.** DNA lesions produced by alkylating agents.

Caffeine and related compounds have been demonstrated to enhance the cytotoxicity of nitrogen mustard. <sup>197</sup> This effect was associated with abrogation of G<sub>2</sub> arrest. O'Connor et al. <sup>198,199</sup> demonstrated that the G<sub>2</sub> arrest associated with nitrogen mustard resistance was associated with decreased activity of cdc2 kinase in the resistant cells. Caffeine has also been shown to inhibit nucleotide excision repair by binding to the subunit that recognizes the damage and helps to mediate this repair activity. <sup>200</sup> Elevated Bcl-2 has also been associated with nitrogen mustard resistance. <sup>201</sup>

A medulloblastoma cell line has been demonstrated to be resistant to activated cyclophosphamide (4-hydroperoxycyclophosphamide) on the basis of increased removal of DNA interstrand cross-links. <sup>34,202</sup> This cell does not appear to repair cross-links produced by BCNU and busulfan, indicating that the recognition of the nitrogen mustard cross-link is fairly specific.

## IN VIVO RESISTANCE

Kobayashi et al. <sup>203</sup> and St. Croix et al. <sup>204</sup> have described resistance to alkylating agents and other antitumor agents that is associated with aggregation of tumor cells. This resistance is present when the tumor cells are growing *invivo* or in three-dimensional *invitro* culture with adherence between the cells but is not present when the cells are dispersed in two-dimensional culture. This type of resistance has also been associated with increased metastatic potential. <sup>205</sup>

## COMMON TOXICITIES

Toxicities that are associated with specific alkylating agents are described in the discussions of the individual agents. The toxicities common to the alkylating agents as a class are described here.

### HEMATOPOIETIC TOXICITY

The usual dose-limiting toxicity for an alkylating agent is hematopoietic toxicity. As described, cyclophosphamide usually produces a relatively rapid nadir of the granulocytes, with recovery within 3 weeks after a single dose or short course. <sup>32,33,206</sup> Cyclophosphamide is also relatively platelet-sparing. The reason for the relative hematopoietic sparing properties of cyclophosphamide is the high concentrations of the enzyme aldehyde dehydrogenase in hematopoietic stem cells and megakaryocytes. <sup>30,31</sup>

The nitrosoureas produce an unusual delayed hematopoietic toxicity, with nadirs of both granulocytes and platelets at 5 to 6 weeks after administration. <sup>123</sup> Severe granulocytopenia and thrombocytopenia are also characteristic of busulfan. <sup>207</sup> An interesting characteristic of busulfan is its relative sparing of lymphocytes. The different hematopoietic effects of alkylating agents, except for the characteristics of cyclophosphamide, are not explained but suggest significant differences in

selectivity of the agents for hematopoietic precursors.

## GASTROINTESTINAL TOXICITY

The alkylating agents frequently produce nausea and vomiting, although this effect is usually not as severe as with the platinum agents. Cyclophosphamide produces severe nausea and vomiting in some patients, but these patients usually tolerate chlorambucil, which is clinically less emetogenic. The nausea and vomiting produced by alkylating agents are known to be mediated significantly through the CNS.<sup>208,209</sup> With the higher doses of alkylating agents used in bone marrow transplantation, increased nausea and vomiting are seen but can usually be controlled by corticosteroids and the newer antiserotonin antiemetics.<sup>210,211</sup> and<sup>212</sup> The alkylating agents can cause significant toxicity to the gastrointestinal mucosa and produce mucositis, stomatitis, and diarrhea, especially with the high doses of melphalan and thiotepa used in bone marrow transplantation.<sup>213</sup>

## GONADAL TOXICITY

The alkylating agents can produce significant gonadal toxicity. The characteristic testicular lesion in men is depletion of germ cells without damage to the Sertoli cells, which was first described with nitrogen mustard in 1948.<sup>214</sup> This lesion is also seen, often in association with oligospermia or aspermia, after treatment with other alkylating agents.<sup>215,216</sup> Spermatogenic dysfunction is reversible in some patients.<sup>217,218</sup>

Women treated with alkylating agents may develop amenorrhea associated with a marked decrease in ovarian follicles.<sup>215,219,220</sup> This complication and its irreversibility increase with the age of the woman.<sup>221</sup>

## PULMONARY TOXICITY

Interstitial pneumonitis and fibrosis were initially reported as a consequence of busulfan therapy but have subsequently been reported to occur after therapy with melphalan,<sup>222</sup> but have subsequently been reported to occur after therapy with melphalan,<sup>223</sup> chlorambucil,<sup>224</sup> cyclophosphamide,<sup>225,226</sup> mitomycin C,<sup>227</sup> and BCNU.<sup>228,229</sup> The clinical manifestations of this toxicity are dyspnea and a nonproductive cough, which can progress to cyanosis, pulmonary insufficiency, and death. The syndrome has particularly been associated in frequency and severity with high doses of BCNU.<sup>230,231</sup> The greater pulmonary toxicity of BCNU may be due to the spontaneous decomposition of BCNU, which produces chloroethyl isocyanate in addition to the alkylating chloroethyl diazonium moiety described.<sup>232</sup> Chloroethyl isocyanate is an analogue of methyl isocyanate, a known pulmonary toxin that produced many deaths when released in an industrial accident in Bhopal, India.<sup>233</sup>

## ALOPECIA

Alopecia from chemotherapy was first described after administration of dimethylmyeleran, an analogue of busulfan.<sup>234</sup> The alkylating agents now most associated with alopecia are cyclophosphamide and ifosfamide. Feil and Lamoureux<sup>235</sup> examined the alopecia-producing effects of metabolites and analogues of cyclophosphamide and proposed that the alopecic effect was due to the facile entry of a lipophilic metabolite (now known to be 4-HC) into the hair follicles. This hypothesis is consistent with the fact that vincristine, doxorubicin, and the taxanes, all associated with alopecia, are fairly lipophilic.

## TERATOGENICITY

All the therapeutically used alkylating agents are teratogenic in animal studies.<sup>236,237,238</sup> and<sup>239</sup> A review of the literature in 1968 found that 4 of 25 children born to mothers who received alkylating agents during the first trimester of pregnancy had fetal malformations.<sup>240</sup> On the basis of the limited information available, women treated with an alkylating agent during the first trimester of pregnancy may have a risk as high as 15% of having a malformed infant. Administration of alkylating agents during the second and third trimesters has not been associated with increased fetal malformations.<sup>241,242</sup> More recent reviews support the lack of malformations produced by treatment during the second and third trimesters,<sup>243,244</sup> and one review cites 19 women treated during the first trimester with no infant malformations.<sup>244</sup>

## CARCINOGENESIS

In the 1970s, there were reports of acute leukemia occurring in patients who had been treated with alkylating agents,<sup>245,246,247,248</sup> and<sup>249</sup> and subsequent experience has confirmed the occurrence of this complication. The incidence of leukemia is difficult to estimate because of the variety of agents, doses, and combinations used but is probably approximately 5%. In one group of 12 ovarian cancer patients receiving a high dose of melphalan, 4 developed acute leukemia.<sup>248</sup> In one report, the incidence of leukemia was found to be higher after melphalan treatment than after cyclophosphamide therapy.<sup>250</sup> This observation may be related to the stem cell-sparing properties of cyclophosphamide.<sup>30</sup> An increased frequency of solid tumors also occurs after alkylating agent therapy.<sup>251,252</sup>

## IMMUNOSUPPRESSION

In 1921, Hektoen and Corper<sup>253</sup> reported an inhibitory effect of sulfur mustard on antibody production. While all the alkylating agents produce some degree of immunosuppression, cyclophosphamide is the most immunosuppressive.<sup>254</sup> Cyclophosphamide and chlorambucil are the alkylating agents most commonly used for the treatment of autoimmune diseases.<sup>255,256,257,258</sup> and<sup>259</sup>

Selective inhibition of immunosuppressor cells with low doses of an activated analogue of cyclophosphamide and with melphalan has been demonstrated *in vitro*<sup>260,261,262</sup> and<sup>263</sup> and *in vivo*<sup>263,264</sup> and enhancement of the immune response has been shown *in vivo*.<sup>263</sup> For this reason, low doses of cyclophosphamide have been used in conjunction with immunotherapy.<sup>265,266</sup> Because of its potent immunosuppressive properties, cyclophosphamide has long been used in preparative regimens for allogeneic stem cell transplantation for malignancy<sup>267</sup> and more recently for the autologous transplantation of autoimmune disease.<sup>268,269</sup> The use of high doses of cyclophosphamide without stem cell support has now been reported to produce complete remissions in autoimmune diseases.<sup>21,270,271</sup>

## INTRODUCTION

The platinum drugs represent a unique and important class of antitumor compounds. Alone or in combination with other chemotherapeutic drugs, *cis*-diamminedichloroplatinum (II) (cisplatin) and its analogues have made a significant impact on the treatment of a variety of solid tumors. The realization that platinum complexes exhibit antitumor activity arose somewhat serendipitously in a series of experiments carried out by Rosenberg and colleagues beginning in 1961.<sup>1</sup> These studies involved determining the effect of electromagnetic radiation on the growth of bacteria in a chamber equipped with a set of platinum electrodes. Exposure of the bacteria to an electric field resulted in a profound change in their morphology and, in particular, the appearance of long filaments that were several hundred times longer than that of their untreated counterparts. This effect was not due to the electric field directly, but to the electrolysis products produced from the platinum electrodes. An analysis of these products revealed that the predominant species was ammonium chloroplatinate  $[\text{NH}_4]_2[\text{PtCl}_6]$ . This compound was inactive at reproducing the filamentous growth originally observed; however, Rosenberg and colleagues<sup>1</sup> soon discovered that the conversion of this complex to a neutral species by UV light resulted in an active species. Attempts to synthesize the active neutral platinum complex failed. They realized, however, that the neutral compound could exist in two isomeric forms, *cis* or *trans*, and that the latter species is the one they had synthesized. Subsequently, the *cis* isomer was synthesized and shown to be the active compound.

The observation that *cis*-diamminedichloroplatinum (II) and *cis*-diamminetetrahydrochloroplatinum (IV) inhibited bacterial growth led to the testing of four neutral platinum compounds for antineoplastic activity in mice bearing the Sarcoma-180 solid tumor and L1210 leukemia cells.<sup>2</sup> All four compounds showed significant antitumor activity, with *cis*-diamminedichloroplatinum (II) exhibiting the most efficacy. Further studies in other tumor models confirmed these results and indicated that cisplatin exhibited a broad spectrum of activity. Although early clinical trials demonstrated significant activity against several tumor types, particularly testicular tumors, the severe renal and gastrointestinal toxicity caused by the drug nearly led to its abandonment. Cvitkovic et al.<sup>3,4</sup> showed that these effects could be ameliorated, in part, by aggressive prehydration, which rekindled interest in its clinical use. Currently, cisplatin is curative in testicular cancer and significantly prolongs survival in combination regimens for ovarian cancer. The drug also has therapeutic benefit in head and neck, bladder, and lung cancer.<sup>5</sup>

The unique activity and toxicity profile observed with cisplatin has fueled the development of platinum analogues that are less toxic and more effective against a variety of tumor types, including those that have developed resistance to cisplatin. Two other platinum drugs are widely used: *cis*-diamminocyclobutanedicarboxylato platinum (II) (carboplatin) and 1,2-diaminocyclohexanecarboxylato platinum (II) (oxaliplatin). Several new analogues with unique activities are currently in various stages of clinical development. Continued progress in the development of superior analogues requires a thorough understanding of the chemical, biological, pharmacokinetic, and pharmacodynamic properties of this important class of drugs. A review of these properties is the focus of this chapter.

## PLATINUM CHEMISTRY

Platinum exists primarily in either a 2+ or 4+ oxidation state. These oxidation states dictate the stereochemistry of the carrier ligands and leaving groups surrounding the platinum atom. Platinum (II) compounds exhibit a square planar geometry, whereas platinum (IV) compounds exhibit an octahedral geometry. Interconversion of the two oxidation states may readily occur. However, the kinetics of this reaction depend on the nature of the bound ligands. The nature of the ligands also determines the stability of the complex and the rate of substitution. For platinum (II) compounds, the rate of substitution of a ligand is strongly influenced by the type of ligand located opposite to it. Therefore, ligands that are bound more strongly stabilize the moieties that are situated *trans* to it. For *cis*-diamminedichloroplatinum (II), the two chloride ligands are prone to substitution, whereas substitution of the amino groups is thermodynamically unfavorable.<sup>6</sup> The stereochemistry of platinum complexes is critical to their antitumor activity, as evidenced by the significantly reduced efficacy observed with *trans*-diamminedichloroplatinum (II).

In aqueous solution, the chloride leaving groups of cisplatin are subject to mono- and diaqua substitution, particularly at chloride concentrations below 100 mmol, which exist intracellularly. The equilibria may be described by the following two equations:

where equilibria constants for each reaction may be written

$$\begin{aligned} K_1 &= \frac{[\text{Cl}^-][\text{cis}-(\text{NH}_3)_2\text{PtCl}(\text{H}_2\text{O})^+]}{[\text{cis}-(\text{NH}_3)_2\text{PtCl}_2]} \text{ and} \\ K_2 &= \frac{[\text{Cl}^-][\text{cis}-(\text{NH}_3)_2\text{Pt}(\text{H}_2\text{O})_2^{2+}]}{[\text{cis}-(\text{NH}_3)_2\text{PtCl}(\text{H}_2\text{O})^+]} \end{aligned}$$

These descriptions illustrate the key role of ambient chloride concentrations in determining aquation rates. In weakly acidic solutions, the monochloromonoaqua and

diaqua complexes become deprotonated to form the neutral dihydroxo species. The monohydroxo and dihydroxo complexes are the predominant species present in low chloride-containing environments, such as the nucleus. A detailed analysis of the equations and rate constants that govern these reactions has been published.<sup>7</sup> Based on studies of the reaction of cisplatin metabolites with inosine, the predominant cisplatin species that react with DNA are likely to be the chloroaqua and hydroxo-aqua species.<sup>7</sup>

## EVOLUTION OF NOVEL PLATINUM COMPLEXES

Cisplatin therapy has two major limitations: an undesirable toxicity profile and the development of resistance by tumor cells. Therefore, substantial effort has gone into developing analogues that are less toxic, with a different spectrum of antitumor activity. Progress in understanding the chemistry and pharmacokinetics of cisplatin has guided the development of new analogues. In general, modification of the chloride leaving groups of cisplatin results in compounds with different pharmacokinetics, whereas modification of the carrier ligands alters the activity of the resulting complex. This section summarizes the features of the more important platinum analogues that have been developed, which are shown in [Figure 19.4-1](#).

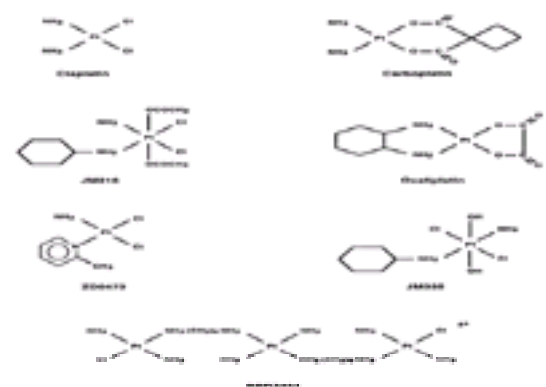

FIGURE 19.4-1. Structures of platinum complexes.

## CARBOPLATIN

The search for a less toxic platinum drug, pursued at the Institute for Cancer Research in the United Kingdom, led to the development of carboplatin.<sup>8,9</sup> It was hypothesized that modification of cisplatin to contain a more stable leaving group could alter toxicity without necessarily influencing the cytotoxicity profile. Using a murine screen for nephrotoxicity, it was discovered that substituting a cyclobutanedicarboxylate moiety for the two chloride ligands of cisplatin resulted in a complex with reduced renal toxicity. Instead, myelosuppression was dose-limiting, a toxicity that is not associated with cisplatin therapy. At effective doses, carboplatin produces less nausea, vomiting, nephrotoxicity, and neurotoxicity than cisplatin and has demonstrated essentially equivalent survival rates in ovarian cancer patients. Similar findings have been observed in other solid tumors. Therefore, based on its superior therapeutic index, greater ease of administration, and more predictable individualized dosing, carboplatin has replaced cisplatin in many chemotherapeutic regimens.

## 1,2-DIAMINOCYCLOHEXANE DERIVATIVES

The example of carboplatin provided a paradigm for the development of other platinum coordination compounds with modified leaving groups. However, the antitumor activity of these drugs generally overlap, and they are not considered effective for the treatment of cisplatin-resistant disease. Therefore, the development of platinum analogues that produce responses in cisplatin/carboplatin-resistant tumors became necessary, and it was hypothesized that modifying the carrier ligands might achieve this. The antitumor activity of a series of platinum compounds containing the 1,2-diaminocyclohexane (DACH) carrier ligand was initially described by Connors et al.<sup>10</sup> in 1972. Several of these compounds exhibited a significantly higher therapeutic index compared with cisplatin using a murine ADJ/PC6A tumor model. Kidani et al.<sup>11</sup> also reported significant antitumor activity of DACH platinum complexes. Burchenal and colleagues<sup>12</sup> selected several DACH derivatives for preclinical development based on their activity in cisplatin-resistant murine leukemias. Subsequent *in vitro* studies supported the idea that DACH-based platinum complexes were non-cross-resistant in cisplatin-resistant cell lines.<sup>12,13</sup> In support of these studies, Rixe et al.<sup>14</sup> showed that DACH derivatives exhibited a unique cytotoxicity profile compared with cisplatin and carboplatin using the National Cancer Institute 60 cell line screen. Several DACH-platinum compounds have been tested in clinical trials; however, each has had limitations that prevented their continued use.

Interest in DACH compounds has been rekindled by the clinical development of oxaliplatin.<sup>15</sup> Oxaliplatin has demonstrated activity alone or in combination with 5-fluorouracil/leucovorin in colon cancer, a disease that was previously considered to be unresponsive to platinum drugs. Like cisplatin, oxaliplatin preferentially forms adducts at the N7 position of guanine and, to a lesser extent, adenine. However, evidence suggests that the three-dimensional structure of the DNA adducts and biological response(s) they elicit are different from that of cisplatin.

## PLATINUM (IV) STRUCTURES

The octahedral stereochemistry adopted by platinum (IV) compounds has led investigators to speculate that they may exhibit a different spectrum of activity than that of platinum (II) drugs. Two compounds that have been tested clinically without much success are ormaplatin and iproplatin. Ormaplatin was neurotoxic in phase I trials, and iproplatin did not demonstrate activity in phase II trials.<sup>16,17</sup> and <sup>18</sup> Two platinum (IV) compounds, JM216 [bis(acetato)amminedichloro(cyclohexylamine) platinum (IV)] and JM335 [*trans*-ammine(cyclohexylamine)dichlorodihydroxo platinum (IV)], have been developed in the United Kingdom and contain several unique features.<sup>19</sup> These compounds may also be classified as mixed amines or ammine/amine platinum (IV) complexes. JM216 is the first orally active platinum compound and is currently undergoing phase II testing. A response rate of 38% was observed in patients with small cell lung cancer<sup>20</sup>; however, no significant antitumor activity was observed in patients with non-small cell lung cancer.<sup>21</sup> Based on the lack of antitumor activity of transplatin [*trans*-diamminedichloroplatinum (II)], it has been generally believed that most, if not all, *trans* platinum compounds were inactive. Renewed interest in *trans* compounds has occurred, however, with the observation that JM335 and a related group of complexes exhibited significant antitumor activity in murine ADJ/PC6 and human ovarian cancer models.<sup>19</sup> Khokhar and colleagues<sup>22</sup> also have produced *trans*-platinum (IV) compounds containing the DACH moiety that they demonstrated to be non-cross-resistant to cisplatin.

## MULTINUCLEAR PLATINUM COMPLEXES

The synthesis and preclinical studies of multinuclear platinum compounds was first reported by Farrell et al.<sup>23</sup> These compounds are unique in that their interaction with DNA is considerably different from that of cisplatin, particularly in the abundance of interstrand cross-links formed. Also, the observation that multinuclear platinum complexes containing the *trans* geometry exhibit antitumor activity contradicts the original dogma that platinum drugs containing the *trans* geometry are inactive. Currently, the lead compound in this class of drugs is BBR3464. Its structure is described as two *trans*-[PtCl(NH<sub>3</sub>)<sub>2</sub>]<sup>+</sup> units linked together by a noncovalent tetraamine [Pt(NH<sub>3</sub>)<sub>2</sub>[H<sub>2</sub>N(CH<sub>2</sub>)<sub>6</sub>NH<sub>2</sub>]<sub>2</sub>]<sup>2+</sup> unit. Preclinical testing of BBR3464 shows it to be significantly more potent than cisplatin and to be active in cisplatin-resistant xenografts and p53 mutant tumors. Preliminary data from a phase I clinical trial of BBR3464 have indicated that diarrhea and myelosuppression are dose-limiting (P. Calvert, H. Calvert, C. Sessa, G. Camboni, personal communication, 1999). In this study, a partial response was observed in a patient with metastatic pancreatic cancer.

## OTHER PLATINUM COMPLEXES

Another approach for the design of novel platinum analogues is to identify compounds that can circumvent specific cisplatin resistance mechanisms. An example of this is ZD0473 (AMD473) [*cis*-amminedichloro(2-methylpyridine) platinum (II)], which is a sterically hindered platinum complex that was designed to preferentially react with nucleic acids instead of thiol-containing molecules such as glutathione.<sup>19</sup> ZD0473 exhibits activity against acquired cisplatin-resistant cell lines and is active when administered by oral or intraperitoneal routes in human ovarian cancer xenografts.<sup>24,25</sup> The results of a phase I clinical trial have indicated that myelosuppression is dose-limiting and that nephrotoxicity, neuropathy, and ototoxicity are not prominent.<sup>26</sup> Antitumor activity was observed in previously platinum-treated head and neck

and ovarian cancer patients.

## MECHANISM OF ACTION

### DNA ADDUCT FORMATION

The observation by Rosenberg<sup>2</sup> that cisplatin induces filamentous growth in bacteria without affecting RNA and protein synthesis implicated DNA as the cytotoxic target of the drug. Evidence from several subsequent experiments supported this idea.<sup>27,28,29,30 and 31</sup> The differential cytotoxic effects observed with platinum drugs are determined, in part, by the structure and relative amount of DNA adducts formed. Cisplatin and its analogues react preferentially at the N7 position of guanine and adenine residues to form a variety of monofunctional and bifunctional adducts.<sup>32</sup> The first step of the reaction involves the formation of monoadducts. These monoadducts may then react further to form intrastrand or interstrand cross-links. The predominant bidentate lesions that are formed with DNA *in vitro* or in cultured cells are the d(GpG)Pt, d(ApG)Pt, and d(GpNpG)Pt intrastrand cross-links. In a study of cisplatin-treated Chinese hamster ovary (CHO) cells, these lesions were determined to account for approximately 60%, 15%, and 20% of the total platinum DNA adducts, respectively.<sup>33</sup> Cisplatin also forms interstrand cross-links between guanine residues located on opposite strands that account for less than 5% of the total DNA bound platinum. These adducts may contribute to the drug's cytotoxicity, because they impede certain cellular processes that require the separation of both DNA strands, such as replication and transcription.

The adducts that are formed between the reaction of carboplatin with DNA in cultured cells are essentially the same as that of cisplatin. However, higher concentrations of carboplatin are required (20- to 40-fold for cells) to obtain equivalent total platinum-DNA adduct levels because of cisplatin's slower rate of aquation.<sup>34</sup> The relative amounts of each lesion are different, with the d(GpNpG)Pt intrastrand adduct being the most prevalent (approximately 40%) followed by the d(GpG)Pt (approximately 30%) and d(ApG)Pt (approximately 15%) intrastrand adducts, respectively.<sup>33</sup> As with cisplatin, a relatively low number of monoadducts and interstrand cross-links are observed. The relative amounts and frequencies of the DNA adducts formed in cultured cells by oxaliplatin have also been examined. Oxaliplatin intrastrand adducts form more slowly because of a slower rate of conversion from monoadducts; however, they are formed at similar DNA sequences and regions as cisplatin adducts. Saris et al.<sup>35</sup> reported that oxaliplatin forms predominantly d(GpG)Pt and d(ApG)Pt intrastrand cross-links *in vitro* and in cultured cells. At equitoxic doses, however, oxaliplatin forms fewer DNA adducts compared with cisplatin. This suggests that oxaliplatin lesions are more cytotoxic than those formed by cisplatin.

The differences observed in cytotoxicity between the diamine (e.g., cisplatin, carboplatin) and DACH platinum compounds is not dependent on the type and relative amounts of the adducts formed, but more likely due to the overall three-dimensional structure of the adduct and its recognition by various cellular proteins. Structural analysis of the cisplatin d(GpG)Pt intrastrand cross-link has been accomplished by both x-ray crystallography and nuclear magnetic resonance spectroscopy. These studies revealed that the binding of platinum to DNA causes a variety of perturbations in the double helix, including a roll of 26 to 50° between the cross-linked guanine bases, displacement of platinum from the planes of the guanine rings, a bend of the helical axis toward the major groove, and an unwinding of the DNA.<sup>36</sup> Scheef et al.<sup>37</sup> used computer modeling to demonstrate that oxaliplatin produces a similar DNA bend, base rotation, and base propeller as cisplatin. The major difference, however, is the protrusion of the DACH moiety of oxaliplatin into the major groove of DNA, thus producing a bulkier adduct than that of cisplatin. This bulkier, more hydrophobic adduct may be recognized differently by a host of cellular proteins involved in sensing DNA damage.<sup>38</sup> The functional consequence of these effects are twofold: Proteins, such as polymerases, that recognize and participate in reactions on DNA under normal circumstances may be perturbed, whereas processes that are controlled by proteins that recognize damaged DNA may become activated. The latter group of proteins may function in the DNA repair process or in the initiation of programmed cell death.

### PLATINUM-DNA DAMAGE-RECOGNITION PROTEINS

Several damage-recognition proteins have been identified that preferentially bind to DNA damaged by cisplatin, but not to the inactive transplatin isomer.<sup>39,40</sup> The first of these to be discovered were the HMG1 (high mobility group 1) and HMG2 proteins. These proteins are capable of bending DNA as well as recognizing bent DNA structures, such as that produced by cisplatin binding. The HMG domain, which consists of a highly basic 80 amino acid motif, has been found in other proteins, most of which are involved in gene expression.<sup>41</sup> Although many theories exist as to how HMG proteins may influence cisplatin sensitivity, relationships between HMG protein function and expression have not yet been clearly established. Recognition of platinum-DNA adducts by the mismatch repair (MMR) complex also has been implicated in cisplatin sensitivity.<sup>42</sup> For example, the MSH2 (MutS homologue) and MLH1 (MutL homologue) proteins participate in the recognition of DNA adducts formed by cisplatin.<sup>43,44</sup> The presence of a platinum lesion results in a continuous futile cycle of repair synthesis on the DNA strand opposite the lesion, possibly causing the accumulation of DNA strand breaks that may result in cell death. Interestingly, oxaliplatin adducts are not recognized by this MMR protein complex, which may account for differences in the cytotoxic mechanism of the two platinum compounds.

### PLATINUM DRUG-INDUCED CELL DEATH

The sequence of events that lead to cell death after the formation of platinum-DNA adducts have not yet been elucidated. However, cells treated with platinum drugs display the biochemical and morphologic features of apoptosis.<sup>45</sup> These features are common to cells treated with other cytotoxic and biological agents. Therefore, understanding the pathway(s) that are involved in the early stages of programmed cell death, including the detection/initiation and decision/commitment phases, are important for understanding the unique activities of platinum drugs. The sensitivity of a cell to a platinum drug depends, in part, on cell cycle. For example, proliferating cells are relatively sensitive, whereas quiescent cells or cells in G<sub>0</sub>/G<sub>1</sub> are relatively insensitive.<sup>46</sup> Thus, it is possible that programmed cell death initiated at various cell-cycle checkpoints is governed by different proteins and signal transduction pathways.

A model for cisplatin-induced cell death in CHO cells has been provided by Sorrenson and Eastman.<sup>47</sup> In this study, cisplatin-treated CHO/AA8 cells experienced slow progression through S phase and accumulated in G<sub>2</sub>. At low drug concentrations, the cells recovered and continued to cycle. At high drug concentrations, the cells died after a protracted G<sub>2</sub> arrest. An aberrant mitosis was observed before apoptosis. Further studies with G<sub>2</sub>-synchronized cells revealed that passage through S phase is necessary for G<sub>2</sub> arrest and cell death, suggesting that DNA replication on a damaged template may result in the accumulation of further damage, ultimately causing the cells to die. Cisplatin-induced accumulation of human tumor cells in G<sub>2</sub> also has been observed in mice. Abrogating the G<sub>2</sub> checkpoint with pharmacologic agents, such as caffeine or 7-hydroxystaurosporine, have been shown to enhance the cytotoxicity of cisplatin.<sup>48</sup> It is not yet clear how these events specifically transduce a proapoptotic signal. However, the observations provide a valuable framework to begin to elucidate the initial steps.

The decision/commitment phase of apoptosis hinges on the balance between survival and death signals. Each cell contains a damage threshold that, once surpassed, results in the onset of apoptosis. It is not clear what signaling pathways influence the response of cells to platinum drugs. However, it has been shown that activators or inhibitors of known signal transduction pathways can influence platinum drug sensitivity. For example, treatment of various cell lines with tamoxifen, epidermal growth factor, interleukin-1 $\alpha$ , tumor necrosis factor- $\alpha$  bombesin, and rapamycin enhance cisplatin cytotoxicity.<sup>49,50,51,52 and 53</sup> Also, the expression of certain protooncogenes, including *Ha-Ras*, *v-abl*, and *Her2/neu*, has been shown in some instances to promote cell survival after cisplatin exposure.<sup>54,55,56 and 57</sup> This is an area of investigation that requires further study, and the overall balance of cell survival and cell death signals may be critical in determining the response of tumors to chemotherapy.

In addition to the mounting evidence supporting the existence of programmed cell death pathways, substantial evidence indicates that cell death is influenced by cellular signal transduction pathways such as those that control growth, differentiation, and stress response. These signals are mediated primarily by small guanosine triphosphatases and protein serine-threonine kinases. Members of the extracellular signal-related kinase/mitogen-activated kinase family, as well as their upstream activators, have been implicated in these events. The c-JUN amino-terminal kinase (JNK)/stress-activated protein kinase (SAPK) and p38 kinase pathways have been shown to be activated by a variety of environmental stimuli and inflammatory cytokines.<sup>58</sup> JNK/SAPK and p38 phosphorylate and regulate the activity of the ATF2 (alcohol acetyltransferase II) and Elk-1 transcription factors. JNK/SAPK also phosphorylates c-JUN, a component of the AP-1 (activating protein 1) transcription factor complex, on serine residues 63 and 73. Considerable evidence suggests that these protein kinases are involved in transmitting a drug-induced cell death signal. For example, Zanke et al.<sup>59</sup> demonstrated that, in mouse fibroblasts, the inhibition of JNK phosphorylation by the stable transfection of a dominant-negative complementary DNA encoding SEK1, the protein kinase responsible for activating JNK, resulted in reduced sensitivity to cisplatin. Sanchez-Perez et al.<sup>60</sup> observed a prolonged activation of JNK by cisplatin that was related to cell death. Modulating the activity of kinases upstream of JNK, including c-Abl, MKK3/MKK6, MEKK1, and ASK1, also influences cellular drug sensitivity.<sup>61</sup> For example, Chen et al.<sup>62</sup> demonstrated that overexpression of a dominant-negative ASK1, which inhibits activation of JNK, resulted in an inhibition of cisplatin-induced apoptosis. Clearly, activation of these pathways occurs after drug exposure in some cells, and it is important to understand the contribution of these intracellular signaling events to overall platinum drug sensitivity. Within these pathways may reside the key to understanding the

molecular basis for platinum drug-induced cell death.

## MECHANISMS OF RESISTANCE

The major limitation to the successful treatment of solid tumors with platinum-based chemotherapy is the emergence of drug-resistant tumor cells.<sup>63</sup> Platinum drug resistance may be intrinsic or acquired and may occur through multiple mechanisms. These mechanisms may be classified into two major groups: (1) those that limit the formation of cytotoxic platinum-DNA adducts and (2) those that prevent cell death from occurring after platinum-DNA adduct formation. The first group of mechanisms includes decreased drug accumulation and increased drug inactivation by cellular protein and nonprotein thiols. The second group of mechanisms includes increased platinum-DNA adduct repair and increased platinum-DNA damage tolerance. These mechanisms have been described previously in *in vitro* resistance models, and their relevance to clinical resistance is unknown (Table 19.4-1).

Resistance Mechanism	In Vitro-Selected Cisplatin-Resistant Model*	Unselected Ovarian Tumor Cell Lines <sup>b</sup>
Glutathione levels	0.94	0.13
Cellular platinum accumulation	0.85	-0.11
Platinum-DNA adduct formation	0.85	-0.58
Platinum-DNA adduct removal	0.83	0.44
Platinum-DNA adduct tolerance	0.99	0.84

**TABLE 19.4-1.** Correlation Coefficients Derived from the Relationships between Cisplatin-Sensitivity and Cisplatin-Resistance Mechanisms in Two Human Ovarian Cancer Model Systems

## REDUCED ACCUMULATION

The majority of cell lines that have been selected for cisplatin resistance *in vitro* exhibit a decreased platinum accumulation phenotype, and it is generally believed that this is due to decreased drug uptake rather than enhanced drug efflux. Cisplatin and its analogues may accumulate within cells by passive diffusion or facilitated transport.<sup>64</sup> Cisplatin uptake has been shown to be nonsaturable, even up to its solubility limit, and not inhibited by structural analogues. Carrier-mediated transport is supported by the observation that uptake is partially energy-dependent, ouabain-inhibitable, sodium-dependent, and influenced by membrane potential and cyclic adenosine monophosphate levels. Although no specific drug transporters have been implicated in the reduced platinum accumulation phenotype, some insight into a possible pathway has been provided. Using two different acquired cisplatin resistance model systems, Shen et al.<sup>65</sup> reported that the loss of the folate binding protein (FBP) was associated with decreased cellular accumulation of cisplatin, methotrexate, arsenate, and arsenite. Although the loss of FBP was not shown to be directly responsible for reduced cisplatin accumulation, the regulatory mechanism responsible for the reduction in FBP gene expression may be linked to the expression of a transport protein that may influence cisplatin uptake.

The prospect of an active efflux mechanism for platinum drugs has been rekindled by the discovery of a group of multidrug resistance protein (MRP)-related transport proteins. MRP is a member of the adenosine triphosphate-binding cassette family of transport proteins that participates in the extrusion of glutathione-coupled and unmodified anticancer drugs out of cells.<sup>66</sup> Overexpression of MRP confers resistance to a variety of drugs, but not to cisplatin. For platinum complexes, the formation of a glutathione-platinum drug conjugate may be the rate-limiting step for producing an MRP substrate. The MRP homologue cMOAT (canalicular multispecific organic anion transporter) shares 49% amino acid sequence identity and a similar substrate specificity with that of MRP. Taniguchi et al.<sup>67</sup> has shown that cMOAT (MRP2) is overexpressed in some cisplatin-resistant human cancer cell lines exhibiting a decreased platinum accumulation phenotype. These investigators also demonstrated that transfection of an antisense cMOAT complementary DNA into HepG2 cells results in decreased cMOAT protein levels and a fivefold increase in cisplatin sensitivity.<sup>68</sup> Kool et al.<sup>69</sup> examined the expression of MRP, cMOAT, and three other MRP homologues (MRP3, MRP4, MRP5) in a set of cell lines selected for cisplatin resistance *in vitro*. MRP1 and MRP4 messenger RNA levels were not increased in any of the cisplatin-resistant sublines. MRP3 and MRP5 were overexpressed in a few cell lines, but the messenger RNA levels were not associated with cisplatin resistance. In contrast, cMOAT was substantially overexpressed in some of the cisplatin-resistant cell lines. An immunohistochemical analysis of the expression of P glycoprotein, MRP1, and MRP2 revealed that none of these transporters was associated with response to platinum-based chemotherapy in ovarian cancer.<sup>70</sup>

## INACTIVATION

As mentioned above, the formation of conjugates between glutathione (GSH) and platinum drugs may be an important step for their inactivation and elimination from the cell. For many years, investigators have attempted to make positive correlations between platinum drug sensitivity, GSH levels, and the relative expression of the enzymes involved in GSH metabolism. There have been many reports showing a strong association between platinum drug sensitivity and GSH levels.<sup>71,72,73</sup> and <sup>74</sup> However, reducing intracellular GSH levels with drugs such as buthionine sulfoximine has resulted in only low to modest potentiation of cisplatin sensitivity.<sup>75,76</sup> Part of the reason for this may be due to the fact that the formation of GSH-platinum conjugates is a slow process.<sup>77</sup> The formation of a GSH-platinum complex, however, has been reported to occur in cultured cells, and GSH has been shown to quench platinum-DNA monoadducts *in vitro*, preventing them from being converted to potentially cytotoxic cross-links.<sup>78,79</sup> and <sup>80</sup> These findings raise the question of whether the intracellular reaction is catalyzed by glutathione S-transferases (GSTs). In support of this theory, a threefold increase in cisplatin resistance was reported in CHO cells transfected with the GSTp isoenzyme.<sup>81</sup> In contrast, transfection of NIH3T3 cells with GSTp resulted in hypersensitivity to cisplatin.<sup>82</sup> Studies attempting to associate GST activity with cisplatin sensitivity in cell lines and tumor biopsies have not consistently shown a positive correlation between GST expression or activity and cisplatin sensitivity.<sup>72,73</sup> and <sup>74,83</sup>

Inactivation of the platinum drugs may also occur through binding to the metallothionein (MT) proteins. The MTs are a family of sulfhydryl-rich, small-molecular-weight proteins that participate in heavy metal binding and detoxication. *In vitro*, cisplatin binds stoichiometrically to metallothionein, and up to ten molecules of cisplatin can be bound to one molecule of metallothionein.<sup>84</sup> Kelley et al.<sup>85</sup> demonstrated that overexpression of the full-length MT-II<sub>A</sub> in mouse C127 cells conferred a fourfold resistance to cisplatin. Furthermore, this group showed that embryonic fibroblasts isolated from MT-null mice were hypersensitive to cisplatin.<sup>86</sup> These studies clearly show that modulating MT levels can alter cisplatin sensitivity. However, the contribution of MT to clinical platinum drug resistance is unclear. In some cell lines, elevated MT levels have been shown to be associated with cisplatin resistance, whereas in others, they have not.<sup>72,87</sup> Studies with human tumors have shown that, in some instances, metallothionein expression level is associated with response to chemotherapy. For example, a significant correlation between MT overexpression and response or survival was reported in urothelial transitional cell carcinoma patients.<sup>88</sup> Overexpression of MT also has been observed in bladder tumors from patients that were unsuccessful with cisplatin chemotherapy.<sup>89</sup>

## INCREASED DNA REPAIR

Once platinum-DNA adducts are formed, cells must either repair or tolerate the damage to survive. The capacity to rapidly and efficiently repair DNA damage clearly plays a role in determining a tumor cell's sensitivity to platinum drugs and other DNA damaging agents. Evidence suggests that cell lines derived from tumors that are unusually sensitive to cisplatin, such as testicular nonseminomatous germ cell tumors, are deficient in their ability to repair platinum-DNA adducts.<sup>90</sup> Increased repair of platinum-DNA lesions in cisplatin-resistant cell lines as compared with their sensitive counterparts has been shown in several human cancer cell lines, including ovarian,<sup>91,92</sup> breast,<sup>93</sup> glioma,<sup>94</sup> and murine leukemia cell lines.<sup>95</sup> Evidence for increased repair of cisplatin interstrand cross-links in specific gene and nongene regions in cisplatin-resistant cell lines also has been demonstrated. These studies have been done using a variety of *in vivo* methods, including unscheduled DNA synthesis, host cell reactivation of cisplatin-damaged plasmid DNA, atomic absorption spectrometry, quantitative polymerase chain reaction, and renaturing agarose gel electrophoresis.

The repair of platinum-DNA adducts occurs predominantly by nucleotide excision repair (NER). However, the molecular basis for the increased repair activity

observed in cisplatin-resistant cells is unknown.<sup>96</sup> Because the rate-limiting step in this process is platinum-adduct recognition/incision, increased expression of the proteins that control this step are likely to enhance nucleotide excision repair activity. Using an *in vitro* assay, Ferry et al.<sup>97</sup> demonstrated that the addition of the ERCC1/XPF (excision repair) protein complex increased the platinum-DNA adduct excision activity of an ovarian cancer cell extract. Circumstantial evidence also implicates *ERCC1* expression with increased NER and cisplatin resistance. For example, expression levels of the *ERCC1* and *XPA* genes have been shown to be higher in malignant tissue from ovarian cancer patients resistant to platinum-based therapy compared with those responsive to treatment.<sup>98</sup> *ERCC1* expression also has been shown to correlate with NER activity and cisplatin resistance in human ovarian cancer cells.<sup>97</sup> Increased levels of XPE, a putative DNA repair protein that recognizes many DNA lesions, including platinum-DNA adducts, has been observed in tumor cell lines resistant to cisplatin.<sup>99</sup> It should be noted, however, that XPE is not a necessary component for the *in vitro* reconstitution of NER.<sup>96,100</sup> Increased expression of DNA polymerases  $\alpha$  and  $\beta$  have been observed in cisplatin-resistant cell lines, and increased expression of these polymerases, as well as DNA ligase, has been described in human tumors after cisplatin exposure *in vivo*.<sup>94</sup> The possible significance of these findings is unclear because the primary polymerases involved in NER are thought to be DNA polymerases  $\delta$  or  $\epsilon$ .<sup>96</sup> Although it is probably not involved in NER, DNA polymerase  $\beta$  may be involved in translesion DNA synthesis.<sup>101</sup>

Inhibiting DNA repair activity to enhance platinum drug sensitivity has been an active area of investigation. Agents that have been used include nucleoside analogues, such as gemcitabine, fludarabine, and cytarabine; the ribonucleotide reductase inhibitor hydroxyurea; and the inhibitor of DNA polymerases  $\alpha$  and  $\gamma$ , aphidicolin. All of these agents interfere with the repair synthesis stage of various repair processes, including nucleotide excision repair, and it should be noted that these compounds are also likely to affect DNA replication and, as such, should not be strictly characterized as repair inhibitors. The potentiation of cisplatin cytotoxicity by treatment with aphidicolin has been studied extensively in human ovarian cancer cell lines. Although some studies have demonstrated a clear synergism with this drug combination,<sup>102,103</sup> others have not.<sup>104</sup> In an *in vivo* mouse model of human ovarian cancer, the combined treatment of cisplatin and aphidicolin glycinate, a water-soluble form of the drug, was found to be significantly more effective than cisplatin alone.<sup>105</sup> The combination of cytarabine and hydroxyurea was found to demonstrate cytotoxic synergy with cisplatin in a human colon cancer cell line<sup>106</sup> and in rat mammary carcinoma cell lines.<sup>107</sup> Moreover, the modulatory effect of cytarabine and hydroxyurea on cisplatin was associated with an increase in DNA interstrand cross-links in both cellular systems. Similarly, the drugs gemcitabine<sup>108</sup> and fludarabine<sup>109</sup> have both been shown to synergize with cisplatin in causing cell death in *in vitro* systems, and both of these drugs have been shown to interfere with the removal of cisplatin-DNA adducts. The likelihood of a significant improvement in the therapeutic index of cisplatin in refractory patients by the coadministration of a repair inhibitor, however, is limited by the multifactorial nature typical of resistant tumor cells. The combination of an inhibitor of the repair process with other modulators of resistance may be a more viable avenue in treating patients with recurrent disease. Furthermore, a modest change in drug sensitivity may bring some refractory tumors into a range that is treatable with conventional chemotherapy.

## INCREASED DNA DAMAGE TOLERANCE

Platinum-DNA damage tolerance is a phenotype that has been observed in both cisplatin-resistant cells derived from chemotherapy-refractory patients and cells selected for primary cisplatin resistance *in vitro*. The contribution of this mechanism to resistance is significant, and it has been shown to correlate strongly with cisplatin resistance as well as to resistance to other drugs in two ovarian cancer model systems (see [Table 19.4-1](#)).<sup>92,110</sup> Like other cisplatin resistance mechanisms, this phenotype may result from alterations in a variety of cellular pathways.

One component of DNA damage tolerance that has been observed in cisplatin-resistant cells involves the loss of function of the DNA MMR system. The main function of the MMR system is to scan newly synthesized DNA and to remove mismatches that result from nucleotide incorporation errors made by the DNA polymerases. In addition to causing genomic instability, it has been reported that loss of MMR is associated with low-level cisplatin resistance and that the selection of cells in culture for resistance to this drug often yields cell lines that have lost a functional MMR system.<sup>111</sup> MMR deficiency may create an environment that promotes the accumulation of mutations in drug-sensitivity genes. Another hypothesis is that the MMR system serves as a detector of platinum-DNA adducts. MSH2 alone, and in combination with MSH6, has been shown to bind to cisplatin 1,2-d(GpG)Pt intrastrand adducts with high efficiency.<sup>44,112</sup> Additionally, MSH2- and MLH1-containing protein-DNA complexes have been observed when nuclear extracts of MMR-proficient cell lines were incubated with DNA preincubated with cisplatin, but not with oxaliplatin. These data suggest that MMR recognition of damage may trigger a programmed cell death pathway, rendering cells with intact MMR more sensitive to DNA damage.<sup>45</sup> Another possibility is that the cytotoxicity involves repeated rounds of synthesis past the platinum-DNA lesions followed by recognition and subsequent removal of the newly synthesized strand by the MMR system. This futile cycling may generate DNA strand gaps and breaks that trigger programmed cell death.<sup>113</sup> Loss of MMR thus increases the cell's ability to tolerate platinum-DNA lesions.

Another possible tolerance mechanism related to MMR is enhanced replicative bypass, which is defined as the ability of the replication complex to synthesize DNA past a platinum adduct.<sup>101,114</sup> Increased replicative bypass has been shown to occur in cisplatin-resistant human ovarian cancer cells.<sup>114</sup> These cells are also MMR-deficient, and it has been shown that in steady-state chain elongation assays, a 2.5- to 6.0-fold increase in replicative bypass of cisplatin adducts occurred. Oxaliplatin adducts are not recognized by the MMR complex, and no significant differences in bypass of oxaliplatin adducts in MMR-proficient and -defective cells were observed. DNA polymerase  $\beta$ , the most inaccurate of the DNA polymerases, may also function in this process.<sup>101</sup> The activity of this enzyme was found to be significantly increased in cells derived from a human malignant glioma resistant to cisplatin compared with its drug-sensitive counterpart.<sup>94</sup>

The tolerance mechanisms just mentioned are related primarily to cisplatin resistance. Because the platinum-DNA damage tolerance phenotype is often associated with cross-resistance to other unrelated chemotherapeutic drugs,<sup>110</sup> the existence of a more general resistance mechanism must be considered. One possible explanation is that the platinum-DNA damage tolerance phenotype is the result of decreased expression or inactivation of one or more components of the programmed cell death pathway. As mentioned above in Platinum Drug-Induced Cell Death, a number of pro- and antiapoptotic signaling pathways have been implicated in cisplatin sensitivity. The possibility exists that cells containing defective or constitutively down-regulated stress signaling pathways, such as SAPK/JNK, may exhibit resistance to platinum drugs. A number of other proteins that regulate these pathways may also have the capacity to influence drug sensitivity. In addition, cell death may also be influenced by expression of members of the bcl-2 gene family. This group of pro- and antiapoptotic proteins regulates mitochondrial function, and they serve as a cell survival/cell death rheostat by forming homo- and heterodimers with one another. The antiapoptotic bcl-2 and bcl-X<sub>L</sub> proteins are localized in the outer mitochondrial membrane and may be involved in the formation of transmembrane channels. Overexpression of bcl-2 or bcl-X<sub>L</sub> has been shown to prevent disruption of the mitochondrial transmembrane potential and to prolong cell survival in some cells after exposure to cisplatin and other anticancer drugs.<sup>115,116</sup> The activity of these proteins is negated, however, in the presence of high levels of the proapoptotic protein BAX, another bcl-2 family member. Therefore, the relative intracellular levels of these proteins may also confer resistance to platinum drugs. An interesting connection between the bcl-2 gene family and SAPK/JNK has been reported by Kharbanda et al.<sup>117</sup> They found that, after genotoxic stress, SAPK/JNK is translocated to the mitochondria, where it phosphorylates bcl-X<sub>L</sub>, presumably rendering it inactive.

## CLINICAL PHARMACOLOGY

### PHARMACOKINETICS

The pharmacokinetic differences observed among platinum drugs may be attributed to the structure of their leaving groups. Platinum complexes containing leaving groups that are less easily displaced exhibit reduced plasma protein binding, longer plasma half-lives, and higher rates of renal clearance. These features are evident in the pharmacokinetic properties of cisplatin, carboplatin, and oxaliplatin, which are summarized in [Table 19.4-2](#). Platinum drug pharmacokinetics also have been reviewed elsewhere.<sup>118,119</sup> and [120](#)

	Cisplatin	Carboplatin	Oxaliplatin
$T_{1/2\beta}$ (min)			
Total platinum	14-49	12-98	26
Ultrafiltrate	9-30	8-87	21
$T_{1/2\beta}$ (h)			
Total platinum	0.7-4.6	1.3-1.7	—
Ultrafiltrate	0.7-0.8	1.7-5.9	—
$T_{1/2\gamma}$ (h)			
Total platinum	24-127	8.2-40.0	38-47
Ultrafiltrate	—	—	14-27
Protein binding	>96%	24-50%	85%
Urinary excretion	23-50%	94-82%	>90%

$T_{1/2\alpha}$ , half-life of first phase;  $T_{1/2\beta}$ , half-life of second phase;  $T_{1/2\gamma}$ , half-life of terminal phase.  
Data adapted from references 120-123.

**TABLE 19.4-2.** Comparative Pharmacokinetics of Platinum Analogues after Bolus or Short Intravenous Infusion**Cisplatin**

After intravenous infusion, cisplatin rapidly diffuses into tissues and is covalently bound to plasma protein. More than 90% of platinum is bound to plasma protein at 4 hours postinfusion.<sup>121</sup> The disappearance of ultrafilterable platinum is rapid and occurs in a biphasic fashion. Half-lives of 10 to 30 minutes and 0.7 to 0.8 hours have been reported for the initial ( $T_{1/2a}$ ) and terminal phases ( $T_{1/2g}$ ), respectively.<sup>122,123</sup> Cisplatin excretion is dependent on renal function, which accounts for the majority of its elimination. The percentage of platinum excreted in the urine has been reported to be between 23% and 40% at 24 hours postinfusion.<sup>124,125</sup> Only a small percentage of the total platinum is excreted in the bile.<sup>126</sup>

**Carboplatin**

The differences in pharmacokinetics observed between cisplatin and carboplatin depend primarily on the slower rate of conversion of carboplatin to a reactive species. Thus, the stability of carboplatin results in a low incidence of nephrotoxicity. Carboplatin diffuses rapidly into tissues after infusion, but it is considerably more stable in plasma. Only 24% of a dose was reported to be bound to plasma protein at 4 hours postinfusion.<sup>127</sup>

The disappearance of platinum from plasma after short intravenous infusions of carboplatin has been reported to occur in a biphasic or triphasic manner. The initial half-lives for total platinum, which vary considerably among several studies, are listed in [Table 19.4-2](#). The  $T_{1/2a}$  ranges from 12 to 98 minutes and ranges from 1.3 to 1.7 hours during the second phase ( $T_{1/2b}$ ). Half-lives reported for the  $T_{1/2g}$  range from 8.2 to 40.0 hours. The disappearance of ultrafilterable platinum is biphasic, with  $T_{1/2a}$  and  $T_{1/2b}$  values ranging from 7.6 to 87.0 minutes and 1.7 to 5.9 hours, respectively. Carboplatin is excreted predominantly by the kidneys, and cumulative urinary excretion of platinum is 54% to 82%, most as unmodified carboplatin. The renal clearance of carboplatin is closely correlated with the glomerular filtration rate (GFR).<sup>127</sup> This observation enabled Calvert et al.<sup>128</sup> to design a carboplatin dosing formula based on an individual patient's GFR.

**Oxaliplatin**

After oxaliplatin infusion, platinum accumulates into three compartments: plasma-bound platinum, ultrafilterable platinum, and platinum associated with erythrocytes. Approximately 85% of the total platinum is bound to plasma protein at 2 to 5 hours postinfusion.<sup>129</sup> Plasma elimination of total platinum and ultrafiltrates is biphasic. The  $T_{1/2a}$  and  $T_{1/2g}$  are 26 minutes and 38.7 hours, respectively, for total platinum and 21 minutes and 24.2 hours, respectively, for ultrafilterable platinum (see [Table 19.4-2](#)).<sup>120</sup> Thus, as with carboplatin, substantial differences between total and free drug kinetics are not observed. Similar to cisplatin, a prolonged retention of oxaliplatin is observed in red blood cells. Unlike cisplatin, however, oxaliplatin does not accumulate to any significant level after multiple courses of treatment.<sup>129</sup> This may explain why neurotoxicity associated with oxaliplatin is reversible. Oxaliplatin is eliminated predominantly by the kidneys, with more than 50% being excreted in the urine at 48 hours.

**PHARMACODYNAMICS**

Pharmacodynamics relates pharmacokinetic indices of drug exposure to biological measures of drug effect, which is usually defined by toxicity to normal tissues or by amount of tumor cell kill. Two issues to be addressed in such efforts are whether the effectiveness of the drug can be enhanced or the toxicity attenuated by knowledge of the platinum pharmacokinetics in an individual. These questions are appropriate to the use of cytotoxic agents with relatively narrow therapeutic indices. Toxicity to normal tissues can be quantitated as a continuous variable when the drug causes myelosuppression. Thus, the early studies of carboplatin demonstrated a close relationship of changes in platelet counts to the area under the concentration-time curve (AUC) in the individual. The AUC was itself closely related to renal function, which was determined as creatinine clearance. Based on these observations, Egorin et al.<sup>130</sup> and Calvert et al.<sup>128</sup> derived formulas based on creatinine clearance to predict either the percent change in platelet count or a target AUC. More recently, Chatelut and colleagues<sup>131</sup> have derived a formula that relies on serum creatinine as well as morphometric determinants of renal function. Application of pharmacodynamically guided dosing algorithms for carboplatin has been widely adopted as a means of avoiding overdosage (by producing acceptable nadir platelet counts) and of maximizing dose intensity in the individual. Good evidence suggests that this approach can decrease the risk of unacceptable toxicity. Accordingly, a dosing strategy based on renal function is recommended for the use of carboplatin.

A key question is whether maximizing carboplatin exposure in an individual can measurably increase the probability of tumor regression or survival. In an analysis by Jodrell et al.,<sup>132</sup> carboplatin AUC was a predictor of response, thrombocytopenia, and leukopenia. The likelihood of a tumor response increased with increasing AUC up to a level of 5 to 7 mg × hr/mL, after which a plateau was reached. Similar results were obtained with carboplatin in combination with cyclophosphamide, and neither response nor survival rates were determined by the carboplatin AUC in a cohort of ovarian cancer patients.<sup>133</sup>

The relationship of pharmacokinetics to response may also be explored by investigating the cellular pharmacology of these agents.<sup>134</sup> As discussed above in DNA Adduct Formation, platinum compounds form various types of DNA adducts. The formation and repair of these adducts in human cells are not easily measured. One approach is to measure specific DNA adducts (using antibody-based assays); another is to measure total platinum bound to DNA. The formation and repair of platinum-DNA adducts has been studied in white blood cells obtained from various groups of patients. Ma et al.<sup>135</sup> have reevaluated the pharmacokinetic and pharmacodynamic interactions of cisplatin administered as a single agent. In a series of patients with head and neck cancer, they found that cisplatin exposure (measured as the AUC) closely correlated with both the peak DNA adduct content in leukocytes and the area under the DNA-adduct-time curve.<sup>136</sup> These measures were important predictors of response, both individually and in logistic regression analysis. An adaptive dosing study in which the dose of cisplatin is modified based on DNA-adduct levels is in progress.

Based on the variability of both pharmacokinetics in individuals and of tumor genotype determinants of susceptibility to platinum agents, it seems most likely that direct investigations of these factors will elucidate how best to use these drugs. Single-nucleotide polymorphism associations with toxicity and tumor gene expression profiles determining susceptibility will, it is hoped, further enhance the therapeutic index by prospectively identifying sensitive and resistant populations.

**FORMULATION AND ADMINISTRATION****Cisplatin**

Cisplatin is administered in a chloride-containing solution intravenously over 0.5 to 2.0 hours. To minimize the risk of nephrotoxicity, patients are prehydrated with at least 500 mL of salt-containing fluid. Immediately before cisplatin administration, mannitol (12.5 to 25.0 g) is given parenterally to maximize urine flow. A diuretic, such as furosemide, may also be used, along with parenteral antiemetics, which currently include dexamethasone together with a 5-hydroxytryptamine<sub>3</sub> (5-HT<sub>3</sub>) antagonist. A minimum of 1 L of posthydration fluid is usually given.<sup>137</sup> The intensity of hydration varies somewhat with the dose of cisplatin. High-dose cisplatin (up to 200 mg/m<sup>2</sup> per course) may be administered in a formulation containing 3% sodium chloride, but this method is no longer widely used. Cisplatin may also be administered regionally to increase local drug exposure and to diminish side effects. Its intraperitoneal use was defined by Ozols et al.<sup>138</sup> and by Howell and colleagues.<sup>139</sup> Measured drug exposure in the peritoneal cavity is some 50-fold higher than levels achieved with intravenous administration.<sup>139</sup> At standard doses in ovarian cancer patients with low-volume disease, a randomized intergroup trial suggested that intraperitoneal administration is superior to intravenous cisplatin in combination with intravenous cyclophosphamide.<sup>140</sup> The development of combinations of carboplatin with paclitaxel has, however, superseded this technique in ovarian cancer, and the intraperitoneal route is now infrequently used. Regional use also includes intraarterial delivery (as for hepatic tumors, melanoma, and glioblastoma), but none has been adopted as a standard method of treatment. There is growing interest in chemoembolization for the treatment of tumors confined to the liver, and cisplatin is a component of many popular regimens.<sup>141</sup>

**Oxaliplatin**

Oxaliplatin is also uncomplicated in its clinical administration. For bolus infusion, the required dose is administered in 500 mL of chloride-free diluent over a period of 2 hours. In studies of colorectal cancer, oxaliplatin has been administered as a 5-day continuous infusion, during which the dosage rate has been modified to observe principles of chronopharmacologic administration.<sup>145</sup> Oxaliplatin is more frequently given as a single dose every 2 weeks (85 mg/m<sup>2</sup>) or every 3 weeks (130 mg/m<sup>2</sup>), alone or with other active agents. It is common to pretreat patients with active antiemetics, such as a 5-HT<sub>3</sub> antagonist, but the nausea is not as severe as with cisplatin. No prehydration is required. The predominant toxicity of oxaliplatin is neurotoxicity. The development of an oropharyngeal dysesthesia, often precipitated by exposure to cold, requires prolongation of the duration of administration to 6 hours.

### Carboplatin

Cisplatin treatment over 3 to 6 hours is burdensome for clinical resources and tiring for cancer patients. Previously given as in-hospital treatment, it is now usually administered in the outpatient setting. The exigencies of the modern health care environment have contributed to the expanding use of carboplatin as an alternative to cisplatin, except in circumstances in which cisplatin is clearly the superior agent. Carboplatin is substantially easier to administer. Extensive hydration is not required because of the lack of nephrotoxicity at standard doses.<sup>142</sup> Carboplatin is reconstituted in chloride-free solutions (unlike cisplatin, because chloride can displace the leaving groups) and administered over 30 minutes as a rapid intravenous infusion. Carboplatin has been incorporated in high-dose chemotherapy regimens at doses more than threefold higher than those of the standard regimens.<sup>143</sup> In some regimens, continuous infusion has been substituted for a rapid intravenous infusion; however, it is doubtful that there is an advantage to this approach. Carboplatin doses up to 20 mg × min/mL may be safely administered in 200 mL of D5W over 2 hours.<sup>144</sup>

### TOXICITY

A substantial body of literature documents the side effects of platinum compounds. The nephrotoxicity of cisplatin almost led to its abandonment, until Cvitkovic and colleagues<sup>3,4</sup> introduced aggressive hydration, which prevented the development of acute renal failure. As already noted, the toxicity of cisplatin was a driving force both in the search for less toxic analogues and for more effective treatments for its side effects, especially nausea and vomiting. The toxicities associated with cisplatin, carboplatin, and oxaliplatin are described in detail in the next three sections and are summarized in [Table 19.4-3](#).

Toxicity	Cisplatin	Carboplatin	Oxaliplatin
Myelosuppression		X	
Nephrotoxicity	X		
Neurotoxicity	X		X
Ototoxicity	X		
Nausea and vomiting	X	X	X

**TABLE 19.4-3.** Toxicity Profiles of Platinum Analogues in Clinical Use

### Cisplatin

The side effects associated with cisplatin (at single doses of more than 50 mg/m<sup>2</sup>) include nausea and vomiting, nephrotoxicity, ototoxicity, neuropathy, and myelosuppression. Rare effects include visual impairment, seizures, arrhythmias, acute ischemic vascular events, glucose intolerance, and pancreatitis.<sup>137</sup> The nausea and vomiting stimulated a search for new antiemetics. These symptoms are currently best managed with 5-HT<sub>3</sub> antagonists and usually given with a glucocorticoid, although other combinations of agents are still widely used. In the weeks following treatment, continuous antiemetic therapy may be required. Nephrotoxicity is ameliorated but not completely prevented by hydration. The renal damage to both glomeruli and tubules is cumulative, and after cisplatin treatment, serum creatinine is no longer a reliable guide to the measurement of glomerular filtration rate. An acute elevation of serum creatinine may follow a cisplatin dose, but this index returns to normal with time. Tubule damage may be reflected in a salt-losing syndrome that also resolves with time.

Ototoxicity is a cumulative and irreversible side effect of cisplatin treatment that results from damage to the inner ear. Therefore, audiograms are recommended every 2 to 3 cycles.<sup>137</sup> The initial audiographic manifestation is loss of high-frequency acuity (4000 to 8000 Hz). When acuity is affected in the range of speech, cisplatin should be discontinued under most circumstances and carboplatin substituted where appropriate. Peripheral neuropathy is also cumulative, although less common than with agents such as vinca alkaloids. This neuropathy usually is reversible, although recovery is often slow. A number of agents with the potential for protection from neuropathy have been developed, but none is yet used widely.<sup>146</sup>

### Carboplatin

Myelosuppression, which is not usually severe with cisplatin, is the dose-limiting toxicity of carboplatin.<sup>142</sup> The drug is most toxic to the platelet precursors, but neutropenia and anemia are frequently observed. The lowest platelet counts after a single dose of carboplatin are observed 17 to 21 days later, and recovery usually occurs by day 28. The effect is dose-dependent, but individuals vary widely in their susceptibility. As shown by Egorin et al.<sup>130</sup> and Calvert et al.,<sup>128</sup> the severity of platelet toxicity is best accounted for by a measure of the drug exposure in an individual, the AUC. Both groups derived pharmacologically based formulas to predict toxicity and guide carboplatin dosing. That of Calvert and colleagues targets a particular exposure to carboplatin:

$$\text{Dose (mg)} = \text{target AUC} \times \left( \frac{\text{mg} \cdot \text{min}}{\text{mL}} \right) \times \left( \frac{\text{GFR mL}}{\text{min} + 25} \right)$$

This formula has been widely used to individualize carboplatin dosing, and it permits targeting at an acceptable level of toxicity. Patients who are elderly or have a poor performance status or a history of extensive pretreatment have a higher risk of toxicity, even when dose is calculated with these methods,<sup>128,130</sup> but the safety of drug administration has been enhanced. In the combination of carboplatin and paclitaxel, AUC-based dosing has helped to maximize the dose intensity of carboplatin.<sup>147</sup> Doses some 30% higher than a dosing strategy based solely on body surface area may safely be used. A determination of whether this approach to dosing improves outcome requires a randomized trial, which is in progress.

The other toxicities of carboplatin are generally milder and better tolerated than those of cisplatin. Nausea and vomiting, although frequent, are less severe, shorter in duration, and more easily controlled with standard antiemetics (i.e., Compazine, dexamethasone, lorazepam) than those symptoms typical after cisplatin treatment. Renal impairment is infrequent, although alopecia is common, especially with the paclitaxel-containing combinations. Neurotoxicity is also less common than with cisplatin, although it is observed more frequently with the increasing use of high-dose regimens. Ototoxicity is also less common.

### Oxaliplatin

The dose-limiting toxicity of oxaliplatin is sensory neuropathy, a characteristic of all DACH-containing platinum derivatives. The severity of the toxicity is dramatically less than that observed with another DACH-containing analogue, ormaplatin. This side effect takes two forms. First, a tingling of the extremities, which may also involve the perioral region, occurs early and usually resolves within a few days. With repeated dosing, symptoms may last longer between cycles but do not appear to be of long duration or cumulative. Laryngopharyngeal spasm and cold dysesthesias also have been reported but are not associated with significant respiratory symptoms; they can be prevented by prolonging the duration of infusion. A second neuropathy, more typical of that seen with cisplatin, affects the extremities and

increases with repeated doses. Definitive physiologic characterization of oxaliplatin-induced neuropathy has proven difficult in large studies. Electromyograms performed in six patients treated by Extra et al.<sup>148</sup> revealed an axonal sensory neuropathy, but nerve conduction velocities were unchanged. Peripheral nerve biopsies performed in this study showed decreased myelination and replacement with collagen pockets. The neurologic effects of oxaliplatin appear to be cumulative in that they become more pronounced and of greater duration with successive cycles. Unlike those with cisplatin, however, they are reversible with drug cessation. In a review of 682 patient experiences, Brienza et al.<sup>149</sup> reported that 82% of patients who experienced grade 2 or higher neurotoxicity had their symptoms regress within 4 to 6 months. Ototoxicity is not observed with oxaliplatin. Nausea and vomiting do occur and generally respond to 5-HT<sub>3</sub> antagonists. Myelosuppression is uncommon and is not severe with oxaliplatin as a single agent, but it is a feature of combinations including this drug. Oxaliplatin therapy is not associated with nephrotoxicity.

## METHOTREXATE

Aminopterin was the first antimetabolite to demonstrate clinical activity in the treatment of patients with malignancy. This antifolate analogue was used to induce remissions in children with acute leukemia in the 1940s.<sup>1</sup> Aminopterin has since been replaced by methotrexate (MTX), the 4-amino, 10-methyl analogue of folic acid. MTX remains the most widely used antifolate in cancer chemotherapy, with documented activity against a wide range of human malignancies, including leukemia, breast cancer, colorectal cancer, head and neck cancer, lymphoma, osteogenic sarcoma, urothelial cancer, and choriocarcinoma. Antifolates have also been used to treat a host of nonmalignant disorders, including psoriasis, rheumatoid arthritis, graft-versus-host disease, bacterial and plasmodial infections, and parasitic infections associated with the acquired immunodeficiency syndrome.<sup>2</sup> This class of agents represents the best-characterized and most versatile of all chemotherapeutic drugs in current clinical use.

## MECHANISM OF ACTION

MTX is a tight-binding inhibitor of dihydrofolate reductase (DHFR), a critical enzyme in folate metabolism ( Fig. 19.5-1).<sup>2</sup> The importance of DHFR stems from its role in maintaining the intracellular folate pool in its fully reduced form as tetrahydrofolates. These compounds serve as one-carbon carriers required for the synthesis of thymidine-5'-monophosphate (thymidylate), purine nucleotides, and certain amino acids. Thymidylate synthase (TS) catalyzes the formation of thymidine-5'-monophosphate from 2'-deoxyuridine 5' monophosphate (deoxyuridylate, dUMP) ( Fig. 19.5-2). This reaction uses 5,10-methylenetetrahydrofolate as a methyl donor and results in the oxidation of the reduced folate to dihydrofolate. The activity of the TS reaction thus creates the requirement for DHFR to maintain the intracellular reduced folate pool needed for one-carbon transfer reactions. The reduced folate, 10-formyltetrahydrofolate, serves as a substrate for two folate-dependent enzymes of *de novo* purine synthesis, glycylamide ribonucleotide (GAR) transformylase and aminoimidazole carboxamide ribonucleotide transformylase. An intact DHFR pathway is therefore necessary for continued *de novo* thymidylate and purine nucleotide biosynthesis.

**FIGURE 19.5-1.** Sites of action of methotrexate (MTX), its polyglutamated metabolites [MTX(Glu<sub>n</sub>)], and folate by-products of the inhibition of dihydrofolate reductase, including dihydrofolate (FH<sub>2</sub>) and 10-formyl-dihydrofolate (10-CHO-FH<sub>2</sub>). Also shown are 5,10-methylenetetrahydrofolate (CH<sub>2</sub>FH<sub>4</sub>), the folate cofactor required for thymidylate synthesis, and 10-formyltetrahydrofolate (10-CHO-FH<sub>4</sub>), the required cofactor for *de novo* purine synthesis. AICAR, aminoimidazole carboxamide ribonucleotide transformylase; AMP, adenosine monophosphate; dTMP, thymidylate; dUMP, deoxyuridylate; GAR, glycylamide ribonucleotide transformylase; GMP, guanine monophosphate; IMP, inosine monophosphate.

**FIGURE 19.5-2.** The thymidylate synthase enzyme pathway. dTDP, thymidine diphosphate; dTMP, thymidylate; dTTP, thymidine triphosphate; dUMP, deoxyuridylate; FdUMP, 5-fluoro-2'-deoxyuridine monophosphate.

The precise mechanism by which MTX produces metabolic inhibition remains a subject of ongoing debate. The long-held view has been that inhibition of DHFR results in an accumulation of oxidized folates at the expense of reduced folates owing to the continued synthetic function of TS. Ultimate depletion of the required reduced folates would result in cessation of *de novo* thymidylate and purine biosynthesis as well as inhibition of protein synthesis. However, several investigators have demonstrated that after exposure of malignant cells to inhibitory concentrations of MTX, intracellular reduced folates are depleted by only 50% to 70%, a level presumably insufficient to account for the observed inhibition of DNA synthesis.<sup>2,3</sup> Additional metabolic effects of MTX result from its transformation to polyglutamate forms (see Fig. 19.5-1). MTX and physiologic folate polyglutamates are formed by the enzyme folylpolyglutamyl synthetase, which adds up to five to seven glutamyl groups in a  $\gamma$ -peptide linkage. Polyglutamation is a time- and concentration-dependent process that occurs in tumor cells and, to a lesser extent, in normal tissues.<sup>4</sup> These polyglutamate metabolites have a prolonged intracellular half-life and allow for prolonged drug action in malignant cells. The relative difference in polyglutamate formation in normal versus malignant cells may account for the selective activity of the drug. As much as 80% of MTX found in malignant tissues is in the polyglutamated forms, and these metabolites are potent, direct inhibitors of several folate-dependent enzymes, including DHFR, TS, and aminoimidazole carboxamide ribonucleotide and GAR transformylases.<sup>1,2 and 3,5,6</sup> Thus, metabolic inhibition resulting from MTX exposure is a multifactorial process and may depend on several factors, including partial depletion of reduced folates and direct inhibition of folate-dependent enzymes by the polyglutamates of both MTX and dihydrofolate that accumulate after inhibition of DHFR.

The precise mechanism by which MTX induces cytotoxicity remains an area of continued investigation. MTX-induced depletion of thymidine triphosphate (dTTP) and purine nucleotides interferes with the cellular capacity to repair DNA, resulting in DNA strand breaks.<sup>7,8</sup> Furthermore, the need for repair is accentuated by an intracellular accumulation of dUMP resulting from the inhibitory effects of MTX on TS. dUMP can be converted to the triphosphate nucleotide form (dUTP), which is then incorporated into DNA, resulting in inhibition of chain elongation and DNA synthesis. Excision repair of the DNA containing these misincorporated dUTP moieties by the enzyme uracil DNA glycosylase results in further DNA fragmentation.

Novel mechanisms by which MTX may exert its cytotoxic action have been described. Treatment with MTX results in a significant dose-dependent reduction in methionine synthase enzyme activity.<sup>9,10</sup> This enzyme catalyzes the folate-dependent reaction in which 5-methyltetrahydrofolate serves as a critical one-carbon carrier methyl donor and mediates the conversion of homocysteine to methionine. Thus, inhibition of methionine synthase leads to inhibition of a number of key downstream pathways, including transmethylation reactions, polyamine biosynthesis, protein synthesis, or all three.<sup>11</sup> Treatment of cultured Ehrlich ascites tumor cells with MTX resulted in up to a 3.5-fold increase in 5'-phosphoribosyl-1-pyrophosphate (PRPP) levels, which was associated with a significant suppression in the rate of glucose transport. Coadministration of MTX and hypoxanthine completely protected against the growth-inhibitory action of MTX and reversed the effect on PRPP production and on the rate of glucose transport.<sup>12</sup> Thus, MTX may exert its anticancer effect, in part, through inhibition of critical glucose transport mechanisms, thereby starving the cancer cell of essential nutrients required to maintain cellular metabolism and growth.

MTX is most active against rapidly proliferating cells, as its cytotoxic effects occur primarily during the S phase of the cell cycle. During longer periods of drug exposure, a higher fraction of cells can enter the S phase of the cell cycle, resulting in greater cell kill. In addition, MTX polyglutamate formation is substantially enhanced with longer periods of drug exposure, thereby increasing cytotoxicity. The cytotoxic effects of MTX are also greater with increasing drug concentrations. Therefore, MTX cytotoxicity is highly dependent on the absolute drug concentration and the duration of drug exposure.

MTX enters cells by the same active transport mechanisms used by physiologic reduced folates. In general, intracellular drug concentrations reach steady state in less than 30 minutes. Folate transport is a complex process with at least two carrier-mediated, energy-dependent mechanisms existing in mammalian cells. The first is the classic reduced folate carrier (RFC) system that has a relatively low affinity for MTX and reduced folates such as leucovorin (LV), with affinity constants in the micromolar range.<sup>2,13,14,15,16 and 17</sup> The RFC system has a large capacity and is primarily responsible for transport of MTX into cells at pharmacologic concentrations. The human RFC gene has been mapped to the long arm of chromosome 1, and it encodes a protein with a predicted molecular weight of 59 to 68 kD.

A second folate transport system involves a high-affinity, membrane-bound folate receptor-binding protein with affinity constants for reduced folates and folic acid in the nanomolar range.<sup>18,19</sup> MTX is a relatively poor substrate for this folate-binding protein, and its affinity is 10- to 30-fold lower than that of physiologic reduced folates. The human folate receptor protein (FR) is a 38- to 40-kD glycoprotein bound to the cellular membrane via a C-terminal, glycosylphosphatidylinositol tail.<sup>20</sup> It is expressed on the surface of various normal tissues, including human placenta, choroid plexus, renal tubules, and fallopian tubes. Of note, this receptor is also highly expressed on the surface of a number of epithelial tumors, including ovarian cancer, but not on normal ovarian tissue, making it an attractive target for antigen-directed anticancer therapies.<sup>21</sup> Alterations in the tissue expression of FR can be induced by changes in the exogenous folate concentration or by alteration in normal physiology such as in pregnancy. At least three different isoforms of the human FR have been described to date, and they are classified as FR-a, FR-b, and FR-g.<sup>17,22</sup> These isoforms have unique folate-binding affinities and variable expression in specific tissues. FR-a is highly expressed in human epithelial tissues and in some cancers such as ovarian cancer, whereas FR-b is expressed in human placenta and other nonepithelial tissues. Although the FR-a and FR-b isoforms share 70% to 80% amino acid sequence homology, they differ significantly in their respective affinities and stereospecificities for reduced folates. Human FR-g lacks a glycosylphosphatidylinositol tail, and this isoform most likely represents a secretory protein.

An additional MTX transport system has been described in murine L1210 leukemic cells that is completely distinct from either the RFC or the FR systems.<sup>23,24</sup> Further studies are under way to characterize the role of this transporter as a determinant of MTX cytotoxicity. It is likely that the relative function of each of these distinct transport systems depends on the extracellular folate concentration, and their expression may vary significantly among different cell lines. Their interrelationship and role in MTX transport remains an active area of research. Nonclassic antifolate compounds, such as trimetrexate and trimethoprim, do not rely on specific transport systems for cellular entry. Such analogues are active against various malignant cell lines resistant to MTX on the basis of decreased transport capacity. In addition to these transport systems, two energy-dependent MTX efflux transport systems have been described in murine leukemic L1210 cells using *inside out* membrane vesicles.<sup>25</sup> These two systems appear to be functionally distinct and sensitive to a different range of chemical inhibitors. The major efflux transporter is identical to a glutathione conjugate membrane pump and accounts for nearly 70% of MTX efflux.

Reduced folates, such as 5-formyltetrahydrofolate (LV), prevent, rescue, or both prevent and rescue cells from the toxic effects of MTX. The predominant species of reduced folate in human plasma, 5-methyltetrahydrofolate, circulates with levels in the range of 5 to 50 nM, a concentration inadequate to rescue cells. Administration of appropriate doses of LV after high-dose MTX therapy can prevent toxicity to the bone marrow and gastrointestinal epithelium, the two most rapidly dividing cells in the body. The dose of LV required to rescue normal tissues is dependent on the antifolate concentration at the time of antidote administration.<sup>26</sup> The competitive nature of this rescue suggests that LV does more than simply replete intracellular reduced folate pools. LV is converted to intracellular folates that can compete with both MTX and dihydrofolate polyglutamates to overcome the inhibition of TS and *de novo* purine synthesis. In addition, MTX and reduced folates compete with one another for transport into cells and for subsequent intracellular polyglutamation. Presumably, rescue from MTX-associated metabolic inhibition occurs only when adequate levels of dihydrofolate have accumulated after LV administration. The administration of exogenous thymidine may also be used to decrease MTX toxicity. This approach appears to be less effective than LV, as inhibition of the *de novo* purine pathway by MTX remains unaffected by its use. Administration of the recombinant bacterial enzyme carboxypeptidase G<sub>2</sub>, which hydrolyzes MTX to inactive metabolites, is currently undergoing clinical testing as an alternative strategy to rescue from high-dose MTX therapy.<sup>27</sup>

## MECHANISMS OF RESISTANCE

The development of cellular resistance to MTX remains a major obstacle to its effective clinical use. In experimental systems, resistance to antifolates may result from several mechanisms, including an alteration in antifolate transport due to either a defect in the RFC or FR systems,<sup>28,29,30 and 31</sup> decreased capacity to polyglutamate MTX through either decreased expression of folylpolyglutamyl synthetase or increased expression of the catabolic enzyme gamma-glutamyl hydrolase,<sup>32,33,34 and 35</sup> and alterations in the target enzyme DHFR through either increased expression of the wild-type protein or overexpression of a mutant protein with reduced binding affinity for MTX.<sup>2,36,37</sup>

Amplification of the DHFR gene is one of the most common forms of MTX resistance observed in experimental systems.<sup>2</sup> The amplified gene may be stably integrated into chromosomal DNA in the form of a homogeneously staining region, or it may exist in extrachromosomal pieces of DNA known as *double-minute chromosomes*.<sup>38</sup> Homogeneously staining region-mediated gene amplification is associated with the development of stable resistance to MTX. In contrast, double-minute chromosomes are unequally distributed during cell division, and, in the absence of continued selective pressure of MTX, cells eventually revert to a sensitive phenotype with wild-type levels of DHFR expression. It was shown that resistant human leukemic HL-60 cells coamplify both DHFR and hMSH3, the human *mutS*

homologue 3 gene.<sup>39</sup> Overproduction of hMSH3 results in virtually complete sequestration of the nuclear hMSH2 mismatch repair (MMR) protein. The net effect of this protein-protein interaction is a marked reduction in the efficiency of base-base MMR. As MMR deficiency has been implicated as a potential mechanism of resistance to the platinum analogues cisplatin and carboplatin, DNA methylating agents, and doxorubicin (Adriamycin), it is conceivable that this same resistance phenotype may contribute to the development of resistance to MTX and other antifolate analogues.

An alternative mechanism of resistance has been ascribed to mutations that result in a DHFR protein product with an altered binding affinity for MTX. There is evidence that naturally occurring DHFR alleles with differing affinities to MTX may exist in cells and provide a mechanism for the rapid emergence of MTX resistance.<sup>40</sup> In several *in vitro* experimental model systems, the levels of DHFR enzyme activity acutely increase after exposure to MTX, other antifolate analogue compounds, or both.<sup>41,42</sup> This acute induction of DHFR in response to drug exposure is mediated, in part, by a translational regulatory mechanism.<sup>43</sup> DHFR protein, in its unbound or free state, is capable of specifically repressing the translation of its own messenger RNA (mRNA). However, when DHFR protein is bound to an antifolate inhibitor, it is unable to repress DHFR mRNA translation, and the rate of new DHFR protein synthesis increases.<sup>43,44</sup> Thus, induction of DHFR may represent a clinically relevant mechanism for the acute development of cellular drug resistance.

Apoptosis, the process of programmed cell death, is a critical event during normal development and in the pathogenesis of several disease states, including cancer, autoimmune disorders, viral infection, and neurodegenerative diseases. Bcl-2 can repress cell death triggered by a wide array of stimuli, including chemotherapy and gamma-irradiation. Bcl-XL, a structural homologue of Bcl-2, has also been shown to provide protection against a wide range of anticancer agents. These prosurvival proteins presumably act at some common final step to prevent or overcome the cell death pathway induced by various anticancer agents. It has been shown that murine lymphoid FL5.12 cells transduced with Bcl-XL as compared with another antiapoptotic gene Bcl-2, become resistant to the cytotoxic effects of MTX.<sup>45</sup> Thus, the expression of Bcl-XL may represent an important indicator for predicting chemosensitivity to MTX and other antifolate analogues.

Despite many years of active investigation, the relative contribution of each of these mechanisms as a determinant of MTX resistance remains unclear. However, there is growing evidence to support the concept that the emergence of MTX resistance, in the clinical setting, is a multifactorial process. In fact, DHFR gene amplification, defective transport, and decreased polyglutamate formation have all been observed in clinical specimens taken from MTX-resistant patients.<sup>46,47,48 and 49</sup>

## CLINICAL PHARMACOLOGY AND PHARMACOKINETICS

Accurate monitoring of MTX concentrations in plasma is essential for the safe and optimal use of this agent in cancer chemotherapy, particularly with high-dose regimens. At least four methods are presently available for the clinical monitoring of MTX drug levels, including the DHFR enzyme inhibition assay, a competitive protein-binding assay, a fluorescence-polarization radioimmunoassay technique, and an enzyme-multiplied immunoassay system.<sup>2</sup>

The absorption of oral MTX is saturable and erratic at higher doses, such that oral doses should be kept to less than 25 mg/m<sup>2</sup>. The drug is usually administered intravenously. The volume of distribution of MTX approaches that of total body water, and approximately 60% of the drug is bound to serum albumin at pharmacologic drug concentrations.<sup>2</sup> Although plasma pharmacokinetics are variable, MTX metabolism generally follows a three-phase pattern. The initial distribution phase, which lasts for only a few minutes, is followed by a second phase lasting 12 to 24 hours, during which time the drug is eliminated with a half-life of 2 to 3 hours. The final phase of drug clearance has a half-life of 8 to 10 hours. The last two phases of drug elimination are considerably lengthened in patients with renal dysfunction. There is substantial evidence that a more rapid systemic clearance of drug is associated with a high risk of relapse in children receiving MTX for maintenance therapy of acute lymphocytic leukemia.

The distribution of MTX into third-space fluid collections, such as pleural effusions and ascitic fluid, can substantially alter MTX pharmacokinetics. The slow release of accumulated MTX from these third spaces over time prolongs the terminal half-life of the drug, leading to potentially increased clinical toxicity.<sup>50</sup> Although no strict guidelines exist for the treatment of patients with ascites or pleural effusions, it is advisable to evacuate these fluid collections before treatment and monitor plasma drug concentrations closely. In addition, patients with bladder cancer who have undergone cystectomy and ileal conduit loop diversion may experience a significant increase in toxicity secondary to MTX treatment.<sup>51</sup> Thus, caution should be given when beginning therapy with MTX in this particular subset of patients.

Elimination of MTX occurs primarily through renal excretion. MTX is filtered by the glomerulus and is actively secreted in the proximal tubule. Renal clearance usually equals or exceeds creatinine clearance. However, rates of drug clearance may vary widely, and they do not precisely parallel renal function. Renal excretion of MTX is inhibited by probenecid, penicillins, cephalosporins, aspirin, and nonsteroidal antiinflammatory drugs.<sup>2</sup> The combination of MTX and nonsteroidal antiinflammatory drugs has been associated with severe toxicity in patients receiving high-dose MTX. Patients with impaired renal function (creatinine clearance less than 60 mL/min) should not be treated with high-dose MTX. Moreover, standard doses of MTX should be reduced in proportion to reductions in creatinine clearance.

The introduction of high-dose MTX regimens led to the identification of at least two MTX metabolites. 7-Hydroxymethotrexate (7-OH-MTX) constitutes 20% to 46% of drug excreted in urine from 12 to 24 hours after the start of a high-dose infusion. It is formed through the action of aldehyde oxidase in the liver and is a weak inhibitor of DHFR. 7-OH-MTX is a substrate for folylpolyglutamyl synthetase, and the resulting polyglutamate metabolites are inhibitors of the folate-dependent enzymes TS and aminoimidazole carboxamide ribonucleotide transformylase, with a potency similar to that of MTX polyglutamates.<sup>52</sup> A second metabolite, 2,4 diamino-N10-methyl pteric acid (DAMPA), a product of bacterial degradation of MTX in the gut lumen, is inactive and constitutes approximately 25% of the excreted drug at 24 to 48 hours after drug infusion. The exact role of these metabolites in producing MTX toxicity or enhancing therapeutic activity remains uncertain.

Biliary excretion of MTX represents approximately 10% of overall MTX drug clearance.<sup>53</sup> However, in the presence of renal dysfunction, enterohepatic circulation may represent an important pathway of drug elimination. Most MTX excreted in bile is reabsorbed as intact drug, but an undefined fraction is converted by intestinal flora to DAMPA. Intestinal binding of drug with oral charcoal or the anion-exchange resin cholestyramine enhances nonrenal drug excretion. Given the relatively minor role of biliary excretion in drug elimination, no adjustments in MTX dose are necessary for patients with hepatic dysfunction.

## SCHEDULES OF ADMINISTRATION

The safe use of high-dose MTX with LV rescue requires a thorough understanding of MTX pharmacokinetics. High-dose MTX therapy is used in the treatment of high-grade lymphomas, osteogenic sarcoma, and acute leukemia. These regimens use otherwise lethal infusions of MTX given over 6 to 42 hours in doses of 500 mg/m<sup>2</sup> or higher. High-dose MTX can be safely administered to patients provided that careful attention is paid to intravenous fluid hydration, urinary alkalization, plasma drug level monitoring, and adequate administration of LV.

During infusion of high-dose MTX, rapid renal excretion results in high urinary drug concentrations. Urinary MTX concentrations approaching 10 mM exceed solubility, resulting in intratubular precipitation and acute renal failure with potentially disastrous consequences. This complication can be avoided by vigorous hydration (3 L fluid/m<sup>2</sup>/24 hours, beginning 12 hours before infusion and continuing for 36 hours), and urinary alkalization to increase drug solubility. Administration of MTX should not begin until urine flow is 100 mL/h and urine pH is 7 or greater, and these parameters should be carefully monitored during the course of therapy. High-dose MTX therapy should not be used in patients with impaired renal function (creatinine clearance less than 60 mL/min).

Close monitoring of MTX plasma levels is essential for guiding the duration and amount of LV required to prevent severe MTX-associated toxicity. Given the competitive interaction between MTX and LV, the dose of the rescue agent must be increased in proportion to the plasma concentration of MTX. If the MTX level exceeds 0.5 μM 48 hours from the start of the infusion, the LV dose may be adjusted to 15, 100, or 200 mg/m<sup>2</sup> every 6 hours for MTX levels of 0.5, 1.0, and 2.0 μM, respectively. Drug levels should be rechecked every 24 hours and the LV dose adjusted until the drug concentration is less than 50 nM. However, clinicians should be aware that overzealous use of LV may counteract the cytotoxic effects of MTX in tumor cells as well as in host cells.<sup>54</sup> For this reason, it is important to use doses of LV that are adequate but not excessive, so that normal but not tumor cells will be rescued. In patients with delayed MTX excretion, LV is usually given intravenously, because its oral bioavailability is decreased at total doses higher than 40 mg.

Despite careful attention to detail, persistent elevations of plasma MTX levels may sometimes occur. Plasma MTX levels higher than 10 μM at 48 hours are poorly rescued even with high doses of LV. Hemodialysis and peritoneal dialysis are ineffective in removing MTX, with clearance rates of only 35 to 40 mL/min. Experimental approaches to reduce toxic levels of MTX include hemoperfusion over a charcoal column, oral administration of activated charcoal or cholestyramine to increase enterohepatic drug loss, and intravenous infusion of the degradative enzyme carboxypeptidase G<sub>2</sub>.<sup>27,55</sup>

MTX penetrates poorly into the cerebrospinal fluid (CSF), and CSF levels are 30-fold lower than plasma levels at equilibrium.<sup>56</sup> However, after high-dose MTX

therapy, peak CSF levels greater than the therapeutic threshold of 1  $\mu\text{M}$  can be achieved. Systemic high-dose MTX therapy has been used to prevent meningeal leukemia and lymphoma. Intrathecal injection of MTX can also be used for prophylaxis. For treatment of meningeal carcinomatosis, injection of MTX through an indwelling Ommaya reservoir is recommended because drug administered into the CSF via the lumbar space circulates poorly into the ventricles, resulting in inadequate CSF drug levels. A total intrathecal dose of 12 mg is advised for all persons older than 3 years of age. In normal patients, the CSF half-life is approximately 12 hours, but it may be prolonged in patients with active meningeal disease. Delayed clearance from the CSF has been associated with an increased risk of MTX neurotoxicity.

## TOXICITY

The primary toxic effects of MTX therapy are myelosuppression and gastrointestinal mucositis. The occurrence of these adverse effects and other toxicities depends on the dose, schedule, and route of drug administration. Mucositis usually appears 3 to 7 days after MTX therapy and precedes the decrease in granulocyte and platelet count by several days. Myelosuppression and mucositis are usually completely reversed within 14 days, unless drug elimination mechanisms are impaired. In patients with compromised renal function, even small doses of MTX may result in serious toxicity.

MTX-induced nephrotoxicity is thought to result from the intratubular precipitation of MTX and its metabolites, 7-OH-MTX and DAMPA, in acidic urine. Antifolates may also exert a direct toxic effect on the renal tubules. Vigorous hydration and urinary alkalization have greatly reduced the incidence of renal failure in high-dose regimens.<sup>2</sup>

MTX is associated with both acute and chronic hepatotoxicity. Acute elevations in hepatic enzyme levels, as well as hyperbilirubinemia, are often observed during high-dose therapy, but these usually return to normal within 10 days. Chronic administration of daily oral MTX, as has been used in the treatment of psoriasis, is associated with the development of hepatic fibrosis in as many as 25% of patients. Cirrhosis of the liver has also been described in this group. Intermittent, weekly MTX therapy, rather than continuous daily treatment, is associated with a lower incidence of hepatotoxicity. Although the precise mechanism of MTX hepatotoxicity is not known, liver biopsies of patients with drug-induced liver disease reveal increased lipid deposition in the liver.

MTX causes a poorly defined, self-limited pneumonitis characterized by fever, cough, and interstitial pulmonary infiltrates. Lung biopsies have not revealed consistent pathologic findings. Although a hypersensitivity reaction has been proposed as a possible explanation, rechallenge with MTX does not uniformly result in a return of symptoms. With the increasing use of chronic, low-dose MTX therapy for rheumatoid arthritis, there is now a growing number of cases of MTX-associated lung damage. No specific therapy for MTX pneumonitis is recommended other than withholding MTX therapy during the acute episode.

Three distinct neurotoxic syndromes are associated with intrathecal MTX therapy.<sup>57</sup> The most common syndrome is an acute chemical arachnoiditis that arises immediately after intrathecal drug administration. This syndrome is characterized by severe headaches, nuchal rigidity, vomiting, fever, and an inflammatory cell infiltrate in the CSF. A subacute form of neurotoxicity is seen in approximately 10% of patients and usually occurs after the third or fourth course of intrathecal therapy. It is most common in adults with active meningeal leukemia and consists of motor paralysis, cranial nerve palsies, and seizures or coma, or both. A change in therapy is absolutely indicated, because continued intrathecal MTX therapy may result in death. The third syndrome is a chronic, demyelinating encephalopathy, typically occurring in children months to years after receiving intrathecal MTX. Patients present with dementia, limb spasticity, and, in advanced cases, coma. Computed tomography scan reveals ventricular enlargement, cortical thinning, and diffuse intracerebral calcifications.<sup>83</sup>

High-dose systemic MTX therapy is occasionally associated with an acute, transient cerebral dysfunction with symptoms of paresis, aphasia, and behavioral abnormalities, and seizures have also been described in 4% to 15% of patients receiving high-dose MTX.<sup>58</sup> Symptoms occur within 6 days of MTX treatment and usually completely resolve within 48 to 72 hours. In addition, a chronic form of neurotoxicity is manifested as an encephalopathy with dementia and motor paresis developing in the second or third month after treatment. At present, the underlying mechanism of CNS toxicity from MTX remains unknown. There is no evidence to support the therapeutic use of LV in patients who develop neurotoxic symptoms.

True anaphylactic reactions to MTX are exceedingly rare. There have been a few reported cases of toxic skin erythema and desquamation of the hands after high-dose MTX therapy. In men treated with high-dose MTX, a reversible defect in spermatogenesis may occur. However, no alterations in reproductive function have been reported in women treated with MTX.

## NEW ANTIFOLATES

### TRIMETREXATE

In the 1990s, several new antifolates were developed in an attempt to circumvent some of the known mechanisms of resistance to MTX, to target folate-dependent enzymes other than DHFR, or both. The more lipid-soluble quinazoline antifolate trimetrexate (TMTX, Neutrexin) differs from MTX by not requiring the RFC system for cellular transport and by lacking the potential for polyglutamation. Like MTX, it is a potent inhibitor of DHFR and produces metabolic inhibition through mechanisms similar to MTX. It was thought that malignant cells that had become resistant to MTX, by virtue of either reduced membrane transport or deficient polyglutamation, would remain sensitive to this antifolate analogue. Because TMTX is not polyglutamated, its intracellular half-life is shorter than MTX, necessitating frequent or continuous dosing schedules. In contrast to MTX, TMTX can serve as a substrate for the P-glycoprotein-associated efflux pump. As a result, cross-resistance to TMTX and a host of natural products, including anthracyclines, taxanes, and vinca alkaloids, can develop in multidrug resistant cancer cells overexpressing the P170 glycoprotein.

TMTX has been tested using a variety of dose schedules. It is highly protein bound (more than 90%) and cleared principally from the body by hepatic metabolism.<sup>59</sup> The terminal plasma half-life of the drug ranges from 12 to 20 hours. TMTX has been tested in the phase II setting for the treatment of a variety of malignancies, principally with a regimen of 8 to 12 mg/m<sup>2</sup> daily for 5 days every 3 weeks.<sup>60,61</sup> The dose-limiting toxicity has been myelosuppression. Other toxicities include rash, mucositis, fever, nausea and vomiting, and reversible transaminasemia. Antitumor responses have ranged from 13% to 26%, with the highest rates in head and neck (26%) and non-small cell lung (19%) cancers. As a single agent, the compound has shown little activity against gastrointestinal cancers. However, when used in combination with 5-fluorouracil (5-FU) and LV, response rates on the order of 30% to 35% have been reported in patients with previously untreated metastatic colorectal cancer.<sup>62</sup>

### TOMUDEX

Raltitrexed (ZD1694, Tomudex) is a quinazoline antifolate that is a potent and specific inhibitor of TS. Like MTX, raltitrexed is transported into the cell via the RFC. To exert its cytotoxic activity, this compound needs to be metabolized to its higher polyglutamated forms. The polyglutamates of raltitrexed are approximately 100-fold more potent than the parent compound with regard to their affinity for TS, and they exhibit prolonged intracellular retention.<sup>63</sup> The principal mechanism of action of this compound is inhibition of TS, resulting in depletion of key nucleotide precursors required for DNA repair and synthesis. Mechanisms of resistance to raltitrexed include reduced transport, decreased polyglutamation, and overexpression of the target enzyme, TS.<sup>64,65</sup>

Raltitrexed has undergone phase I testing, and the recommended dosing schedule is 3 mg/m<sup>2</sup> given as a 15-minute intravenous infusion every 3 weeks.<sup>66,61</sup> The drug is cleared from the body principally by renal excretion, and its clearance follows a three-compartment elimination model with a terminal half-life of 10 to 22 hours. The major toxicities include an anorexia and fatigue syndrome, diarrhea, myelosuppression, and reversible transaminasemia. Several phase II clinical trials have investigated the activity of this drug in patients with a wide spectrum of malignancies, including advanced colorectal, breast, hepatocellular, platinum-resistant ovarian, non-small cell lung, gastric, and pancreas cancers.<sup>66</sup> Response rates have ranged from 14% for patients with pancreas cancer to 25% for those with breast cancer. The largest reported experience has been for first-line treatment of patients with advanced colorectal carcinoma. An overall response rate of 26% was observed in a phase II trial involving 176 patients. Randomized, phase III trials to compare the efficacy of raltitrexed versus LV-modulated 5-FU have been completed.<sup>67,68</sup> Raltitrexed has comparable response rates and similar palliative and survival benefits when compared with 5-FU/LV. Reduced toxicity was observed with this novel antifolate analogue, however, and it was associated with a more convenient administration schedule. This drug is approved as first-line therapy for patients with advanced colorectal cancer in Australia, Canada, and several European countries. Further studies are ongoing to determine the role of this antifolate TS inhibitor compound, either alone or in combination with other anticancer agents, in the therapy of colorectal cancer in North America.

## OTHER ANTIFOLATES

Several pteroyl glutamate analogues have shown superior preclinical activity compared with MTX, and this enhanced effect is thought to be due to enhanced transport, more avid polyglutamation, or a unique site of action. 10-Ethyl-5-deaza-aminopterin (Edatrexate), a potent inhibitor of DHFR with enhanced transport and more efficient polyglutamation relative to MTX, has demonstrated activity against non-small cell lung cancer. <sup>60,61,69</sup> Mucositis is the dose-limiting toxicity. 5,10-Dideazatetrahydrofolate (Lometrexol) is a new antifolate that impairs *de novo* purine synthesis by virtue of its direct inhibitory effects on GAR transformylase. Phase I studies have been performed, and this agent is currently undergoing phase II clinical investigation.

LY231514 was originally developed as a pure antifolate inhibitor of TS. However, preclinical studies suggest that it is not entirely specific for TS and that it inhibits other folate-dependent enzymes, including DHFR and GAR transformylase. <sup>60,61,70</sup> Like raltitrexed, this analogue requires polyglutamation for its potent inhibitory effects on TS, and it uses the RFC for entry into cells. This compound has been investigated in several phase I studies, and the major toxicities include neutropenia, anorexia and fatigue syndrome, gastrointestinal toxicity, and reversible transaminasemia. <sup>71</sup> Promising antitumor activity has been noted in a wide variety of tumor types, and phase II studies have confirmed activity against non-small cell lung cancer and mesothelioma. <sup>72</sup>

## 5-FLUOROPYRIMIDINES

The rationale for the synthesis of the fluoropyrimidines stemmed from the observation that rat hepatoma cells use uracil more efficiently than normal rat intestinal mucosa. <sup>73</sup> This finding suggested that uracil metabolism might represent a potential target for cancer chemotherapy.

The chemical structures of the fluoropyrimidines in common clinical practice are shown in [Figure 19.5-3](#). 5-FU has a fluorine atom substituted in place of hydrogen at the carbon-5 position of the pyrimidine ring (see [Fig. 19.5-3](#)). The deoxyribonucleoside derivative, 5-fluoro-2'-deoxyuridine (FUdR) is limited in its clinical use because of its rapid degradation in normal and tumor tissues. It has mainly been used for hepatic arterial infusions. Ftorafur and 5'-deoxyfluorouridine represent two fluoropyrimidine analogues that have been incorporated in oral prodrug forms of 5-FU, and they both demonstrate promising clinical activity.

**FIGURE 19.5-3.** Structures of fluoropyrimidines of clinical interest.

5-FU has antitumor activity against a wide spectrum of solid tumors, including epithelial malignancies arising in the breast, gastrointestinal tract, head and neck, and ovary, with single-agent response rates of 10% to 30%. <sup>74</sup> Significant efforts have focused on identifying agents that can biochemically modulate the cytotoxic effects of 5-FU. Such modulators of 5-FU include other antineoplastic agents such as MTX, cisplatin, and CPT-11, ionizing radiation, cytokines such as the interferons, and agents that by themselves have little to no activity such as LV and 5-ethynyluracil (EU). <sup>74,75</sup> Thus, in the clinical setting, 5-FU is most often incorporated as part of a combination regimen.

### Intracellular Metabolism and Mechanism of Action

Intracellular activation is required for the fluoropyrimidines to exert their cytotoxic effects. 5-FU readily enters cells via the facilitated uracil transport mechanism, whereas FUdR is a substrate for the facilitated nucleoside transport system. These compounds are anabolized to cytotoxic forms by several biochemical pathways ([Fig. 19.5-4](#)). 5-FU is converted to FUdR by thymidine phosphorylase. Subsequent phosphorylation of FUdR by thymidine kinase results in formation of the active 5-FU metabolite, 5-fluoro-2'-deoxyuridine monophosphate (FdUMP). In the presence of the reduced folate cofactor, 5,10-methylenetetrahydrofolate, FdUMP forms a stable covalent complex with TS. <sup>76</sup> TS catalyzes the sole intracellular *de novo* formation of thymidine-5'-monophosphate from dUMP (see [Fig. 19.5-2](#)). Inhibition of TS leads to depletion of dTTP, thus interfering with DNA biosynthesis and repair. 5-FU may be anabolized to fluorouridine monophosphate through the sequential action of uridine phosphorylase and uridine kinase. In the presence of PRPP, orotic acid phosphoribosyltransferase directly converts 5-FU to fluorouridine monophosphate. This metabolite is further metabolized to fluorouridine diphosphate and then to the triphosphate form (FUTP), which is subsequently incorporated into RNA. An alternate pathway for FdUMP synthesis is via conversion of fluorouridine diphosphate to fluorodeoxyuridine diphosphate (FdUDP) by ribonucleotide reductase (RR).

**FIGURE 19.5-4.** Metabolism of 5-fluorouracil (5-FU). 5-FdUMP, 5-fluoro-2'-deoxyuridine monophosphate; 5-FUDP, fluorouridine diphosphate; 5-FUdR, 5-fluoro-2'-deoxyuridine; FUMP, fluorouridine monophosphate; 5-FUR, fluorouridine; 5 FUTP, fluorouridine triphosphate.

Inhibition of TS by FdUMP is one of the principal mechanisms of 5-FU action. The TS-FdUMP-folate ternary complex is slowly dissociable, and the intracellular level of 5,10-methylenetetrahydrofolate is critical for ternary complex formation as well as for maintaining enzyme inhibition. Depletion of intracellular reduced folate pools prevents ternary complex formation in various tissue culture systems. <sup>74</sup> Pharmacologic concentrations of LV enhance the cytotoxicity of 5-FU by expanding the intracellular pools of 5,10-methylenetetrahydrofolate, thereby increasing the extent and duration of TS inhibition. Randomized clinical trials in advanced colorectal cancer indicate that the addition of LV to bolus 5-FU significantly improves the response rate compared with bolus 5-FU alone. <sup>77,78</sup> However, the actual benefit in patient survival is marginal and on the order of only 2 to 3 months.

5-FU is extensively incorporated into both nuclear and cytoplasmic RNA species, and this process interferes with normal RNA processing and function. <sup>79,80,81,82,83</sup> and <sup>84</sup> The extent of 5-FU-RNA incorporation correlates with cytotoxicity in some *in vitro* tissue culture and *in vivo* models. The following effects have been described as a consequence of 5-FU-RNA incorporation: alteration of the secondary structure of RNA; inhibition of mRNA polyadenylation, which decreases mRNA stability; inhibition of the conversion of high-molecular-weight nuclear RNA species to lower molecular-weight ribosomal RNA; quantitative and qualitative changes in protein synthesis; and incorporation into uracil-rich small nuclear RNA species, which interferes with normal splicing. 5-FU-containing transfer RNA forms covalent complexes with enzymes involved in posttranslational modification of uracil residues, thereby inhibiting their function. Despite the significant progress made in this

area of research, it remains unclear as to how these 5-FU-mediated RNA effects translate into cytotoxicity.

Inhibition of TS leads not only to depletion of dTTP, but to accumulation of dUMP. Both FdUMP and dUMP may be subsequently metabolized to their respective triphosphate forms. Incorporation of dUTP and FdUTP into cellular DNA, with resultant inhibition of DNA synthesis and function, may represent another mechanism of cytotoxicity. Two enzymatic mechanisms limit the DNA incorporation of (F)dUTP: dUTP nucleotidohydrolase degrades the triphosphate forms, and uracil-DNA glycosylase removes uracil residues from DNA.<sup>85,86</sup> The combined effects of dTTP depletion and (F)dUTP-DNA incorporation are associated with inhibition of nascent DNA chain elongation, altered DNA stability, production of DNA single-strand breaks, and interference with DNA repair. The genotoxic stress resulting from TS inhibition may activate programmed cell death pathways in susceptible cells, resulting in induction of parental DNA fragmentation. Both internucleosomal DNA laddering typical of classic apoptosis and very high-molecular-weight DNA fragmentation (50 kb or greater) have been described.<sup>87</sup> Factors operating downstream from TS (e.g., bcl-2 and p53 status) may influence the cellular response to such genotoxic stress.<sup>88,89</sup> Some studies suggest that in some human colon cancer cells, the process of thymineless death resulting from 5-FU therapy may be mediated via the Fas-signaling pathway.<sup>90</sup>

The relative contribution of each of these mechanisms of action to the cytotoxicity of 5-FU remains unclear and may depend on the specific patterns of intracellular 5-FU metabolism, which vary among different normal tissues and tumor types. The concentration of drug and the duration of exposure play crucial roles in determining the ultimate mechanism of cytotoxicity. However, there is now increasing support for the critical role of TS as a therapeutic target. The specific lines of evidence for this view include the enhanced activity of LV-modulated 5-FU in the therapy of both early stage and advanced colorectal cancer, the strong correlation between low TS content in tumor tissue and response to 5-FU-based therapy, the correlation between level of TS enzyme inhibition in tumors after 5-FU administration and response to 5-FU therapy, and the clinical activity of selective TS inhibitors such as Tomudex.<sup>74,91,92</sup>

### **Mechanisms of Resistance**

Given the multiple sites of cytotoxic action of 5-FU and the various metabolic pathways required for its activation, it is not surprising that several mechanisms of resistance have been identified in experimental and clinical settings.<sup>74,92</sup> However, the relative contribution of each of these mechanisms in the development of cellular resistance to 5-FU in the actual clinical setting remains unclear.

In human and murine tumor cells selected *in vitro* for resistance to 5-FU, a variety of mechanisms have been described. Deletion or diminished activity of thymidine or uridine kinase, thymidine or uridine phosphorylase, and orotate phosphoribosyl transferase interferes with metabolic activation. Decreased accumulation of FUTP, FdUMP, and (F)dUTP may result from increased activity of catabolic enzymes [acid and alkaline phosphatases, dUTP hydrolase, and dihydropyrimidine dehydrogenase (DPD)].<sup>93</sup> Expansion of intracellular cytidine triphosphate (CTP) pools associated with elevated CTP synthase activity results in feedback inhibition of uridine kinase, thus decreasing the metabolism of 5-FU to ribonucleotide forms. Decreased incorporation of 5-FU into both RNA and DNA may result in decreased sensitivity.<sup>92,94</sup> A relative deficiency of the reduced folate substrate 5,10-methylenetetrahydrofolate may also compromise the cytotoxic action of FdUMP on TS. This may result from low extracellular levels of reduced folates, decreased membrane transport of reduced folates, or reduced activity of folylpolyglutamate synthase, thereby preventing its polyglutamation.<sup>95</sup>

Alterations in the target enzyme TS represent the most commonly described mechanism of resistance to 5-FU. A decrease in binding affinity of the 5-FU metabolite FdUMP to the TS target has resulted from point mutations in the protein-coding region of the TS gene.<sup>96</sup> *In vitro*, *in vivo*, and clinical model systems have shown a strong correlation between the levels of TS enzyme activity and TS protein and chemosensitivity to 5-FU. In this regard, cell lines, tumors with higher levels of TS, or both are relatively more resistant to 5-FU. This increase in TS protein content is usually associated with amplification of the TS gene.<sup>97</sup> In cell lines made resistant to cisplatin or doxorubicin, cross-resistance to 5-FU may develop on the basis of increased TS expression as a consequence of increased transcription of the TS gene.<sup>98</sup> In several *in vitro* and *in vivo* model systems, the levels of TS enzyme activity and TS protein have been shown to acutely increase after exposure to 5-FU, other specific TS inhibitor compounds, or both.<sup>74,99,100</sup> Moreover, acute increases in the expression of TS protein have been identified in the clinical setting in paired tumor tissue biopsies obtained from patients before and during therapy with 5-FU.<sup>101</sup> This acute induction of TS protein in response to drug exposure is mediated by a translational regulatory mechanism.<sup>102</sup> TS protein, in its unbound or free state, is capable of specifically repressing the translation of its own mRNA. However, when TS protein is bound to either nucleotide, antifolate inhibitors, or both, it is unable to repress TS mRNA translation, and the rate of new TS protein synthesis increases.<sup>103</sup> Thus, induction of TS may represent an efficient and clinically relevant mechanism for the acute development of drug resistance.

### **Clinical Pharmacology**

An understanding of 5-FU pharmacokinetics is important given the wide choice of routes and schedules of administration available, each of which has advantages in terms of differing spectrum of host toxicity. The most widely used methods for quantitating 5-FU in biologic fluids are high-pressure liquid chromatography (HPLC) and gas chromatography-mass spectrometry.<sup>104</sup> Nuclear magnetic resonance imaging with <sup>19</sup>F offers the potential for noninvasive monitoring of intratumoral accumulation of 5-FU; trapping of 5-FU within tumor tissue has been associated with clinical response.

5-FU is administered by either intravenous bolus or continuous infusion. The volume of distribution is slightly larger than the extracellular space, and 5-FU readily penetrates into tissues, CSF, and extracellular third-space accumulations such as ascites or pleural effusions. After intravenous bolus doses of 370 to 720 mg/m<sup>2</sup>, peak plasma concentrations reach 300 μM to 1 mM; thereafter, metabolic elimination is rapid, with a primary half-life of 8 to 14 minutes. Plasma levels of 5-FU fall below 1 μM within 2 hours, an approximate threshold for cytotoxic effects. A prolonged third elimination phase of 5-FU after intravenous bolus (half-life, approximately 5 hours), detected by a sensitive gas chromatography-mass spectrometry method, may reflect release of 5-FU from tissues. Less than 10% of parent drug is excreted in the urine, whereas the balance is cleared through metabolic pathways (catabolism is greater than intracellular anabolism). 5-FU is enzymatically inactivated to dihydrofluorouracil by DPD.<sup>105</sup> Although the liver expresses the highest levels of DPD in the body, this enzyme is widely distributed in other tissues, including gastrointestinal mucosa and peripheral lymphocytes. Dihydropyrimidinase subsequently converts dihydrofluorouracil to α-fluoro-ureidopropionic acid, then β-alanine synthase catalyzes the irreversible formation of α-fluoro-β-alanine with the release of ammonia and CO<sub>2</sub>. 5-FU and its catabolites undergo biliary excretion and enterohepatic circulation.

5-FU clearance is saturable; total body clearance decreases with increasing doses and deviates from a linear relationship above a certain dose (depending on schedule of administration). For example, clearance ranges from approximately 350 to 850 mL/min/m<sup>2</sup> with bolus doses of 720 and 370 mg/m<sup>2</sup>. It may be difficult to predict plasma concentrations or the risk of severe toxicity at high doses.

Rare patients with inherited DPD deficiency may have life-threatening or fatal toxicity if treated with fluoropyrimidine-based chemotherapy.<sup>106,107</sup> Because affected individuals are otherwise in good health, the first indication of the presence of this inborn error of metabolism usually follows an unexpectedly severe reaction to 5-FU chemotherapy. Careful testing of DPD-deficient patients has revealed an autosomal recessive pattern of inheritance. It is now estimated that as many as 3% to 5% of adult cancer patients may have this pharmacogenetic syndrome. Several molecular defects, including point mutations and deletions due to exon skipping, have been identified in DPD-deficient patients who experience severe toxicity to 5-FU. Further studies are in progress to establish the precise relationship between the level of DPD activity and 5-FU host toxicity.

Frequently used continuous infusion schedules include protracted venous infusion (300 mg/m<sup>2</sup>/d when given alone), 96- to 120-hour infusion every 3 weeks (1000 mg/m<sup>2</sup>/d), and a weekly 24-hour infusion (2600 mg/m<sup>2</sup>/d). 5-FU clearance is faster with constant infusion, varying from approximately 2000 to 3000 mL/min/m<sup>2</sup> depending on the dose rate. The incidence of serious clinical toxicity tends to increase with higher systemic exposure (steady-state plasma concentrations during constant infusion and total area under the concentration time curve with bolus administration). Pharmacologic monitoring with intracycle dose modifications offers the potential to avoid serious toxicity. Variation in 5-FU steady-state plasma levels according to time of day have been reported during constant infusion, although the time of day at which peak and trough plasma values occurred has not been consistent between studies.

Hepatic metastases obtain their blood supply predominantly from the arterial circulation via the hepatic artery. In patients with metastases confined to the liver, hepatic arterial infusion of 5-FU or FUdR provides high local drug concentrations to the tumor. The first-pass extraction of FUdR by the normal hepatic parenchyma approaches 95%, and little drug enters the systemic circulation. In contrast, the first-pass extraction of 5-FU ranges from 20% to 50%.<sup>108</sup> The recommended dosage of FUdR is 0.2 mg/kg/d for up to 14 days (7 mg/m<sup>2</sup>/d), whereas 440 to 555 mg/m<sup>2</sup>/d of 5-FU may be given for up to 14 days; lower 5-FU doses (total of 300 mg/d) may be tolerated for longer periods. The response rates reported for previously untreated colorectal carcinoma approach 50% in selected series.<sup>109</sup> Although the time to hepatic disease progression is significantly longer compared with systemic therapy with single-agent 5-FU or 14-day intravenous infusion of FUdR, the time to extrahepatic disease progression and overall survival remain unchanged. Approximately 30% of patients with liver-only metastases who have failed to respond to

systemic 5-FU may respond to hepatic arterial infusion FUdR. Systemic toxicities are usually dose limiting with hepatic arterial infusion of 5-FU, presumably because a higher concentration of drug reaches the systemic circulation. These side effects include oral mucositis and gastrointestinal symptoms such as nausea, vomiting, and diarrhea. Myelosuppression occurs less often. Local and regional toxicities include peptic ulceration and chemical hepatitis (usually mild). In contrast, systemic toxicities are less common with FUdR, whereas local and regional toxicities predominate. Hepatic toxicity is dose limiting, and gastritis, duodenitis, or frank ulcers occur in 20% to 25% of patients.

5-FU and FUdR may also be given by the intraperitoneal route. Both drugs are absorbed primarily through the portal circulation and are subject to first-pass clearance in the liver before reaching the systemic circulation. In early trials, dialysate concentrations of 5 mM or less 5-FU maintained by intermittent exchanges of fluid for up to 5 days were tolerated, and the ratio of intraperitoneal to plasma 5-FU levels was approximately 300. 5-FU clearance is slower from the peritoneal cavity than from plasma (half-life approximately 1.5 hours). Up to 20 mM 5-FU given intraperitoneally for 4 hours with 90 mg/m<sup>2</sup> cisplatin every 4 weeks is tolerated, except for mild nausea and vomiting and sometimes diarrhea, whereas granulocytopenia occurs with higher dialysate concentrations. FUdR, 3000 mg given in 2 L of dialysate for 4 hours daily for 3 days, is well tolerated. The major systemic toxicity is nausea and vomiting, and this is usually well controlled. The peritoneal to plasma FUdR ratio is approximately 2700, suggesting a potential pharmacologic advantage for the use of intraperitoneal FUdR over 5-FU.

### **Clinical Toxicity**

The primary effects of 5-FU are exerted on rapidly dividing tissues, specifically gastrointestinal mucosa and bone marrow. The spectrum of toxicities associated with 5-FU varies considerably according to the dose, schedule, and route of administration. The most frequently used dose and schedules of single-agent 5-FU given by bolus injection are 600 mg/m<sup>2</sup>/week and 425 mg/m<sup>2</sup>/d for 5 days every 3 to 4 weeks. The dose of 5-FU generally should be reduced when used in combination with LV, the magnitude of which varies according to the schedule and LV dose. Epithelial ulceration may occur throughout the gastrointestinal tract and may manifest as mucositis, pharyngitis, dysphagia, esophagitis, gastritis, colitis, or proctitis. Diarrhea may be watery or bloody, and the combination of nausea, vomiting, and profuse diarrhea can lead to profound dehydration and hypotension. Disruption of the integrity of the gut lining may permit access of enteric organisms into the blood stream, with the potential for overwhelming sepsis, particularly if the granulocyte nadir coincides with diarrhea. 5-FU should be withheld in the face of ongoing mucositis or diarrhea, even if mild, and subsequent doses should be reduced when the patient has fully recovered. If diarrhea occurs, supportive care and vigorous hydration should be given. Antidiarrheal agents, such as diphenoxylate and loperamide, may help control mild diarrhea, but they are generally ineffective in controlling diarrhea of greater severity.<sup>110</sup> In this setting, the somatostatin analogue octreotide seems to have greater efficacy. Mouth cooling (oral cryotherapy) with oral ice chips for 30 minutes starting immediately before bolus 5-FU substantially reduces the severity of mucositis. Nausea and vomiting may occur but are usually controlled with antiemetics. Myelosuppression may also be observed, with granulocytopenia occurring more than thrombocytopenia. With the schedule of a daily dose for 5 days, the granulocyte and platelet nadirs tend to occur during the second or third week of treatment. In contrast, myelosuppression generally occurs after the fourth weekly dose of the weekly bolus 5-FU schedule.

Continuous intravenous infusion of 5-FU at doses of 1000 mg/m<sup>2</sup>/d for 5 days every 3 weeks results in only minor myelosuppression, whereas stomatitis and diarrhea are the principal dose-limiting toxicities. With protracted venous infusion of 5-FU (300 mg/m<sup>2</sup>/d), serious myelosuppression is less common. The infusion can be interrupted at the first signs of mouth soreness or diarrhea, thus limiting the severity of toxicity. However, palmar-plantar erythrodysesthesia (hand-foot syndrome) is a more subacute toxicity that may eventually be dose limiting.<sup>111</sup> With a weekly 24-hour infusion of 2600 mg/m<sup>2</sup> 5-FU, neurotoxicity and gastrointestinal toxicity are dose limiting.

Other dermatologic toxicities associated with 5-FU therapy include alopecia, changes in the fingernails, and dermatitis that varies from a pruritic erythematous rash followed by scaling to more severe cases with vesicle formation. 5-FU enhances the cutaneous toxicity of radiation, and reactions usually occur within 7 days of radiation. Photosensitivity reactions, increased pigmentation over the veins into which 5-FU has been administered, as well as more generalized hyperpigmentation, and atrophy are possible. Hand-foot syndrome most often occurs with protracted infusion schedules of 5-FU, but may also be seen in patients receiving LV-modulated 5-FU. Ocular toxicity includes blepharitis, epiphora, tear duct stenosis, and acute and chronic conjunctivitis. The acute inflammatory response is reversible when the drug is discontinued early in the treatment course, but progression may require surgical correction of ectropion and tear duct stenosis.

Acute neurologic symptoms, including somnolence, cerebellar ataxia, and upper motor signs, are primarily seen in patients receiving intracarotid infusions for head and neck tumors, but neurologic toxicity may also occur with weekly schedules (24-hour infusion is greater than bolus). The premise that 5-FU catabolites play a role in the neurotoxicity is supported by preclinical models of neurotoxicity. However, patients with DPD deficiency may experience severe neurologic toxicity in the absence of myelosuppression and gastrointestinal toxicity after 5-FU therapy.<sup>112</sup> Thus, the exact 5-FU metabolite responsible for 5-FU neurotoxicity remains unclear.

A syndrome of chest pain, cardiac enzyme elevations, and electrocardiographic changes consistent with myocardial ischemia may be seen in temporal association with 5-FU administration. In some patients, coronary angiography revealed no abnormalities, suggesting vasospasm as a possible mechanism. This toxicity has been attributed to parent drug and to the catabolites, fluoro-b-alanine and fluoroacetate. Concentration-dependent vasoconstriction occurs when isolated vascular smooth muscle rings are exposed *in vitro* to 5-FU, and this can be reversed with nitrates.

Intrahepatic administration of FUdR is complicated mainly by cholestatic jaundice and biliary sclerosis. These adverse side effects are thought to result from direct perfusion of the blood supply to the gallbladder and upper bile duct with high local drug concentrations. Of note, this complication occurs much less frequently with hepatic arterial infusion of 5-FU. Biliary sclerosis typically occurs by the third cycle of treatment. Therapy with FUdR may be reinstated at a lower dose after normalization of serum hepatic enzyme levels, but most patients become progressively less tolerant. Catheter-related complications include thrombosis of the catheterized vessel, hemorrhage or infection at the site of insertion, and slippage of the catheter into the gastroduodenal artery with resultant necrosis of the intestinal epithelium, hemorrhage, and perforation.

### **Drug Interactions**

A host of drug interactions have been investigated in an attempt to enhance the cytotoxicity and therapeutic selectivity of fluoropyrimidine chemotherapy. The interaction of 5-FU with MTX is of particular interest as both drugs are often used in combination chemotherapy for breast and colorectal cancer. When given before 5-FU, MTX-mediated inhibition of DHFR results in accumulation of PRPP.<sup>74</sup> Increased availability of PRPP promotes formation of fluorouridine monophosphate via the reaction catalyzed by orotic acid phosphoribosyltransferase, with enhanced FUTP incorporation into RNA. In contrast, administration of 5-FU before MTX antagonizes the antipurine effects of MTX by preventing the accumulation of dihydrofolate and maintaining the pool of reduced folates needed for *de novo* purine synthesis. A 24-hour interval is superior to a 1-hour interval in some preclinical and clinical studies.<sup>113</sup> The dose of MTX in clinical trials has varied, but doses of 100 mg/m<sup>2</sup> or more are usually followed by LV rescue. A metaanalysis of randomized trials of MTX and 5-FU revealed a higher response rate compared with single-agent bolus 5-FU.<sup>114</sup>

Synergy between 5-FU and cisplatin has been noted in several preclinical models. Possible mechanisms of interaction include cisplatin-mediated increases in the intracellular content of the reduced folate pool, enhanced DNA damage, and interference with repair of cisplatin-DNA adducts. In some preclinical models, concurrent exposure to both drugs produces synergy, whereas other models suggest that preexposure to 5-FU before cisplatin administration is superior to the opposite sequence. Clinical synergy between infusional 5-FU and cisplatin is evident in tumor types that are sensitive to both drugs, such as squamous cell cancers of the head and neck and esophagus, whereas randomized trials in colorectal cancer show no benefit with the addition of cisplatin. The influence of sequence of cisplatin and 5-FU on therapeutic outcome has not been carefully studied in clinical trials.

The salvage enzyme thymidine kinase converts thymidine to thymidine monophosphate, thereby bypassing the TS-mediated inhibition of *de novo* thymidylate production. In tissue culture models, thymidine (10 to 20 μM) is frequently used to replete dTTP pools and thus negate its potential contribution to toxicity. In some models, pharmacologic concentrations of thymidine promote 5-FU RNA incorporation (by feedback inhibition of thymidine kinase and RR).<sup>74</sup> *In vivo*, however, thymidine (and its catabolite thymine) increased the half-life of 5-FU by interfering with the catabolism of 5-FU to dihydrofluorouracil, leading to a marked increase in 5-FU toxicity with no improvement in antitumor activity. Simultaneous exposure to pharmacologic concentrations of uridine may antagonize the RNA-directed cytotoxicity of 5-FU by decreasing its activation to the ribonucleotide level by uridine kinase; furthermore, expanded UTP pools may decrease FUTP incorporation into RNA. Delayed administration of uridine increases the rate of recovery from 5-FU-associated inhibition of both RNA and DNA synthesis in some models.<sup>115</sup> Delayed administration of oral uridine to patients decreases the myelosuppression associated with weekly bolus 5-FU, but the effect on therapeutic activity has yet to be determined.<sup>116</sup>

Interferons (IFNs) enhance the *in vitro* and *in vivo* activity of 5-FU and FUdR in a cell-line-dependent manner.<sup>117</sup> Heterogeneity exists among cancer cell lines as to the specific type of IFN that enhances fluoropyrimidine toxicity. IFN-α may increase the activity of thymidine and uridine phosphorylases, and increased FdUMP

formation has been reported in some cell lines. In other models, IFN- $\alpha$  may enhance fluoropyrimidine-mediated DNA damage in the absence of a direct effect on FdUMP pools or the extent of TS inhibition. In a human colon cancer cell line, IFN- $\gamma$  abrogated the acute increase in TS protein accompanying 5-FU exposure, and in so doing, enhanced the cytotoxic effects of 5-FU.<sup>118</sup> IFN- $\alpha$  may decrease the clearance of 5-FU in some individuals in a dose- and schedule-dependent manner, particularly with consecutive daily administration of IFN- $\alpha$  in conjunction with bolus 5-FU. Initial clinical trials appeared promising, although the toxicity of IFN- $\alpha$ -modulated 5-FU was substantial. The final results from several randomized trials evaluating IFN- $\alpha$ -modulated 5-FU alone or with LV in advanced colorectal cancer reveal no benefit of IFN to 5-FU therapy in terms of overall response rate and survival.<sup>119,120</sup> Moreover, toxicity was significantly increased with the addition of IFN. A large randomized trial testing the contribution of IFN- $\alpha$  to a daily schedule for 5 days of bolus 5-FU/LV has been conducted by the National Surgical Adjuvant Breast and Bowel Project in the adjuvant treatment of colon cancer. The results from this trial have been published, and as in the case of advanced disease, IFN- $\alpha$  therapy is of no added benefit in the adjuvant setting.<sup>121</sup>

Preexposure to inhibitors of *de novo* pyrimidine synthesis, such as N-(phosphonoacetyl)-L-aspartic acid and brequinar, results in depletion of UTP, CTP, dUMP, and dCTP pools. These biochemical effects are associated with enhanced anabolism of 5-FU to FUTP, increased 5-FU-RNA incorporation, and enhanced DNA-directed cytotoxicity. Although promising results were initially reported with a weekly schedule of low-dose N-(phosphonoacetyl)-L-aspartic acid (250 mg/m<sup>2</sup> intravenously) given 1 day before a 24-hour infusion of 5-FU (2600 mg/m<sup>2</sup>), a randomized phase II trial conducted by the Southwest Oncology Group failed to demonstrate an improvement in response rate compared with the same schedule of 5-FU alone.<sup>122</sup> Results from other multiinstitutional phase III trials are pending.

Preclinical studies show that 5-FU enhances the cytotoxicity of ionizing radiation, and both preclinical and clinical studies have revealed that radiosensitization appears to be enhanced with prolonged exposure. The underlying mechanisms for this synergistic interaction may include increased DNA damage, inhibition of DNA repair, and accumulation of cells in S phase.<sup>74,123,124</sup> Some work suggests that the G<sub>1</sub>/S checkpoint may play a critical role in determining the ability of 5-FU to enhance the cytotoxic effects of radiation therapy. Moreover, this effect may not depend on normal p53 function, but instead, may rely on intact cyclin E-dependent kinase activity. One example highlighting the successful clinical application of this approach is the use of protracted infusional 5-FU during pelvic radiation in the adjuvant treatment of rectal cancer.<sup>125</sup>

## STRATEGIES TO PERMIT ORAL ADMINISTRATION OF FLUOROPYRIMIDINES

### TEGAFUR, URACIL, 5-FLUOROURACIL

Administration of 5-FU by the oral route has generally been avoided because of erratic bioavailability. Several strategies to allow oral dosing by decreasing the catabolism of 5-FU are being explored. One approach involves the drug tegafur, uracil, 5-fluorouracil (UFT), a combination of Ftorafur (1-[2-tetrahydrofuryl]-5-fluorouracil, tegafur; see Fig. 19.5-3), a 5-FU prodrug, in a 1:4 molar ratio with uracil. Preclinical studies indicated that UFT resulted in significantly higher tumor-to-serum 5-FU ratios than Ftorafur alone. UFT is administered orally in divided doses, and it has been given daily for 5 to 28 days. With oral doses ranging from 50 to 300 mg/m<sup>2</sup>, maximum plasma levels of Ftorafur and 5-FU occur between 0.6 and 2.1 hours. Ftorafur levels (2.7 to 20.0  $\mu$ g/mL) exceed 5-FU levels (0.025 to 0.9  $\mu$ g/mL, 0.2 to 7.0  $\mu$ M), and Ftorafur clearance is approximately 70 mL/min. Combined phase II data from 438 patients treated with UFT in Japan reveal the drug has single-agent activity (19% to 32% response rate) in adenocarcinomas arising in the gastrointestinal tract and breast. Hematologic toxicity is mild. Gastrointestinal toxicity includes anorexia (24%), nausea and vomiting (12.5%), and diarrhea (12%). UFT in combination with LV has been tested here in the United States in both phase I and phase II studies. When UFT was used at a dose of 300 mg/m<sup>2</sup>/d with 150 mg/d LV in patients with advanced colorectal cancer, an overall response rate of 42% was observed.<sup>126</sup> This treatment was well tolerated, and there was only a 24% incidence of grade 3 gastrointestinal toxicity, as manifested by diarrhea, vomiting, and abdominal cramps, and asthenia and fatigue. The results of two randomized, phase III studies comparing oral UFT (300 mg/m<sup>2</sup>/d) and oral LV (75 or 90 mg/d) for 28 days every 35 days with the Mayo Clinic regimen of 5-day bolus 5-FU (425 mg/m<sup>2</sup>/d) and LV (20 mg/m<sup>2</sup>/d) given every 35 days in previously untreated patients with metastatic colorectal cancer show that the oral and intravenous regimens have similar response rates, time to disease progression, and overall survival. However, the oral regimen was associated with a significantly lower incidence of severe neutropenia and need for hospitalization.<sup>127</sup> Thus, UFT/LV is an acceptable alternative to intravenous 5-FU/LV for treatment of advanced colorectal cancer. Studies are ongoing to determine its potential role in the adjuvant therapy of early-stage colorectal cancer.

### CAPECITABINE (XELODA)

Capecitabine (Xeloda) represents another oral prodrug of 5-FU that was designed with the rationale of generating selective 5-FU activation in tumor tissue.<sup>128</sup> When administered orally, it is absorbed intact through the intestinal mucosa, metabolized by a carboxylesterase enzyme in the liver to 5'-deoxy-5-fluorocytidine, and then converted to 5'-deoxy-5-fluorouridine by cytidine deaminase, an enzyme principally located in the liver. 5'-Deoxy-5-fluorouridine is then converted directly at the tumor site by the thymidine-metabolizing enzyme, thymidine phosphorylase, a protein that has been shown to function as an angiogenic factor.

Preclinical studies have shown that tumor 5-FU concentrations are significantly higher than those measured in plasma. Moreover, this oral prodrug has shown activity against a broad spectrum of human tumor xenografts with relatively mild host toxicity. Currently, this agent is approved for use as a third-line agent in the treatment of anthracycline- and taxane-resistant advanced breast cancer.<sup>129</sup> Studies are ongoing to determine the role of this compound in the therapy of advanced colorectal cancer. Preliminary results of a randomized phase III North American trial comparing capecitabine (2500 mg/m<sup>2</sup>/d for 14 days every 3 weeks) with a Mayo Clinic regimen of a daily dose for 5 days show that overall response rates are significantly higher for capecitabine (23.2%) versus 5-FU/LV (15.5%).<sup>130</sup> Both the duration of response and progression-free survival are similar. Although survival data remains immature at this time, capecitabine appears to have a more favorable toxicity profile than intravenous 5-FU/LV and the most common toxicities observed were hand-foot syndrome (17.7%) and diarrhea (16.3%), with myelosuppression being relatively uncommon.

### S1

S1 is an oral formulation composed of the 5-FU prodrug Ftorafur, the DPD inhibitor 5-chloro-2,4-dihydropyridine, and oxonic acid.<sup>75</sup> 5-Chloro-2,4-dihydropyridine is a competitive, reversible inhibitor of DPD that helps to significantly prolong the half-life of 5-FU and improve oral bioavailability. Oxonic acid is an inhibitor of pyrimidine phosphoribosyltransferase, and it acts to prevent 5-FU phosphorylation and subsequent incorporation of 5-FU metabolites into the RNA of normal tissues in the gastrointestinal tract. Given its mechanism of action, the goal of oxonic acid is to protect against 5-FU-mediated gastrointestinal toxicity. Phase I studies revealed that the dose-limiting toxicity was myelosuppression mainly in the form of neutropenia. In Japan, where this drug was initially developed, phase II trials have been conducted in several malignancies, including gastric, colorectal, breast, and head and neck cancer. Response rates have ranged between 30% and 50%, and toxicity has been generally mild, with myelosuppression predominating. Phase I and II studies are under way in the United States to confirm its clinical activity.

### 5-ETHNYLURACIL

The uracil analogue 5-ethynyluracil (Eniluracil, EU, GW776, 776C85) is a potent, mechanism-based inhibitor of DPD.<sup>75</sup> On binding of EU to DPD (apparent K<sub>m</sub> approximately 2  $\mu$ M), an unstable intermediate is formed, following which the drug becomes covalently linked to the enzyme. Administration of EU to both animals and humans results in complete inhibition of total body DPD, as evidenced by inhibition of DPD enzyme activity in peripheral mononuclear cells and by up to 100-fold elevations of plasma uracil levels.<sup>131,132</sup> Treatment with EU completely inhibits DPD enzyme activity in both the tumors and peripheral lymphocytes of patients with colorectal cancer, a finding that confirms the use of peripheral mononuclear cells as an accurate and reliable surrogate marker for tumoral DPD activity. Preclinical studies *in vivo* show that treatment with EU significantly improves 5-FU pharmacokinetics, resulting in a marked elevation of both the plasma half-life and area under the concentration time curve of 5-FU.

This work has been extended to the clinical setting in which phase I studies investigating the combination of 5-FU and EU have been performed. EU significantly increased 5-FU plasma half-life by up to 20-fold and decreased 5-FU clearance by 18-fold, leading to a prolonged half-life of 4 to 6 hours.<sup>133</sup> Moreover, in the presence of EU, the oral bioavailability of 5-FU approaches 100%. This then allows for effective oral administration of 5-FU. The 5-FU/EU combination has subsequently been advanced to the phase II setting in patients with metastatic colorectal cancer. When 5-FU and EU were administered for 28 days on an every 35-day cycle at the respective doses of 1.0 and 10.0 mg/m<sup>2</sup>/d, a 29% objective response rate was observed. Treatment was relatively well tolerated, and grade 3 to 4 diarrhea was noted in 16% of patients, stomatitis and mucositis in 4%, and neutropenia in 4%.

EU is a promising biochemical modulator of 5-FU, and clinical studies suggest that it may help to improve the antitumor activity and host toxicity profile of 5-FU chemotherapy. Currently, there are two large randomized, phase III studies comparing 5-FU and EU with either the Mayo Clinic daily for 5 days regimen of 5-FU and

LV or with protracted infusional 5-FU. The results from these studies will provide critical insights as to the precise role of the 5-FU and EU combination in the therapeutic armamentarium of patients with metastatic colorectal cancer. Moreover, this combination may find clinical application in the treatment of other solid tumors such as advanced breast cancer.<sup>133a</sup>

## CYTARABINE

Cytarabine (1-β-D-arabinofuranosylcytosine, Ara-C) is one of several arabinose nucleosides isolated from the sponge *Cryptothethya crypta*,<sup>134</sup> differing from its physiologic counterpart by virtue of a stereotypic inversion of the 2'-hydroxyl group of the sugar moiety ( Fig. 19.5-5). Ara-C is regarded as one of the most important drugs in the treatment of acute myelogenous leukemia (AML). A regimen of Ara-C combined with an anthracycline, given as a 5- or 7-day continuous infusion is considered the standard induction treatment for AML. Furthermore, Ara-C is used in the treatment of other hematologic malignancies, such as non-Hodgkin's lymphoma, chronic myelogenous leukemia, and acute lymphocytic leukemia.

**FIGURE 19.5-5.** Structures of deoxycytidine analogues of clinical interest.

### Intracellular Metabolism and Mechanism of Action

As with other nucleoside analogues and their physiologic counterparts, Ara-C enters cells via nucleoside-specific transmembrane transport proteins, the most important one being the es (equilibrative inhibitor-sensitive) receptor. Studies with blasts from patients with acute leukemias have shown a strong correlation between expression of es transporters and *in vitro* sensitivity to Ara-C.<sup>135</sup>

Once within the cytoplasm, Ara-C requires activation for its cytotoxic effects. The first metabolic step is the conversion of Ara-C to ara-cytidine monophosphate (Ara-CMP) by the enzyme deoxycytidine kinase (dCK) ( Fig. 19.5-6). This enzyme is the rate-limiting step in intracellular anabolism of Ara-C. This metabolic step is saturable, and the  $K_m$  is approximately 20  $\mu\text{M}$ .<sup>136</sup> Ara-CMP is subsequently phosphorylated to ara-cytidine diphosphate (Ara-CDP) and Ara-CTP by the enzymes pyrimidine monophosphate kinase and pyrimidine diphosphate kinase, respectively. Ara-CTP competes with the native substrate deoxycytidine triphosphate (dCTP) for DNA incorporation by DNA-directed DNA polymerase ( $K_i$  approximately 1  $\mu\text{M}$ ). The incorporated Ara-CTP residue is a potent inhibitor of DNA polymerase  $\alpha$  (involved in Okazaki fragment synthesis on the lagging strand of the replication fork), DNA polymerase  $\delta$  (the leading strand replicase), and DNA polymerase  $\beta$  (involved in the repair of chemically induced DNA damage).<sup>137,138 and 139</sup> Inhibition of DNA polymerases, in turn, interferes with DNA chain elongation during both semiconservative DNA replication and DNA repair.<sup>140</sup> The incorporated Ara-CTP residue functions as a relative DNA chain terminator, and interference with chain elongation is influenced by sequence specificity of the DNA template.<sup>138,140</sup> Initiation of new DNA replication intermediates continues, however, with accumulation of nascent DNA fragments.<sup>140</sup> This process may result in abnormal duplication of limited portions of DNA, thus increasing the possibility of recombination, crossover, and gene amplification. Over time, the nascent DNA strand can be extended beyond the arabinosyl nucleotide residue, and digestion of DNA reveals the presence of Ara-CMP in the internucleotide (internal) position.<sup>138,139 and 140</sup> In some human leukemic cell lines, Ara-C-mediated DNA damage is accompanied by a pattern of internucleosomal DNA fragmentation typical of apoptosis (programmed cell death).<sup>141</sup> There is evidence suggesting that Ara-C metabolism in AML blasts differs from that in normal bone marrow mononuclear cells and CD34+ hematopoietic stem cells.<sup>142</sup> The total levels of phosphorylated Ara-C metabolites, including Ara-CMP, Ara-CDP, Ara-CTP, Ara-CDP-choline, and Ara-UMP, were two- to fourfold higher in leukemic blast cells when compared with normal bone marrow cells, both at standard and high doses of Ara-C. The most striking difference was found with the Ara-CDP-choline metabolite in the setting of Ara-C dose escalation. The level of this metabolite was 4.3-fold higher in leukemic blast cells.<sup>142</sup>

**FIGURE 19.5-6.** Metabolism of Ara-C. Gemcitabine shares the same metabolic pathway as Ara-C. Ara-CDP, ara-cytidine diphosphate; Ara-CTP, ara-cytidine triphosphate; Ara-U, ara-uridine; Ara-UMP, ara-uridine monophosphate; dCMP, deoxycytidine monophosphate.

In animal studies, Ara-CMP inhibits transfer of galactose, N-acetylglucosamine, and sialic acid to cell surface glycoproteins. Ara-CTP (0.1 to 1.0 mM) inhibits synthesis of CMP-acetylneuraminic acid, and Ara-CDP choline can be incorporated into membranes. These effects on phospholipid synthesis and incorporation into membranes may possibly affect membrane structure and function.

Catabolism of Ara-C involves two key enzymes, cytidine deaminase and deoxycytidylate deaminase. They convert Ara-C and Ara-CMP into their respective nontoxic two metabolites, Ara-U and Ara-UMP. Other catabolic enzymes that may affect Ara-C metabolism include dCTP pyrophosphatase, 5'-nucleotidase, and alkaline and acid phosphatases. The balance between intracellular activation and degradation is critical in determining the amount of drug that is ultimately converted to Ara-CTP and, thus, its subsequent cytotoxic and antitumor activity (see Fig. 19.5-6).

### Mechanisms of Resistance

Ara-C is most active during the S phase of the cell cycle.<sup>134</sup> The rate of DNA synthesis influences Ara-C cytotoxicity, with maximum effects observed when cells are exposed to Ara-C during periods of rapid DNA synthesis. Longer exposures allow a greater proportion of cells to enter S phase and are associated with enhanced incorporation of Ara-CTP into DNA.<sup>143</sup> Therefore, the duration of Ara-C exposure seems to be a critical determinant of its cytotoxicity.

Several mechanisms of resistance to Ara-C have been described. Impaired transmembrane transport, decreased rate of anabolism, increased rate of catabolism, or all three may result in the development of Ara-C resistance. *In vitro* studies have demonstrated that amplification of the cytidine deaminase gene with resultant overexpression of the corresponding protein product leads to Ara-C resistance.<sup>144</sup> The level of cytidine deaminase enzyme activity has been shown to correlate with

clinical response in patients with AML undergoing induction chemotherapy with Ara-C-containing regimens.<sup>145</sup> Blasts from patients who attained complete remission and from those with previously untreated leukemia had significantly higher levels of cytidine deaminase than blasts from patients with refractory disease.

Deletion of the gene encoding deoxycytidine kinase, expansion of CTP and dCTP pools, overexpression of bcl-2, and decreased intracellular half-life of Ara-CTP after drug removal are mechanisms that have been implicated in Ara-C resistance.<sup>143,146,147</sup> The cytotoxicity of Ara-C in leukemic cells isolated from patients correlates well with both the extent of DNA incorporation and the intracellular retention of Ara-CTP after drug exposure.<sup>148</sup>

Cellular sensitivity to Ara-C can also be influenced by the concomitant use of other drugs. For example, all- *trans*-retinoic acid was found to enhance Ara-C cytotoxicity, as well as Ara-C-induced apoptosis in HL-60 human leukemia cells.<sup>149</sup> However, the mechanism by which this sensitization is mediated remains unknown. The sensitivity of human leukemic cell lines to Ara-C has also been tested in the presence of stem cell factor. The addition of stem cell factor to a suspension culture system leads to a significant increase in the toxicity of Ara-C to self-renewing blast progenitors, especially when associated with high concentrations of Ara-C.<sup>150</sup> Although limited in its current clinical application, 6-mercaptopurine (6-MP) has shown a positive interaction with Ara-C. By inhibiting cytidine deaminase enzyme activity in L1210 murine leukemic cells, 6-MP is able to maintain high concentrations of Ara-C in the culture medium. This effect results in enhanced incorporation of Ara-C into cells and subsequent activation to Ara-CTP.<sup>141</sup>

### **Clinical Pharmacology and Pharmacokinetics**

Ara-C has poor oral bioavailability (approximately 20%) due to extensive deamination within the gastrointestinal tract. Consequently, Ara-C is administered via the intravenous route. The drug can also be given subcutaneously. After intravenous bolus administration, Ara-C is rapidly cleared with biphasic elimination: The initial half-life is approximately 12 minutes, whereas the terminal half-life is approximately 2 hours. Within 24 hours, 78% of a bolus dose is excreted in the urine (71% as Ara-U, 7% as Ara-C). During continuous intravenous infusion, steady-state plasma levels of Ara-C increase linearly to 5 to 10  $\mu\text{M}$ , and drug clearance is approximately 1000 mL/min/ $\text{m}^2$ . Thereafter, deamination is saturated, and plasma levels can increase unpredictably.<sup>151</sup> With continuous infusion of doses from 100 to 200 mg/ $\text{m}^2$ /d, steady-state plasma levels range from 0.2 to 1.0  $\mu\text{M}$ , and CSF levels are approximately 50% of the plasma levels.<sup>134,152</sup>

When administered as a high-dose (greater than 2 g/ $\text{m}^2$ ) intravenous infusion over 1 to 3 hours, the plasma elimination is triphasic: a, b, and g half-lives are 16 minutes, 1.8 hours, and 6 hours, respectively.<sup>152,153</sup> The mean plasma concentration at the end of infusion ranges from approximately 60 to 150  $\mu\text{M}$ , but 12 hours later falls to less than 0.5  $\mu\text{M}$ . Ara-C crosses the blood-brain barrier when used at high doses, with CSF levels between 7% to 14% of plasma levels, reaching peak levels of up to 10  $\mu\text{M}$ . Because cytidine deaminase enzyme activity is nearly completely absent in CSF, the drug displays a longer half-life in the CSF (approximately 2 to 4 hours).<sup>153</sup>

Ara-C can also be given intrathecally as prophylaxis against CNS tumor involvement and to treat leptomeningeal disease of both hematologic and solid malignancies. The usual dose is anywhere from 30 to 60 mg in 5 to 10 mL diluent twice weekly until documentation of three consecutively negative CSF cytology results. Intrathecal administration of 50 mg/ $\text{m}^2$  Ara-C yields peak concentrations of 1 mM, and cytotoxic concentrations (0.4  $\mu\text{M}$  or above) are maintained for 24 hours.<sup>134</sup> Of note, the diluent supplied with commercial formulations of Ara-C contains 0.945% benzyl alcohol. Given the potential toxicity of benzyl alcohol, diluents containing this preservative should not be used for intrathecal administration in neonates or with high-dose regimens. In these situations, preservative-free 0.9% sodium chloride injection or other isotonic buffered diluents should be used to reconstitute the drug. Finally, Ara-C can also be used intraperitoneally. This approach is commonly used as second-line treatment for ovarian cancer patients presenting primarily with intraperitoneal disease, and it is usually given in combination with cisplatin.

### **Toxicity**

The toxicity profile of Ara-C is highly dependent on the dose and schedule of administration. Myelosuppression is the dose-limiting toxicity with a standard regimen of 100 to 200 mg/ $\text{m}^2$ /d for 7 days. Leukopenia and thrombocytopenia are the most severe cytopenias, with the nadir occurring between days 7 and 14 after drug administration. However, the duration of the nadir can be significantly influenced by the concomitant use of other cytotoxic agents and also by previous treatment with chemotherapy.

Gastrointestinal toxicity commonly manifests as a mild to moderate degree of anorexia, nausea, and vomiting. Mucositis, diarrhea, ileus, and abdominal pain can also be observed. Less commonly, epithelial ulceration can occur, ranging from superficial ulceration to intramural hematoma formation and perforation. Transient hepatic dysfunction, manifested as elevation of liver enzymes, may also occur with Ara-C given at conventional doses. Acute pancreatitis has been associated with Ara-C, mostly when given as a continuous infusion. The Ara-C syndrome has been described in pediatric patients receiving Ara-C for hematologic malignancies and is characterized by fever, myalgia, bone pain, maculopapular rash, conjunctivitis, malaise, and occasional chest pain. These symptoms usually begin within 12 hours after Ara-C infusion. This syndrome most likely represents an allergic reaction to Ara-C, as patients usually develop symptoms months after the first dose, and corticosteroids can prevent its onset.<sup>154</sup>

Administration of Ara-C at high doses (2 to 3 g/ $\text{m}^2$  intravenously over 1 to 3 hours, every 12 hours; 100 mg/ $\text{m}^2$ /h for 24 hours) produces severe myelosuppression, sometimes with prolonged nadirs. Severe gastrointestinal toxicity in the form of mucositis, diarrhea, or both, is also frequently observed. Neurologic toxicity is significantly more common with high-dose Ara-C than with standard doses. The clinical manifestations of neurologic toxicity are diverse and include seizures, cerebral and cerebellar dysfunction, peripheral neuropathy, bilateral rectus muscle palsy, aphasia, and Parkinsonian symptoms.<sup>155</sup> Clinical signs of cerebellar dysfunction occur in up to 15% of patients within 8 days and include dysarthria, dysdiadochokinesia, dysmetria, and ataxia.<sup>156</sup> Change in alertness and cognitive ability, memory loss, and frontal lobe release signs reflect cerebral toxicity. Despite discontinuation of therapy, clinical recovery is incomplete in up to 30% of affected patients. The severity of peripheral neuropathy increases with higher cumulative Ara-C doses. Electromyography and nerve conduction test results suggest a demyelinating polyneuropathy with axonal degeneration. Significant neurotoxicity appears uncommon at cumulative doses of 36 g/ $\text{m}^2$  or less. Neurotoxicity may also be reduced by prolonged intravenous administration (over 3 hours or more). Patients older than 50 years and patients with elevated serum creatinine levels are particularly susceptible to neurologic toxicity.

Other side effects are less commonly seen. Pulmonary complications may include noncardiogenic pulmonary edema, acute respiratory distress, and pneumonia, resulting from *Streptococcus viridans* infection.<sup>157</sup> Other side effects associated with high-dose Ara-C include conjunctivitis (often responsive to topical corticosteroids), a painful hand-foot syndrome, and, rarely, anaphylactic reactions. A fatal case of toxic epidermal necrolysis has been described. Neutrophilic eccrine hidradenitis, an unusual cutaneous reaction manifested as plaques or nodules, can occur during the second week after high-dose Ara-C.

Intrathecal administration of Ara-C is usually uneventful. However, it may produce fever, seizures, and alterations in mental status within the first 24 hours of administration. Ara-C is teratogenic in animals. Although Ara-C produces chromosomal breaks in both cultured cells and bone marrow, it is not an established carcinogen in humans.

### **Drug Interactions**

*In vitro* studies and animal tumor model systems have provided evidence for synergistic activity between Ara-C and alkylating agents, platinum compounds, purine analogues, antifolates, and fluoropyrimidines. More recently, synergism has also been observed with Ara-C and other agents, such as bryostatin 1, fludarabine, and paclitaxel. The use of IFN- $\alpha$  combined with Ara-C in low doses is useful in the treatment of patients with early chronic phase chronic myelogenous leukemia, despite the existence of *in vitro* data suggesting a negative interaction for these two drugs.<sup>158</sup> Specific biochemical, cellular, or both, kinetic mechanisms have been described for each of these interactions, and the sequence of drug administration seems to be critical in some cases. Ara-C enhances the cytotoxicity of various DNA-damaging agents, including alkylating agents (cyclophosphamide, carmustine), topoisomerase II inhibitors (amsacrine, etoposide), cisplatin, and ionizing radiation. The mechanism underlying these positive interactions appears to be interference by Ara-C with the process of DNA repair, resulting in enhanced DNA damage.

The metabolism of Ara-U, the main catabolic by-product of Ara-C, is important for the metabolism and toxicity of Ara-C. Ara-U is mainly excreted in the urine. High concentrations of Ara-U can decrease deamination of Ara-C through feedback inhibition of cytidine deaminase, thus resulting in increased intracellular levels of Ara-CTP.<sup>146,178</sup> Ara-U also increases the fraction of murine leukemic cells entering S phase, thereby enhancing Ara-C cytotoxicity.<sup>159</sup> Accumulation of high levels of Ara-U may occur in both plasma and CSF in patients receiving high-dose Ara-C, with a possible increase in Ara-CTP formation in brain tissue.<sup>153,160</sup> These observations may explain the increased risk of neurotoxicity with high-dose Ara-C, especially in those with impaired renal function.

Interference with the DNA incorporation of Ara-C (e.g., by pretreatment with TS inhibitors) may antagonize its cytotoxicity. <sup>161</sup> MTX pretreatment, however, may increase Ara-CTP formation. Antimetabolites that decrease the competing pools of dCTP may enhance Ara-C anabolism, DNA incorporation, and its subsequent cytotoxicity. Such agents include inhibitors of RR (fludarabine, hydroxyurea, and high-dose thymidine), and inhibitors of CTP synthase (the investigational drugs acivicin, cyclopentenol cytosine, and 3-deazauridine).

Interactions between various cytokines and Ara-C may have potential clinical implications. A 24-hour exposure of human myeloid leukemic cells to p1XY 321, a fusion protein combining granulocyte-macrophage colony-stimulating factor and interleukin-3, enhances high-dose Ara-C-mediated induction of apoptosis. <sup>162</sup>

## GEMCITABINE

Gemcitabine (2',2'-difluorodeoxycytidine, dFdC, Gemzar) is a difluorinated analogue of deoxycytidine (see Fig. 19.5-5). This compound has shown significant preclinical and clinical activity against several human solid tumors, including cancer of the pancreas, small cell and non-small cell lung cancer, and bladder cancer. In contrast to Ara-C, the spectrum of antitumor activity of gemcitabine is much broader, despite the similarities in structure, metabolism, and mechanism of action. <sup>163</sup> The most commonly used schedule in clinical practice is 1000 mg/m<sup>2</sup> intravenously administered weekly for 3 weeks, followed by a 1-week rest. This schedule seems to provide the most acceptable toxicity profile with the greatest dose intensity. This compound has been moved rapidly from phase I/II studies into phase III studies, mostly in combination with other established anticancer agents.

### Intracellular Metabolism and Mechanism of Action

Transport of gemcitabine into cells requires the nucleoside transporter system. Nucleoside transport-deficient cells are highly resistant to the drug. Furthermore, the specific type of nucleoside transporter expressed on the cell surface may be an important determinant of drug sensitivity. <sup>164,165</sup> The intracellular concentration of adenosine triphosphate (ATP) may also be an additional sign of the sensitivity to gemcitabine. In head and neck cancer cell lines, ATP-replete cells accumulated significantly less gemcitabine, when compared with ATP-deplete cells. This finding suggests the existence of an active efflux mechanism for gemcitabine. <sup>166</sup> Gemcitabine is fivefold more lipophilic than Ara-C, a feature that is thought to contribute to the 65% greater rate of accumulation of gemcitabine in cells when compared with Ara-C.

Gemcitabine requires intracellular activation for its cytotoxic effects. The steps involved in its metabolic activation of gemcitabine are similar to those observed with Ara-C, with both drugs being activated by the same enzymatic machinery. Deoxycytidine kinase converts dFdC into dFdCMP. <sup>166,167</sup> The drug is subsequently phosphorylated by nucleoside monophosphate and diphosphate kinases to the respective 5'-diphosphate (dFdCDP) and 5'-triphosphate derivatives (dFdCTP). <sup>166,167</sup> dFdCTP is the major cellular metabolite of dFdC. The intracellular concentration of dFdCTP determines to a large extent its subsequent metabolism. In cells with lower concentrations of this metabolite (less than 100 μmol/L) the main route of elimination is by deamination, whereas in cells with higher concentrations (greater than 100 μmol/L) dephosphorylation and urinary excretion predominate. Furthermore, dFdCTP, by inhibiting dCMP deaminase, establishes a mechanism of self-potential, with a marked prolongation of its terminal half-life from 3.6 hours to 19.0 hours. This phenomenon may explain, at least in part, the differences observed between Ara-C and dFdC in their spectrum of clinical activity.

dFdCDP is an inhibitor of RR, and thus decreases the intracellular pools of deoxynucleotide triphosphates (dNTPs). Depletion of dCTP, as a consequence of RR inhibition, leads to decreased feedback inhibition of deoxycytidine kinase and increased phosphorylation of dFdC. dFdCTP directly inhibits deoxycytidylate deaminase; as dCTP is a required activator of this enzyme, dFdCDP-mediated depletion of dCTP also diminishes deoxycytidylate deaminase activity. dFdCTP competes with dCTP for incorporation into DNA by DNA polymerase, and depletion of dCTP favors incorporation of dFdCTP. Inhibition of DNA synthesis may result from both perturbations of deoxynucleotide pools and interference with DNA chain elongation. <sup>168,169</sup> The majority of incorporated residues are found in the internucleotide linkage (internal position). Incorporation of [<sup>3</sup>H]dFdC into purified RNA has also been reported. <sup>170</sup> At equimolar concentrations of Ara-C and dFdC, dFdCTP formation is greater than Ara-CTP, and dFdCTP is retained for a much longer period after drug removal. <sup>166</sup>

*In vitro* primer extension studies indicate that dFdCTP competes with dCTP for incorporation into growing DNA strands by purified DNA polymerases α and ε (involved in DNA replication and repair). <sup>168</sup> The exonuclease activity of DNA polymerase ε is unable to remove the incorporated dFdC residue, and a major pause in the polymerization process occurs once the primer is extended by one deoxynucleotide beyond the dFdC residue. Incorporation of dFdC into a synthetic DNA template strand interferes with base insertion by bacterial DNA polymerase (Klenow fragment). Thermal denaturation measurements show that dFdCMP•dGMP base pairs are less stable than dCMP•dGMP base pairs. In intact HL-60 cells, dFdC markedly slowed nascent DNA chain elongation as monitored by pH step alkaline elution. <sup>170</sup> Pulse-chase experiments with [<sup>3</sup>H]dFdC indicate that a nascent DNA fragment containing [<sup>3</sup>H]dFdC progressed over time into larger DNA intermediates and ultimately into genomic-length DNA. <sup>170</sup> Thus, dFdC does not function as an absolute chain terminator in intact cells. Cytidine deaminase converts dFdC to the inactive uridine metabolite, dFdU. The drug is cell-cycle specific, and blocks cells in the G<sub>1</sub>/S interface. Cytotoxicity is schedule dependent and increases with increasing duration of exposure. In a T-cell lymphoblastoid line, dFdC-DNA incorporation was necessary for induction of apoptosis.

### Mechanisms of Resistance

Several mechanisms of resistance to gemcitabine in cell lines have been described. Nucleoside transport-deficient cells are highly resistant to gemcitabine. <sup>164</sup> Furthermore, the efficiency of gemcitabine uptake can vary significantly according to the specific nucleoside transporter expressed on the cell surface. <sup>164</sup>

Several enzymes involved in the intracellular metabolism of gemcitabine have been implicated in the development of resistance to this drug. Initial *in vitro* studies suggested that dCK enzyme activity deficiency was the most important cause of resistance to gemcitabine. Gemcitabine-sensitive human ovarian carcinoma cell lines express tenfold higher dCK enzyme activity than gemcitabine-resistant cells. <sup>171</sup> However, experiments using human epidermoid carcinoma KB cells suggest that the enzyme RR may play an important role as well. RR is an S-phase-specific, rate-limiting enzyme of the DNA synthesis pathway. Cells exhibiting resistance to gemcitabine demonstrated a ninefold overexpression of RR mRNA, a twofold overexpression of RR protein, and a 2.3-fold higher RR enzyme activity when compared with gemcitabine-sensitive cells. <sup>172</sup> The potential role of RR as a determinant of drug resistance has been confirmed in the human erythroleukemia K562 cell line, where high RR enzyme activity was directly correlated with resistance. <sup>173</sup>

The pattern of cross-resistance between various nucleoside analogues may have potential clinical implications. For example, gemcitabine was found to have higher antitumor activity than Ara-C in both Ara-C-sensitive (L1210 and BCLO) and Ara-C-resistant (LA46 and Bara-C) cell lines. <sup>174</sup> In another *in vitro* experiment, human promyelocytic leukemia HL-60 cells were made cladribine resistant, resulting in two resistant sublines (R13 and R23). Neither subline was found to have cross-resistance to gemcitabine. <sup>175</sup> Enzymatic characterization of these sublines revealed that both dCK and 5'-nucleotidase enzymatic activities are likely to be involved. The ratio of dCK to 5'-nucleotidase activity was reduced by approximately 65% in both sublines.

### Clinical Pharmacology and Pharmacokinetics

dFdC can be measured in plasma samples by HPLC and an enzyme-linked immunosorbent assay. As dFdC is rapidly deaminated, blood collection tubes must contain tetrahydrouridine for accurate determination of plasma drug levels. After a 30-minute intravenous infusion of dFdC at doses ranging from 50 to 1000 mg/m<sup>2</sup>, the plasma concentration versus time curve (area under the concentration time curve) increases in a linear fashion. <sup>176</sup> The compound is rapidly eliminated from plasma, mainly by deamination. The median half-life and clearance of dFdC are 8 minutes and 119 L/h/m<sup>2</sup>, respectively. <sup>176</sup> Renal clearance of parent drug is less than 10% of the systemic clearance. dFdU, the main catabolic by-product, is eliminated by biphasic kinetics characterized by a long terminal phase (half-life of 14 hours). The pharmacokinetics and toxicity of dFdC in patients with impaired hepatic and renal function has not yet been determined. The accumulation of dFdCTP in circulating mononuclear cells appears to be saturated when plasma levels exceeded 15 to 20 μM; the median half-life for intracellular retention was 4.7 hours. <sup>176</sup>

A phase I trial of dFdC in cancer patients explored the maximally tolerated duration of dFdC infused at a dose rate of 10 mg/m<sup>2</sup>/min, calculated to produce steady-state levels of 20 μM. The maximally tolerated duration was 8 hours (total dose of 4800 mg/m<sup>2</sup>), with mean steady-state plasma levels of approximately 26 μM and median clearance of 149 L/h. Cellular pharmacokinetics of dFdCTP in circulating leukemic cells vary considerably among patients. In eight patients with linear dFdCTP elimination, the median half-life was 4.6 hours. In seven patients with biphasic dFdCTP elimination, the median initial and terminal phase half-life values were 2.5 hours and 6.8 hours.

## Toxicity

Although gemcitabine is a relatively well-tolerated drug when used as a single agent, its toxicity profile can vary significantly according to the schedule of administration. The most commonly used schedule is a weekly dose of 800 to 1250 mg/m<sup>2</sup>, administered intravenously over 30 minutes, for 3 weeks on an every 4-week cycle. With this schedule, myelosuppression is the dose-limiting toxicity, and all three lineages can be affected. A published series of more than 3000 patients treated with gemcitabine for pancreatic carcinoma revealed that nonhematologic side effects are relatively uncommon. They include fever (7.3%), pain (6.8%), asthenia (6.0%), abdominal pain (5.5%), dyspnea (5.0%), vomiting (3.9%), anorexia (3.6%), and deep venous thrombosis (3.2%).<sup>177</sup> A particularly unusual side effect of dFdC is anal pruritus, which may be prevented with the use of corticosteroids.

Although dyspnea is a relatively uncommon side effect of gemcitabine, its development during the treatment with the drug may require discontinuation of the treatment. Continuation of treatment once dyspnea develops may lead to a fatal outcome.<sup>178</sup> Patients usually present with a clinical picture consistent with acute respiratory distress syndrome, with hypoxemia, pulmonary infiltrates, and no evidence of left ventricular failure. The onset of acute respiratory distress syndrome in these patients can take place anywhere between 2 and 40 days after the first dose of the drug. Thus, close monitoring of patients for any change in baseline respiratory status is crucial.

A rare yet potentially fatal complication of dFdC is hemolytic-uremic syndrome (HUS).<sup>179</sup> The incidence of this complication has been estimated to be less than 1%. Early recognition of HUS is important and should prompt the immediate discontinuation of therapy to prevent death from HUS-related complications.

## Drug Interactions

Gemcitabine has been combined with various chemotherapeutic agents in the treatment of several solid tumors. Preclinical *in vitro* studies have provided evidence of synergism between gemcitabine and various anticancer agents to support these associations. Cisplatin is one of the agents most commonly used in combination with gemcitabine. *In vitro* studies with different human cancer cell lines have shown synergistic interaction between gemcitabine and cisplatin.<sup>179,180 and 181</sup> This synergism is thought to be mainly due to an increase in platinum-DNA adduct formation, which in turn results from dFdC incorporation into DNA.<sup>180</sup> Synergism has also been demonstrated between gemcitabine and etoposide in human ovarian and lung cancer cell lines.<sup>182</sup> Moreover, sequencing of agents in this combination is important as the synergism is maximum when cells are exposed first to etoposide and then to gemcitabine.<sup>182</sup> This may be due to the fact that cells exposed first to etoposide have low levels of dCTP in the cytoplasm, which then allow for enhanced phosphorylation of dFdC and subsequent incorporation of dFdCTP into DNA.<sup>182</sup>

## 6-THIOPURINES

The development of the purine analogues in cancer chemotherapy began in the early 1950s with the synthesis of the thiopurines. For this seminal work, Hitchings and Elion received the Nobel Prize in Medicine in 1988. The purine analogues, 6-MP and 6-thioguanine (6-TG) continue to be used principally in the management of acute leukemia.<sup>183</sup> 6-MP has an important role in the maintenance therapy of acute lymphoblastic leukemia (ALL), whereas 6-TG is active in remission induction and in the maintenance therapy of AML. These analogues have a single substitution of a thiol group in place of the 6-hydroxyl group of the purine base ( Fig. 19.5-7). 6-MP is a structural analogue of hypoxanthine, whereas 6-TG is an analogue of guanine. Azathioprine is a derivative of 6-MP and acts as a prodrug to provide sustained release of 6-MP.

FIGURE 19.5-7. Purine analogues and their physiologic counterparts, hypoxanthine and guanine.

## Intracellular Metabolism and Mechanism of Action

6-MP and 6-TG act similarly with regard to their cellular biochemistry. In their respective monophosphate nucleotide form, they inhibit *de novo* purine synthesis and purine interconversion reactions, whereas the nucleotide triphosphate metabolites are incorporated directly into nucleic acids. The relative contribution of each of these actions to the mechanism of cytotoxicity of these agents is unclear.<sup>183</sup> Both 6-MP and 6-TG are converted to their respective monophosphate forms by hypoxanthine-guanine phosphoribosyl transferase (HGPRT) ( Fig. 19.5-8). These ribonucleotide monophosphates inhibit the first step of *de novo* purine synthesis catalyzed by glutamine phosphoribosylpyrophosphate aminotransferase and block the conversion of inosinic acid to adenylic acid or to guanylic acid. Inhibition of purine nucleotide synthesis leads to the build-up of PRPP, which facilitates the activation of 6-MP and 6-TG to their active nucleotide forms by HGPRT.

FIGURE 19.5-8. Metabolic pathways for activation and degradation of 6-mercaptopurine (6-MP). HGPRT, hypoxanthine-guanine phosphoribosyl transferase; TPMT, 6-thiopurine methyltransferase.

Inhibitors of *de novo* purine biosynthesis, such as MTX, interact in a synergistic manner with 6-thiopurines because the MTX-induced block in purine synthesis expands the PRPP pool required for thiopurine activation. Both ribonucleotide and deoxyribonucleotide metabolites of the thiopurines are formed, which can then be incorporated into cellular RNA and DNA. Incorporation of fraudulent nucleotides into DNA interferes with DNA replication and results in the formation of DNA strand breaks.<sup>184</sup> In some model systems, incorporation of thiopurine nucleotides into DNA correlates with cytotoxicity.

In addition to 6-MP effects on DNA biosynthesis, there is now evidence that the glycolytic pathway may also be affected. 6-Phosphofructo-2-kinase, an essential enzyme for carbohydrate metabolism, is inhibited by 6-MP.<sup>185</sup> Finally, this class of compounds may inhibit the process of angiogenesis, as studies have shown *in vivo*

antiangiogenic activity of a thiopurine metabolite, methylmercaptapurine riboside, in a human endometrial adenocarcinoma xenograft model. <sup>186</sup>

### **Mechanisms of Resistance**

Biochemical resistance to 6-thiopurines results from a decreased ability to form cytotoxic nucleotide metabolites. In experimental systems, resistant cells express either a complete or partial deficiency of HGPRT. <sup>187</sup> An alteration in the affinity of HGPRT for 6-thiopurines has also been described. <sup>188</sup> Studies have shown that decreased transmembrane transport of 6-TG can also result in drug resistance. <sup>189</sup> In the HHUA, DLD-1, and HCT 166 human cancer cell lines, MMR-defective cells exhibited higher levels of drug resistance and increased mutagenic response at the HGPRT locus to 6-TG when compared with their MMR-proficient counterparts. Thus, the inability to properly repair damaged or mutant DNA may provide a selective growth advantage for MMR-defective cells. Moreover, this finding may provide a mechanism by which 6-TG treatment results in the development of secondary malignancies. <sup>190</sup>

In clinical samples derived from patients with AML, drug resistance has also been associated with either increased concentrations of a membrane-bound alkaline phosphatase or a conjugating enzyme, 6-thiopurine methyltransferase (TPMT). <sup>191</sup> Patients who express high levels of TPMT activity are unable to form sufficiently high levels of active nucleotide metabolites after treatment with 6-MP. As such, they may be more likely to benefit from treatment with 6-TG. <sup>192</sup>

### **Clinical Pharmacology and Pharmacokinetics**

HPLC analysis using the phenylmercury or sulfonated derivatives of the thiopurines is able to detect plasma drug levels as low as 0.1 mM. An HPLC method was developed to measure thiopurine levels in erythrocytes in the 18 to 20 pmol range. <sup>193</sup> Oral doses of 6-MP of 70 to 100 mg/m<sup>2</sup>/d are commonly used in the maintenance therapy of ALL. Oral absorption of 6-MP is highly erratic, with only 16% to 50% of the administered dose reaching the systemic circulation. This effect is mainly due to rapid first-pass metabolism in the liver. <sup>194</sup> Food intake and coadministration with the antibiotic cotrimoxazole significantly reduce drug absorption. The variable bioavailability of oral 6-MP may be an important determinant of therapeutic outcome, because low plasma drug concentration over time measurements correlate with an increased risk of relapse in children with ALL. <sup>195</sup> 6-MP bioavailability is increased when combined with high-dose (2 to 5 g/m<sup>2</sup> intravenous) MTX. <sup>196</sup> Studies have shown that MTX inhibits xanthine oxidase, an enzyme important in the catabolism of thiopurines. <sup>197</sup>

Oral 6-MP is well distributed into most body compartments, with the exception of the CSF. With high-dose intravenous 6-MP (200 mg/m<sup>2</sup> bolus followed by 800 mg/m<sup>2</sup> over 8 hours), a CSF to plasma ratio of 0.15 is achieved. This schedule is currently being used to prevent CNS relapse in ALL. <sup>198</sup> Approximately 30% of the drug binds weakly to plasma proteins. The plasma half-life is approximately 50 minutes after intravenous injection and 90 minutes after oral administration. When studied in children with ALL, plasma concentrations and erythrocyte thioguanine nucleotide levels are highly variable and independent from dose. <sup>199</sup>

The major route of drug elimination is via metabolism by several enzymatic pathways. 6-MP is oxidized to the inactive metabolite 6-thiouric acid by xanthine oxidase. Enhanced 6-MP toxicity may result from the concomitant administration of both oral and intravenous 6-MP and the xanthine oxidase inhibitor allopurinol. <sup>200</sup> In patients receiving both 6-MP and allopurinol, the 6-MP dose should be reduced by at least 50–75%.

6-MP also undergoes S-methylation by the enzyme TPMT to yield 6-methylmercaptapurine. After further phosphorylation, 6-methylmercaptapurine nucleotides are, themselves, capable of inhibiting *de novo* purine biosynthesis, but to a lesser extent than thioguanine nucleotides (TGNs). TPMT plays a similar role in 6-TG and azathioprine metabolism. <sup>201</sup> It has been shown that TPMT enzyme activity may vary considerably between patients. Moreover, the levels of TPMT enzyme activity correlate inversely with intracellular levels of TGNs and with the duration of 6-MP-induced cytopenia, suggesting that the level of inherited TPMT activity may affect directly 6-MP cytotoxicity and host toxicity. <sup>191</sup> Due to an autosomal codominant genetic polymorphism, a series of TPMT phenotypes, with alleles of differing enzymatic activity, are present in the general population. Point mutations or loss of alleles of TPMT resulting in altered enzyme activity correlate with a defect in thiopurine metabolism, thus defining a true pharmacogenetic syndrome. <sup>202</sup> A polymerase chain reaction–based method is widely used for the genetic detection of these TPMT mutations. <sup>203</sup> Approximately 0.3% of the white population expresses either a homozygous deletion or mutation of both alleles of the TPMT gene. In these patients, grossly elevated TGN concentrations, profound myelotoxicity with pancytopenia, and extensive gastrointestinal symptoms are seen after only a brief course of thiopurine treatment. <sup>201</sup> An estimated 10% of patients may be at increased risk for toxicity due to heterozygous loss of the gene or a mutant allele coding for a less enzymatically active TPMT. <sup>202,203</sup> Drug interactions affecting TPMT activity have also been reported with aspirin, sulfasalazine, 5-aminosalicylic acid, furosemide, and disulfiram. <sup>201</sup>

Renal excretion of 6-MP is minimal, but at high doses, as much as 20% to 40% of the drug is removed by the kidneys. <sup>204</sup> Exceedingly high doses of 6-MP (more than 1 g/m<sup>2</sup>) in children may cause renal precipitation of drug with hematuria and crystalluria. In patients with renal dysfunction, dose reductions of 6-MP should be considered.

### **6-THIOGUANINE**

The main intracellular pathway for 6-TG activation is catalyzed by HGPRT, with resultant formation of ribonucleotide monophosphates. Although the main metabolites of 6-TG are TGNs, thioinosine nucleotides are formed as well. However, the clinical significance of these respective metabolites as determinants of 6-TG cytotoxicity remains unclear. <sup>205</sup> Although higher erythrocyte levels of TGNs are detected after treatment with maximum tolerated dose levels of 6-TG than 6-MP, this pharmacodynamic parameter does not clearly correlate with the myelosuppression associated with 6-TG. <sup>206</sup>

6-TG is administered orally in doses of 75 to 200 mg/m<sup>2</sup>/d for 5 to 7 days in the treatment of AML. Its oral bioavailability is erratic, with peak plasma levels occurring 2 to 4 hours after ingestion. The median plasma half-life of 6-TG is approximately 90 minutes. The catabolism of 6-TG differs from 6-MP in that S-methylation with subsequent removal of the sulfur atom is an important pathway of drug elimination. <sup>183</sup> In a second catabolic pathway, 6-TG undergoes deamination by the enzyme guanine deaminase (guanase), resulting in 6-thioxanthene, which is then oxidized by xanthine oxidase to 6-thiouric acid. In contrast to 6-MP, 6-TG is not a direct substrate for xanthine oxidase. Because the inhibition of xanthine oxidase results in the accumulation of 6-thioxanthene, an inactive metabolite, adjustments in 6-TG dosage are not required for patients receiving allopurinol.

### **Toxicity**

The major dose-related toxicities of 6-MP are myelosuppression and gastrointestinal toxicity. Leukopenia and thrombocytopenia are maximal 7 days after treatment. Full hematologic recovery usually occurs after 14 days. In TPMT-deficient patients, dose reduction to 5% to 25% of the standard dose (75 mg/m<sup>2</sup>/d) is necessary to prevent excessive toxicity. <sup>207</sup> Gastrointestinal toxicities include nausea and vomiting, anorexia, diarrhea, and stomatitis. 6-MP hepatotoxicity occurs in up to 30% of adult patients and is manifested as mainly cholestatic jaundice, although elevations of hepatic transaminases may also be seen. Hepatotoxicity is usually mild and reversible after discontinuation of 6-MP, but frank hepatic necrosis can occur after high doses of the drug. Combinations of 6-MP with other known hepatotoxic agents should be avoided, and liver function test results should be closely monitored. The mechanism of liver toxicity is not known, but may relate to the P-450–dependent metabolism of 6-MP to a hepatotoxic metabolite or accumulation of 6-MP metabolites in the liver. <sup>183</sup> 6-TG also causes dose-limiting bone marrow suppression but is associated with fewer gastrointestinal side effects and less hepatotoxicity than 6-MP.

As a class of drugs, the 6-thiopurine analogues are potent suppressors of cell-mediated immunity. As such, prolonged therapy results in an increased predisposition to bacterial and parasitic infections. Given their immunosuppressive effects, these agents have been used to prevent rejection of transplanted organs and to treat autoimmune diseases, such as Crohn's disease, ulcerative colitis, and rheumatoid arthritis. Therapeutic immunosuppression occurs at 100 mg/d, a dose associated with only mild leukopenia. Long-term immunosuppressive therapy with azathioprine increases the risk of squamous carcinoma of the skin, non-Hodgkin's lymphoma, and Kaposi's sarcoma. Chronic 6-MP treatment is associated with teratogenic effects during the first trimester of pregnancy, and AML has been reported as a secondary malignancy after 6-MP treatment for Crohn's disease. <sup>208</sup>

### **FLUDARABINE**

Fludarabine (9-b-D-arabinosyl-2-fluoroadenine, Fludara) was synthesized as part of a rational process to develop more active analogues of cytarabine ( [Fig. 19.5-9](#)). <sup>209</sup> The first compound in this series was adenine arabinoside (vidarabine; Ara-A). However, this compound was deaminated to its inactive form to a significant extent, thereby negating its clinical application. The 2'-fluoro derivative of Ara-A was subsequently found to be relatively resistant to deamination, but was difficult to formulate and poorly soluble. Addition of a 5'-monophosphate moiety to the sugar group yielded fludarabine, which is relatively resistant to deamination and displays

enhanced solubility.

**FIGURE 19.5-9.** Structures of adenosine analogues.

### **Mechanism of Action**

After intravenous administration, F-Ara-adenosine monophosphate (F-Ara-AMP) is rapidly dephosphorylated to F-Ara-A, which enters cells by nucleoside-specific membrane transport mechanisms. The  $es$  and  $e_1$  nucleoside transporter systems facilitate the cellular uptake of the hydrophilic nucleoside analogues.<sup>210</sup> F-Ara-A is then rephosphorylated by dCK to F-Ara-AMP, which is subsequently metabolized to the triphosphate form. This nucleotide is the active metabolite of the drug. It competes with deoxyadenosine triphosphate (dATP) for incorporation into DNA, and serves as a highly effective chain terminator. In addition, F-Ara-ATP directly inhibits DNA polymerases involved in DNA synthesis and repair, such as DNA polymerase  $\alpha$  and  $\beta$ , and inhibits other enzymes involved in DNA synthesis, such as DNA primase, DNA ligase I and RR. DNA polymerase  $\epsilon$  is unable to remove F-Ara-AMP from the 3'-end of DNA even in the presence of excess enzyme and substrate nucleotides, resulting in the formation of dead-end complexes.<sup>211</sup>

Fludarabine is also incorporated into RNA, causing inhibition of RNA function, processing, and mRNA translation.<sup>212</sup> In contrast to other antimetabolites, fludarabine is also active against nondividing lymphocytes. In fact, the primary effect of fludarabine may result from activation of apoptosis, as evidenced by the presence of typical apoptotic fragmentation of DNA into high-molecular-weight fragments, after drug treatment.<sup>213</sup> The induction of apoptosis may explain the activity of this drug in indolent lymphoproliferative diseases with relatively low S-phase fractions.<sup>214</sup>

### **Mechanisms of Resistance**

Fludarabine-resistant cell lines, such as JOK-1 [human hairy cell leukemia (HCL)], K562 (human erythroleukemia), and L1210 (murine leukemia) have been established. In these resistant lines, nucleoside transport of F-Ara-A is intact, and no alterations in intracellular drug accumulation or multidrug-resistant (mdr 1) expression are observed. However, decreased dCK activity with diminished intracellular formation of F-Ara-ATP is the principal mechanism of resistance in each of these cell lines.<sup>215</sup> Subsequent work has shown that deletion of one allele of deoxycytidine kinase is sufficient to result in decreased expression of dCK. Of note, a high degree of cross-resistance develops to multiple nucleoside analogues requiring activation by dCK, including Ara-C, 2-CdA, and gemcitabine.<sup>216</sup> Fludarabine resistance in WSU-CLL xenografts in SCID mice can be decreased by pretreatment with bryostatin, a macrocyclic lactone.<sup>217</sup> Although the underlying mechanisms for this interaction remain to be defined, preliminary studies suggest that bryostatin may induce differentiation of B-CLL cells into HCL-like cells, with expression of CD11c, CD25, and tartrate-resistant acid phosphatase (TRAP), markers typically seen in HCL.

### **Clinical Pharmacology and Pharmacokinetics**

Peak concentrations of F-Ara-A are reached 3 to 4 hours after intravenous or oral administration. Mean plasma levels are proportional to dose. After intravenous administration, the decline in plasma levels has been reported to be bi-exponential, with a distribution half-life of 0.6 to 2.0 hours and a terminal half-life of 6.9 to 19.7 hours. However, other reports describe a three-compartment model with a terminal half-life between 10 and 30 hours.<sup>212,218</sup> The rate-limiting step in elimination is release from tissues and renal function affecting clearance. Dose adjustment in the setting of renal impairment is recommended, and a 30% dose reduction in patients with a serum creatinine above 1.5 mg/dL or creatinine clearance below 70 mL/min should be considered.

The median peak concentration of F-Ara-ATP in lymphocytes of leukemic patients occurs approximately 4 hours after the start of a 30-minute intravenous infusion of 25 mg/m<sup>2</sup>. Intracellular F-Ara-ATP elimination exhibits a single phase with a dose-dependent terminal phase. The oral bioavailability of liquid fludarabine is 60% to 80%, leading to approximately two-thirds of the intracellular F-Ara-ATP levels in chronic lymphocytic leukemia (CLL) cells achieved with intravenous administration.<sup>219</sup>

### **Treatment**

Fludarabine is the most active single agent in the treatment of CLL.<sup>220,221 and 222</sup> It is also active against indolent non-Hodgkin's lymphoma,<sup>223,224</sup> prolymphocytic leukemia, cutaneous T-cell lymphoma, and Waldenström's macroglobulinemia.<sup>225</sup> This agent has shown promising activity in approximately one-third of patients with mantle cell lymphoma, albeit with relatively brief response.<sup>226</sup> In contrast to its activity in hematologic malignancies, this compound displays minimal activity against common solid tumors.

### **Toxicity**

In initial trials, fludarabine, when administered as a single 260 mg/m<sup>2</sup> dose or 112 mg/m<sup>2</sup> given daily for 5 days, resulted in profound myelosuppression. This effect was not initially predicted from preclinical *in vivo* studies in mice and beagle dogs, given the extensive tissue binding and relatively low renal excretion in humans. In addition, a dose range of 75 to 150 mg/m<sup>2</sup> four times a day for 5 to 7 days resulted in severe prohibitive neurotoxicity characterized by delayed onset cortical blindness, seizures, coma, and death.<sup>227</sup> Subsequent trials demonstrated that fludarabine could be safely administered at much lower doses of 25 to 30 mg/m<sup>2</sup> daily for 5 days every 28 days. At standard doses, neurotoxicity occurs in approximately 15% of patients. This toxicity is rarely severe, generally reversible, and usually presents as headache, somnolence, or peripheral neuropathy.<sup>228</sup>

At currently used doses, myelosuppression and immunosuppression are the major side effects of fludarabine.<sup>229</sup> Dose-limiting and possibly cumulative lymphopenia and thrombocytopenia are well established.<sup>218</sup> Suppression of the immune system affects T-cell more than B-cell function. Fevers, often in the setting of neutropenia, occur in 20% to 30% of patients. Lymphocyte counts, particularly CD4+ cells, decrease rapidly after initiation of therapy, and levels can drop to as low as 150/ $\mu$ L by approximately 6 months.<sup>230</sup> CD4+ cell recovery is slow and may take longer than 1 year to recover to normal levels. Common opportunistic pathogens include herpes zoster, *Candida*, and *Pneumocystis carini*.<sup>229</sup> The addition of prednisone to fludarabine does not improve the response rate or survival, but significantly increases the risk of opportunistic infections, notably listeriosis and *Pneumocystis carini*.<sup>230</sup> If concurrent corticosteroids are necessary, such as in patients with autoimmune anemia or thrombocytopenia, long-term prophylaxis against *Pneumocystis carini* is mandatory. Hemolytic anemia has been observed, and in some instances, has resulted in death on rechallenge with fludarabine.<sup>231</sup> Thrombocytopenia, precipitation of Evan's syndrome, and fulminant fatal myelofibrosis have also been reported. The prolonged immunosuppression experienced with fludarabine has raised the possibility of an increased incidence of secondary malignancies. However, this increased risk is now thought to be due to the underlying immune defects of the malignancy and not to the carcinogenic effects of the nucleoside analogue.<sup>232</sup>

Tumor lysis syndrome occurs in less than 1% of patients, and in some cases, it can be fatal. However, this event does not usually recur on retreatment with fludarabine. Prophylaxis is not uniformly effective. Other uncommon toxicities include rash, nausea, vomiting, diarrhea, stomatitis, anorexia, increased salivation, abdominal cramps, a metallic taste, transient elevations in hepatic enzymes, and renal dysfunction. Treatment-associated disseminated skin rash, progressing to pemphigus-like epidermal necrolysis, has been described. Pulmonary toxicity, in the form of interstitial pneumonitis, can develop after multiple courses of treatment. At times, the pulmonary sequelae may be difficult to distinguish from those associated with opportunistic infections. This toxicity usually responds to corticosteroids and

does not tend to recur on retreatment.

### Drug Interactions

Purine analogues achieve significant response rates in low-grade lymphomas, presumably due to their ability to induce apoptosis in these otherwise drug-resistant malignancies. The responses seen, however, are mostly partial and of short duration. This fact has fostered interest in identifying drug regimens incorporating fludarabine with enhanced activity. Fludarabine inhibits the nucleotide excision repair used by cells to remove the DNA cross-links induced by alkylating agents (cyclophosphamide, cisplatin).<sup>233</sup> Complete response rates of nearly 90% have been observed when fludarabine and cyclophosphamide are used in combination for patients with previously untreated low-grade lymphomas.<sup>234</sup> The combination of fludarabine with the anthracycline analogue mitoxantrone in the presence or absence of dexamethasone (FN and FND regimens) has been successfully used to treat indolent non-Hodgkin's lymphomas.<sup>235,236</sup> In fact, response rates in excess of 90%, with half of these being complete responses, are seen with the triple combination, FND. This compares favorably with the 60% to 70% response rate observed with single-agent fludarabine.<sup>224</sup>

Fludarabine-induced dCTP depletion increases deoxycytidine kinase activity in K562 human leukemic cells. This enzyme, in addition to playing a key role in generating active fludarabine metabolites, is also capable of phosphorylating Ara-C into its active metabolite, Ara-CTP. The resulting synergistic effect of fludarabine on Ara-C is now established both *in vitro*<sup>237</sup> and *in vivo* in leukemic blast cells derived from patients with AML.<sup>238</sup> This combination has clinical efficacy in childhood AML in combination with idarubicin,<sup>239</sup> in adult CLL,<sup>240</sup> in refractory or relapsed AML,<sup>241,242</sup> and perhaps in patients with myelodysplastic syndromes.

The immunosuppressive effect of fludarabine is being used in a novel, nonmyeloablative bone marrow transplant preparative regimen called *transplant lite*. The goal of this approach is to achieve allogeneic stem cell engraftment and graft-versus-leukemia/lymphoma effect in patients with CLL and low-grade lymphomas. In a pilot study, engraftment was achieved in 11 of 15 patients, with eight showing complete response.<sup>243</sup>

### CLADRIBINE

2-Chlorodeoxyadenosine (Cladribine, 2-CdA) is a deoxyadenosine purine nucleoside analogue. A single substitution of a chlorine atom for a hydrogen atom at the 2 position of the purine ring of deoxyadenosine renders this compound resistant to adenosine deaminase (ADA) (see Fig. 19.5-9). It was developed initially as an immunosuppressive agent. 2-CdA exhibits a dose-dependent *in vitro* inhibition of lymphoid neoplasms and human leukemic cell lines,<sup>244</sup> but has no activity against solid tumors. Currently, it is the drug of choice in HCL with activity in low-grade lymphoproliferative disorders as well.

### Mechanism of Action

Deoxyadenosine is cleaved within cells by the enzyme ADA, to the deoxyinosine form. A deficiency of this enzyme leads to toxic accumulation of deoxyadenosine in lymphocytes, manifesting as the severe combined immunodeficiency clinical syndrome. 2-CdA enters cells via the nucleoside transporter system.<sup>245</sup> Given its resistance to deamination by ADA, an ADA-deficiency-like state develops, in which 2-CdA accumulates within cells, eventually reaching lymphotoxic levels. On entry into the cell, it first undergoes conversion to cladribine-monophosphate (Cld-AMP), which is then eventually metabolized to the active metabolite, cladribine-triphosphate (Cld-ATP).<sup>246</sup> The rate-limiting step is catalyzed by dCK. In contrast, catabolism of 2-CdA is mediated by a 5'-nucleotidase. The greatest accumulation of Cld-ATP is observed in cells with high levels of dCK and low 5'-nucleotidase activity. Cld-ATP competitively inhibits incorporation of the normal nucleotide dATP into DNA, a process that results in termination of chain elongation.<sup>213</sup> Progressive accumulation of Cld-ATP leads to an imbalance in deoxyribonucleotide pools, thereby inhibiting further DNA synthesis and repair.<sup>247</sup> At concentrations of 0.3  $\mu\text{M}$ , 2-CdA inhibits DNA synthesis by 90% within 30 minutes.<sup>248</sup> The accumulation of unrepaired DNA breaks over time may initiate the apoptosis of quiescent, nondividing lymphocytes. Activation of the caspase-3 proteolytic cascade has been implicated as a potential mechanism for the onset of apoptosis.<sup>249</sup> Finally, 2-CdA is a potent inhibitor of RR, and in so doing, it may further inhibit the synthesis of key nucleotide substrates required for DNA biosynthesis.

### Mechanisms of Resistance

Resistance to 2-CdA has been attributed to altered intracellular metabolism of the drug. A reduction in dCK activity, the enzyme responsible for generating cytotoxic nucleotide metabolites, is a major determinant of acquired resistance.<sup>250</sup> Cld-AMP and Cld-ATP are dephosphorylated by the cytoplasmic enzyme, 5'-nucleotidase. WSU-CLL cells, derived from a patient with CLL, exhibit both low levels of dCK expression, and high-levels of 5'-nucleotidase, and accordingly, they are resistant to 2-CdA. Interestingly, restoration of 2-CdA chemosensitivity by pretreatment of WSU-CLL cells *in vitro* with bryostatin has been reported. Bryostatin may induce differentiation of CLL cells into a hairy cell-like phenotype, evidenced by the induced expression of TRAP, CD11c, and CD25 in WSU-CLL cells.<sup>251</sup>

### Clinical Pharmacology and Pharmacokinetics

Pharmacokinetic analysis suggests a two-compartment model, with mean a and b half-lives of  $35 \pm 12$  minutes and  $6.5 \pm 2.5$  hours, respectively. The steady-state concentration after a 2- or 24-hour infusion of 0.14 mg/kg was  $22.5 \pm 11.1$  nM. After a 2-hour infusion of 0.14 mg/kg, the mean maximum plasma concentrations were in the range of 100 to 400 nmol/L. The disposition of 2-CdA in plasma remains linear over a dose range of 0.2 to 2.5 mg/m<sup>2</sup>, with limited interindividual variability.<sup>252</sup> Although there seems to be a close relationship between dose and plasma steady-state concentrations, the relationship between dose and clinical activity remains to be defined.<sup>253</sup> When mean plasma concentrations were fitted to a three-compartment model, the half-lives of the a, b, and g phases ranged between 3 and 12 minutes, 0.7 to 1.5 hours, and 5.7 to 19.0 hours, respectively.

The dose of 2-CdA used in early clinical trials was 0.09 to 0.10 mg/kg/d administered as a 7-day continuous infusion. As the long terminal half-life suggested the feasibility of intermittent infusions, 2-CdA has also been tested as a 2-hour infusion of 0.09 to 0.10 mg/kg/d for 5 to 7 days or a 1-hour infusion at 6 mg/m<sup>2</sup> for 5 days with a 28-day cycle. A dose-escalation study of bolus daily cladribine established no dose-limiting nonhematologic toxicity up to 21.5 mg/m<sup>2</sup>/d, given on a daily 1-hour intravenous bolus infusion for 5 days to patients with advanced hematologic malignancies. At higher dose levels, prolonged cytopenias and severe infections define the upper dose limit of the drug.<sup>254</sup> In a small series of patients with HCL, no significant difference in response rate or toxicity was observed between a 7-day continuous infusion and a daily 2-hour bolus for 5 days. The daily dose for 5 days appears to be better suited as an outpatient regimen. After a 2-hour or a continuous infusion of 0.12 mg/kg in patients with CLL, mean intracellular concentrations of 2-CdA nucleotides are 12.2 and 10.8  $\mu\text{mol/L}$ , respectively. Intracellular concentrations of phosphorylated CdA derivatives thus exceed plasma concentrations of the metabolites by several hundredfold.<sup>255</sup>

In circulating leukemic cells of CLL patients treated with 2-CdA for 10 mg/m<sup>2</sup>/d for 3 days, Cld-AMP and Cld-ATP median half-lives of 15 and 10 hours were observed, respectively. While maximum plasma 2-CdA and intracellular Cld-AMP concentrations correlate well, no clear relationship exists between the level of deoxycytidine kinase activity, the levels of the intracellular metabolites (Cld-AMP, Cld-ATP), and response to treatment.<sup>253</sup> These findings indicate that other, as yet, unknown determinants of clinical efficacy may be present.

2-CdA is effectively cleared by the kidneys. Renal clearance is approximately 50%, while 20% to 35% of the drug is excreted unchanged in the urine.<sup>252</sup> 2-CdA is able to cross the blood-brain barrier and penetrates into the CSF. While CSF concentrations in patients, in the absence of meningeal disease, reach only 25% of detected plasma levels, CSF levels exceed plasma levels in patients with meningeal involvement.<sup>252</sup>

The bioavailability of the drug is almost 100% when given at a dose of 0.14 mg/kg via the subcutaneous route. The area under the curve achievable with subcutaneous administration is almost identical to that of the intravenous route.<sup>256</sup> Oral 2-CdA reaches lower, but clinically relevant levels of bioavailability at 37% to 51%. Absorption of the oral form is decreased by gastric pH values below 2, an effect that cannot be prevented or reversed with concomitant proton pump inhibitor use. The bioavailability of oral 2-CdA correlated linearly with dosing in a small study with oral and intravenous cross-over design.<sup>257</sup> Oral dosing showed no cumulative peak concentration or toxicity, and its pharmacokinetics are well-described by a three-compartment model. An oral dose of 0.28 mg/kg achieved similar peak concentrations and area under the concentration time curve as 0.14 mg/kg given either intravenously or subcutaneously.<sup>256</sup> The overall feasibility of intermittent intravenous, subcutaneous, or oral dosing suggests that these different routes of administration may compete with and possibly replace continuous infusional schedules.

### Treatment

A single course of CdA achieves durable complete remissions in 65% to 91% of patients with HCL. <sup>258,259</sup> and <sup>260</sup> Salvage treatment of patients previously treated with IFN- $\alpha$  or splenectomy is as effective as first-line treatment. Maintenance therapy is not required. Although minimal residual disease is often found on reexamination of bone marrow specimens of HCL patients in clinical complete response, relapse rates are low. Retreatment with cladribine results in complete response in up to 60% of relapsing patients. <sup>261</sup> However, it remains unclear whether cladribine offers any significant long-term survival benefit over another nucleoside analogue, pentostatin. Responses in patients with CLL and non-Hodgkin's lymphoma tend to be brief, and salvage of relapsed or refractory disease is less efficacious than in HCL. <sup>262,263</sup> 2-CdA achieves high response rates in pediatric patients with AML, but not in adult patients. 2-CdA has minimal activity against solid tumors.

### **Toxicity**

At conventional doses, myelotoxicity is dose limiting. Decreased counts in all three cell lines are typically observed. Thrombocytopenia usually recovers within 2 to 4 weeks, and neutropenia in 3 to 5 weeks, after a single course of the drug. Severe, prolonged myelotoxicity is reported, however, after repeated cycles of cladribine used in the treatment of CLL or low-grade lymphomas. <sup>229</sup> Severe autoimmune hemolytic anemia with fatal bone marrow aplasia has been described in CLL patients receiving repeated cycles of the drug, as CdA-induced lymphopenia may exacerbate autoimmune hemolysis. Of note, foci of bone marrow hypoplasia are seen in cladribine-treated patients, although the long-term clinical significance of this effect remains unclear.

Immunosuppression accounts for the late morbidity observed in CdA-treated patients. Lymphocyte counts, particularly CD4+ cells, decrease within 1 to 4 weeks of drug administration and may remain depressed for several years. <sup>264</sup> After discontinuation of cladribine, a median time of up to 40 months may be required for complete recovery of normal CD4+ counts. <sup>229</sup> Fevers occur in 40% to 50% of patients, typically correlating with the duration of granulocytopenia. These episodes may be profound, prolonged, and cumulative. <sup>259</sup> Opportunistic infections are common, although usually seen less frequently than with fludarabine. Herpes zoster is most typical, and a variety of other pathogens are also seen, including *Candida*, *Pneumocystis*, *Pseudomonas aeruginosa*, *Listeria monocytogenes*, *Cryptococcus neoformans*, *Aspergillus*, cytomegalovirus, and common bacterial infections. Infectious complications correlate with decreases in CD4+ count, and they are more frequent with repeated courses of therapy. <sup>229</sup> Treatment-related deaths have been reported in more than 30% of patients. <sup>265</sup>

In patients with HCL and CLL, long-term studies have failed to identify an increase in drug-related mortality. Specifically, initial concerns about an increased risk for secondary malignancies have not been confirmed, as the incidence of second cancers is not higher than what would be expected from the underlying hematologic disorder. <sup>232,266</sup>

Severe neurotoxicity was encountered at high doses of 2-CdA in phase I trials, with quadriplegia and paraparesis, proximal neuromyopathy, and rarely, Brown-Séquard and Guillain-Barré syndromes. At currently recommended doses, mild to moderate neurotoxicity occurs in 15% of patients and is, at least, partly reversible with discontinuation of the drug. <sup>228</sup>

Tumor lysis syndrome is rare, tends to occur after the first course, and is generally mild and reversible. However, in rare instances, this process may be fatal, even in patients with prior therapy. Cardiotoxicity is uncommon, but cardiac deaths have been reported, mainly in patients with a prior cardiac history. Pulmonary complications of 2-CdA therapy are uncommon, but in some cases, they have been fatal. Rashes, although uncommon, may be severe and can present as fatal toxic epidermal necrolysis. Mild to severe gastrointestinal toxicities occur in 15% of patients, with nausea, vomiting, and diarrhea, and there have been rare reports of anorexia, severe mucositis, or both. Transient elevations in hepatic enzymes may occur, with exacerbation of hepatitis B, which may be fatal. Renal failure occurs only at high doses.

### **Drug Interactions**

Inhibition of RR by 2-CdA depletes intracellular dCTP pools. This effect leads to compensatory increases in intracellular dCK activity. dCK activity plays a critical role in the formation of the active intracellular Ara-C metabolite, Ara-CTP. Synergistic interaction between 2-CdA and Ara-C was observed in leukemic blast cells isolated from patients with AML, in which 2-CdA pretreatment led to increases of intracellular Ara-CTP pools by up to 40%, with sustained inhibition of DNA synthesis in the circulating leukemia blasts. <sup>267</sup> Studies are ongoing to translate the positive interaction between Ara-C and 2-CdA into the clinical setting.

## **2'-DEOXYCOFORMYCIN**

2'-Deoxycoformycin (Pentostatin), a fermentation product of *Streptomyces antibioticus*, was developed as a potent inhibitor of ADA (see [Fig. 19.5-9](#)). <sup>268</sup> ADA is present in high concentrations in lymphoid tissues, and this enzyme plays a vital role in the differentiation of both T and B cells. Genetic absence of ADA leads to severe combined immunodeficiency disorder in children, and this syndrome is characterized by profound T- and B-cell lymphopenia. Inhibition of this enzyme leads to an accumulation of deoxyadenosine as there is no alternate route for its metabolic conversion to deoxyinosine and uric acid. Deoxyadenosine is subsequently phosphorylated by deoxycytidine kinase to deoxyadenosine monophosphate, which is then further metabolized to the triphosphate form. This metabolite accumulates within cells and inhibits RR, a key enzyme in DNA synthesis. <sup>212,268</sup>

### **Mechanism of Action**

Pentostatin enters cells via the nucleoside transport system, and once within the cell, it forms a tight inhibitory complex with ADA. <sup>268</sup> Exposure of both murine L1210 leukemic cells and normal resting human lymphocytes results in progressive accumulation of DNA breaks along with a decrease in RNA synthesis. In response to drug treatment, DNA repair is activated, resulting in depletion of critical intracellular nicotinamide-adenine dinucleotide levels. This then leads to exhaustion of ATP pools, resulting in eventual cell death.

### **Clinical Pharmacology and Pharmacokinetics**

After rapid intravenous infusions (1 to 9 minutes), pentostatin shows dose-independent first-order elimination, with a biphasic decay characteristic of a two-compartment open model. The rapid disposition phase is short, with a mean half-life of 8.72 minutes and a mean terminal half-life of 4.93 hours. The mean volume of distribution is  $23.1 \pm 6.16$  L/m<sup>2</sup>, and the mean steady-state volume of distribution is  $20.0 \pm 5.31$  L/m<sup>2</sup>. Nearly 100% of an administered dose is excreted in the urine, and there is a significant correlation between plasma levels and creatinine clearance. <sup>269</sup>

### **Treatment**

Initial clinical trials with high doses of pentostatin in patients with ALL and HCL revealed prohibitive myelosuppression and neurotoxicity, the latter manifesting as somnolence, lethargy, confusion, seizures, and coma. <sup>270</sup> Current standard regimens consist of 4 mg/m<sup>2</sup> doses every 1 or 2 weeks. <sup>271</sup> With this schedule, pentostatin exhibits remarkable activity against HCL. In phase II studies, durable response rates over 90% are routinely achieved, and maintenance treatment is not required. On relapse, retreatment with the drug can be effective. <sup>272</sup> In a large, prospective phase III trial, pentostatin achieved significantly higher response rates (79% vs. 38%) and relapse-free-survival than IFN- $\alpha$ . <sup>2a</sup> However, this effect was not translated into overall survival benefit. <sup>273</sup> Although a small number of pentostatin-pretreated patients show good response to cladribine, pentostatin use in patients who have progressed on cladribine has not been investigated in a systematic manner. Minimal residual disease on immunohistochemical examination of bone marrow specimens is detectable in 20% to 40% of HCL patients, who achieve complete response after pentostatin treatment. Although minimal residual disease may be associated with an increased risk of relapse, it remains unclear whether treatment of asymptomatic patients with minimal residual disease provides clinical benefit. <sup>274</sup>

Pentostatin is also active in CLL, prolymphocytic leukemia, cutaneous T-cell lymphoma, indolent non-Hodgkin's lymphoma, chronic myelogenous leukemia, and Langerhans' cell histiocytosis. <sup>268,275</sup> Overall response rates in these malignancies are less than that achieved with either fludarabine and cladribine or that observed with pentostatin in HCL. No significant activity is seen in multiple myeloma or in solid tumors.

### **Toxicity**

The profound immunosuppression associated with pentostatin may persist for several years after therapy is discontinued. <sup>276</sup> T-cell function is affected more than B-cell or natural killer cell function, perhaps because of higher baseline levels of ADA in T cells. A standard course of pentostatin is associated with more prolonged

immunosuppression than that observed with a single-course of cladribine treatment in patients with HCL. The mean time of recovery of CD4+ cells to normal levels is up to 50 months after completion of treatment.<sup>277</sup> Myelosuppression with neutropenia and thrombocytopenia is commonly described. Thrombotic thrombocytopenic purpura and HUS and persistent bone marrow failure with myelodysplastic features have been reported. Neutropenic fever is seen in up to 30% of cases, and opportunistic infections occur with *Candida*, herpes zoster, *Pneumocystis carinii*, and a variety of other pathogens.<sup>229</sup> Although an increased incidence of second cancers is noted in pentostatin-treated patients, the relative risk is similar to that observed with the underlying disease in the absence of nucleoside analogue treatment.<sup>232</sup>

Ocular complications include conjunctivitis, desquamative keratitis, or periorbital edema. Dermatologic toxicity in the form of skin rash, photosensitivity reactions, and a case of fatal erythroderma have been reported. Nausea and vomiting with pentostatin are dose dependent. Other uncommon side effects include stomatitis, constipation, diarrhea, cardiac toxicity, pulmonary toxicity, renal insufficiency, urate nephropathy, and allergic reactions. Transient and reversible increases in hepatic enzymes and fulminant hepatic failure have been described.

#### INTRODUCTION

Isolation and characterization of the topoisomerase enzymes have provided a basis for development of anticancer drugs that contribute to the treatment of patients with a wide range of malignancies.<sup>1</sup> Simply stated, the topoisomerase enzymes control and modify the topologic states of DNA.<sup>2</sup> The mechanisms of these enzymes involve DNA cleavage and strand passage through the break, followed by religation of the cleaved DNA. The precise manner by which these complicated events occur in a single cell is the source of intense research, and the results of this research promise to provide additional targets for anticancer drug therapy.

The length and intricate structure of DNA in eukaryotic cells requires efficient organization to fit in the nucleus. This organization presents a challenge to the cell to access and segregate portions of DNA required for cellular functions, especially because it is done within an extremely complex and dense intracellular milieu. The DNA topoisomerases are nuclear enzymes that assist in these cellular functions. These enzymes reduce DNA twisting and supercoiling that occur in selected regions of DNA as a result of essential cellular processes such as transcription, replication, and repair recombination. All known DNA topoisomerases possess two characteristics: to cleave and reseal the phosphodiester backbone of DNA; and to form a covalent enzyme-DNA linkage, which allows the passage of another single- or double-strand DNA through the nicked DNA. Thus, topoisomerases enable the DNA within a cell to be tightly packed and yet still accessible for processes necessary for proper cellular function.

The first DNA topoisomerase was discovered in the early 1970s.<sup>3</sup> Since then, many different DNA topoisomerases have been found in eukaryotic and prokaryotic cells. In mammalian cells, these enzymes have been differentiated into two types—type I and type II—based on their mechanistic and physical properties. The characteristics of each topoisomerase are summarized and compared in [Table 19.6-1](#).<sup>4</sup>

Characteristic	Topoisomerase I	Topoisomerase II
Size	100 kD, monomer	170 kD, dimer
Catalytic intermediate	DNA single-strand break, covalent linkage to 3'-OH terminus	DNA double-strand break, covalent linkage to 5'-phosphate
Energy dependent	No	ATP dependent
Cofactor requirement	Requires metal ions (e.g., Mg <sup>2+</sup> ); dimeric activity but not essential	Requires divalent metal ions (e.g., Mg <sup>2+</sup> )
Activities	Relaxes DNA tension; inhibits replication, transcription, recombination	Relaxes DNA tension; inhibits replication, transcription, recombination

ATP, adenosine triphosphate.  
\*The activities of topoisomerase II are, topoisomerase IIα (or IIβ) hyperactive in the cell primarily reflect topoisomerase IIα.

**TABLE 19.6-1.** Characteristics and Comparison of Mammalian DNA Topoisomerases

The type I topoisomerase (top I) found in mammals is a monomeric protein encoded by a single-copy gene located on chromosome 20; its activity is adenosine triphosphate (ATP)–independent.<sup>5</sup> This enzyme binds preferentially to double-stranded DNA and cleaves one of the DNA strands of the duplex, simultaneously forming an enzyme-DNA covalent bond between a tyrosine residue and the 3'-phosphate of the cleaved DNA. Through a swivel mechanism, the unbroken strand can pass through this enzyme-mediated nick and release the torsional stress of the DNA double helix.<sup>6</sup> Top I has been shown to be regulated at the transcriptional, translational, and posttranslational levels. Phosphorylation-dephosphorylation and poly(adenosine-diphosphoribo)sylation are important mechanisms of top I regulation *in vitro*, but the therapeutic implications of these findings are not known.

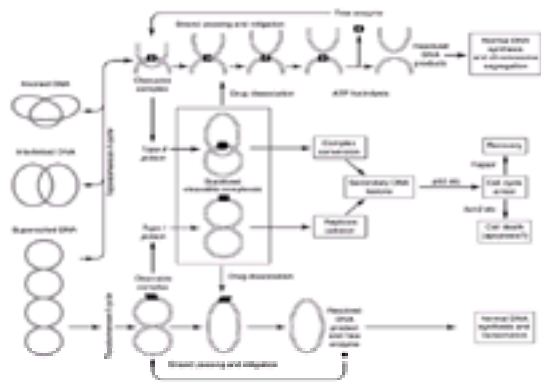

Numerous reports have shown malignant tissue to contain higher levels of top I than its normal counterpart. Specifically, this was observed for colon and ovarian carcinoma, chronic lymphocytic leukemia, and diffuse histiocytic lymphoma.<sup>7,8</sup> This initial observation of increased levels of top I in malignant tissues suggested to investigators that use of top I interactive agents might lead to a selective antitumor effect; however, results from subsequent clinical trials have not supported this hypothesis. In fact, more recent studies *in vitro* suggest that the apparent high level of top I in malignant tissue might be related to differences in malignant compared to normal tissue. Other factors, such as rate of DNA synthesis, repair of drug-induced double-strand breaks, or presence of drug transporters, are also potential determinants of drug activity in the cell.

Two top II isoenzymes have been identified in humans.<sup>9</sup> The a form, which has an apparent molecular weight of 170 kd, is encoded by a single-copy gene located on chromosome 17q21-22. The b form has a molecular weight of 180 kd and has been mapped to chromosome 3p4. Top II a and b have different subnuclear distributions and DNA binding patterns, supporting the hypothesis that each isoform has a specific cellular function, but these precise functions are not known. Whereas top II b is relatively constant over cell and growth cycles, top II a increases in rapidly proliferating cells.<sup>10</sup>

In contrast to type I topoisomerase, the function of type II topoisomerases is ATP-dependent.<sup>11</sup> Once top II binds to duplex DNA, nucleophilic reactions sequentially cleave the two complementary strands of DNA 4 base pairs apart, and the resulting 5'-phosphoryl groups become covalently linked to a pair of tyrosine groups, one in each half of the dimeric top II enzyme. Once the double-strand break has been made, the cleaved ends must be moved apart by at least 2 nm (the diameter of a double-stranded DNA helix) and a second double-strand segment of DNA passed through the break. DNA strand passage is completely dependent on the binding of magnesium and ATP. Once strand passage is complete, the cleaved DNA is religated. As with top I, top II is a phosphoprotein, and casein kinase II and protein kinase C can phosphorylate it *in vitro*, resulting in an enhancement of enzyme activity.

#### MECHANISM OF ACTION OF TOPOISOMERASE INTERACTIVE AGENTS

Although much is known about the biochemical effects of the topoisomerase interactive agents, very little is known about the actual mechanism by which cell death mediated by these agents occurs. Presumably, the damage done to DNA ultimately leads to necrosis or apoptosis through a series of cellular processes, such as cell cycle perturbations (possibly involving cyclins or cyclin-dependent kinases) or DNA repair deficiency. [Figure 19.6-1](#) is a diagrammatic depiction of the normal activities of the topoisomerases and the effect of topoisomerase interactive agents.

**FIGURE 19.6-1.** Diagrammatic representation of the normal activities of type I and type II topoisomerases, the effects of specific topoisomerase interactive agents, and the cellular consequences of trapping topoisomerase-DNA complexes. ATP, adenosine triphosphate. (From ref. 152, with permission.)

Top I interactive agents, thus far consisting primarily of camptothecin analogues, interact with the enzyme-DNA complex.<sup>12</sup> This interaction prevents the resealing of the top I-mediated DNA single-strand breaks. However, these breaks result in cell death only if DNA synthesis is ongoing. A collision between the advancing replication fork and the drug-stabilized single-strand break in DNA results in replication fork breakage and double-strand breaks in the DNA. Treatment of mammalian cells with top I inhibitors induces inhibition of DNA synthesis, cell cycle arrest in G<sub>2</sub>, and cell death by apoptosis. Drug-induced G<sub>2</sub> arrest has been associated with a failure to activate cdc2 kinase. Because the cytotoxicity associated with top I interactive agents is highly dependent on DNA synthesis, any deregulation of cyclins, cell cycle-regulated kinases, or phosphatases may influence the cytotoxicity of top I interactive agents (see Fig. 19.6-1). Several other types of chemotherapeutic agents, such as doxorubicin or actinomycin D, inhibit both top I and top II by a similar mechanism, but at different sites in the DNA.

Top II is the molecular target for many anticancer drugs, such as the aminoacridines, anthracyclines, and epipodophyllotoxins.<sup>13</sup> These drugs inhibit religation of DNA cleaved by top II and induce protein-linked breaks in the DNA, as documented by DNA alkaline elution assays. When drug is removed, these breaks are reversible. The demonstration that drug-induced, protein-associated strand breaks were mediated through interaction with top II occurred when Chen and Liu<sup>9</sup> were able to show that the protein covalently bound to DNA fragments induced by these drugs was top II. They used the term *cleavable complex* to refer to these lesions because the enzyme-DNA complex could be isolated (cleaved) after protein denaturation. The cleavable complex *in situ* is a covalent topoisomerase-DNA complex.

In addition to the top II interactive agents that stabilize top II-DNA complexes, other inhibitors apparently inhibit the enzyme before covalent binding to DNA occurs. However, these agents have not yet proven useful clinically. Except for the epipodophyllotoxins, all mammalian top II inhibitors are DNA intercalators that insert a planar moiety between two adjacent base pairs in duplex DNA. However, as more is learned about the biochemical mechanisms of the top II interactive agents, it becomes clear that the historical characterization of top II interactive agents based simply on DNA-binding properties is no longer an appropriate means of classifying their mechanism of action. Further study is required to understand the molecular mechanisms by which DNA strand breaks lead to antitumor activity.

## EPIPODOPHYLLOTOXINS

### ETOPOSIDE AND TENIPOSIDE

The historical details of the development of the epipodophyllotoxins for clinical use have been reviewed.<sup>14</sup> The path that led to the final development of etoposide and teniposide began in 1820 with the inclusion of podophyllin in the *United States Pharmacopeia Drug Information*. Although extracts of the *Podophyllum peltatum* (May apple, mandrake plants) had been used for years by natives of the Himalayas and the Americas as cathartics and anthelmintics, it was not until 1942, when the curative effect of podophyllin in condylomata acuminata was demonstrated, that a number of derivatives were isolated and synthesized. Early clinical trials of constituents of the resinous extract of podophyllin included the derivative podophyllotoxin, but clinical responses were poor, with excessive toxicity. Further chemical modification of podophyllotoxin by addition of the carbohydrate moiety β-D-thenylidene glucoside led to the compound teniposide, which was first introduced into clinical trials in 1970 (Fig. 19.6-2). The second derivative formed by addition of β-D-ethylidene glucoside to the podophyllotoxin molecule led to the compound etoposide, which, because of advantages in formulation, has been studied more thoroughly. The differences in physicochemical properties of these two compounds are presented in Table 19.6-2.

**FIGURE 19.6-2.** Structures of etoposide and teniposide.

Property	Etoposide	Teniposide
Molecular weight	588.6	666.7
pK <sub>a</sub>	9.7 (ring E)	10.1 (phenol group)
Solubility	Poorly soluble in water; soluble in methanol, chloroform, DMSO, THF; slightly soluble in ethanol	Insoluble in water; soluble in methanol, chloroform, DMSO, THF; slightly soluble in ethanol

DMSO, dimethylsulfonide; pK<sub>a</sub>, measure of acid strength.

**TABLE 19.6-2.** Physicochemical Properties of Etoposide and Teniposide

Etoposide (VP-16-213), a semisynthetic podophyllotoxin derivative, was introduced into clinical trials in 1973 and within 1 year had a major role in the treatment of small cell lung cancer (SCLC) and lymphoma. Clinical trials of teniposide began in the United States in 1967 and, because antitumor effects were seen in early trials, generated enthusiasm. Since then more aggressive teniposide dosing regimens have been evaluated, and teniposide has shown activity as a single agent in the treatment of SCLC. In 1983 etoposide was approved in the United States for combination therapy of refractory testicular tumors and SCLC; however, it is now used in frontline combination therapy for many malignancies. In 1993, teniposide was approved for use in combination with other approved anticancer drugs for induction therapy in patients with refractory acute lymphoblastic leukemia. The enhanced role of epipodophyllotoxins in anticancer therapy has resulted primarily from an improved understanding of their clinical pharmacology. Through rational application of pharmacologic principles, the role of these agents in cancer therapy can be

further refined. Future clinical studies must include biochemical pharmacology studies to identify and exploit potential pharmacologic differences between etoposide and teniposide. These studies should also focus on schedule dependency, rational drug combinations, new disease targets, central nervous system (CNS) penetration, and toxicity considerations.<sup>15</sup>

Therapeutic success with oral epipodophyllotoxin therapy, primarily etoposide, has stimulated an increase in the understanding of etoposide and teniposide oral absorption (Table 19.6-3). Because of solubility concerns, the commercially available form of etoposide has a special formulation; however, in some pediatric studies of oral etoposide and all studies of oral teniposide, the injectable formulation has been used orally. Although delayed absorption of etoposide (e.g., longer than 4 hours) has been observed in patients receiving concurrent narcotics, the basis for this observation is unknown.<sup>16</sup> Marked inpatient and outpatient variability characterizes both etoposide and teniposide oral bioavailability.<sup>17</sup> Oral absorption of etoposide and teniposide is nonlinear, with less than a proportional increase in etoposide in the area under the plasma concentration-time curve (AUC) with increased oral dose. The cause for these findings is unknown, but they suggest that more frequent oral administration of low doses are preferable to less frequent administration of high doses to increase dose intensity.

Oral Absorption Property	Etoposide	Teniposide
Formulation	Liquid formulation containing etoposide as a vehicle consisting of citric acid, pectin, purified water, and polyethylene glycol 400	Solid formulation; intravenous formulation has been marketed; 3,3'-diethylsuccinyl, polyacrylate ester of succinic acid, dibutyl sebacate
Bioavailability	Median 30%; interpatient variability 26-17%; inpatient variability 15-25%	Approximately 40%; interpatient variability 15-25%; inpatient variability 15-16%
Terminal half-life (hr)	10-11.0	10-11.0
Interpatient variability	None	None
$F$ (oral 10 mg/m <sup>2</sup> )	$F=0.3$	$F=0.3$
$F$ (oral 20 mg/m <sup>2</sup> )	$F=0.3$	$F=0.3$

TABLE 19.6-3. Comparison of Oral Absorption between Etoposide and Teniposide

Etoposide and teniposide have comparable distribution properties within the body (Table 19.6-4); however, the extent of plasma protein binding is different between the two drugs. Etoposide is highly bound to plasma proteins, with approximately 6% to 8% of the total drug concentration not bound to plasma proteins;<sup>18,19</sup> whereas less than 1% of the total teniposide concentration is unbound.<sup>20</sup> The etoposide binding ratio measured in patients correlated directly with serum albumin concentration, consistent with *in vitro* studies that show etoposide primarily binds to albumin.<sup>21</sup> Hyperbilirubinemia (e.g., total bilirubin >10 mg/dL) is associated with an increased etoposide percent unbound. *In vitro* studies confirmed that bilirubin displaces etoposide from binding sites on albumin, leading to an increased percent unbound. A model to predict etoposide percent unbound, based on serum albumin and total bilirubin, has been prospectively validated in cancer patients.<sup>22</sup> This model provides clinicians and investigators with a method of estimating a patient's etoposide plasma protein binding using easily accessible patient data.

Pharmacokinetic Parameters	Etoposide	Teniposide
$V_d$ (L/m <sup>2</sup> )	6.7-12.6	3-16
Percent unbound	6-8* (up to 40 in patients with hypoalbuminemia and hyperbilirubinemia)	0.44-1.25* (more than 2 in patients with hypoalbuminemia)
Terminal half-life (hr)	4.1-11.0	5.2-13.9
$Cl_s$ (mL/min/m <sup>2</sup> )	17.7-31.8	9.4-15.4
$Cl_r$ (mL/min/m <sup>2</sup> )	3.4-7.4	0.97
$Cl_{nr}$ (mL/min/m <sup>2</sup> )	10.3-28.4	8.4-14.4

$Cl_s$ , systemic clearance;  $Cl_r$ , renal clearance;  $Cl_{nr}$ , nonrenal clearance;  $V_d$ , steady-state volume of distribution.  
\*In patients with normal albumin and hepatic function.

TABLE 19.6-4. Comparison of Clinical Pharmacokinetic Parameters between Etoposide and Teniposide

The activity of etoposide against tumors of the CNS in preclinical and clinical studies is intriguing because etoposide penetrates poorly into the cerebrospinal fluid (CSF) after standard and high intravenous doses or oral doses (e.g., CSF to plasma concentration ratio of approximately 2%).<sup>23</sup> The CSF penetration of teniposide is lower (i.e., CSF to plasma concentration ratio of 0.03% to 0.55%)<sup>24</sup>; however, after intravenous doses of 50 to 100 mg/m<sup>2</sup> significant amounts of teniposide were found in cerebral tumor samples. Teniposide demonstrated a greater penetration into tumor tissue than peritumoral tissue, suggesting further evaluation of teniposide for use in treatment of patients with brain tumors,<sup>25,26</sup> although more recent work suggests that presence of blood in tissue specimens may hinder the accurate assessment of teniposide penetration into brain tumor tissue.<sup>27</sup>

Nonrenal clearance accounts for 70% to 90% of etoposide and teniposide elimination, respectively. The exact extent and clinical relevance of this route of elimination are unknown. Numerous metabolites of etoposide have been identified, although they comprise only a minor percentage of the administered dose and have little, if any, inherent cytotoxic activity. Similarly, only trace quantities of teniposide metabolites have been found in humans.<sup>28</sup> More recent work with *in vitro* incubation of etoposide or teniposide with human liver microsomes has shown that O-demethylation by cytochrome P-450 enzymes leads to formation of a catechol metabolite.<sup>29</sup> Further studies with a panel of prototypical substrates and inhibitors demonstrated the catechol formation is catalyzed by human CYP3A4.<sup>30</sup> Formation of these reactive metabolites may have important clinical consequences because they covalently bind to DNA and cellular protein and have intrinsic cytotoxic activity.<sup>31,32</sup> Renal clearance of etoposide is greater than teniposide. Approximately 10% or 50% of an administered dose is recovered in the urine as unchanged teniposide or etoposide, respectively.

The disposition of etoposide in patients with renal and hepatic dysfunction has been extensively studied, whereas little is known about the effect of organ dysfunction on teniposide.<sup>33,34,35,36,37,38</sup> and <sup>39</sup> From early reports, etoposide clearance in patients with chronic renal failure was not altered by hemodialysis<sup>40,41</sup>; however, this may be attributed to poor dialyzer efficiency, lack of penetration of etoposide into the dialysis membrane, or high protein binding. Etoposide systemic clearance is significantly correlated with creatinine clearance<sup>42</sup>; however, few of these studies have reported the clinical relevance of altered renal function on etoposide toxicity. In a study of patients with normal albumin and hepatic transaminases, an increase in etoposide AUC was seen in patients with serum creatinine greater than 1.4 mg/dL.<sup>43</sup> Based on increased myelosuppression seen in the patients with elevated creatinine, the authors recommend a 30% decrease in etoposide dose for patients with serum creatinine greater than 1.4 mg/dL. Other approaches to adjusting etoposide dosage for altered renal function include use of measured renal function [e.g., <sup>51</sup>Cr-EDTA clearance],<sup>44,45</sup> or adaptive control dosing based on measured plasma concentrations.<sup>46</sup> These approaches provide more accurate methods of determining patient-specific dose reductions for renal dysfunction; furthermore, they allow for dose escalation in patients with unusually rapid renal function. Thus far, all dosage adjustment recommendations for etoposide in patients with renal dysfunction are based on hematopoietic toxicity; whether adjusting etoposide dosage compromises antitumor efficacy is unknown.

Although etoposide is renally excreted (approximately 50%), a significant nonrenal or metabolism component exists (primarily etoposide glucuronide formed in the liver and excreted in the urine).<sup>47</sup> However, data from three studies show that total etoposide clearance and half-life are not significantly altered in patients with hepatic dysfunction (i.e., total bilirubin 2 to 32 mg/dL and elevated transaminases) compared with controls. This seeming contradiction of no change in etoposide total systemic clearance in patients with hepatic dysfunction could be explained by concomitant increases in unbound drug (e.g., bilirubin displacement or hypoalbuminemia) countering a reduction of nonrenal clearance (e.g., hepatocellular metabolism of unbound drug). The relationship between reduced unbound clearance and increased fraction unbound, leading to offsetting changes in total drug clearance, is depicted in Figure 19.6-3.

**FIGURE 19.6-3.** Bar graphs relating changes in etoposide total systemic clearance (CL), unbound clearance, and fraction unbound for patients with total bilirubin levels of more than 1.0 mg/dL (striped bar), and patients with total bilirubin levels of less than 1.0 mg/dL (solid bar). Statistically significant differences were noted (asterisks) for unbound etoposide clearance and fraction unbound (*t* test  $P < .05$ ). (From ref. 37, with permission.)

Etoposide dosage adjustment in patients with organ dysfunction should not be made solely on changes in etoposide pharmacokinetics, although they can aid in the understanding of altered drug toxicity and therapeutic efficacy associated with impairment of renal and hepatic function. Quantitation of the relation between pharmacokinetics and clinical outcome (pharmacodynamics) provides the clinician with a model to optimize etoposide dosage for an individual patient. The three primary determinants of etoposide disposition, and presumably pharmacologic effect, include excretion (renal), metabolism (hepatic), and protein binding. In a clinical situation in which excretion or metabolism is altered, the pharmacologic effect of etoposide could also be affected. In the absence of prospectively validated dosing recommendations, any recommendations for dosage alterations can only be considered as guidelines for initial dosing. Clinical effects and patient tolerance should guide subsequent etoposide dosing. Other clinical considerations include the current condition of the patient (e.g., performance status), previous cytotoxic chemotherapy, and the therapeutic goal (palliation vs. cure). Arbitrary reductions in etoposide dosage based solely on estimates of renal and hepatic function without regard to pharmacologic effect may lead to overdosing and toxicity or to underdosing and inadequate antitumor effects. Table 19.6-5 summarizes what effect different clinical conditions may have on etoposide protein binding and suggested dosage adjustments.

Excretion (Renal)	Metabolism (Hepatic)	Fraction of Dose Not Bound to Protein	Anticipated Pharmacologic Effect
Normal	Normal	Increased (e.g., hypoalbuminemia)	Unchanged
Decreased	Normal	Normal	Increased
Normal	Decreased	Normal	Increased
Decreased	Normal	Increased (e.g., hypoalbuminemia)	Increased (±)
Normal	Decreased	Increased (e.g., hypoalbuminemia)	Increased (±)
Decreased	Decreased	Increased (e.g., hypoalbuminemia)	Increased (±)

\*Excretion and metabolism are assumed to remove etoposide from the body, and no active metabolites are formed in circulation. Pharmacologic effect is against both normal tissue (toxicity) and tumor tissue (efficacy).

**TABLE 19.6-5.** Examples of Clinical Conditions in Which Etoposide Elimination, Metabolism, or Protein Binding Are Affected, and the Anticipated Pharmacologic Effect<sup>a</sup>

The results of *in vitro* cell culture studies and murine tumor models have firmly established a relation between epipodophyllotoxin exposure and cytotoxicity<sup>48</sup>; however, most clinical pharmacodynamic studies focus on the relation between etoposide exposure (e.g., AUC, steady-state drug concentration ( $C_{p,ss}$ ), time above a particular concentration, or trough concentration) and toxicity (e.g., neutropenia or thrombocytopenia). One clinical pharmacodynamic study of continuous infusion teniposide in children with acute leukemia, lymphoma, or neuroblastoma, showed the median  $C_{p,ss}$  was higher in responding patients (24 vs. 8  $\mu M$ ), presumably due to a greater teniposide clearance in the nonresponder group.<sup>49</sup> From this study, a range of teniposide systemic exposure associated with a high probability of response and an acceptable degree of reversible myelotoxicity was defined. In another study, teniposide unbound systemic exposure was significantly correlated with percent decrease in white blood cell count (WBC), whereas total systemic exposure was not as well correlated.<sup>50</sup>

Inclusion of patient-specific variables, such as serum albumin in pharmacodynamic models,<sup>51,52</sup> provides indirect evidence for the importance of protein binding to etoposide pharmacodynamics. Because only unbound drug is active, systemic exposure to unbound drug should be more informative of response in a patient population in which protein binding might be considered to be variable. In a number of clinical trials, a statistically significant mathematical relation between systemic exposure to unbound etoposide and myelosuppression has been observed.<sup>53,54</sup> and <sup>55</sup> Thus, in patients with anticipated variable etoposide protein binding (e.g., hypoalbuminemia), measured unbound etoposide systemic exposure could be a more informative measure of drug effect than total systemic exposure.

The effect of schedule on etoposide activity has been the source of intense investigation. Although an early study<sup>56</sup> suggested prolonged schedules of etoposide were more effective in patients with SCLC, convincing evidence for schedule dependency came from two studies of single-agent intravenous etoposide in previously untreated SCLC.<sup>57,58</sup> In the first study, 500 mg/m<sup>2</sup> was given either as a 24-hour infusion or in five daily 2-hour infusions. The systemic exposure to total etoposide was identical between the two treatment arms, but the duration of exposure to putatively cytotoxic concentrations (1  $\mu g/mL$ ) was 95 hours in the daily arm compared to 46 hours in the 24-hour infusion arm. Furthermore, the overall response rate in the 5-day arm was 89%, compared with only 10% in the 24-hour arm. Confirmation of this observation was derived from a randomized trial of 500 mg/m<sup>2</sup> given intravenously over either a 5-day or an 8-day schedule.<sup>59</sup> No difference in antitumor activity was noted between the two schedules, although hematologic toxicity was more severe in the 5-day schedule.

Etoposide total systemic clearance is increased in the presence of the anticonvulsants (e.g., phenytoin or phenobarbital) often administered with high-dose chemotherapy. Because etoposide undergoes hepatic metabolism, induction of hepatic enzymes by anticonvulsants may be of clinical relevance. Median etoposide systemic clearance in adults receiving phenytoin was approximately 40% greater than in patients not receiving anticonvulsants as part of their bone marrow conditioning regimen.<sup>60</sup> In children, median etoposide systemic clearance was 77% higher in those receiving phenobarbital or phenytoin than in those not taking anticonvulsants.<sup>60</sup> The increased systemic clearance associated with anticonvulsant coadministration translates into a lower systemic exposure at the same dose. Thus, patients receiving anticonvulsants or other drugs known to induce hepatic enzymes need a higher dose of etoposide to achieve a similar systemic exposure to that attained in the absence of this interaction. In contrast, etoposide systemic clearance is decreased in patients receiving cyclosporine<sup>61</sup> or its analogue valspodar,<sup>62</sup> suggesting inhibition of P-450 metabolism, disruption of P glycoprotein function, or modulation of other mechanisms of etoposide elimination.<sup>63</sup>

Etoposide and cisplatin are widely used to treat solid tumors. Because cisplatin causes both acute and chronic decreases in renal function, numerous studies have investigated the potential for it to alter etoposide excretion. The concurrent infusion of cisplatin with high-dose etoposide (i.e., 350 mg/m<sup>2</sup>/d for 5 consecutive days) did not alter the pharmacokinetics of cisplatin or etoposide.<sup>64,65</sup> However, etoposide systemic clearance was significantly lower in the first 48 hours after cisplatin, as compared to 21 days later.<sup>66</sup> Early studies suggested cumulative cisplatin exposure was associated with lower etoposide systemic clearance<sup>67</sup>; however, data from more patients have failed to demonstrate a persistent decrease in clearance with up to 360 mg/m<sup>2</sup> cisplatin. Whether etoposide excretion would be affected by larger cumulative cisplatin doses remains to be determined.

Phenylbutazone and sodium salicylate (at pharmacologic concentrations) were able to displace etoposide from plasma protein binding sites.<sup>68</sup> Other drugs (e.g., ifosfamide, indomethacin, nafcillin) were able to displace etoposide, but only at suprapharmacologic plasma concentrations. Unpublished data suggest that therapeutically relevant concentrations of tolbutamide, sodium salicylate, and sulfamethiazole can displace protein-bound teniposide in fresh human serum. The clinical relevance of this displacement is unknown.

Myelosuppression is the dose-limiting toxicity for etoposide and teniposide, and only at very high doses is mucositis dose-limiting (i.e., >1000 mg/m<sup>2</sup>). Granulocyte nadir counts occur between 5 and 15 days after intravenous drug administration, and recovery is usually complete by day 28. After continuous oral administration, the nadir granulocyte count occurs between day 21 and 28, and in most patients, recovery is sufficient by day 35 for retreatment.<sup>69,70 and 71</sup> Thrombocytopenia occurs less often, with nadir counts observed within 9 to 16 days after drug administration. Regardless of route of administration, myelosuppression is reversible and usually not cumulative. To avoid the potential of severe myelosuppression, consideration should be given to reducing the etoposide dosage for patients who have received extensive prior myelosuppressive chemotherapy or radiation to marrow-bearing areas of the skeleton. Mild to moderate nausea and vomiting occur in approximately 30% to 40% of patients and may be more frequent with oral than intravenous administration. Other gastrointestinal toxicities, including constipation, diarrhea, stomatitis, and anorexia, have been reported but are infrequent at standard intravenous doses; however, with divided-dose oral etoposide, diarrhea and mucositis were dose-limiting. At etoposide dosages used in bone marrow transplantation regimens, mucositis occurs more frequently, and as the dosage increases, the severity also increases. Two patients receiving high-dose etoposide (cumulative dose at least 6.8 g/m<sup>2</sup>) had elevations in bilirubin, alkaline phosphatase, and aminotransferase levels that reversed within 12 weeks.<sup>72</sup>

Hypersensitivity reactions (including vasomotor changes), symptoms related to the gastrointestinal tract, and pulmonary symptoms are observed after therapy with etoposide. Although the rate reported in adults is less than 3%, children with acute lymphocytic leukemia have an incidence as high as 51%<sup>73</sup>; however, children appear to develop more frequent reactions to etoposide than adults.<sup>74</sup> Premedication with histamine (H<sub>1</sub> and H<sub>2</sub>) blockers and a slower infusion rate may reduce the risk of further hypersensitivity reactions upon rechallenge with etoposide, although patients developing bronchospasm, urticaria, and severe hypotension or in whom symptom resolution was slow probably should not be rechallenged.

Therapy-associated acute nonlymphocytic leukemia (t-ANLL) has been described after epipodophyllotoxin-containing therapy for both solid tumors and acute lymphocytic leukemia.<sup>75,76,77,78,79 and 80</sup> The incidence of t-ANLL varies widely from 1.6% to as high as 25%. These leukemias appear relatively early after diagnosis of the primary tumor (<5 years), present in overt leukemia without preceding myelodysplasia, and are usually French-American-British (FAB) subtypes of M4 and M5. Relationships between the cumulative dose and schedule of etoposide therapy and development of t-ANLL have been described. Cumulative etoposide doses greater than 2 g/m<sup>2</sup> or 3 g/m<sup>2</sup> have been associated with a greater incidence of t-ANLL, although this association has not been found in all studies. A relationship between schedule of administration and development of t-ANLL also has been suggested, with frequent administration of high-dose intravenous epipodophyllotoxin associated with an increased incidence of t-ANLL. Reports suggest that t-ANLL may also occur with oral etoposide therapy.<sup>81,82</sup> If the metabolism of the epipodophyllotoxins has prognostic significance to the development of t-ANLL, as suggested by some investigators,<sup>83</sup> then pharmacogenetic differences may be important.<sup>84</sup>

A somewhat unexpected adverse event associated with teniposide is characterized by somnolence, hypotension, and metabolic acidosis and has been described in three children receiving more than 500 mg/m<sup>2</sup> of intravenous teniposide over 4 hours.<sup>85</sup> Due to poor water solubility, teniposide is formulated with polyoxyethylated castor oil (Cremophor EL) and 42.7% (volume to volume ratio) dehydrated ethanol, and in these patients, clinically significant (i.e., >60 mg/dL) ethanol concentrations were detected at the time of the adverse event. To avoid high ethanol and teniposide concentrations, teniposide doses of more than 500 mg/m<sup>2</sup> should be given over 8 hours. With the exception of this acute, vehicle-related reaction, the pattern of toxicity for teniposide and etoposide are identical.

## ETOPOSIDE PHOSPHATE

Because of poor water solubility, etoposide is formulated with modified polysorbate 80 (Tween 80), polyethylene glycol 300, and ethanol. Preparation of an etoposide prodrug by modification of the etoposide molecule to add a phosphate group at the 4 position in the E ring led to a more water-soluble compound.<sup>86</sup> Etoposide phosphate is rapidly and completely converted by endogenous phosphatases to etoposide. Initial studies have evaluated parenteral administration, but etoposide phosphate can also be given orally.<sup>87,88 and 89</sup>

In early phase I studies, etoposide generated from etoposide phosphate showed the same pharmacokinetic and toxicity pattern as etoposide, but with a number of advantages over the parent compound.<sup>90,91 and 92</sup> Excipients known to be toxic are not found in etoposide phosphate. The drug can be given by intravenous bolus (i.e., 5 minutes vs. 30 to 60 minutes), reducing the cost of drug preparation and increasing patient convenience. Etoposide phosphate is more stable and can be given at high concentrations, making it ideal for high-dose therapy or continuous infusion regimens. Whether these advantages will translate into improved clinical efficacy remains to be answered.

## CAMPTOTHECIN ANALOGUES

The antitumor activity of 20(S)-camptothecin, a plant alkaloid isolated from *Camptotheca acuminata*, has been recognized for more than 20 years.<sup>93,94</sup> Although 10-hydroxycamptothecin demonstrated activity in studies conducted primarily in China, its use was associated with severe and unpredictable toxicity. Several camptothecin derivatives have been evaluated in clinical trials, including 9-amino-20(S)-camptothecin (9-AC), 9-nitrocamptothecin (rubitecan), lurtotecan (GI 147211), 9-dimethylaminomethyl-10-hydroxycamptothecin (topotecan), and 7-ethyl-10-(4-[1-piperidino]-1-piperidino)-carbonyloxy-camptothecin (irinotecan) ( Fig. 19.6-4). The two camptothecin analogues approved for clinical use (topotecan and irinotecan) contain the camptothecin pentacyclic structure with a lactone (closed ring) moiety in the E ring. This lactone is essential for cytotoxicity because the open ring, or hydroxy acid form, is inactive. Because of logistical difficulties in stabilizing the lactone ring before analysis, many investigators have chosen to acidify the plasma sample, which makes all hydroxy acid convert back to the lactone form. Thus, these investigators measure the sum of lactone and hydroxy acid, or *total* drug. The clinical pharmacokinetics of the camptothecin analogues are summarized in Table 19.6-6. Many different doses, routes, and schedules of administration have been evaluated for the camptothecin analogues, and controversy exists over which is optimal.

FIGURE 19.6-4. Camptothecin analogues.

Parameter	Topotecan	Irinotecan
Bioavailability (F)	0.19-0.91	NA

Major metabolites	Naloxonemethyl topotecan, topotecan O-glucuronide	NN-38, NN-39 glucuronide, APC, NPG

CL, systemic clearance; NA, not available; V<sub>d</sub>, steady-state volume of distribution.  
 \*Active metabolite; NN-38, is approximately 2% unchanged.

**TABLE 19.6-6.** Comparison of Clinical Pharmacokinetic Parameters between Topotecan and Irinotecan

Studies of low-dose, protracted topotecan in mice bearing xenografts of human tumors have shown less toxicity and equal or greater antitumor activity over shorter, more intense courses,<sup>95,96</sup> and <sup>97</sup> stimulating interest in oral administration of camptothecin analogues. Clinical studies of oral topotecan show a variable time to peak concentration<sup>98,99</sup> and have marked interpatient variability. However, in a study of either 15 or 21 days of oral topotecan in children, inpatient variability for the oral topotecan AUC and bioavailability (F) was smaller than interpatient variability.<sup>100</sup> In most clinical trials, topotecan is administered on an empty stomach, although in one study, co-administration of topotecan gelatin capsules with a high-fat meal led to a small decrease in the rate, but not extent, of absorption.<sup>101</sup> Pharmacokinetic data from a study of the oral absorption of intravenous irinotecan showed that irinotecan was rapidly absorbed, and peak irinotecan concentrations were observed within 1 to 2 hours of administration.<sup>102</sup> The relative extent of conversion of irinotecan to SN-38 was high, with mean ratios of 0.8 and 0.7 on days 1 and 5, respectively. This compares with values of 0.02 and 0.07 after intravenous administration<sup>103</sup> and suggests that presystemic formation of SN-38 occurs after oral administration. Preliminary results of a small pediatric study suggest that the absolute bioavailability of intravenous irinotecan administered orally is approximately 10%, which is in agreement with preclinical studies in the mouse.<sup>104</sup>

Topotecan and irinotecan both have a large steady-state volume of distribution ( $V_{d_{ss}}$ ), consistent with either extensive plasma protein or tissue binding. Topotecan and irinotecan are approximately 20% and 50% bound to plasma protein, respectively, thus the high  $V_{d_{ss}}$  is most likely due to extensive tissue binding; SN-38 is approximately 98% bound to plasma proteins.<sup>105</sup> The impact of human serum albumin on the conversion of the lactone to carboxylate form is an important aspect of camptothecin drug-protein interactions.<sup>106,107</sup> Variations in the camptothecin molecular structure may alter these interactions, with SN-38 lactone having enhanced stability in the presence of human serum albumin, compared with irinotecan or topotecan. The d-lactone ring moiety of 9-aminocamptothecin hydrolyzes almost immediately (more than 99.5%) in the presence of human serum albumin, substantially reducing the pharmacologically active lactone form in human blood. In contrast, topotecan does not associate with human serum albumin, resulting in a higher level of lactone stability in human plasma.<sup>108</sup> The clinical significance of variability in serum albumin concentrations on camptothecin toxicity and antitumor activity is presently unknown.

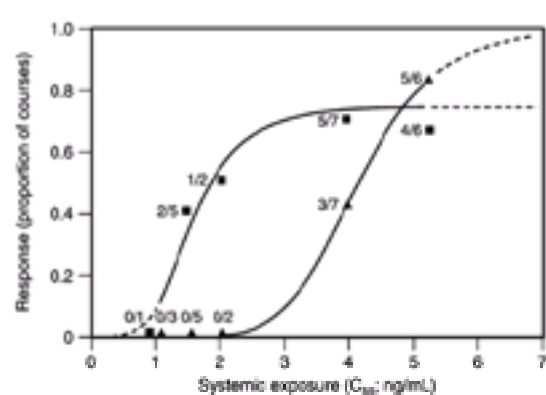

Topotecan CSF penetration in children was determined from the ratio of CSF to plasma AUC during a 24- and 72-hour continuous topotecan infusion.<sup>109</sup> The median CSF penetration of topotecan lactone was 29% (range, 10% to 59%) and 42% (range, 11% to 97%) for the 24- and 72-hour continuous infusions, respectively. The degree of penetration is consistent with that reported for the nonhuman primate model.<sup>110</sup>

The primary route of elimination from the body varies between topotecan and irinotecan. For topotecan, 50% to 65% of a dose is recovered in the urine; thus, renal excretion is a major route of elimination.<sup>111,112</sup> and <sup>113</sup> Although topotecan has been measured in human bile, the importance of biliary excretion is unknown. Approximately 30% to 40% of topotecan is eliminated by nonrenal pathways, and the N-desmethyl metabolite of topotecan has been isolated from urine of patients receiving topotecan.<sup>114</sup> This metabolite has antitumor activity equal to that of the parent compound, and its formation is catalyzed by the cytochrome P-450 system. The maximum plasma concentration of total (sum of lactone and hydroxy acid) N-desmethyl topotecan is only 0.5% of total topotecan, and the average urinary recovery is less than 5% of the administered dose. Two other metabolites, topotecan O-glucuronide and N-desmethyl topotecan O-glucuronide have been reported; however, they accounted for only 13.5% of the urinary recovery of the administered dose. Thus, other nonrenal routes (e.g., metabolism) of topotecan elimination are yet to be identified.<sup>115</sup>

In contrast, irinotecan itself has little *in vitro* cytotoxicity<sup>116</sup> and requires conversion, by the carboxylesterase enzyme, to 7-ethyl-10-hydroxycamptothecin (SN-38) for antitumor activity. *In vitro* studies have shown decreased carboxylesterase activity may be a mechanism of cellular resistance to irinotecan.<sup>117</sup> Furthermore, transfection of carboxylesterases into tumor cells increases the activation and cytotoxicity of irinotecan.<sup>118,119</sup> SN-38 is conjugated to glucuronic acid at the C<sub>10</sub> position by UGT1A1, and this metabolite has no intrinsic antitumor activity.<sup>120</sup> The extent of conversion of SN-38 to its glucuronide has been inversely correlated with the risk of severe diarrhea, because the other major route of SN-38 excretion is biliary excretion by canalicular multispecific organic anion transporter (cMOAT)<sup>121,122</sup> (presumably leading to mucosal injury).<sup>123</sup> In addition to SN-38 and SN-38 glucuronide, 7-ethyl-10-[4-N-(5-aminopentanoic acid)-1-piperidino]carbonyloxycamptothecin (APC) and 7-ethyl-10-(4-amino-1-piperidino)carbonyloxycamptothecin (NPC) are oxidative metabolites of irinotecan formed by CYP3A4.<sup>124,125</sup> Renal excretion is a minor route of elimination for irinotecan and SN-38.

The disposition of topotecan in patients with renal and hepatic dysfunction has been studied in adults receiving intravenous topotecan daily for 5 consecutive days.<sup>126,127</sup> and <sup>128</sup> Patients with renal dysfunction were placed into three groups according to their creatinine clearance (20 or below, 21 to 40, or 41 to 60 mL/min), and hepatic dysfunction was defined as a total bilirubin greater than 1.5 mg/dL. A control group of patients with normal renal and hepatic function was also studied. Topotecan disposition and hematologic toxicity were not significantly altered in patients with hepatic dysfunction (as defined by elevated total bilirubin); therefore, no dosage alteration is recommended for these patients. Severe neutropenia was observed in patients with moderate to severe renal dysfunction treated at one-third of the adult maximal tolerated dosage (i.e., 0.5 mg/m<sup>2</sup>/d). Based on the results of this study, the investigators recommended an initial topotecan dosage of 0.75 mg/m<sup>2</sup>/d when given daily for 5 consecutive days to patients with moderate renal dysfunction (i.e., creatinine clearance <39 mL/min). In another study of patients with renal dysfunction, no correlation was found between total topotecan clearance and a more specific measure of glomerular filtration rate [technetium Tc 99m DPTA clearance]. Furthermore, one patient studied with a technetium clearance of 19 mL/min/m<sup>2</sup> had a normal topotecan total clearance, suggesting topotecan may undergo renal tubular secretion in addition to glomerular filtration. Results of a study in mice showed that probenecid would inhibit renal tubular secretion of topotecan and decrease topotecan renal and systemic clearance, leading to an increase in topotecan lactone systemic exposure.<sup>129</sup> Irinotecan undergoes significant hepatic metabolism, and preliminary pharmacokinetic and toxicity results of a study of irinotecan administration in adults with liver dysfunction suggest that the irinotecan dosage should be reduced by one-third in patients with total bilirubin more than three times the upper limit of normal.<sup>130</sup>

As with the epipodophyllotoxins, results of preclinical studies of the camptothecin analogues show a definite relationship between dose and antitumor effect in mice bearing human tumor xenografts. These studies have evaluated a variety of schedules and routes of administration, and the results suggest that the camptothecin analogues are highly schedule-dependent.<sup>131</sup> Early clinical studies of the relationship between systemic exposure and pharmacologic effect reported a statistically significant and clinically relevant relationship between drug exposure and myelosuppression (i.e., percentage change in absolute neutrophil count and platelets).<sup>132,133</sup> A significant correlation was reported between systemic exposure to 9-aminocamptothecin lactone and the extent of neutropenia observed after a 72-hour continuous infusion.<sup>134</sup> Few studies have looked at the relationship between drug exposure and antitumor efficacy; however, one study of continuous infusion topotecan in children with relapsed acute leukemia found a correlation between topotecan lactone systemic exposure and toxicity and topotecan lactone systemic exposure and oncolytic effect (Fig. 19.6-5).<sup>135</sup>

**FIGURE 19.6-5.** Plot of topotecan lactone systemic exposure ( $C_{ss}$ ; steady-state concentration) versus proportion of courses of therapy with either an oncolytic response (*upper curve; square*) or grade 2 to 4 mucositis (*lower curve; triangle*). Twelve courses of topotecan were associated with an oncolytic response, defined as greater than 75% reduction in circulating blast count or a complete or partial response based on bone marrow aspirate. In this figure, the number of courses associated with a response or mucositis is shown in the numerator over the total number of courses at each level of systemic exposure. (From ref. 135, with

permission.)

The presence of the pH-sensitive lactone ring present in the two commercially available camptothecin analogues, topotecan and irinotecan, raises the question of whether lactone or total systemic exposure is a better representation of pharmacologic effect. The advantage of measuring total drug is the elimination of the more cumbersome determination of the lactone concentrations, which require immediate sample processing. Total concentrations (lactone plus hydroxy acid) may be determined without immediate processing, and assays may be performed several weeks or months later, thus, making it feasible to do large population studies. Use of total drug as a surrogate for systemic exposure to the active lactone has potential drawbacks (e.g., presence of active metabolites, inpatient variability), although the lactone and hydroxy acid exist in a pH-dependent equilibrium that varies little at physiologic pH.

Reversible myelosuppression, with both neutropenia and thrombocytopenia, is the dose-limiting toxicity observed with topotecan. After intravenous dosing of topotecan, the neutrophil nadir occurs between 8 and 10 days, and recovery is usually complete by day 21. On a schedule of extremely high doses given daily for 5 days, hemolytic anemia was observed as a dose-limiting toxicity.<sup>136</sup> Reversible moderate to severe anemia also has been reported with topotecan. The use of growth factors to further escalate the topotecan dose has been used with mixed success.<sup>137</sup> With oral topotecan, prolonged oral administration (i.e., twice daily for 21 days every 28 days) resulted in gastrointestinal side effects as the dose-limiting toxicity, whereas, when given in the short term (i.e., once daily for 5 days every 21 days), myelosuppression was the dose-limiting toxicity.<sup>138</sup> For topotecan, the only nonhematologic dose-limiting toxicity reported is mucositis, but only after a 120-hour continuous topotecan infusion.<sup>139,140</sup>

The major dose-limiting toxicities for irinotecan are myelosuppression and diarrhea. Irinotecan-induced diarrhea is generally of two types. The first type has an early onset, beginning during or immediately after the irinotecan infusion. This is often accompanied by facial flushing and abdominal cramping characteristic of diarrhea associated with vasoactive compounds. Standard-dose anticholinergic drugs, such as scopolamine or atropine, can be used to control this diarrhea, which is caused by the cholinergic effects of irinotecan. The second type of diarrhea, a cholera-like syndrome unresponsive to loperamide or codeine, is often dose-limiting. Many therapeutic approaches have been tried to ameliorate or prevent the diarrhea associated with irinotecan, including the use of the cyclooxygenase inhibitor indomethacin and the enkephalinase inhibitor acetorphan, but none has been universally successful.<sup>141,142</sup> Modulation of irinotecan pharmacokinetics by inhibitors of SN-38 biliary excretion or inducers of SN-38 glucuronidation may be another method to reduce the severity of irinotecan-associated diarrhea.<sup>143,144 and 145</sup>

Other nonhematologic toxicities seen with the camptothecin analogues are generally reversible and not dose-limiting. Mild nausea and vomiting have occurred in approximately 20% to 30% of patients. Low-grade fever has been observed in approximately 20% of patients, and alopecia occurs at higher doses. Other mild toxicities observed include fatigue, anorexia, and skin rash. Top I interactive agents have not been in clinical use long enough for therapy-associated malignancies to be reported; however, sister chromatid exchanges and gene deletions or rearrangements have been induced *in vitro*.<sup>146</sup>

Topotecan systemic clearance and the formation of the N-desmethyl topotecan metabolite are increased in the presence of enzyme-inducing anticonvulsants (e.g., phenytoin).<sup>147</sup> Although hepatic metabolism is a relatively minor component of topotecan disposition, the steep exposure-response relationship observed with topotecan makes this interaction clinically relevant. Patients concomitantly administered enzyme-inducing anticonvulsants may require an increase in topotecan dose to achieve a similar pharmacologic effect as a patient not receiving anticonvulsants. This interaction with anticonvulsants was also observed in a group of patients receiving 9-aminocamptothecin, a camptothecin analogue that has no known hepatic metabolism. In this study, patients receiving 9-aminocamptothecin and anticonvulsants did not have the expected extent of myelosuppression. On further study of 9-aminocamptothecin pharmacokinetics, it was found that the median steady-state 9-aminocamptothecin plasma concentrations in patients on anticonvulsants (25.3 nM) was significantly lower than patients not receiving anticonvulsants (76.5 nM).<sup>148</sup> Anticonvulsants also increased irinotecan clearance in a study of patients with glioma, which led to a decrease in the mean irinotecan and SN-38 AUC.<sup>149</sup> Although the numbers of patients studied were small, it appears that phenobarbital may have a different effect from carbamazepine and phenytoin, in that phenobarbital increased SN-38 glucuronide and APC AUC by 1.6- and 2.6-fold, respectively. In another study of adults with malignant glioma receiving irinotecan and anticonvulsants and dexamethasone, the irinotecan clearance was twofold and the systemic exposure to irinotecan, SN-38, and SN-38 glucuronide was statistically lower compared with a historical control group of patients with non-CNS tumors.<sup>150</sup>

## ANTHRACYCLINES AND RELATED COMPOUNDS

Anthracyclines, anticancer agents consisting of a pigmented aglycone, an amino sugar, and a lateral chain ( Fig. 19.6-6), have been in clinical practice since the 1960s and represent one of the most commonly used classes of anticancer drugs.<sup>151</sup> The first anthracyclines in clinical use, doxorubicin and daunorubicin, were produced by the *Streptomyces* species, and the anthracyclines have thus been classified as antitumor antibiotics; however, classification by mechanism of action is more rational, especially because the second-generation anthracyclines (e.g., idarubicin, epirubicin) are synthetic. The first anthracycline, doxorubicin, still remains the most widely used and is the benchmark against which new analogues are compared.

**FIGURE 19.6-6.** Structures of the four anthracyclines in current clinical use. Epirubicin differs from doxorubicin in the steric position of the 4'-OH group, whereas idarubicin differs from daunorubicin in lacking an A-ring methoxy substitution.

The anthracyclines induce formation of covalent topoisomerase-DNA complexes and prevent the enzyme from completing the religation portion of the ligation-religation reaction. These agents are also DNA intercalators that insert part of their planar structures between two adjacent base pairs in DNA, causing single-stranded and double-strand breaks. The anthracyclines can undergo chemical reduction through enzymatically catalyzed or iron-catalyzed pathways to yield reactive free radical intermediates. Through hydrogen peroxide and hydroxyl radicals, these free radical intermediates can cause oxidative damage to cellular proteins. Under hypoxic conditions, these free radicals can rearrange to form metabolites capable of covalently binding to DNA. Although the anthracyclines are associated with all of these reactions, it is their interaction with top II that is the most important mechanism of cytotoxicity.<sup>152</sup>

With the exception of idarubicin, none of the anthracyclines are administered orally. Idarubicin, a synthetic analogue of daunorubicin, has increased lipophilicity compared to daunorubicin, which allows it to be readily absorbed from the gastrointestinal tract.<sup>153</sup> Absorption of idarubicin is erratic and incomplete ( Table 19.6-7); however, higher concentrations of its active metabolite, idarubicinol, are achieved after oral than intravenous administration because of first-pass hepatic metabolism.

Parameter	Doxorubicin	Daunorubicin	Epirubicin	Idarubicin
Bioavailability (%)	51	51	51	34-47
$V_d$ (L/m <sup>2</sup> )	24-88	100-107	95-261	90-236
Protein bound (%)	55-65	~8	51	3-6 (for idarubicin)
$t_{1/2}$ (h)	18-21	15-21	18-21	18-21
$t_{1/2}$ (h)	216-412	154-473	155-413	155-417
Cl (L/h/m <sup>2</sup> )	275-385	385-393	315-413	385-425
Metabolite	Daunorubicinol (active)	Daunorubicinol (inactive)	Epirubicinol (low potency)	Idarubicinol (potent)

Cl, systemic clearance;  $V_d$ , apparent volume of distribution;  $t_{1/2}$ , elimination half-life;  $t_{1/2}$ , terminal half-life. Bioavailability calculated as sum of idarubicin and idarubicinol.

**TABLE 19.6-7.** Comparison of Clinical Pharmacokinetic Parameters between Doxorubicin, Daunorubicin, Epirubicin, and Idarubicin

Anthracyclines as a class are unable to cross the blood–brain barrier either because of low lipophilicity, the presence of P glycoprotein in the cells of brain endothelial vessels, or both.<sup>154</sup> However, after intravenous administration of idarubicin, its metabolite, idarubicinol, can be detected in the CSF (1% to 13% simultaneous plasma concentration) at concentrations associated with *in vitro* cytotoxicity. The plasma protein binding for the anthracyclines is probably not clinically relevant, with the exception of idarubicin and idarubicinol, as hypoalbuminemia may increase systemic exposure to unbound idarubicin and idarubicinol.

Several metabolic pathways have been reported for the anthracyclines. Reduction of the ketone on carbon 13 yields 13S-dihydro derivatives, which are then named after the parent anthracycline with the suffix -ol (e.g., doxorubicinol). This reaction is catalyzed by the ubiquitous aldo-ketoreductases, which in general convert daunorubicin and idarubicin more rapidly than doxorubicin and epirubicin. Thus, plasma concentrations of daunorubicinol and idarubicinol rapidly exceed those of the parent drug (AUC ratio of metabolite to parent drug, 2 to 5), compared with doxorubicinol and epirubicinol (AUC ratio, 0.3 to 0.5). Most 13-dihydro metabolites of the anthracyclines do not have antitumor activity; however, idarubicinol is an exception, primarily due to its lipophilicity, which allows entry into the cell. At one time, deglycosylation was thought to represent a metabolic pathway, but now the clinical significance of the anthracycline aglycones is unknown. Epirubicin, an epimer of doxorubicin, is characterized by a unique metabolic step present only in humans. The equatorial position of the 4' hydroxyl group allows epirubicin to be conjugated to glucuronic acid. The glucuronide AUC is similar to that of the parent compound, potentially explaining the lower myelotoxic and cardiotoxic properties of epirubicin compared with doxorubicin; however, the exact clinical significance of this metabolic step is unknown.

Elimination of the anthracyclines proceeds primarily through the bile, with urinary excretion accounting for less than 10% of the total dose administered. No evidence for enterohepatic recirculation has been observed. Although epirubicin is excreted in the bile, a larger proportion of an injected dose is recovered in the urine relative to the other anthracyclines, due to formation of soluble glucuronides.<sup>155</sup>

In patients with hyperbilirubinemia or reduced renal function, dose reduction recommendations for daunorubicin and doxorubicin are provided in the package literature. These dose reductions are based on retrospective data and have not been prospectively validated. The results of a study of patients with hyperbilirubinemia receiving doxorubicin raise questions about the validity of adjusting doses in patients with hyperbilirubinemia.<sup>156</sup> The systemic clearance of epirubicin and idarubicin in patients with liver disease is decreased, and although a dosage reduction is recommended based on bilirubin or serum aspartate, as with doxorubicin, it is unclear if a dosage reduction is clinically indicated. Whereas renal impairment reduces the clearance of epirubicin and idarubicin, only idarubicin has been adequately studied to provide dosing guidelines.

As with other anticancer drugs, few clinical studies have related exposure to anthracyclines and antitumor effect. Early studies suggested doxorubicin concentration, peak or 3 hours after end of infusion, was associated with outcome of remission induction or reduction of tumor mass, respectively. These findings have led investigators to speculate that improved tumor response might be linked to high initial plasma doxorubicin concentrations. The contribution of the anthracycline metabolite to the overall effect depends on the anthracycline under study. As discussed previously, idarubicinol has significant cytotoxic activity; patients with a low rate of epirubicin glucuronidation had a lower percent change in neutrophils and better tumor response. The only pharmacodynamic relation between doxorubicin systemic exposure and toxicity (e.g., decrease in WBC) was noted after continuous doxorubicin infusion.<sup>157</sup> A positive correlation was noted between the AUC for epirubicin, or epirubicin and epirubicinol, and logarithm of the WBC survival fraction.<sup>158</sup>

Although a number of drugs have been reported to interact with doxorubicin, most of these have been in experimental systems, so their clinical significance is unknown. Of the drug interactions reported in patients with cancer, only a few are of clinical consequence. Despite numerous studies showing pharmacologic prevention of anthracycline-induced cardiotoxicity, only dexrazoxane has been able to significantly retard development of cardiotoxicity. The reversal of doxorubicin-induced multidrug resistance has been attempted using a variety of pharmacologic modulators, such as trifluoperazine, verapamil, and cyclosporine, and has met with mixed success.

The dose-limiting acute toxicity of the anthracyclines is myelosuppression, primarily affecting the neutrophils; in the treatment of leukemia, however, this may be considered a desirable side effect. The onset of myelosuppression is usually 7 days after administration, with maximum effect seen at approximately day 10 to 14. Recovery is usually complete by day 21 to 28. Gastrointestinal toxicities are common, including nausea and vomiting, diarrhea, and mucositis. Although not dose-limiting, alopecia also occurs in almost all patients. Although not always readily apparent when it occurs, extravasation of the anthracyclines can lead to severe local tissue damage and deep ulcerations that progress over weeks. These lesions are slow to heal and often require skin grafting, although the graft is not always successful. Once an extravasation has been discovered, the optimal method of management is unknown, although most agree that local measures such as ice packs and subcutaneous injections of saline, steroids, or bicarbonate may be useful. Topical dimethylsulfoxide has been suggested to be a safe and effective approach to reducing the tissue damage associated with anthracycline-induced extravasation.<sup>159,160</sup> The best approach to avoiding extravasation is to take all possible precautions when administering an anthracycline, such as ensuring good blood return on the intravenous line, monitoring the intravenous site carefully, and good patient education.

The anthracyclines are associated with both acute and chronic cardiac toxicity. The less common acute cardiac toxicity includes nonspecific electrocardiographic changes that may be observed during or immediately after the infusion. In its extreme form, this acute toxicity can include a pericarditis-myocarditis syndrome with onset of fever, pericarditis, and congestive heart failure.<sup>161</sup> No association between the acute toxicity and later development of chronic toxicity has been shown. Besides symptomatic management, no specific therapy is recommended for this relatively rare syndrome.

Anthracyclines also produce a dose-dependent congestive myopathy that often leads to congestive heart failure. This typically becomes apparent 4 to 8 weeks after the last anthracycline dose, although it may occur during treatment or years later. The clinical significance of this chronic toxicity has been its inability to treat it, leading to a drug-induced mortality ranging in early reports from 33% to 70%, and in more recent reports to less than 30%. If a sufficiently high cumulative dose is administered, all anthracyclines can cause cardiac toxicity; however, idarubicin and epirubicin are associated with a lower incidence than doxorubicin and daunorubicin. The mechanisms of the chronic cardiotoxicity have been reviewed extensively. To summarize, they include enzymatic-mediated formation of oxygen free radicals that initiate lipid peroxidation and a nonenzymatic pathway for free radical formation.<sup>162</sup> Iron is central to both pathways; it is required to begin hydroxyl radical production in the first pathway, and to form an iron-drug complex in the second. The risk of anthracycline-associated congestive heart failure is increased by the presence of preexisting heart disease or hypertension, prior radiation to the heart or mediastinum, age (generally, children younger than 4 years are more susceptible), prior cyclophosphamide therapy (questionable), and cumulative anthracycline dose. For doxorubicin, a cumulative dose of less than 450 mg/m<sup>2</sup>, in the absence of other risk factors, is rarely associated with cardiomyopathy, whereas as the cumulative dose increases to 550, 600, and 700 mg/m<sup>2</sup>, the incidence increases to 7%, 15%, and 30%, respectively. For daunorubicin, the overall incidence of congestive heart failure is low (approximately 1.2% in a population of 5613 patients), and the incidence was related to the cumulative daunorubicin dose administered.<sup>163</sup> At daunorubicin doses of 550 mg/m<sup>2</sup>, the incidence of congestive heart failure was 4%, whereas at a total dose of 1050 mg/m<sup>2</sup>, the incidence increased to 14%. A retrospective study of idarubicin cardiotoxicity found few clinically significant symptoms at cumulative doses of 290 mg/m<sup>2</sup>, although left ventricular ejection fraction (LVEF) decreased during therapy. A metaanalysis of studies comparing epirubicin and doxorubicin found epirubicin as active as doxorubicin (1:1) and less cardiac toxic (1:1.8).<sup>164</sup>

Patients receiving anthracyclines should be monitored for the onset of cardiomyopathy. The most useful noninvasive test is serial radionuclide angiography, which provides a reproducible measure of LVEF and is sensitive to subclinical cardiac dysfunction. This technique and others have done much to allow earlier detection of subclinical cardiac toxicity and to reduce the mortality associated with it. Management of the cardiomyopathy involves bed rest and afterload reduction.

With continued conservative management, patients may experience a gradual improvement; this improvement, however, may take more than 1 year.

Many different approaches have been tried to prevent anthracycline-induced cardiac toxicity, including analogue synthesis, altering dosing schedules, and the use of biochemical antagonists. Although many of the anthracycline analogues are associated with a lower incidence of toxicity, they still are associated with decreased LVEF, albeit asymptomatic. The use of continuous infusion schedules of anthracyclines has reduced the incidence of cardiac toxicity somewhat, providing a pharmacokinetic basis for the hypothesis that high peak concentrations are associated with an increased incidence of cardiotoxicity.<sup>165</sup> However, this approach is not widely used because of concern over compromising antitumor efficacy, unpredictable toxicities, and logistical issues.

Dexrazoxane (ICRF-187) is the first biochemical antagonist shown in a randomized clinical trial to dramatically reduce the incidence of cardiac toxicity in patients with breast cancer, without altering the antitumor activity of the doxorubicin combination regimen. Although its mechanism is not fully elucidated, dexrazoxane either acts as a free radical scavenger or prevents formation of free radicals.

In addition to oral and intravenous administration, doxorubicin and epirubicin have been administered via the intraarterial route for well-defined, nonresectable metastatic and primary tumors of the liver. Consistent with their metabolic profile, the systemic toxicity for doxorubicin was not reduced using this route of administration, whereas relatively low levels of epirubicin were produced because of substantial first-pass effect. Intrapleural doxorubicin has been used to treat malignant pleural effusions, and intravesical administration is an effective therapy for recurrent, superficial transitional cell bladder carcinoma.

## MITOXANTRONE AND LOSOXANTRONE

Cumulative cardiotoxicity limits the clinical use of the anthracyclines, and much work has been directed at synthesizing related compounds less prone to undergo reductive metabolism to form free radicals.<sup>166,167</sup> and <sup>168</sup> Mitoxantrone, a member of the anthracenedione class of synthetic antitumor compounds, is an example of one effort. It lacks the sugar moiety of the anthracycline drugs, but retains the planar polycyclic aromatic ring structure that permits its intercalation into DNA. More important, mitoxantrone lacks the ability to produce the quinone-type free radicals thought to be responsible for anthracycline-associated cardiac toxicity. Losoxantrone (biantrazole; CI-941) is a member of the anthrapyrazole group of antitumor agents, which are structurally similar to the anthracyclines. The anthrapyrazoles were synthesized to have antitumor activity similar to the anthracyclines, but without cardiotoxicity. The rationale underlying the development of the anthrapyrazoles was to make the electron-deficient quinone chromophore of the anthracyclines more resistant to enzymatic reduction by forming a quasi-iminoquinone. The planar conformation and cationic nature of the anthracyclines, necessary for intercalative binding to DNA, is retained in the anthrapyrazoles. Losoxantrone can also cause cytotoxicity by inhibition of top II.<sup>169</sup> Preclinical studies demonstrated that a number of anthrapyrazoles had a spectrum of activity and potency similar to doxorubicin and were superior to mitoxantrone.

The clinical pharmacokinetics of mitoxantrone and losoxantrone are summarized in [Table 19.6-8](#). Both compounds have very large distribution volumes and are highly protein bound (percentage unbound, <5%).<sup>170,171</sup> Both compounds undergo hepatic metabolism, but the clinical relevance of these metabolites is unknown, as is whether the dosage of either compound should be reduced in patients with hepatic dysfunction. The low urinary recovery for both compounds suggests no dosage adjustment is necessary for patients with mild to moderate renal dysfunction.

Pharmacokinetic Parameter	Mitoxantrone	Losoxantrone
V <sub>d</sub> (L/m <sup>2</sup> )	450-5288	17-409
Percent unbound	~4	5
Terminal half-life (h)	42-189	6-38
Cl <sub>s</sub> (mL/min/m <sup>2</sup> )	180-2150	132-496
Percent dose in urine	4-10	1-16

Cl<sub>s</sub>, systemic clearance; V<sub>d</sub>, steady-state volume of distribution.

**TABLE 19.6-8.** Comparison of Clinical Pharmacokinetic Parameters between the Two Anticancer Drugs Mitoxantrone and Losoxantrone

The primary dose-limiting toxicity of both compounds is myelosuppression, primarily neutropenia, although thrombocytopenia has been reported.<sup>172,173</sup> Cumulative myelosuppression was not noted. At higher doses, moderate nausea and vomiting have been reported, but only mild nausea and vomiting at lower doses. Although mitoxantrone is associated with less cardiotoxicity than the anthracyclines, it can cause decreases in LVEF. For losoxantrone, data for 183 patients showed mild to severe cardiotoxicity in 25 and congestive heart failure in 2 patients.

## DACTINOMYCIN (ACTINOMYCIN D)

Dactinomycin is a member of a class of compounds first isolated from *Streptomyces parvullus*. The only member to be clinically useful, dactinomycin is highly effective in the treatment of Wilms' tumor, Ewing's sarcoma, embryonal rhabdomyosarcoma, and gestational choriocarcinoma. Responses have also been reported in testicular cancer, Kaposi's sarcoma, and lymphoma.<sup>174</sup>

Dactinomycin is composed of a planar tricyclic ring chromophore (phenoxazone) to which two identical cyclic polypeptides are attached.<sup>175</sup> The compound binds to DNA by intercalation, depending on a specific interaction between the polypeptide chains and deoxyguanosine. This interaction blocks the ability of DNA to act as a template for RNA and DNA synthesis in a concentration-dependent manner. Low drug concentrations inhibit RNA synthesis more than higher drug concentrations, which block both RNA and DNA syntheses. Dactinomycin can also cause topoisomerase-mediated single-strand breaks in DNA, although the contribution of these breaks to cytotoxicity is unclear.<sup>176</sup> *In vitro* studies suggest that concomitant actinomycin D and hyperthermia (e.g., 42° or 43°C) resulted in an increased uptake and prolonged retention of actinomycin D.<sup>177</sup>

After an intravenous bolus, dactinomycin has a rapid disappearance phase followed by a long elimination half-life of 36 hours.<sup>178</sup> Dactinomycin is minimally metabolized, is concentrated in nucleated red blood cells, and does not cross the blood-brain barrier. Dactinomycin is primarily eliminated by renal and biliary excretion, although only 30% has been recovered in the urine and stool over the week after a dose. Inadequate data exist to formulate dosage recommendations for use of dactinomycin in patients with renal or hepatic dysfunction.

The dose-limiting toxicity for dactinomycin is myelosuppression, affecting both platelets and neutrophils. Severe nausea and vomiting occur during the first few hours after administration, but these side effects are responsive to antiemetic therapy. Gastrointestinal toxicity manifests primarily as stomatitis, accompanied by pain, and diarrhea may occur. Extravasation of this drug after intravenous use may result in severe soft tissue damage and ulceration. Dactinomycin is a radiation sensitizer, leading to enhanced skin and gastrointestinal toxicity when administered concurrently with radiation.<sup>179</sup> In addition, late radiation damage to lung and liver appears increased, potentially because of the ability of dactinomycin to block repair of radiation-mediated DNA damage. This recall reaction can be observed even when months separate radiation therapy and dactinomycin administration.

#### INTRODUCTION

The microtubule is increasingly recognized as a strategic subcellular target against which to direct therapeutic efforts, owing to the widespread use of the vinca alkaloids in both curative and palliative chemotherapeutic regimens and the successful incorporation of the taxanes in cancer chemotherapeutics. This chapter reviews the vinca alkaloids, taxanes, and estramustine and other novel antimicrotubule agents in early development.

#### MICROTUBULES

Microtubules are integral components of the mitotic spindle, which can be disrupted by the vinca alkaloids, taxanes, and an increasing number of both natural products and synthetic compounds, resulting in metaphase arrest in dividing cells.<sup>1,2 and 3</sup> However, they are also involved in nonmitotic functions, such as chemotaxis, membrane and intracellular scaffolding, transport, secretory processes, anchorage of subcellular organelles and receptors, cell adhesion, and locomotion transmission of receptor signaling. Antimicrotubule agents may disrupt a range of these nonmitotic functions.<sup>1,2 and 3</sup>

Microtubules are polymers of dimeric subunits of  $\alpha$ - and  $\beta$ -tubulin (each tubulin subunit consisting of approximately 450 amino acids with a molecular weight of 50,000 D) that are arranged into 13 protofilaments ([Fig. 19.7-1](#)).<sup>1,2,3 and 4</sup> The dimers are aligned side by side around an apparently hollow core with the  $\beta$  subunit of one dimer in contact with the  $\alpha$ -tubulin subunit of the next. The microtubule polymer is in a dynamic equilibrium with the intracellular pool of tubulin dimers, which results in the simultaneous incorporation of free dimers into the polymerized structures and release of dimers into the soluble tubulin pool. The direction of the equilibrium—toward polymerization or depolymerization—is influenced by several cofactors, including guanosine triphosphate (GTP), the ionic environment, and microtubule-associated proteins (MAPs), which is a family of proteins that regulate tubulin polymerization and microtubule function (discussed later in the section [Microtubule-Associated Proteins and Microtubule Motors](#)). Microtubule growth occurs spontaneously at the plus end, resulting in the hydrolysis of GTP, which weakens the binding affinity of tubulin for adjacent molecules. This, in turn, favors the opposing process: depolymerization. Net shortening occurs at the opposite minus end. In essence, microtubules are under the control of two dynamic processes. The first is dynamic instability, which is the process whereby microtubule ends switch spontaneously and stochastically between slowly growing and rapidly shrinking states.<sup>4</sup> The rate of dynamic instability is accelerated during some processes, such as mitosis, so that chromosomes can readily be “captured” by growing microtubules, thereby leading to the formation of mitotic spindles; dynamic instability is suppressed, perhaps by MAPs, during nonproliferative processes (e.g., differentiation). When both these actions occur simultaneously, the microtubule is said to be *treadmilling*, which plays a role in the polar movement of the chromosomes during anaphase.<sup>5</sup>

**FIGURE 19.7-1.** Microtubules are composed mainly of dimeric subunits of  $\alpha$ - and  $\beta$ -tubulin that are arranged into protofilaments. The cylindrical microtubule is approximately 25 nm in diameter and may reach several micrometers in length. (From I Ringel, IR Horwitz, Paclitaxel affects microtubule dynamics and apoptosis. *Adv Onco* 1999;15:1, with permission.)

There are at least six isotypes of both  $\alpha$ - and  $\beta$ -tubulin in humans; they are distinguished by slightly different amino acid sequences and appear to be encoded by different genes.<sup>6,7,8 and 9</sup> The C-terminal amino acid sequence of  $\beta$ -tubulin is the most variable in terms of amino acid composition, and both posttranslational modifications, including phosphorylation and glutamylation (which may account in part for their structural diversity) have been described.<sup>9,10</sup> Equivalent isotypes expressed in specific tissues of different species are highly conserved, indicating that expression of tubulin isotypes may be important in specific microtubule functions.<sup>7,8,9 and 10</sup> Analysis of tubulin isotype expression in various tissues has demonstrated a complex pattern of isotype distribution, suggesting functional specificity.<sup>7,8,9 and 10</sup> In neurons, for example, isotype segregation within cells, and both differential isotype synthesis and posttranslational modification during neurite outgrowth, suggest functional specialization. A third member of the tubulin superfamily,  $\gamma$ -tubulin, which is less abundant than the  $\alpha$  and  $\beta$  forms, completes the microtubule-organizing center (MTOC) or centrosome.<sup>11</sup> Although tubulin can polymerize into microtubules in acellular preparations, they are polymerized from, and nucleated by, the MTOC, with minus ends located at the MTOC.<sup>12</sup> The MTOC in the cytoplasm of mammalian cells duplicates and separates before cell division,

forming the two poles of the mitotic spindle.

## MICROTUBULE-ASSOCIATED PROTEINS AND MICROTUBULE MOTORS

The dynamic behavior of microtubules is regulated by a variety of MAPs.<sup>1,2</sup> and<sup>3</sup> The number of MAPs identified is increasing rapidly, and these proteins appear to be diverse, differing from species to species and cell type to cell type. Among the best characterized MAPs are those that come from mammalian brain, including the tau proteins, MAP1, MAP1c (an adenosine triphosphatase), MAP2, MAP4, and dynein (a GTPase), which promote tubulin polymerization and microtubule stability. Some MAPs, such as the dyneins and kinesins, function as microtubule motors, transmitting chemical energy to mechanical sliding force and moving various solutes and subcellular organelles along the microtubule.<sup>1,2</sup> and<sup>3,13</sup> Motor proteins function in many types of cellular events, such as mitosis, premeiotic events, and organelle transport.

## VINCA ALKALOIDS

The vinca alkaloids are naturally occurring or semisynthetic compounds that are found in minute quantities in the periwinkle plant *Catharanthus roseus* g. Don.<sup>14,15,16,17,18,19,20,21,22</sup> and<sup>23</sup> The early medicinal uses of this plant led to the screening of these compounds for their hypoglycemic activity, which was of little importance as compared to their cytotoxic effects. Although many vinca alkaloids have been investigated clinically, only vincristine (VCR), vinblastine (VBL), and vinorelbine (VRL) are approved for use in the United States. The vinca alkaloids are dimeric molecules composed of two multiringed units ( Fig. 19.7-2), an indole nucleus (catharanthine) and a dihydroindole nucleus (vindoline). VCR and VBL are structurally identical except for a single substitution on the vindoline nucleus, where VCR and VBL possess formyl and methyl groups, respectively. Despite this small difference, these two agents significantly differ in their antitumor and toxicologic profiles. VCR is used more commonly in pediatric oncology than in adults with cancer, most likely owing to the higher level of sensitivity of pediatric malignancies to VCR and to the better tolerance of higher VCR doses in children. VCR is an essential part of the combination chemotherapeutic regimens used for acute lymphocytic leukemia and lymphoid blast crisis of chronic myeloid leukemia and plays an important role in the treatment of both Hodgkin's and non-Hodgkin's lymphomas. The agent also plays a role in the multimodality therapy of Wilms' tumor, Ewing's sarcoma, neuroblastoma, and rhabdomyosarcoma in children, as well as in the treatment of multiple myeloma and small cell lung cancer in adults. VBL has been an integral component of chemotherapeutic regimens for germ cell malignancies and advanced lymphoma and is used in combination with other agents to treat Kaposi's sarcoma and bladder, brain, and breast cancers.<sup>14,15,16</sup> and<sup>17</sup>

FIGURE 19.7-2. Structural modifications of the vindoline and catharanthine rings in various vinca alkaloids.

Deacetyl VBL (vindesine, or VDS), initially identified as a metabolite of VBL, was introduced in the 1970s.<sup>18</sup> VDS is registered in many countries but available only for investigational purposes in the United States. The agent is most commonly used in combination with other agents, particularly the platinating agents or mitomycin C (or both), in treating non-small cell lung cancer, but it is also active in several hematologic and solid neoplasms.<sup>17,18</sup> The semisynthetic VBL derivative VRL (5'-norhydro-VBL), which is structurally modified on its catharanthine nucleus, is approved in the United States for treating non-small cell lung cancer as either a single agent or in combination with cisplatin and has been registered for advanced breast cancer in many other countries.<sup>19,20</sup> VRL has also demonstrated anticancer activity in advanced ovarian carcinoma and lymphoma; however, a unique role in the therapy of these malignancies has not been defined.

## MECHANISM OF ACTION

The principal mechanism of cytotoxicity of the vinca alkaloids is by interacting with tubulin and disrupting microtubule function, particularly of microtubules that compose the mitotic spindle apparatus, leading to metaphase arrest.<sup>21,22,23,24</sup> and<sup>25</sup> However, they are also capable of many other biochemical and biologic activities that may or may not be related to their effects on microtubules.<sup>26</sup> In support of antimicrotubule actions or, more specifically, antimitotic actions as the principal cytotoxic effect of the vinca alkaloids is that the dissolution of the mitotic spindle apparatus, appearance of mitotic figures, and cytotoxicity strongly correlate with both the duration and concentration of drug treatment.<sup>26</sup> Nevertheless, the vinca alkaloids and other antimicrotubule agents also affect both nonmalignant and malignant cells in the nonmitotic cell cycle, which is not surprising, as microtubules are involved in many nonmitotic functions.

The vinca alkaloids bind to sites on tubulin that are distinct from the binding sites of the taxanes, colchicine, podophyllotoxin, and GTP.<sup>20,21,22,23,24</sup> and<sup>25</sup> Binding is rapid and readily reversible. There appear to be two binding sites per mole of tubulin dimer. Vinca alkaloid binding to tubulin induces tubulin to self-associate into nonmicrotubule polymers and ordered aggregates through a self-association pathway, which in turn increases the affinity of one of the binding sites for the drug. The vinca alkaloid self-association of tubulin can lead to the formation of paracrystalline structures *in vitro*, which generally occurs at high drug concentrations. The vinca alkaloids bind to their binding sites in intact microtubules with different affinities, depending on whether the binding sites are located at the microtubule ends or situated along the microtubule surface.<sup>25</sup> There are approximately 16 to 17 high-affinity binding sites per microtubule ( $K_d$ , 1 to 2  $\mu$ mol) located at the ends of each microtubule. Binding of the vinca alkaloids to these sites disrupts microtubule assembly. The main effect of low drug concentrations is to decrease the rates of both growth and shortening at the assembly end of the microtubule, which in effect produces a "kinetic cap" and suppresses function.<sup>21,22,23,24</sup> and<sup>25</sup> The potent kinetic suppression of tubulin exchange that occurs at low vinca alkaloid concentrations (<1  $\mu$ mol) is almost certainly due to drug binding at the high-affinity sites at the microtubule ends. This action suppresses dynamic instability and increases the time that microtubules spend in a state of attenuated activity, neither growing nor shortening. The disruptive effects of the vinca alkaloids on microtubule dynamics, particularly at the ends of the mitotic spindle, which leads to metaphase arrest, occur at drug concentrations below those that decrease microtubule mass. There are also one to two low-affinity binding sites per mole of tubulin dimer ( $K_d$ , 0.25 to 3.0 mmol) along the microtubule surface.<sup>25</sup> Binding of the vinca alkaloids to these sites appears to be responsible for the splaying of microtubules into spiral aggregates or spiral protofilaments, which leads to microtubule disintegration. This effect occurs at high drug concentrations (>1 to 2  $\mu$ mol) by a self-propagated mechanism, initially involving drug binding to a limited number of sites, which progressively weakens the lateral interactions between the protofilaments and thereby exposes new sites. Spiral protofilaments may then associate to form paracrystals.

Despite the wide range of sensitivities of different tissues to the actions of the vinca alkaloids *in vivo*, the qualitative effects of these agents on tubulin, as well as both tubulin-binding and inhibitory constants, are similar. The differential sensitivities of various tissues appear to be multifactorial. One of the most likely explanations is that each tissue type has a distinct tubulin isotype composition and that vinca alkaloid sensitivity is, in part, tubulin isotype-dependent. In addition, differences in the tissue content of cofactors, such as MAPs and GTP, which may influence drug interactions with tubulin, and variability in cellular permeation and retention may influence the formation and stability of vinca alkaloid-tubulin complexes.<sup>26,27,28,29,30,31,32,33,34,35</sup> and<sup>36</sup> Differences in the pharmacokinetics between the vinca alkaloids may also contribute to differential tissue sensitivity.

The vinca alkaloids are rapidly taken up into cells and then accumulate intracellularly, with intracellular-extracellular concentration ratios as high as 5- to 500-fold, depending on the cell type.<sup>37,38</sup> and<sup>39</sup> In murine leukemia cells, the intracellular concentrations of VCR are 5- to 20-fold higher than the extracellular concentrations, and this ratio has been reported to range from 150- to 500-fold for other vinca alkaloids in human leukemia cell lines.<sup>40</sup> In isolated human hepatocytes, VRL is more rapidly taken up and metabolized than other vinca alkaloids.<sup>39,40</sup> There are also marked differences in cellular retention between the vinca alkaloids.<sup>31,39,41,42,43</sup> VBL is retained to a much greater degree than either VCR or VDS. Overall, the most important determinant of the rates of drug accumulation and retention is lipophilicity.<sup>39</sup> Drug uptake and retention may also be tissue-specific as well as drug-specific, as illustrated by studies indicating that the accumulation and retention of VRL in

neurons are much less than with other vinca alkaloids.<sup>31</sup>

It was originally believed that the vinca alkaloids entered cells by both energy-dependent and temperature-dependent transport processes.<sup>39</sup> However, it appears that temperature-independent, nonsaturable mechanisms, analogous to simple diffusion, account for the majority of drug transport, and temperature-dependent, saturable processes are less important.<sup>39,40</sup> and <sup>41</sup> Although the drug concentration and duration of treatment are important determinants of both drug accumulation and cytotoxicity, the duration of drug exposure above a critical threshold concentration appears to be the most important determinant.<sup>41,42</sup>

## MECHANISMS OF RESISTANCE

Two mechanisms of resistance to the vinca alkaloids *in vitro* have been well characterized. The first is pleiotropic or multidrug resistance (MDR), which can be innate or acquired. MDR-mediating proteins include permeability glycoprotein (P-gp), MDR protein, and lung resistance protein, which are overexpressed in resistant cells and function as drug efflux pumps.<sup>43,44,45,46,47,48,49</sup> and <sup>50</sup> The best characterized mechanism is mediated by the 170-kD P-gp drug efflux pump that is encoded by the *mdr1* gene and results in decreased drug accumulation. The MDR phenotype confers varying degrees of cross-resistance to other structurally bulky natural products, such as the taxanes, anthracyclines, epipodophyllotoxins, and colchicine.<sup>44,45,46,47,48,49</sup> and <sup>50</sup> The amino acid sequence of the specific P-gp associated with resistance to the vinca alkaloids differs slightly from P-gp of cells selected for resistance to other agents.<sup>47,48</sup> These proteins also undergo posttranslational modifications, resulting in further structural diversity, which may explain the greater degree of resistance for the specific agent, in which resistance was selected against, and the variable degrees of resistance to agents aside from that specific agent. The composition of membrane gangliosides in VCR-resistant cells has also been demonstrated to be different from wild-type cells, which may have functional significance.<sup>49</sup> The clinical ramifications of these mechanisms are not entirely known. In one study in childhood acute lymphoblastic leukemia, VCR resistance measured *in vitro* did not correlate with P-gp overexpression.<sup>50</sup> Although many types of agents reverse resistance conferred by P-gp *in vitro* and the role of MDR modulators has been a source of great contemporary interest, the interpretation of clinical studies of resistance modulation has been confounded by the fact that MDR modulators also enhance drug uptake in normal cells, decrease biliary elimination and drug clearance, and lead to enhanced toxicity.<sup>51,52</sup> Overall, strategies aimed at reversing resistance to the vinca alkaloids in the clinic with pharmacologic modulators of MDR have been disappointing.<sup>52</sup>

Structural and functional alterations in  $\alpha$ - and  $\beta$ -tubulins, resulting from either genetic mutations or posttranslational modifications, have also been identified in tumor cells with acquired resistance to the vinca alkaloids.<sup>53,54</sup> and <sup>55</sup> Tubulin alterations may result in either decreased drug-binding affinity of the altered tubulin or increased resistance to microtubule disassembly. These “hyperstable” microtubules are collaterally sensitive to the taxanes, which inhibit microtubule disassembly (discussed later in [Taxanes, Mechanisms of Resistance](#)). Although the precise mechanisms that lead to cell death after treatment with the vinca alkaloids are not entirely clear, these mechanisms appear similar to those that have been elucidated for the taxanes and involve the action of such genes as *p53*, *bcl-2*, and *bcl-x* and gene products that trigger programmed cell death or apoptosis after significant microtubule disruption.<sup>56,57</sup>

## PHARMACOLOGY

### General Overview

The vinca alkaloids are usually administered intravenously as a brief infusion, and their pharmacokinetic behavior in plasma is optimally described by three-compartment models. [Table 19.7-1](#) displays several pertinent pharmacokinetic features of these agents. At conventional adult doses, peak plasma concentrations range from 100 to 500 nmol, but levels of this magnitude are sustained in plasma for only short periods (alpha half-lives, <5 minutes).<sup>15,17,18</sup> and <sup>19,40,58,59,60</sup> and <sup>61</sup> The vinca alkaloids share many pharmacokinetic characteristics, including large volumes of distribution, high clearance rates, and long terminal half-lives, which reflect the high magnitude and avidity of drug binding in peripheral tissues. There is also great interindividual and intraindividual variability in their pharmacologic behaviors, which has been attributed to many factors, including differences in protein binding and both hepatic and biliary clearance.<sup>40</sup> Although it has been proposed that prolonged infusion schedules may avoid excessive toxic peak concentrations and increase the duration of drug exposure in plasma above biologically relevant threshold concentrations for any given tumor, there is little (if any) evidence to support the notion that prolonged infusion schedules are more effective than bolus schedules. This approach has primarily been directed at achieving plasma concentrations that likely underestimate drug concentrations in peripheral tissues where binding is high and avid, owing to the ubiquitous nature of tubulin.

	Vincristine	Vinorelbine	Vindesine	Vincetabine
Usual adult dose (mg/m <sup>2</sup> )	1-2	3-4	1-4	3-8
Pharmacokinetic behavior	Triphasic	Triphasic	Triphasic	Triphasic

SQU, syndrome of inappropriate secretion of antidiuretic hormone.

**TABLE 19.7-1.** Vinca Alkaloids: Comparative Pharmacokinetic and Toxicologic Characteristics

In comparative studies of the vinca alkaloids, VCR had the longest terminal half-life and the lowest clearance rate, VBL had the shortest terminal half-life and the highest clearance rate, and VDS had intermediate characteristics.<sup>15,18,19</sup> and <sup>20,59,60</sup> Comparable values for VLR overlap with those of VDS and VBL. The longest half-life and lowest clearance rate of VCR may account for its greater propensity to induce neurotoxicity,<sup>58,59</sup> but there are many other nonpharmacologic determinants of tissue sensitivity (discussed earlier in the section [Mechanism of Action](#) under Vinca Alkaloids).

### Vincristine

After conventional doses of VCR (1.4 mg/m<sup>2</sup>) given as brief infusions, peak plasma levels approach 0.4  $\mu$ mol.<sup>15,17,18,62,63</sup> VCR binds extensively to both plasma proteins (48%) and formed blood elements, particularly platelets, which contain high concentrations of tubulin and led, in the past, to the use of VCR-loaded platelets for treating disorders of platelet consumption, such as idiopathic thrombocytopenia purpura.<sup>17</sup> The platelet count inversely has been demonstrated to influence drug exposure.<sup>17,64</sup> Penetration of VCR across the blood–brain barrier is poor, probably because of its large size and the fact that it is an avid substrate for the multidrug transporter pumps that maintain the integrity of the blood–brain barrier.<sup>15,18,40,64,65,66,67,68</sup> and <sup>69</sup> Plasma clearance is slow, and terminal half-lives range from 23 to 85 hours.<sup>15,17,18,40,58,59,62</sup>

VCR is metabolized and excreted primarily by the hepatobiliary system. Seventy-two hours after the administration of radiolabeled VCR, approximately 12% of the radiolabel is excreted in the urine (50% of which consists of metabolites), and approximately 70% is excreted in the feces (40% of which consists of metabolites).<sup>15,18,40,63,65,66,70</sup> The nature of the VCR metabolites identified to date, as well as the results of metabolic studies *in vitro*, indicate that VCR metabolism is mediated by hepatic cytochrome P-450 CYP3A.<sup>15,18,40</sup> There has been conflicting, albeit sparse, evidence indicating that peak VCR plasma concentration or systemic exposure correlates positively with the degree of neurotoxicity.<sup>15</sup>

### VINBLASTINE

The clinical pharmacology of VBL is similar to that of VCR. Binding of VBL to plasma proteins and formed elements of blood is extensive.<sup>40,71,72</sup> Peak plasma drug concentrations are approximately 0.4  $\mu$ mol after rapid intravenous injections of VBL at standard doses. Distribution is rapid, and terminal half-lives range from 20 to 24 hours.<sup>17,40,58,59,66,72,73</sup> Tissue sequestration appears to be greater for VBL than VCR, with 73% of radioactivity retained in the body 6 days after treatment with

radiolabeled drug.<sup>72</sup> Like VCR, VBL disposition is principally through the hepatobiliary system.<sup>40</sup> Fecal excretion of the parent compound is low, indicating that the metabolism is significant. *In vitro* studies indicate that the cytochrome P-450 CYP3A isoform is primarily responsible for the drug biotransformation.<sup>40,73</sup> Although the metabolic fate of VBL has not been fully characterized, 4-deacetyl-VBL, or VDS, which appears to be as active as the parent compound, is the principal metabolite of VBL.<sup>72</sup>

## VINDESINE

VDS is rapidly distributed to tissues, and terminal half-lives range from 20 to 24 hours.<sup>18,40,58,59,69,74,75,76,77,78</sup> and <sup>79</sup> The large volume of distribution, low renal clearance, and long terminal half-life of VDS suggest that it undergoes extensive tissue binding and delayed elimination and that drug accumulation may occur with repeated administration at short intervals. Although peak VDS concentrations ranging from 0.1 to 1.0  $\mu\text{mol}$  are achieved with rapid injections, levels typically decline to less than 0.1  $\mu\text{mol}$  in 1 to 2 hours after treatment. Plasma levels achieved with rapid injections are approximately 16-fold higher than those achieved with protracted infusions; however, prolonged periods of exposure above concentrations resulting in cytotoxicity *in vitro* (0.01 to 0.1  $\mu\text{mol}$ ) are readily achieved using protracted infusions (1.2 to 2.0  $\text{mg}/\text{m}^2/\text{d}$  for 2 to 5 days).<sup>18,40,62,76,77,78,79</sup> and <sup>80</sup> Renal clearance is negligible, accounting for 1% to 12% of drug disposition.<sup>18,40,77,79</sup> Similar to the other vinca alkaloids, VDS disposition is primarily by hepatic metabolism and biliary clearance, and the cytochrome P-450 isoform CYP3A plays a major role in drug metabolism.<sup>18,40,67,81,82</sup>

## VINORELBINE

The pharmacologic behavior of VRL is essentially similar to that of the other vinca alkaloids, with plasma concentrations declining in either a biexponential or triexponential manner.<sup>17,19,20,40,83,84</sup> and <sup>85</sup> After intravenous administration, there is a rapid decay of VRL concentrations followed by a much slower elimination phase (terminal half-life, 18 to 49 hours). Plasma protein binding has been reported to range from 80% to 91%, with binding primarily to a  $\gamma$ -acid glycoprotein, albumin, and lipoproteins,<sup>19,20,40,86</sup> and drug binding to platelets is also extensive. The unbound fraction has been reported to range from 0.09 to 0.20.<sup>19</sup>

VRL is widely distributed, and high concentrations are found in virtually all tissues, except brain.<sup>19,20,40,87,88</sup> The wide distribution of VRL reflects the agent's lipophilicity, which is among the highest of the vinca alkaloids.<sup>22</sup> In fact, drug concentrations in human lung have been demonstrated to be 300-fold greater than plasma levels and 3.4- to 13.8-fold higher than lung concentrations achieved with VDS and VCR, respectively.<sup>87</sup> As with other vinca alkaloids, the liver is the principal excretory organ, and 33% to 80% of the drug is excreted in the feces, whereas urinary excretion represents only 16% to 30% of total drug disposition, the bulk of which is unmetabolized VLR.<sup>18,19,40,89,90</sup> Studies in humans indicate that 4-O-deacetyl-VRL, 3,6-epoxy-VRL, and several hydroxy-VRL isomers are the principal metabolites.<sup>19,20,90</sup> Although most metabolites are inactive, deacetyl-VRL may be as active as VRL. The cytochrome P-450 CYP3A isoenzyme appears to be principally involved in biotransformation.<sup>19,20,40</sup> Human studies of powder- and liquid-filled gelatin capsules have shown that bioavailability of the parent compound is 43% for the powder-filled and 27% for the liquid-filled capsules.<sup>85,91</sup> Plasma concentrations peak within 1 to 2 hours after oral treatment, and interindividual variability is moderate.

## DRUG INTERACTIONS

Methotrexate accumulation in tumor cells is enhanced *in vitro* by the presence of VCR or VBL, an effect mediated by a vinca alkaloid-induced blockade of drug efflux; however, the minimal concentrations of VCR required to achieve this effect occur only transiently *in vivo*.<sup>92,93</sup> and <sup>94</sup> The vinca alkaloids also inhibit the cellular influx of the epipodophyllotoxins *in vitro*, resulting in less cytotoxicity, but the clinical ramifications of this effect are unknown.<sup>95</sup> L-Asparaginase may reduce the hepatic clearance of the vinca alkaloids, particularly VCR, which may result in increased toxicity. To minimize the possibility of this interaction, VCR should be given 12 to 24 hours before L-asparaginase.

Treatment with the vinca alkaloids has precipitated seizures associated with subtherapeutic plasma phenytoin concentrations.<sup>94,96,97</sup> Reduced plasma phenytoin levels have been noted from 24 hours to 10 days after treatment with both VCR and VBL. Because of the importance of the cytochrome P-450 CYP3A isoenzyme in vinca alkaloid metabolism, administration of the vinca alkaloids with erythromycin and other inhibitors of CYP3A may lead to severe toxicity.<sup>98</sup> Concomitantly administered drugs, such as pentobarbital and  $\text{H}_2$ -receptor antagonists, may also influence VCR clearance by modulating hepatic cytochrome P-450 metabolic processes.<sup>94,99</sup> Another potential drug interaction may occur in patients who have Kaposi's sarcoma related to acquired immunodeficiency syndrome (AIDS) and are receiving concurrent treatment with 3' azido-3'-deoxythymidine (AZT) and the vinca alkaloids, as the vinca alkaloids may inhibit glucuronidation of AZT to its 5'-O-glucuronide metabolite.<sup>100</sup>

## TOXICITY

Despite close similarities in structure, the vinca alkaloids differ significantly in their toxicologic profiles. VCR principally induces neurotoxicity characterized by a peripheral, symmetric mixed sensory-motor, and autonomic polyneuropathy.<sup>15,17,18,19</sup> and <sup>20,101,102,103,104</sup> and <sup>105</sup> The primary pathologic effects are axonal degeneration and decreased axonal transport due to interference with microtubule function. Initially, only symmetric sensory impairment and paresthesias in a length-dependent manner (distal extremities first) usually are encountered. Neuritic pain and loss of deep tendon reflexes may develop with continued treatment, which may be followed by foot drop, wrist drop, motor dysfunction, ataxia, and paralysis. Back, bone, and limb pains occasionally occur. Nerve conduction velocities are usually normal, although diminished amplitude of sensory and motor nerve action potentials and prolonged distal latencies, suggesting axonal degeneration, may be noted.<sup>15,101,104,105</sup> Cranial nerves may be affected rarely, resulting in hoarseness, diplopia, jaw pain, and facial palsies. The uptake of VCR into the brain is low, and central nervous system effects, such as confusion, mental status changes, depression, hallucinations, agitation, insomnia, seizures, coma, inappropriate secretion of antidiuretic hormone (SIADH), and visual disturbances, are rare.<sup>15,65,66</sup> and <sup>67,106</sup> Acute, severe autonomic neurotoxicity is uncommon but may arise as a consequence of high-dose therapy (>2  $\text{mg}/\text{m}^2$ ) or in patients with altered hepatic function. Toxic manifestations include constipation, abdominal cramps, paralytic ileus, urinary retention, orthostatic hypotension, and hypertension.<sup>107,108</sup> and <sup>109</sup> Laryngeal paralysis has also been reported.<sup>110</sup>

In adults, neurotoxic effects may begin with cumulative doses as little as 5 to 6 mg, and manifestations may be profound after cumulative doses of 15 to 20 mg. Children may be less susceptible than adults, but the elderly are particularly prone. However, the apparent influence of age may, in fact, be due to previously inadequate dose calculation by body weight in children and adults and by body surface area in infants.<sup>103,104,111,112</sup> In infants, VCR doses are calculated now according to body weight. Patients with antecedent neurologic disorders, such as Charcot-Marie-Tooth disease, hereditary and sensory neuropathy type 1, Guillain-Barré syndrome, and childhood poliomyelitis, are highly predisposed.<sup>113,114</sup> VCR treatment in patients with hepatic dysfunction or obstructive liver disease is associated with an increased risk of developing neuropathy because of impaired drug metabolism and delayed biliary excretion.

The only known treatment for VCR neurotoxicity is discontinuation of the drug or reduction of the dose or frequency of treatment.<sup>116</sup> Although a number of antidotes, including thiamine, vitamin B<sup>12</sup>, folinic acid, and pyridoxine, have been used, these treatments have not been clearly shown to be effective.<sup>15,17,116</sup> However, results with several other protective agents appear promising.<sup>15,17,115,116</sup> In one randomized, double-blind trial, coadministration of glutamic acid and VCR has been demonstrated to decrease neurotoxicity.<sup>15,117</sup> The adrenocorticotrophic hormone (4-9) analogue ORG 2766 has also been shown to protect against VCR-induced neuropathy both in an animal model and in cancer patients in a double-blind, placebo-controlled pilot study.<sup>15</sup> However, the younger age of the ORG 2766-treated group as compared to the placebo group may have accounted for this result. Experimental results indicate that several other agents, such as nerve growth factor, insulin-like growth factor I, and amifostine, might alter the natural course of drug-induced neurotoxicity.<sup>15</sup>

The manifestations of neurotoxicity are similar for the other vinca alkaloids; however, they are typically less common and severe.<sup>15,17,18,19</sup> and <sup>20</sup> Severe neurotoxicity is observed infrequently with both VBL and VDS. VRL has been shown to have a lower affinity for axonal microtubules than either VCR or VBL, which seems to be confirmed by clinical observations.<sup>31,118</sup> Mild to moderate peripheral neuropathy, principally characterized by sensory effects, occurs in 7% to 31% of patients, and constipation and other autonomic effects are noted in 30% of subjects, whereas severe toxicity occurs in 2% to 3%. Muscle weakness, jaw pain, and discomfort at tumor sites may also occur. In a study in patients with non-small cell lung cancer randomly assigned to treatment with either VRL alone, VRL plus cisplatin, or VDS plus cisplatin, the rate of severe neurotoxicity was lower in both the single-agent VRL and VRL plus cisplatin arms than in the VDS plus cisplatin arm.<sup>119</sup> Furthermore, the addition of cisplatin did not significantly increase the incidence of severe toxicity in excess of that observed with VRL alone.

Neutropenia is the principal dose-limiting toxicity of VBL, VDS, and VRL. Thrombocytopenia and anemia are usually less common and less severe. The onset of

neutropenia is usually 7 to 11 days after treatment, and recovery is generally by days 14 to 21. Myelosuppression is not typically cumulative.

Gastrointestinal toxicities, aside from those caused by autonomic dysfunction, may be caused by all the vinca alkaloids. <sup>15,16,17,18,19 and 20,120</sup> Gastrointestinal autonomic dysfunction, as manifested by bloating, constipation, ileus, and abdominal pain, occur most commonly with VCR or high doses of the other vinca alkaloids. Mucositis occurs more frequently with VBL than with VRL or VDS and is least common with VCR. Nausea, vomiting, and diarrhea may also occur to a lesser extent. Pancreatitis has also been reported with VRL. <sup>121</sup>

All vinca alkaloids are potent vesicants and may cause significant tissue damage if extravasation occurs. If extravasation occurs or is suspected, treatment should be discontinued, and aspiration of any residual drug remaining in the tissues should be attempted. <sup>122,123</sup> The application of local heat and the injection of hyaluronidase, 150 mg subcutaneously, in a circumferential manner around the needle site are thought to minimize both discomfort and latent cellulitis. Phlebitis may also occur along the course of an injected vein, with resultant sclerosis. The risk of phlebitis may increase if veins are not adequately flushed after treatment.

Mild and reversible alopecia occurs in approximately 10% and 20% of patients treated with VLR and VCR, respectively. Acute cardiac ischemia, chest pains without evidence of ischemia, fever without an obvious source, acute pulmonary effects (alone or in combination with mitomycin C), Raynaud's phenomenon, hand-foot syndrome, and both pulmonary and liver toxicity have also been reported with the vinca alkaloids. <sup>124,125,126,127,128,129,130 and 131</sup> All the vinca alkaloids have been implicated as a cause of SIADH, and patients who are receiving intensive hydration are particularly prone to severe hyponatremia secondary to SIADH. <sup>15,17,18,19 and 20</sup> This entity has been associated with elevated plasma levels of antidiuretic hormone and usual remits in 2 to 3 days. Hyponatremia generally responds to fluid restriction, as with hyponatremia associated with SIADH due to other causes.

## ADMINISTRATION

VCR is commonly administered to children weighing more than 10 kg as a bolus intravenous injection at a dose of 1.5 to 2.0 mg/m<sup>2</sup> weekly, whereas 0.05 to 0.65 mg/kg weekly is commonly used in smaller children. For adults, the conventional weekly dose is 1.4 mg/m<sup>2</sup>. A restriction of the absolute dose of VCR to 2.0 to 2.5 mg in children and 2.0 mg in adults (often called *capping*) has been adopted based on early reports of substantial gastrointestinal toxicity in small numbers of patients treated at higher doses. However, this practice is largely unfounded, and available evidence suggests that it should be reconsidered, particularly in light of the wide interpatient variability in pharmacokinetic behavior and tolerance. <sup>103</sup> There is significant interpatient variability in the clearance of VCR (as much as 11-fold), and some patients are able to tolerate much higher doses with little or no toxicity. Moreover, the safety and efficacy of treatment regimens that do not employ capping at 2.0 mg have been documented in adults. <sup>132</sup> In any case, doses should not be reduced for mild peripheral neurotoxicity, particularly if the agent is being used in a potentially curative setting. Instead, doses should be modified for manifestations indicative of more serious neurotoxicity, including severe symptomatic sensory changes, motor and cranial nerve deficits, and ileus, until toxicity resolves. In clearly palliative situations, dose reductions, lengthened dosing intervals, or selection of an alternative agent may be justified in the event of moderate neurotoxicity. A routine prophylactic regimen to prevent severe autonomic toxicity, particularly severe constipation, is also recommended.

The most common schedule for VBL in combination chemotherapeutic regimens uses a rapid intravenous injection at a dose of 6 mg/m<sup>2</sup> weekly. Approved dosing recommendations for weekly dosing are 2.5 and 3.7 mg/m<sup>2</sup> for children and adults, respectively, followed by gradual escalation in increments of 1.8 and 1.25 mg/m<sup>2</sup> weekly based on hematologic tolerance. It is recommended that weekly VBL doses of 18.5 mg/m<sup>2</sup> in adults and 12.5 mg/m<sup>2</sup> in children not be exceeded as a single agent; however, these doses are substantially higher than most patients can tolerate because of myelosuppression, even on less-frequent schedules of administration. Because the severity of leukopenia that may occur with identical VBL doses varies widely, VBL should probably not be given more frequently than once each week.

VDS has been administered intravenously on many schedules, including weekly and biweekly bolus and prolonged infusion schedules. The agent has also been given in fractionated doses as either an intermittent or a continuous infusion over 1 to 5 days. VDS is most commonly administered as a single intravenous dose of 2 to 4 mg/m<sup>2</sup> every 7 to 14 days. Intermittent or continuous infusion schedules usually employ VDS doses of 1 to 2 mg/m<sup>2</sup>/d for 1 to 2 days or 1.2 mg/m<sup>2</sup>/d for 5 days every 3 to 4 weeks. <sup>62</sup>

VRL is usually administered at a dose of 30 mg/m<sup>2</sup> on a weekly or biweekly schedule as a 6- to 10-minute intravenous injection through a side-arm port into a running infusion (alternatively, a slow bolus injection followed by flushing the vein with 5% dextrose or 0.9% sodium chloride solutions) or as a short infusion over 20 minutes. <sup>17,18,19 and 20</sup> It appears that the more rapid infusions are associated with less local venous toxicity. Oral doses of 80 to 100 mg/m<sup>2</sup> given weekly are generally well tolerated, but an acceptable oral formulation has not yet been approved. Other dosing schedules that have been evaluated include chronic oral administration of low doses, intermittent high dose, and prolonged intravenous infusion schedules.

The vinca alkaloids are potent vesicants and should not be administered intramuscularly, subcutaneously, intravesically, or intraperitoneally. Direct intrathecal injection of VCR and other vinca alkaloids, which has occurred as an inadvertent clinical mishap, induces a severe myeloencephalopathy characterized by ascending motor and sensory neuropathies, encephalopathy, and rapid death. <sup>133</sup>

Although it has not been carefully evaluated, the major role of the liver in the disposition of the vinca alkaloids implies that dose modifications should be considered for patients with hepatic dysfunction. <sup>134</sup> However, firm guidelines have not been established. A 50% dose reduction is often recommended for patients with total bilirubin levels between 1.5 and 3.0 mg/dL (50% dose reduction for bilirubin levels between 2.0 and 3.0 mg/dL is recommended for VRL), and at least a 75% dose reduction for plasma total bilirubin levels greater than 3.0 mg/dL. Dose reduction for renal dysfunction is not indicated.

## THE TAXANES

The unique chemical structure and mechanism of action of the taxanes, coupled with their antitumor activities against a broad range of cancers, has rendered the taxanes one of the most important new classes of anticancer agents. Interest in the taxanes began in 1963, when a crude extract of the bark of the Pacific yew tree, *Taxus brevifolia*, was shown to have broad activity in preclinical tumor models. In 1971, paclitaxel was identified as the active constituent of the bark extract. <sup>135,136</sup> The initial development of paclitaxel was hampered by the limited supply of its primary source; the difficulties inherent in large-scale isolation, extraction, and preparation of bulk compound for a natural product; and its poor aqueous solubility. <sup>135,136 and 137</sup> Interest was maintained during this time by the characterization of its novel mechanism of cytotoxic action and the availability of an adequate drug supply for requisite preclinical and limited clinical evaluations. The early search for taxanes derived from more abundant and renewable resources led to the development of docetaxel, which is synthesized by the addition of a side chain to 10-deacetylbaccatin III, an inactive taxane precursor found in the needles and other components of more abundant yew species. <sup>137,138</sup> The supply of paclitaxel is no longer a limiting issue because the agent is also produced semisynthetically from 10-deacetylbaccatin III and other abundant precursors.

The structures of paclitaxel, docetaxel, and their precursor 10-deacetylbaccatin III are shown in [Figure 19.7-3](#). The taxanes are complex esters consisting of a 15-member taxane ring system linked to an unusual 4-member oxetan ring. The taxane rings of both paclitaxel and docetaxel (but not 10-deacetylbaccatin III) are linked to an ester side chain attached to the C13 position of the ring, which is essential for antimicrotubule and antitumor activity. The structures of paclitaxel and docetaxel differ in substitutions at the C10 taxane ring position and on the ester side chain attached at C13.

**FIGURE 19.7-3.** Structures of paclitaxel, docetaxel, and a precursor 10-deacetylbaaccatin III.

The most impressive clinical activity of paclitaxel has been in patients with ovarian and breast cancers. <sup>135,136,137,138,139,140 and 141</sup> Paclitaxel initially received regulatory approval in the United States and many other countries for the treatment of patients with ovarian cancer after failure of first-line or subsequent chemotherapy. It subsequently received regulatory approval for patients with advanced breast cancer after failure of combination chemotherapy or at relapse within 6 months of adjuvant chemotherapy. Its use in combination with a platinum compound as primary induction therapy in suboptimally debulked stage III or IV ovarian cancer and as a component of adjuvant chemotherapy after primary local treatment in high-risk patients with early-stage breast cancer has demonstrated a survival advantage in randomized phase III studies. <sup>139,141</sup> Paclitaxel has also received regulatory approval in the United States for second-line treatment of Kaposi's sarcoma associated with AIDS, in combination with cisplatin as primary treatment of non-small cell lung cancer, and as a component of adjuvant chemotherapy in high-risk lymph node-positive breast cancer. <sup>139,140,141,142 and 143</sup>

Docetaxel initially received regulatory approval in the United States for patients with metastatic breast cancer that has progressed on or relapsing after anthracycline-based chemotherapy, which was later broadened to a general second-line indication. <sup>137,138</sup> Its role as a component of adjuvant and neoadjuvant chemotherapy after local treatment of early-stage breast cancer and first-line chemotherapy for locally advanced or metastatic breast cancer is being evaluated. Furthermore, docetaxel has received regulatory approval in many countries for treatment of locally advanced or metastatic non-small cell lung carcinoma and in the United States for treatment of non-small cell lung cancer after failure of cisplatin-based therapy. The clinical antitumor spectra for paclitaxel and docetaxel are similar, with activity noted in many other diverse tumor types that are generally refractory to conventional therapies, including lymphoma, and small cell lung, head and neck, esophageal, endometrial, bladder, and germ cell carcinomas.

## MECHANISMS OF ACTION

Schiff et al., <sup>144</sup> Schiff and Horwitz, <sup>145</sup> and Manfredi et al. <sup>146</sup> initially identified the unique mechanism of action for paclitaxel in 1979. The taxanes bind to tubulin polymers (microtubules) at binding sites that are distinct from exchangeable GTP, colchicine, podophyllotoxin, and the vinca alkaloids. Paclitaxel binds preferentially to the N-terminal 31 amino acids of the  $\beta$ -tubulin subunit, although additional sites of interaction on  $\beta$ -tubulin and  $\alpha$ -tubulin may also be involved. <sup>147,148</sup> The binding of paclitaxel to polymerized tubulin is reversible, with a binding constant of approximately 1  $\mu\text{mol}$ . <sup>146,149</sup> Docetaxel, which most likely shares the same tubulin-binding site as paclitaxel, appears to have a 1.9-fold higher affinity for the site. <sup>149</sup> Tubulin assembly induced by docetaxel also proceeds with a critical protein concentration that is 2.1-fold lower than that of paclitaxel. <sup>149</sup> However, these differences may not translate into greater therapeutic indices for docetaxel in the clinic, as greater potency may also portend more severe toxicity at identical drug concentrations *in vivo*. Nevertheless, the results of both preclinical and clinical studies suggest that the taxanes may not be completely cross-resistant. <sup>150,151</sup>

The taxanes stabilize the microtubule against depolymerization, thereby disrupting normal microtubule dynamics. <sup>2,25,144,145 and 146,152,153,154,155,156 and 157</sup> They profoundly alter the tubulin dissociation rate constants at both ends of the microtubule, suppressing both treadmilling and dynamic instability. Association rate constants are not appreciably affected. The ability of the taxanes to induce polymerization is associated with stoichiometric drug binding to microtubules, which occurs at submicromolar concentrations that are readily achieved in the clinic. At substoichiometric concentrations, the taxanes suppress microtubule dynamics without increasing the amount of polymerized tubulin. <sup>152</sup> Taxane-treated microtubules are very stable, resisting depolymerization by cold, calcium ions, dilution, and other mitotic drugs. This stability inhibits the dynamic reorganization of the microtubule network, which is essential for normal function during both mitosis and interphase.

Both stoichiometric and substoichiometric binding of the taxanes inhibit the proliferation of cells, principally by inducing a sustained mitotic block at the metaphase-anaphase boundary; however, the taxanes also affect interphase microtubules in nonproliferating cells. <sup>25,144,152</sup> Distinct morphologic evidence that the taxanes affect microtubules during interphase and mitosis include the formation of microtubule bundles during the nonmitotic cell cycle phases and multiple mitotic spindle asters during mitosis. <sup>154</sup> Many taxane-induced disturbances in cellular processes lead to apoptosis or programmed cell death (discussed later in the section [Taxanes, Drug Resistance](#), and in [Chapter 7](#)). <sup>56,57,157,158,159,160,161,162,163,164,165 and 166</sup> On removal of the drug after treatment, even at substoichiometric concentrations that do not increase microtubule mass, cells exit from mitosis but do not continue to proliferate. Instead, the cells undergo apoptosis, and cell death ensues in 2 to 3 days. Although the precise mechanism by which microtubule disturbances lead to apoptosis has not been determined, the taxanes interact with numerous substances, including regulatory molecules and oncogenes that bind to the mitotic apparatus. Paclitaxel has been reported to induce transcription factors and enzymes that govern proliferation, apoptosis, and inflammation and, interestingly, some of these effects, such as the induction of tumor necrosis factor- $\alpha$ . <sup>157,167</sup> The taxanes also inhibit angiogenic activity at concentrations below those that induce cytotoxicity. <sup>165,168,169</sup>

Both paclitaxel and docetaxel have been shown to enhance the effects of ionizing radiation *in vitro* at clinically achievable concentrations (<50 nmol) and *in vivo*, which may be related to the inhibition of cell-cycle progression in the  $G_2$  phase, which is the most radiosensitive phase of the cell cycle. <sup>170,171 and 172</sup>

## MECHANISMS OF RESISTANCE

The best characterized mechanism of resistance to the taxanes is the MDR phenotype, mediated by the 170-kD P-gp efflux pump, encoded by the *mdr1* gene (discussed previously in the section [Vinca Alkaloids, Mechanisms of Resistance](#)). <sup>44,45,46,47,48 and 49,173,174</sup> The MDR protein has been shown to be an efficient transporter of the vinca alkaloids but not of the taxanes. <sup>45,175,176</sup> The results of early studies evaluating the role of MDR in the clinic indicate that cross-resistance to the taxanes and anthracycline is incomplete, which has significant clinical ramifications in treating breast cancer. <sup>140</sup> Strategies aimed at reversing drug resistance in the clinic with various types of P-gp substrates and inhibitors are also being evaluated, but the interpretation of the results is confounded by the effects of P-gp modulators on taxane clearance. <sup>177,178</sup>

Several taxane-resistant mutant cell lines that have structurally altered  $\alpha$ - and  $\beta$ -tubulin proteins and an impaired ability to polymerize into microtubules also have been identified (discussed previously in the section [Vinca Alkaloids, Mechanisms of Resistance](#)). <sup>54,157,179</sup> These mutants lack normal interpolar mitotic spindles and have an inherently slow rate of microtubule assembly, which is normalized in the presence of the drug. Mutants with "hypostable" microtubules exhibit collateral sensitivity to the vinca alkaloids. A number of cell lines resistant to tubulin-binding agents, including the taxanes, have been shown to have alterations in tubulin content, expression of tubulin isotypes, tubulin polymerization dynamics, or tubulin isotype content. <sup>180,181,182,183,184 and 185</sup> Mutations of tubulin isotype genes have also been reported in taxane-resistant cell lines, and  $\beta$ -tubulin gene mutations have been reported to be a strong determinant of paclitaxel resistance in a series of patients with non-small lung cancer. <sup>186</sup>

The regulation and integrity of genes that regulate apoptosis, such as *p53*, *bcl-2*, and *bcl-x*, may be determinants of sensitivity to the taxanes. <sup>56,57,157,162,163 and 164,187,188</sup> MAPs are also likely to be involved in these mechanisms of resistance to drug-induced apoptosis, as illustrated by the fact that MAP4, which is negatively regulated by wild-type *p53*, has been shown to increase the sensitivity to paclitaxel. <sup>189,190</sup> It has been proposed that paclitaxel induces apoptosis through two different mechanisms—a *p53*-independent pathway in cells blocked in prophase and a *p53*-dependent mechanism in cells that accumulate in the  $G_1$  cell-cycle phase—and requires functional *p53*. <sup>157,191</sup> However, there are conflicting experimental data as to the role of *p53* as a determinant of cell sensitivity to paclitaxel and other antitumor agents. Several lines of experimental evidence suggest that the induction of *p53* in cells treated with paclitaxel represents a mechanism of drug resistance. <sup>192,193</sup> The taxanes have been also shown to modulate the function of genes involved in apoptotic regulation and in the disruption of microtubule dynamics by paclitaxel and other antimicrotubule drugs, and docetaxel results in the phosphorylation of such regulatory proteins as Bcl-x<sub>L</sub> and Bcl-2, thereby annulling the antiapoptotic functions of these regulators. <sup>194,195</sup>

Interestingly, paclitaxel-resistant cell lines, which have mutations in tubulin and fail to exhibit phosphorylation of Bcl-x<sub>L</sub> after paclitaxel treatment, have been described. <sup>56</sup> These cells demonstrate Bcl-x<sub>L</sub> phosphorylation in the presence of other antimicrotubule agents, suggesting that apoptosis mediated by paclitaxel is related to the drug's ability to interact with microtubules.

## PHARMACOLOGY

The taxanes are commonly administered by intravenous infusion at doses ranging from 175 to 225 mg/m<sup>2</sup> over 3 hours (for paclitaxel) or 75 to 100 mg/m<sup>2</sup> over 1 hour (for docetaxel) every 3 weeks. Various other administration schedules have been evaluated (discussed later in the section [Administration, Dose, and Schedule](#)). The oral bioavailability of both paclitaxel and docetaxel is poor, owing in part to the constitutive overexpression of P-gp by enterocytes or first-pass metabolism in the liver or intestines (or both). However, biologically relevant plasma concentrations are transiently achieved if the taxanes are administered orally after treatment with oral cyclosporin or other modulators of P-gp and cytochrome P-450 mixed-function oxidases.<sup>196,197</sup> As shown in [Table 19.7-2](#), paclitaxel and docetaxel share the following pharmacologic characteristics: large volumes of distribution, rapid and avid binding to all tissues except for the unperturbed central nervous system, long terminal half-lives and substantial hepatic metabolism, biliary excretion, and fecal elimination.

	Paclitaxel	Docetaxel
Standard adult dose range (mg/m <sup>2</sup> /7 d)	175–225 (24 infusion), 175–225 (24 infusion)	75–100 (16 infusion)
Pharmacokinetic behavior	Biphasic elimination and distribution	Triphasic
Plasma half-life (terminal)	16–20 h	16–20 h
Clearance	24–51 L/h	30 L/h
Primary route	Hepatic metabolism and biliary elimination	Hepatic metabolism and biliary elimination
Principal toxicity	Neutropenia	Neutropenia
Other toxicities	Alpecia, mucositis, emphyse, hypotension, hypotension, asthenia	Alpecia, skin and nail toxicity, asthenia, neuropathy, hypotension, mucositis, hypotension, asthenia

Dose schedule: 175 mg/m<sup>2</sup> over 3 hours

**TABLE 19.7-2.** Taxanes: Comparative Pharmacokinetic and Toxicologic Characteristics

### Paclitaxel

Pharmacologic studies of paclitaxel on both long and short administration schedules have been performed (discussed later in the section [Administration, Dose, Schedule](#)). In early studies that principally evaluated prolonged (6- and 24-hour) schedules, substantial interpatient variability was noted, and nonlinear, dose-dependent behavior was not observed.<sup>136,137,198</sup> In these studies, drug disposition was characterized as a biphasic process, with values for alpha and beta half-lives averaging approximately 20 minutes and 6 hours, respectively. However, more recent studies of paclitaxel administered on shorter schedules, particularly as a 3-hour infusion, indicate that the pharmacokinetic behavior of paclitaxel is nonlinear.<sup>199,200,201,202</sup> and <sup>203</sup> Nonlinearity occurs with all administration schedules, but it is more apparent with shorter infusions that result in higher plasma paclitaxel concentrations that more effectively saturate both drug elimination and tissue distribution processes. Both saturable distribution and elimination processes may be, in part, responsible for paclitaxel's nonlinear behavior, with tissue distribution becoming effectively saturated at lower drug concentrations (achieved with paclitaxel doses <175 mg/m<sup>2</sup> over 3 hours) compared to elimination processes that are effectively saturated at higher concentrations (achieved with paclitaxel doses >175 mg/m<sup>2</sup> over 3 hours). The use of shorter infusion schedules also results in higher plasma concentrations of paclitaxel's polyoxyethylated castor oil vehicle, which may also be responsible for this nonlinearity.<sup>202</sup> This nonlinear profile may have several important clinical implications, particularly regarding dose modifications, because dose escalation may result in a disproportionate increase in drug exposure and hence toxicity, whereas dose reductions may result in a disproportionate decrease in drug exposure, thereby decreasing antitumor activity.

Paclitaxel's volume of distribution is much larger than the volume of total body water, indicating extensive drug binding to plasma proteins or other tissue elements, probably tubulin. Plasma protein binding is high (>95%) and readily reversible.<sup>198</sup> Drug binding to platelets is extensive and saturable, and animal distribution studies with radiolabeled paclitaxel indicate extensive drug uptake and retention by virtually all tissues, except for the normal brain and testes.<sup>204</sup> In humans, peak plasma concentrations achieved with 3- to 96-hour schedules (>0.05 to 10 μmol) and drug concentrations in third-space fluid collections, such as ascites (>0.1 μmol), are capable of inducing significant biologic effects *in vitro*, but drug penetration into the normal central nervous system is negligible.<sup>198,204,205</sup>

The liver is the principal organ involved with paclitaxel clearance, which metabolizes and excretes both paclitaxel and metabolites into the bile.<sup>198,206,207,208</sup> and <sup>209</sup> Ninety-eight percent of radioactivity is recovered from feces collected for 6 days after rats are treated with radiolabeled paclitaxel, and approximately 71% of an administered dose of paclitaxel is excreted in the feces over 5 days as either parent compound or metabolites in humans, with 6a-hydroxypaclitaxel being the largest component and accounting for 26% of the dose. Only 5% is unchanged paclitaxel. Renal clearance of paclitaxel and metabolites is minimal, accounting for 14% of the administered dose.<sup>198</sup> In humans, cytochrome P-450 mixed-function oxidases are responsible for the bulk of drug disposition, specifically the isoenzymes CYP2C8, and CYP3A4, which metabolize paclitaxel to hydroxylated 6a-hydroxypaclitaxel (major) and another hydroxylated metabolite, both of which are inactive.

Pharmacodynamic analyses as part of individual phase I and II trials demonstrated that several pharmacokinetic indices of drug exposure can be related to the various toxicities of paclitaxel, the most important and consistent of which is the relationship between the severity of neutropenia and the duration of drug exposure above biologically relevant plasma concentrations ranging from 0.05 to 0.1 μmol.<sup>198,199,200</sup> and <sup>201,210</sup> However, a prospective analysis of pharmacokinetic determinants of outcome in several hundred patients with advanced non-small cell lung cancer treated with the combination of cisplatin and paclitaxel at either 135 or 250 mg/m<sup>2</sup> over 24 hours demonstrated that the magnitude of the steady-state plasma paclitaxel concentration correlated poorly with antitumor activity, disease-free survival, and overall survival.<sup>211</sup>

### Docetaxel

The pharmacokinetics of docetaxel on a 1-hour schedule are linear at doses of 115 mg/m<sup>2</sup> or less and optimally fit a three-compartment model.<sup>137,138,212,213,214,215</sup> and <sup>216</sup> Terminal half-lives ranging from 11.1 to 18.5 hours have been reported. In one population study, plasma concentration data were optimally fit by a three-compartment model, and the following pharmacokinetic parameters were generated: *t*<sub>1/2β</sub> of 12.4 hours, clearance of 1 L/h/m<sup>2</sup>, and steady-state volume of distribution of 74 L/m<sup>2</sup>.<sup>212,213</sup> and <sup>214</sup> The most important determinants of docetaxel clearance were the body surface area, hepatic function, and plasma a1-acid glycoprotein concentration, whereas age and albumin level had significant (albeit minor) influences on clearance. As with paclitaxel, plasma protein binding is high (>80% to 90%), and binding is primarily to a1-acid glycoprotein, albumin, and lipoproteins.<sup>213</sup> Docetaxel is also distributed to all tissues except the central nervous system.<sup>212,217</sup> In both dogs and mice treated with radiolabeled drug, fecal excretion accounts for 70% to 80% of total radioactivity, whereas urinary excretion accounts for 10% or less.<sup>212,217</sup> The hepatic cytochrome P-450 mixed-function oxidases, particularly isoforms CYP3A4 and CYP3A5, are primarily involved in biotransformation that, in contrast to paclitaxel, principally affects the C13 side chain and not the taxane ring.<sup>212,213,218,219</sup> and <sup>220</sup>

The main pharmacokinetic determinants of toxicity, particularly the principal toxicity neutropenia, are drug exposure and the time that plasma concentrations exceed biologically relevant concentrations.<sup>213,214</sup> A population pharmacodynamic analysis of determinants of outcome in phase II trials of docetaxel revealed that the most important determinants of the time to progression in patients with metastatic breast cancer are the pretreatment plasma concentration of a1-acid glycoprotein, number of prior chemotherapeutic regimens, and number of disease sites, whereas both drug exposure and the pretreatment plasma concentration of a1-acid glycoprotein were strong positive determinants of time to progression in patients with advanced lung cancer treated with docetaxel.<sup>214</sup> Conversely, the pretreatment plasma level of a1-acid glycoprotein was negatively—albeit significantly—related to the probability of experiencing both severe neutropenia and febrile neutropenia.

## DRUG INTERACTIONS

Both sequence-dependent pharmacokinetic and toxicologic interactions between paclitaxel and several other chemotherapy agents have been noted.<sup>198</sup> The sequence of cisplatin followed by paclitaxel (24-hour schedule) induces more profound neutropenia than the reverse sequence, which is explained by a 33% reduction in the clearance of paclitaxel after cisplatin.<sup>221</sup> The least toxic sequence—paclitaxel before cisplatin—was demonstrated to induce more cytotoxicity *in vitro*; therefore, this drug sequence was selected for further clinical development.<sup>222</sup> However, sequence dependence does not appear to be a clinically relevant

phenomenon on shorter schedules. Treatment with paclitaxel on either a 3- or 24-hour schedule followed by carboplatin has been demonstrated to produce equivalent neutropenia and less thrombocytopenia as compared to carboplatin as a single agent, which is not explained by pharmacokinetic interactions.<sup>223,224</sup> Although sequence dependence has not been noted with carboplatin and paclitaxel in clinical studies, this phenomenon has been noted with other paclitaxel-based chemotherapy combinations, the most important of which involve the anthracyclines.<sup>225</sup> Both neutropenia and mucositis are more severe when paclitaxel on a 24-hour schedule is administered before doxorubicin, compared to the reverse sequence, which is most likely due to an approximately 32% reduction in the clearance of doxorubicin and doxorubicinol when it is administered after paclitaxel.<sup>225,226</sup> Although neither sequence-dependent pharmacologic interactions nor toxicologic interactions between doxorubicin and paclitaxel on a shorter (3-hour) schedule have been noted, pharmacologic interactions occur with both sequences, and combined treatment with paclitaxel (3-hour schedule) and doxorubicin as a bolus infusion has been associated with a higher frequency of congestive cardiotoxicity than would have been expected from an equivalent cumulative doxorubicin dose given without paclitaxel (discussed later in the section [Toxicity](#)).<sup>227</sup> Similar decrements in the clearance of epirubicin and its metabolites have also been noted in studies of paclitaxel combined with epirubicin, but a similar enhancement of cardiotoxicity has not been observed.<sup>228</sup> The precise etiology for these interactions is unclear; however, competition for the hepatic or biliary P-gp transport of the anthracyclines with paclitaxel or its polyoxyethylated castor oil vehicle (or both) is a logical explanation.<sup>226,229</sup> The vehicle is suspected because similar effects have not been noted with docetaxel, which is not formulated in polyoxyethylated castor oil. Hematologic toxicity has been more profound with the sequence of cyclophosphamide before paclitaxel (24-hour schedule) than the reverse sequence.<sup>230</sup> In human tumor xenografts, both paclitaxel and docetaxel have been demonstrated to induce thymidine phosphorylase activity, which may increase the metabolic activation of the oral fluoropyrimidine prodrug capecitabine.<sup>231</sup>

Drug interactions may also result from the effects of other classes of drugs on the cytochrome P-450–dependent metabolism of the taxanes. Various inducers of cytochrome P-450 mixed-function oxidases, such as the anticonvulsants phenytoin and phenobarbital, accelerate in the metabolism of both paclitaxel and docetaxel in human microsomal studies and in both children and adults who are concurrently receiving treatment with these anticonvulsants, as manifested by rapid drug clearance and tolerance of high drug doses.<sup>209,219,232,233</sup> and <sup>234</sup> Conversely, many types of agents that inhibit cytochrome P-450 mixed-function oxidases, such as orphenadrine, erythromycin, cimetidine, testosterone, ketoconazole, fluconazole, midazolam, polyoxyethylated castor oil, and corticosteroids, interfere with the metabolism of paclitaxel and docetaxel in human microsomes *in vitro*; however, the inhibitory concentrations of these agents exceed those achieved in clinical practice, and the clinical relevance of these findings is not known.<sup>207,208</sup> and <sup>209,217,218,219</sup> and <sup>220,235</sup> Although there has been concern that the use of corticosteroids and different H<sub>2</sub>-receptor antagonists with variable cytochrome P-450 inhibitory activities as components of premedication regimens may differentially affect drug clearance and hence toxicity, neither toxicologic nor pharmacologic differences between the agents were noted in a randomized clinical trial.<sup>236</sup>

## TOXICITY

Myelosuppression is the principal toxicity of paclitaxel and docetaxel. However, despite similar structures, these agents differ modestly in their toxicity spectra.

### **Paclitaxel**

Neutropenia is the principal toxicity of paclitaxel. The onset is usually on days 8 to 10, and recovery is generally complete by days 15 to 21. The main clinical determinant for the severity of neutropenia is the extent of prior myelosuppressive therapy. Neutropenia is noncumulative, and the duration of severe neutropenia, even in heavily pretreated patients, is usually brief. The most important pharmacologic determinant of the severity of neutropenia is the duration that plasma concentrations are maintained above biologically relevant levels (0.05 to 0.10 μmol; discussed earlier in the section [Pharmacology](#)), which may explain why neutropenia is more severe with longer infusion schedules.<sup>237</sup> This does not necessarily mean that longer schedules will portend optimal antitumor activity in the clinic. Instead, most randomized clinical data do not indicate that there is an optimal schedule for any particular tumor, although treatment with higher doses should be considered if shorter schedules are used.<sup>238</sup> At paclitaxel doses exceeding 175 mg/m<sup>2</sup> on a 24-hour schedule and 225 mg/m<sup>2</sup> on a 3-hour schedule, nadir neutrophil counts are typically less than 500 μL for fewer than 5 days in most courses, even in untreated patients. Even patients who have received extensive prior therapy can usually tolerate paclitaxel doses of 175 to 200 mg/m<sup>2</sup> over 3 or 24 hours. More frequent administration schedules (e.g., weekly treatment) have been associated with less severe neutropenia as compared to single-dose schedules (discussed later in the section [Administration, Dose, and Schedule](#)). Severe thrombocytopenia and anemia are unusual, except in heavily pretreated patients.

Although the incidence of major hypersensitivity reactions in early phase I trials approached 30%, the incidence is 1% to 3% with effective prophylaxis.<sup>135,136,237,239,240</sup> Most major reactions, which are characterized by dyspnea with bronchospasm, urticaria, and hypotension, occur within the first 10 minutes after the first (and less frequently after the second) treatment and resolve completely after stopping treatment and occasionally occur after treatment with antihistamines, fluids, and vasopressors. Patients who have major reactions have been rechallenged successfully after receiving high doses of corticosteroids, but this approach has not always been successful.<sup>241,242</sup> Although minor reactions, such as flushing and rashes, have been noted in as many as 40% of patients, minor hypersensitivity reactions do not portend the development of major reactions. The hypersensitivity reactions are most likely caused by a nonimmunologically mediated release of histamine or histamine-like substances, owing to the taxane moiety or, more likely, its polyoxyethylated castor oil vehicle, possibly through complement activation.<sup>243</sup> Although the incidence of major hypersensitivity reactions is reduced with lower administration rates and longer infusion durations, the rates of major reactions are low on both 3- and 24-hour schedules when patients are premedicated with corticosteroids and both H<sub>1</sub>- and H<sub>2</sub>-receptor antagonists (discussed later in the section [Administration, Dose, and Schedule](#)).<sup>237</sup> In an assessment of the relative safety of two different paclitaxel schedules (3 vs. 24 hours), the rates of major reactions were low and similar (2.1% vs. 1.0%) in patients receiving paclitaxel for 3 or 24 hours, respectively, with premedication.<sup>237</sup>

Paclitaxel induces a peripheral neuropathy characterized by sensory symptoms, such as numbness in a symmetric glove-and-stocking distribution.<sup>244,245</sup> and <sup>246</sup> Neurologic examination reveals sensory loss and loss of deep tendon reflexes. Neurophysiologic studies support a primary disruption of neuronal microtubules resulting in axonal degeneration and demyelination as the primary pathogenic mechanism; however, manifestations suggestive of microtubule disruption resulting in a neuronopathy may be noted, particularly at higher doses or when combined with other neurotoxic agents, such as cisplatin.<sup>245</sup> Severe neurotoxicity is uncommon when paclitaxel is given alone at doses below 200 mg/m<sup>2</sup> on a 3- or 24-hour schedule every 3 weeks or below 100 mg/m<sup>2</sup> on a continuous weekly schedule, but almost all patients experience mild or moderate effects. Symptoms may begin as soon as 24 to 72 hours after treatment with higher doses (250 mg/m<sup>2</sup> or greater) but usually occur only after multiple courses at 135 to 250 mg/m<sup>2</sup> every 3 weeks. Neurotoxicity is generally more pronounced when paclitaxel is administered on short infusion schedules, indicating that peak plasma concentration is a principal determinant. The combination of paclitaxel on a 3-hour schedule and cisplatin is particularly neurotoxic. Motor and autonomic dysfunction may occur, especially at high doses and in patients with preexisting neuropathies due to diabetes mellitus and alcoholism. Transient myalgia, usually noted 24 to 48 hours after therapy, is also common, and a myopathy has been described in patients receiving high doses with cisplatin. Although several measures, such as the administration of amifostine, glutamate, and pyridoxine, appear to reduce the neurotoxic effects of paclitaxel in experimental models, there is no convincing clinical evidence that any specific measure is effective at ameliorating existing manifestations or preventing the development or worsening of neurotoxicity.<sup>244,246</sup> Optic nerve disturbances, manifested by scintillating scotoma, may also occur.<sup>247,248</sup> Acute encephalopathy, which can progress to coma and death, has been reported after treatment with high doses (600 mg/m<sup>2</sup> or greater).<sup>249</sup>

Paclitaxel causes cardiac rhythm disturbances, but the clinical relevance of these effects is not known.<sup>239,250,251</sup> and <sup>252</sup> The most common rhythm disturbance, a transient bradycardia, was noted in 29% of patients in one trial.<sup>239,250,251</sup> Isolated asymptomatic bradycardia without hemodynamic effects does not appear to be an indication for discontinuing paclitaxel. More important bradyarrhythmias, including Mobitz type I (Wenckebach syndrome), Mobitz type II, and third-degree heart block, have been noted, but the incidence in a large National Cancer Institute database was only 0.1%.<sup>251</sup> Most documented episodes have been asymptomatic. These events primarily occurred in patients enrolled in early trials that required continuous cardiac monitoring, indicating that second- and third-degree heart block are likely underreported because such monitoring is not usually performed. These bradyarrhythmias are probably caused by paclitaxel, as related taxanes affect cardiac automaticity and conduction, and similar disturbances have occurred in humans and animals who have ingested various species of yew plants. Myocardial infarction, cardiac ischemia, atrial arrhythmias, and ventricular tachycardia have been noted, but whether there is a causal relationship between paclitaxel and these events is uncertain.

There is no evidence that chronic, long-term treatment with paclitaxel causes progressive cardiac dysfunction. Routine cardiac monitoring during paclitaxel therapy is not necessary but is advisable for patients who may not be able to tolerate bradyarrhythmias, such as those with atrioventricular conduction disturbances or ventricular dysfunction. Although patients with a wide range of cardiac abnormalities and cardiac histories were broadly and empirically restricted from participating in early clinical trials, paclitaxel treatment has been reported to be well tolerated in a small series of gynecologic cancer patients with major cardiac risk factors.<sup>252</sup> On the other hand, repetitive treatment of patients with the combined regimen of paclitaxel on a 3-hour schedule and doxorubicin as a brief infusion is associated with a higher frequency of congestive cardiotoxicity than would be expected to occur with the same cumulative doxorubicin dose given without paclitaxel (discussed previously in the section [Drug Interactions](#)).<sup>226,227</sup> In one study of previously untreated women with advanced breast cancer treated with escalating doses of paclitaxel as a 3-hour infusion and doxorubicin, 60 mg/m<sup>2</sup> to a cumulative dose of 480 mg/m<sup>2</sup>, which would be predicted to result in a less than 5% incidence of congestive

cardiotoxicity in patients treated with doxorubicin alone, the incidence of congestive cardiotoxicity was approximately 25%.<sup>227</sup> However, the incidence of cardiotoxicity was less than 5% when similar patients received identical schedules of paclitaxel and doxorubicin, but the cumulative doxorubicin dose did not exceed 360 mg/m<sup>2</sup>. Both experimental and early clinical results suggest that dexrazoxane may reduce the cardiotoxicity of the doxorubicin and paclitaxel combination.<sup>253,254</sup> The incidence of congestive heart failure was also significantly higher in breast cancer patients treated with the combination of trastuzumab and paclitaxel than paclitaxel alone in a phase III trial; therefore, careful monitoring of patients receiving this combination is warranted.<sup>255</sup>

Drug-related gastrointestinal effects, such as vomiting and diarrhea, are uncommon. Higher paclitaxel doses may cause mucositis, especially in patients with leukemia who may be more prone to mucosal barrier breakdown or in patients receiving 96-hour infusions.<sup>256,257</sup> Rare cases of neutropenic enterocolitis and gastrointestinal necrosis have been noted, particularly in patients given high doses of paclitaxel in combination with doxorubicin or cyclophosphamide.<sup>230,239,258,259</sup> Severe hepatotoxicity and pancreatitis have also been noted, but these events are rare.<sup>260,261</sup> Acute bilateral pneumonitis has been reported in fewer than 1% of patients treated on a 3-hour schedule in one series, and both interstitial and parenchymal pulmonary toxicity have been reported, but clinically significant pulmonary effects are uncommon.<sup>262,263</sup>

Paclitaxel also induces reversible alopecia of the scalp, but all body hair is usually lost with cumulative therapy. Although the agent is often not considered a vesicant, extravasation of large volumes can cause moderate soft tissue injury. Inflammation at the injection site and along the course of an injected vein may occur. Alopecia occurs in most patients. Nail disorders have been reported, particularly in patients treated on weekly schedules.<sup>264</sup> Recall reactions in previously irradiated sites have also been noted.

### **Docetaxel**

Neutropenia is the principal toxicity of docetaxel.<sup>137,138,265</sup> At a dose of 100 mg/m<sup>2</sup>, neutrophil counts are below 500/μL in most patients. Similar to paclitaxel, the onset of neutropenia occurs on approximately day 8, and complete resolution typically occurs by days 15 to 21. As with paclitaxel, neutropenia is significantly less when low doses are administered frequently (i.e., on a weekly schedule; discussed later in the section [Administration, Dose, and Schedule](#)). The most important determinant of neutropenia is the extent of prior treatment. Significant effects on platelets and red blood cells are uncommon.

Although docetaxel is not formulated in polyoxyethylated castor oil, hypersensitivity reactions have been reported in approximately 31% of patients receiving docetaxel without premedications in early phase II studies.<sup>137,138,265</sup> As with paclitaxel, major reactions characterized by dyspnea, bronchospasm, and hypotension typically occur during the first two courses and within minutes after the start of treatment. Signs and symptoms generally resolve within 15 minutes after cessation of treatment, and docetaxel is usually able to be reinstated without sequelae, occasionally after treatment with an H<sub>1</sub>-receptor antagonist. However, most hypersensitivity reactions are minor. Both the incidence and severity of hypersensitivity reactions appear to be reduced by premedication with corticosteroids and H<sub>1</sub>- and H<sub>2</sub>-receptor antagonists (discussed later in the section [Administration, Dose, and Schedule](#)). Like paclitaxel, patients who experience major reactions have been retreated successfully after the resolution of symptoms and after treatment with corticosteroids and H<sub>1</sub>-receptor antagonists.

Docetaxel induces a unique fluid retention syndrome characterized by edema, weight gain, and third-space fluid collection.<sup>137,138,265,266</sup> and <sup>267</sup> Fluid retention is cumulative and does not appear to be due to hypoalbuminemia or cardiac, renal, or hepatic dysfunction. Instead, several lines of evidence indicate that it is due to increased capillary permeability.<sup>266</sup> Capillary filtration studies in patients who were not receiving corticosteroid premedication have revealed a two-stage process, with progressive congestion of the interstitial space by proteins and water starting between the second and fourth course, followed by insufficient lymphatic drainage.<sup>266</sup> In early studies in which prophylactic medication was not used, fluid retention was not usually significant at cumulative docetaxel doses below 400 mg/m<sup>2</sup>; however, the incidence and severity of fluid retention increased sharply at cumulative doses of 400 mg/m<sup>2</sup> or greater and often resulted in the delay or termination of treatment. Prophylactic treatment with corticosteroids with or without H<sub>1</sub>- and H<sub>2</sub>-receptor antagonists have been demonstrated to reduce the overall incidence of fluid retention and increase the number of courses and cumulative docetaxel dose before the onset of this toxicity (discussed later in the section [Administration, Dose, and Schedule](#)).<sup>267</sup> Fluid retention typically resolves slowly after docetaxel is stopped, with complete resolution occurring several months after treatment in patients with severe toxicity. Aggressive and early treatment with progressively more potent diuretics starting with potassium-sparing diuretics has been successfully used to manage fluid retention. The incidence of fluid retention appears to be lower in studies using lower doses (60 to 75 mg/m<sup>2</sup>) of docetaxel during each course, but this may be due to the administration of lower overall cumulative doses, and the effects of lower doses on antitumor activity are unknown.

Skin toxicity may occur in as many as 50% to 75% of patients<sup>137,138,265,268</sup>; however, premedication may reduce the overall incidence of this effect. An erythematous pruritic maculopapular rash that affects the forearms, hands, or feet is typical. Other cutaneous effects include desquamation of the hands and feet, palmar-plantar erythrodysesthesia that may respond to pyridoxine or cooling,<sup>269,270</sup> and onychodystrophy characterized by brown discoloration, ridging, onycholysis, soreness, and brittleness and loss of the nail plate.

Both neurosensory and neuromuscular effects are generally less frequent and less severe with docetaxel as compared to paclitaxel. Mild to moderate peripheral neurotoxicity occurs in approximately 40% of previously untreated patients,<sup>137,138,265,271,272</sup> and patients who were previously treated with cisplatin appear to be particularly susceptible, with the incidence approaching 74% in one trial.<sup>273</sup> The neurotoxicity is qualitatively similar to that of paclitaxel. Patients typically complain of paresthesia and numbness, but peripheral motor effects may also occur. Severe toxicity has been unusual after repetitive treatment with docetaxel doses less than 100 mg/m<sup>2</sup>, except in patients with antecedent disorders, such as alcohol abuse. Transient arthralgia and myalgia are occasionally noted within days after treatment. Malaise or asthenia have been prominent complaints in patients who have been treated with large cumulative doses, particularly when docetaxel is administered on a continuous weekly schedule.<sup>137,138,265,274</sup> Stomatitis appears to occur more frequently with docetaxel than paclitaxel, particularly with prolonged infusions, which are utilized rarely. Mild to moderate conjunctivitis, which is responsive to topical corticosteroids, may also occur, particularly with weekly administration. Nausea, vomiting, and diarrhea have also been observed, but severe gastrointestinal toxicity is rare.

## **ADMINISTRATION, DOSE, AND SCHEDULE**

### **Paclitaxel**

Many investigations have focused on optimal dosing and scheduling since the regulatory approval of paclitaxel.<sup>238</sup> Early clinical studies were limited to the 24-hour schedule, largely owing to an apparent increased rate of severe hypersensitivity reactions on shorter schedules, but the development of effective premedication regimens has facilitated evaluations of a broad range of dosing schedules. Although paclitaxel, 135 mg/m<sup>2</sup> on a 24-hour schedule, was initially approved for patients with refractory and recurrent ovarian cancer, regulatory approval was subsequently obtained for paclitaxel, 175 mg/m<sup>2</sup> on a 3-hour schedule. In patients with advanced breast and ovarian cancers, the cumulative body of randomized study results indicate that both schedules are equivalent, particularly with regard to event-free survival and overall survival, although response rates have occasionally been superior with the 24-hour infusion.<sup>238,275</sup>

Intriguing results were initially obtained with more protracted schedules, such as a 96-hour infusion schedule in patients with advanced breast cancer.<sup>140,238,276</sup> The development of such schedules was based on the observation that duration of exposure above a biologically relevant threshold is one of the most important determinants of cytotoxicity *in vitro* (discussed earlier in the section [Pharmacology](#)), but there has been no clear evidence that protracted infusion schedules are superior to shorter schedules with regard to clinical efficacy or toxicity.<sup>238,276,277</sup> and <sup>278</sup> The extensive and rapid distribution of the taxanes to peripheral tissues and the avid and protracted tissue binding of these agents may explain the lack of substantial differences in antitumor activity between short and more protracted administration schedules despite substantial differences *in vitro*. There has also been considerable interest in intermittent schedules, particularly those in which paclitaxel is administered as a 1-hour infusion weekly, which results in substantially less myelosuppression than conventional 3- and 24-hour every 3-week schedules.<sup>279,280</sup> However, the reports that antitumor activity on weekly schedules is superior to that noted with less frequent schedules are largely anecdotal, and randomized trials are in progress. Nevertheless, the weekly schedule may be advantageous for patients who are at high risk of developing severe myelosuppression.

Paclitaxel is generally administered every 3 weeks at a dose of 175 mg/m<sup>2</sup> over 3 hours or 135 to 175 mg/m<sup>2</sup> over 24 hours. Several phase III studies in patients with advanced lung, head and neck, and ovarian cancers have consistently failed to show that paclitaxel doses greater than 135 to 175 mg/m<sup>2</sup> on a 24-hour schedule are superior to conventional doses.<sup>143,238,281</sup> Nearly identical results have been obtained in a phase III study in patients with metastatic breast cancer, in which efficacy was not increased in patients treated with paclitaxel doses greater than 175 mg/m<sup>2</sup> on a 3-hour schedule.<sup>155,277,326</sup> The following doses have been recommended on less conventional schedules: 200 mg/m<sup>2</sup> over 1 hour as either a single dose or 3 divided doses every 3 weeks; 140 mg/m<sup>2</sup> over 96 hours every 3 weeks; and 80 to 100

mg/m<sup>2</sup> weekly. The most common schedules evaluated in patients with AIDS-associated Kaposi's sarcoma are paclitaxel, 135 mg/m<sup>2</sup> over 3 or 24 hours every 3 weeks, and 100 mg/m<sup>2</sup> every 2 weeks.<sup>142</sup> Paclitaxel has also been administered into the pleural and peritoneal cavities.<sup>282,283</sup> Biologically relevant plasma concentrations have been achieved with intraperitoneal administration, and concentrations in the peritoneal cavity are several orders of magnitude greater than plasma concentrations.<sup>282</sup>

The following premedication is recommended to prevent major hypersensitivity reactions: dexamethasone, 20 mg orally or intravenously, 12 and 6 hours before treatment; an H<sub>1</sub>-receptor antagonist (such as diphenhydramine, 50 mg intravenously) 30 minutes before treatment; and an H<sub>2</sub>-receptor antagonist (such as cimetidine, 300 mg; famotidine, 20 mg; or ranitidine, 150 mg intravenously) 30 minutes before treatment. A single dose of a corticosteroid (dexamethasone, 20 mg intravenously) administered 30 minutes before treatment has been reported to confer very effective prophylaxis of major hypersensitivity reactions.<sup>284,285</sup> Contact of paclitaxel with plasticized polyvinyl chloride equipment or devices must be avoided because of the risk of patient exposures to plasticizers that may be leached from polyvinyl chloride infusion bags or sets. Paclitaxel solutions should be diluted and stored in glass or polypropylene bottles or suitable plastic bags (polypropylene or polyolefin) and administered through polyethylene-lined administration sets that include an in-line filter with a microporous membrane not greater than 0.22 μm.

The extensive involvement of hepatic metabolism and biliary excretion in the disposition of paclitaxel—similar to that of other anticancer drugs, such as the vinca alkaloids—in which dose modifications are required indicates that doses should be modified in patients with hepatic dysfunction. Official recommendations have not been formulated, but prospective evaluations indicate that patients with moderate to severe elevations in serum concentrations of hepatocellular enzymes or bilirubin (or both) are more likely to develop severe toxicity than patients without hepatic dysfunction.<sup>286,287</sup> Therefore, it would be prudent to reduce paclitaxel doses by at least 50% in patients with moderate or severe hepatic excretory dysfunction (hyperbilirubinemia) or significant elevations in hepatic transaminases. Renal clearance contributes minimally to overall clearance (5% to 10%), and patients with severe renal dysfunction do not appear to require dose modification.<sup>288</sup> Based on the pharmacologic behavior, particularly the wide distributive properties of the taxanes, dose modifications are not required solely for peripheral edema and third-space fluid collections.

### Docetaxel

In the United States, docetaxel is indicated at a dose range of 60 to 100 mg/m<sup>2</sup> and 75 mg/m<sup>2</sup> over 1 hour in patients with breast and non-small cell lung cancers, respectively, but most early clinical trials in advanced breast, ovarian, and non-small cell lung cancers evaluated doses in the higher end of this range (75 to 100 mg/m<sup>2</sup>), with scant data available for patients treated at 60 mg/m<sup>2</sup>.<sup>137,138,265</sup> Although some untreated or minimally pretreated patients generally tolerate docetaxel at a dose of 100 mg/m<sup>2</sup> without severe toxicity, emerging data indicate poorer tolerance in more heavily pretreated patients in whom 75 mg/m<sup>2</sup> appears to be more reasonable from a toxicologic perspective.<sup>289</sup> Like paclitaxel, docetaxel has also been administered as a 1-hour infusion weekly. Although there are no clear benefits of chronic weekly drug administration in terms of antitumor activity, hematologic toxicity is much less than with conventional dose schedules, with a high incidence of cumulative asthenia and neurotoxicity noted with docetaxel doses exceeding 36 mg/m<sup>2</sup>/wk.<sup>274</sup> Despite the use of a polysorbate 80 formulation instead of polyoxyethylated castor oil, which is used to formulate paclitaxel, a relatively high rate of hypersensitivity reactions and profound fluid retention in patients who did not receive premedication has led to the use of several effective premedication regimens, the most popular of which is dexamethasone, 8 mg orally twice daily for 3 or 5 days starting 1 or 2 days, respectively, before docetaxel, with or without both H<sub>1</sub>- and H<sub>2</sub>-receptor antagonists given 30 minutes before docetaxel.<sup>267</sup>

A retrospective review of docetaxel pharmacokinetics in patients without hyperbilirubinemia demonstrated that docetaxel clearance is reduced by approximately 25% in patients with elevations in serum concentrations of both hepatic transaminases (1.5-fold or greater) and alkaline phosphatase (2.5-fold or greater), regardless of whether the elevations are due to hepatic metastases.<sup>212,213 and 214</sup> Therefore, dose reductions by at least 25% are recommended for such individuals. More substantial reductions (50% or greater) may be required in patients who have moderate or severe hepatic excretory dysfunction (hyperbilirubinemia).<sup>287</sup> As with paclitaxel (discussed previously in the section [Administration, Dose, and Schedule, Paclitaxel](#)), there is no rationale for dose modification solely for renal deficiency or third-space fluid accumulation (or both). Also similar to the case with paclitaxel, glass bottles or polypropylene or polyolefin plastic products should be used for preparation and storage, and docetaxel should be administered through polyethylene-lined administration sets.

### ESTRAMUSTINE PHOSPHATE

Estramustine phosphate ([Fig. 19.7-4](#)) is a conjugate of the alkylating agent nor-nitrogen mustard linked to 17β-estradiol by a carbamate ester. This agent was originally designed so that estramustine would accumulate specifically in estrogen receptor-bearing breast cancer cells via the 17β-estradiol component followed by degradation of the carbamate ester and release of the alkylating nor-nitrogen mustard moiety. Estramustine phosphate, however, did not demonstrate useful anticancer activity in clinical trials in breast cancer and, thereafter, it was determined that alkylation of DNA did not occur.<sup>290</sup> Further investigations later established that preferential accumulation of radiolabeled estramustine phosphate in the ventral prostate of rats occurred unrelated to the estrogen receptor.<sup>291</sup> This selective accumulation was mediated by the presence of a specific protein in prostate tissue, subsequently labeled *estramustine-binding protein* (EMBP).<sup>291,292</sup> Clinical studies of estramustine phosphate were initiated in advanced prostate cancer based on this unique pattern of drug distribution.<sup>293,294</sup> Anticancer activity was subsequently demonstrated in prostate cancer patients with disease refractory to diethylstilbestrol.

**FIGURE 19.7-4.** Structure of estramustine phosphate undergoing dephosphorylation to estramustine.

### MECHANISMS OF ACTION

Several mechanisms of cytotoxic activity have been attributed to estramustine phosphate. The preponderance of data indicates that cell death is principally mediated through a direct effect on microtubules. Estramustine is known to inhibit mitotic microtubule networks and to depolymerize interphase microtubules.<sup>296,297</sup> Consonant with other antimicrotubule agents, estramustine-treated cells arrest in the G<sub>2</sub>/M phase of the cell cycle and then undergo apoptosis. Estramustine inhibits microtubule function through direct binding to β-tubulin independent of MAPs while also inhibiting microtubule function through an interaction with MAPs.<sup>298,299,300,301 and 302</sup> Once bound to tubulin, estramustine inhibits the dynamic growth and shortening of microtubules. Like the taxanes, estramustine can also exert an antiproliferative effect via stabilization of spindle microtubules.<sup>300</sup> The binding of estramustine to β-tubulin, however, occurs at a unique site distinct from those of the taxanes, colchicine, and vinca alkaloids.<sup>303</sup> Finally, the antimicrotubule effects of estramustine are mediated by the intact conjugate and not the individual nor-nitrogen or estradiol components.<sup>304</sup>

The specific binding of estramustine and its metabolite, estromustine, to EMBP permits tissue selectivity for estramustine accumulation and action.<sup>304,305</sup> After exposure to estramustine, cell lines that contain high levels of EMBP exhibit a greater fraction of cells arresting in the G<sub>2</sub>/M phase as compared to those with low levels of EMBP expression.<sup>304,305 and 306</sup> Proteins similar to EMBP have also been found in other tumors, including gliomas and astrocytomas.<sup>307,308 and 309</sup> Because estramustine phosphate induces a G<sub>2</sub>/M block, crosses the blood-brain barrier, and accumulates in gliomas and astrocytomas, the potential for estramustine selectively to sensitize central nervous system tumor cells to irradiation is an area of active investigation.<sup>310,311</sup>

Other proposed mechanisms of action attributed to estramustine include interaction and disruption of the nuclear matrix, alterations of the actin microfilaments of the cytoskeleton, and alterations of ion flux across the plasma membrane.<sup>312,313 and 314</sup>

## MECHANISMS OF RESISTANCE

Investigations with cell lines made resistant to estramustine have characterized several mechanisms of acquired drug resistance. Consistent with its antimicrotubule mechanism of action, resistance to estramustine can be mediated by alterations at the site of estramustine-tubulin interaction, increased microtubule stability through overexpression of specific tubulin isotypes, or alterations in MAPs. A drug efflux mechanism, distinct from classical MDR has been described.

The targets of estramustine—b-tubulins—are composed of multiple isotypes encoded by separate cellular genes. An increase in b<sub>III</sub>- and b<sub>IVa</sub>-tubulin isotypes relative to other b-tubulin isotypes occurs in human prostate cancer cells rendered eight- to ninefold resistant to estramustine.<sup>301</sup> Although the precise site of estramustine binding is not known, microtubules containing b<sub>III</sub>-tubulin isotypes appear to bind estramustine less efficiently as compared to either other b-tubulins or a-tubulin.<sup>301</sup> Furthermore, tubulin isotypes differ from one another principally at MAP binding sites. Because the binding of different b-tubulin subtypes to a-tubulin alters the dynamic properties of microtubule growth and stability, a change in the relative b-tubulin isotypes may counter the inhibitory and destabilizing effects of estramustine on microtubule assembly.<sup>315,316</sup>

Some prostate cancer cell lines with acquired resistance to estramustine overexpress the MAP tau. The capacity to maintain microtubule stability and kinetics involves the interaction of tubulin with MAPs. Exposure to estramustine induces both quantitative and qualitative changes in tau, leading to a sevenfold increase in estramustine resistance in some cell lines.<sup>317</sup> To what extent alterations in tau or other altered MAPs contribute to clinical estramustine resistance is not known.

Although estramustine can bind to the classical MDR efflux pump, P-gp-overexpressing cells are not cross-resistant to estramustine.<sup>318,319 and 320</sup> Estramustine may, in fact, act as a competitive inhibitor of P-gp action, reducing the efflux of other cytotoxic agents subject to P-gp-mediated resistance.<sup>318,320</sup> A drug efflux mechanism distinct from P-gp has been described that is distinct from P-gp and can mediate estramustine resistance.<sup>321</sup> Some cell lines with acquired estramustine resistance exhibit a sixfold resistance to estramustine commensurate with the degree of overexpression of the gene encoding this new efflux pump.

## PHARMACOLOGY

After oral administration, estramustine phosphate undergoes rapid dephosphorylation within the gastrointestinal tract, as shown in [Figure 19.7-4](#). The bioavailability of oral estramustine phosphate is 37% to 75%.<sup>322,323</sup> The majority of absorbed estramustine is rapidly metabolized to an oxidized isomer, estromustine, which is the principal component detected in the plasma.<sup>324</sup> Maximal estromustine plasma concentrations are reached within 2 to 4 hours after oral consumption, and the mean elimination half-life is 14 hours.<sup>322</sup> Estromustine pharmacokinetics are linear over the usual administered oral doses of estramustine phosphate. Peak plasma concentrations in patients treated chronically with oral estramustine phosphate at 560 mg/d have been 227 ng/mL for estromustine, 23 ng/mL for estramustine, 95 ng/mL for estrone, and 9.3 ng/mL for estradiol.<sup>324</sup>

Further hydrolysis of the estromustine and estramustine carbamate linker in the liver yields estrone and estradiol, respectively, and the nor-nitrogen group. Studies of oral and intravenously administered radiolabeled estramustine phosphate indicate that estromustine and estramustine and their metabolites are largely excreted in the feces, with only small amounts of conjugated estrone and estradiol found in the urine (<1%).<sup>322,323,324 and 325</sup>

In contrast to oral administration, intravenous estramustine phosphate delivers significantly higher plasma concentrations of estramustine phosphate and metabolites while reducing the marked interpatient variability noted for the oral route.<sup>322,323,324 and 325</sup> Intravenous estramustine phosphate is currently investigational in the United States.

## DRUG INTERACTIONS

Coadministration of food or dairy products significantly impairs the absorption of estramustine phosphate.<sup>326</sup> Calcium-rich foods appear to lead to the formation of a poorly absorbable calcium complex. Current recommendations include fasting before the oral administration of estramustine phosphate and avoidance of calcium-rich foods and calcium antacids.<sup>326</sup>

Preliminary evidence suggests that oral estramustine phosphate, when coadministered with intravenous docetaxel, significantly delays the clearance of docetaxel, with disproportionate increases in docetaxel concentrations.<sup>327</sup> This has led to a reduction in the recommended dose for docetaxel when combined with estramustine phosphate despite the fact that, for the most part, these two agents have nonoverlapping toxicities. The mechanism by which estramustine impairs docetaxel clearance is not known.

## TOXICITY

Nausea and vomiting, which are the principal toxicities encountered with oral estramustine phosphate, may infrequently necessitate discontinuation. At conventional dosing schedules, nausea and vomiting can be prevented by antiemetic therapy. Diarrhea has also been observed in some patients with chronic use. Myelosuppression is not associated with estramustine phosphate when administered as a single agent.

Commonly observed estrogenic side effects of estramustine therapy include gynecomastia, nipple tenderness, and fluid retention. Caution should be exercised in prescribing estramustine phosphate to patients with congestive heart failure because of the risk for fluid retention and edema. Thromboembolic complications represent the most hazardous toxicity of estramustine phosphate therapy and may occur in as many as 10% of patients. These include venous thrombosis, pulmonary emboli, and cerebrovascular and coronary thrombotic events. Transient elevations in hepatic transaminases occur in approximately one-third of patients receiving estramustine phosphate therapy. The rate of hepatic toxicity is similar to that described for diethylstilbestrol in a randomized study of estramustine phosphate versus diethylstilbestrol.<sup>328</sup>

## ADMINISTRATION, DOSE, AND SCHEDULE

Estramustine phosphate is approved for the treatment of metastatic prostate cancer, particularly hormone-refractory disease. The recommended daily dose of estramustine phosphate (available as a 140-mg capsule) is 14 mg/kg of body weight given in three to four divided doses, though most patients are usually treated in the dosing range of 10 to 16 mg/kg. Patients should be instructed to take estramustine phosphate with water at least 1 hour before or 2 hours after meals. Patients are generally treated for 30 to 90 days before assessment of therapeutic benefit. Chronic oral therapy can be maintained for months or even years as long as the favorable response continues. Abbreviated 5-day courses of oral estramustine phosphate have been proposed for use with such chemotherapy agents as docetaxel. This schedule allows for the concurrent administration of estramustine phosphate with intravenous chemotherapeutic agents while reducing some of the toxicity of chronic oral administration.

## NOVEL COMPOUNDS TARGETING MICROTUBULES

Many other structurally—and functionally—unique antimicrotubule compounds are the focus of discovery efforts, preclinical development, and clinical evaluations. Although the majority of efforts are being directed toward agents that interfere with tubulin, other potential strategic components of the microtubule, including motor proteins, are the focus of discovery and developmental efforts.<sup>13</sup>

The successes with the taxanes have provided the impetus to discover new chemotypes that work by a similar mechanism but yet have higher therapeutic indices. Several natural products that are structurally dissimilar to the taxanes, share their mechanism of action, and show comparable activities have been identified. For example, rhazinilam, like paclitaxel, originates from tree bark but is the first nontaxane identified that induces cold-stable tubulin polymerization *in vitro* and microtubule bundling in cells.<sup>329</sup> Unlike paclitaxel, rhazinilam is capable of inducing tubulin polymerization at 0°C; however, the resulting polymerized product is unstable. In contrast, discodermolide, which originates from a marine sponge, polymerizes tubulin at 37°C *in vitro* more potently and rapidly than does paclitaxel,

yielding polymerization products that are cold-stable, and it polymerizes tubulin almost as rapidly at 0°C.<sup>330</sup> Unlike rhaznilam, discodermolide-induced tubulin polymers are completely stable to treatment with calcium ions and are composed of very short microtubules instead of tubulin spirals. The epothilones A and B, which are derived by microbial fermentation, appear to be more like the taxanes in their polymerization products.<sup>331,332</sup> The microtubules they induce are relatively long, rigid, and resistant to destabilization by cold temperature and calcium ions. These epothilones and their analogues are at least as potent as paclitaxel and cause mitotic arrest and microtubule bundling. Epothilone B analogues are currently undergoing clinical evaluation. The marine soft coral-derived natural products—sarcotidicytins A and B and eleutherobin also promote tubulin polymerization in a manner analogous to that of paclitaxel.<sup>333</sup>

All the aforementioned compounds are likely substrates for P-gp to some extent, expressing varying degrees of cross-resistance against P-gp-expressing cells. However, other marine-derived, microtubule-stabilizing cytotoxins, such as laulimalide and isolaulimalide, appear to be poor substrates for the P-gp drug efflux pump.<sup>334</sup> Because eleutherobin, epothilones A and B, and discodermolide competitively inhibit [<sup>3</sup>H]paclitaxel binding to microtubules, a common pharmacophore has been sought and identified and may enable the development of hybrid constructs with more desirable biologic characteristics.<sup>335</sup>

Other natural products and semisynthetic antimicrotubule compounds under evaluation interact with tubulin in the vinca alkaloid- or colchicine-binding domains. Among the most potent are the cryptophycins, which are a family of cyanobacterial macrolides that deplete microtubules in intact cells, including cells with the MDR phenotype.<sup>336,337</sup> The cryptophycins compete for the binding of [<sup>3</sup>H]VBL, but neither for radiolabeled paclitaxel nor for colchicine, and inhibit GTP hydrolysis by isolated tubulin. They also have excellent activity against several types of tumor xenografts, including tumors resistant to the vinca alkaloids. One semisynthetic analogue, cryptophycin-52, is currently undergoing initial clinical evaluation.<sup>336</sup> The dolastatins constitute a series of oligopeptides isolated from the sea hare, *Dolabella auricularia*.<sup>337,338,339</sup> and <sup>340</sup> Two of the most potent dolastatins, dolastatin-10 and -15, noncompetitively inhibit the binding of vinca alkaloids to tubulin, inhibit tubulin polymerization and tubulin-dependent GTP hydrolysis, stabilize the colchicine-binding activity of tubulin, and possess cytotoxic activity in the picomolar to low nanomolar range. Dolastatin-10 and semisynthetic dolastatin analogues are undergoing preclinical development and clinical evaluation.<sup>340</sup> Phomopsin A, halichondrin B, homohalichondrin B, and spongistatin 1, which interact with tubulin in the vinca alkaloid-binding domain and with the natural products combretastatin and steganacin and the synthetic compounds pyridine and pyridazine, and the pentafluorophenylsulfonamides, which interact with tubulin at the colchicine-binding domain, are currently being evaluated in preclinical or early clinical evaluations.<sup>341,342</sup>

#### HOMOHARRINGTONINE

Homoharringtonine (HHT) and its congener, harringtonine, are cephalotaxine esters isolated from the evergreen tree *Cephalotaxus fortunei* Hook F, which is distributed throughout southern and northeastern China. The two esters differ by only a single methylene group, and they have similar activity against murine leukemia.<sup>1</sup> The greater availability of HHT led to its further testing in the United States.

The primary action of HHT appears to be inhibition of protein synthesis, with degradation of polyribosomes, delayed inhibition of initiation of protein synthesis, and inhibition of chain elongation by interference with peptide bond formation.<sup>2</sup> DNA effects may also be important, with a block in progression of cells from G<sub>1</sub> into S phase and from G<sub>2</sub> phase into M phase.<sup>3</sup> Prolonged drug exposure is necessary for maximal antileukemic effect *in vitro*. Preclinical toxicology identified toxicities of the bone marrow, gastrointestinal tract, kidneys, and heart.<sup>4,5</sup>

Radiolabeled HHT exhibits a triphasic plasma decay, with a terminal half-life of 65.3 hours and an apparent volume of distribution of 2.4 L/kg.<sup>6</sup> In early phase I studies, HHT was administered as a daily 10- to 360-minute infusion for up to 10 days.<sup>7</sup> Dose-limiting cardiovascular toxicity with hypotension began 4 or more hours after drug administration, which is presumed secondary to vasodilatation with a compensatory increase in cardiac output. Hypotension is ameliorated by interrupting the infusion or by fluid administration, or both, and prolonging the duration of administration. The major dose-limiting toxicity with currently used infusion schedules is myelosuppression.

Initial clinical studies with HHT conducted in China identified activity against acute myeloid leukemia and chronic-phase chronic myelogenous leukemia (CML).<sup>8</sup> Clearing of central nervous system blasts occurred after intrathecal administration. Variable activity was observed in the initial series of phase II trials in U.S. pediatric and adult patients with acute leukemia or myelodysplastic syndrome.<sup>9,10</sup> In late chronic-phase CML, a continuous intravenous infusion of HHT, 2.5 mg/m<sup>2</sup>/d, for 10 to 14 days each month induces complete hematologic remission in 72% of cases, with cytogenetic response in 31%.<sup>11</sup> HHT is being combined with interferon or cytarabine in early chronic-phase CML. O'Brien et al.<sup>12</sup> reported that HHT followed by interferon did not achieve a higher cytogenetic response rate than previously observed with HHT alone.

Nonmyelosuppressive toxicities have been minimal, including diarrhea, hyperglycemia, nausea and vomiting, tachycardia, chest pain, headache, and fatigue.

#### SURAMIN

Suramin is a polysulfonated naphthylurea first used for the treatment of onchocerciasis and trypanosomiasis in the 1920s. Its use against parasites and discoid lupus erythematosus was abandoned because of the availability of more effective drugs. Its inhibition of reverse transcriptase and other RNA polymerases led to trials in patients with autoimmune deficiency syndrome.<sup>13</sup> However, initial clinical enthusiasm was not substantiated by additional study.<sup>14,15</sup>

The precise mechanism of suramin's antitumor action is unknown. The drug binds nonspecifically to a wide variety of plasma proteins and enzymes. It inhibits the binding and mitogenic action of many polypeptide autocrine growth factors, including platelet-derived growth factor, fibroblast growth factor, transforming growth factor- $\alpha$  and - $\beta$ , epidermal growth factor, insulin-like growth factor-1 and -2, interleukin-2, transferrin, and nerve growth factor.<sup>16</sup> It is capable of dissociating growth factors from their receptors, with higher affinity to heparin binding growth factors. It interferes with glycosaminoglycan catabolism, leading to an accumulation in the liver and blood of heparan sulfate and dermatan sulfate, which are thought to be related to cell proliferation. Suppression of bone resorption may contribute to the decreased pain reported in patients with prostate cancer.

Suramin exhibits antitumor activity against a number of cell lines, notably growth factor-responsive tumors, but low doses induce proliferation in some cell lines. It inhibits the growth of malignant, but not normal, prostate cells. Early clinical trials suggested activity against adrenal, renal, and other cancers.<sup>16</sup> Activity in prostate cancer has led to phase III studies.

#### CLINICAL PHARMACOLOGY

Suramin has limited absorption from the gastrointestinal tract. The intravenous route is recommended because of better bioavailability.

The original dosing schedule of 1 g weekly for 6 weeks resulted in plasma concentrations that fell over the first few hours after administration but gradually increased over time, with increasing trough levels before each injection.<sup>17</sup> The pharmacokinetics were described by a two-compartment model, with an initial (distribution) half life ( $t_{1/2a}$ ) of 2 days and an elimination half life ( $t_{1/2b}$ ) of 48 days (range, 44 to 54 days). Suramin is 99.7% protein bound, primarily to albumin, and may persist in the blood for 3 months after administration, with no evidence of metabolism and 80% renal clearance. The total body clearance is only 0.41 mL/min, with little interpatient variability. Suramin does not cross the blood-brain barrier. It may displace other highly protein-bound drugs.

#### DOSE AND SCHEDULE

The optimal schedule of administration is still being determined.<sup>18,19,20,21,22,23</sup> and <sup>24</sup> Earlier schedules used adaptive control feedback<sup>25</sup> in which the timing and calculated dose were pharmacologically computed for individual patients to maintain plasma concentrations in the range of 200 to 300  $\mu$ g/mL. Labor-intensive

pharmacologic monitoring was used because of concern that the severe neurologic toxicity with suramin was directly correlated with high blood levels. More recently, other pharmacokinetic correlations have been postulated, including time above a threshold concentration, total dose, and others.<sup>26</sup> The relative importance of free drug concentration is unknown. However, several phase I studies have determined that concentrations in the 200 to 300 µg/mL range are better tolerated overall. Phase I studies have demonstrated little pharmacokinetic variability, making complex adaptive control algorithms unnecessary. This observation has led to investigation of a wide variety of schedules, including a 14-day continuous infusion, intermittent short infusions, and intermittent bolus administration.<sup>20,27,28 and 29</sup>

Suramin has modest activity in patients with prostate cancer.<sup>19,27,28,30,31</sup> Combinations with other agents have been studied in prostate cancer and other solid tumors, but without clear additive benefit.<sup>32,33,34,35,36 and 37</sup> The future of this drug is uncertain.

## TOXICITY

The most serious toxic effect of suramin is a polyneuropathy, which may begin within several weeks of therapy and peaks in severity 3 to 6 months after the drug is discontinued. It ranges from mild stocking-glove paresthesia to paralysis requiring mechanical ventilation, and it is an indication to discontinue treatment.<sup>38,39</sup> At 350 mg/m<sup>2</sup>/d by continuous infusion, a Guillain-Barré syndrome occurred in 11% of patients; the incidence increased to 40% with levels of more than 350 µg/mL.<sup>38</sup> Suramin may lead to a progressive, reversible myopathy; hyperesthesia of palms and soles; headache; and altered taste. Adrenal insufficiency is very common and may be irreversible. All patients receive concurrent corticosteroids until normal adrenal function can be documented.

Infections are frequent with suramin therapy because the drug induces lymphocytotoxicity and myelosuppression and inhibits phagocytosis and bacterial killing, which is compounded by the addition of hydrocortisone.

Other common toxicities include renal dysfunction, transaminase elevations, and coagulopathy.<sup>40,41</sup> Prophylactic vitamin K has been used to minimize the contribution from other causes. Bleeding is managed by replacement of blood and plasma. Heparin can be given safely using careful monitoring. An increase in serum creatinine or the development of a coagulopathy necessitates interruption of therapy. Other serious toxicities include supraventricular arrhythmias, especially atrial fibrillation, pericardial effusions, and deep venous thromboses.

Rash has been reported, occasionally with desquamation or toxic epidermolysis as well as keratoacanthomas and superficial actinic keratoses. Vortex keratopathy, which resolves after therapy, also has been reported. Metabolic consequences include hyponatremia, hypokalemia, hypocalcemia, hypermagnesemia, hypophosphatemia, hypouricemia, and elevations in amylase and lipase. Rash and renal dysfunction may not recur if the drug is resumed.

## BLEOMYCIN

The bleomycins are a group of glycopeptides originally extracted from a strain of *Streptomyces verticillus* from culture broths obtained from the soil of a Japanese coal mine.<sup>42</sup> The most active agent was a mixture of peptides now known as *bleomycin*, with a molecular weight of 1200.

The primary action of bleomycin is to produce single- and double-strand DNA breaks, which result from the production of free radicals by an Fe(II)-bleomycin complex intercalated between opposing strands of DNA. It is ineffective in producing strand breaks of native RNA or synthetic ribonucleotide polymers. Cells are most sensitive to bleomycin during the G<sub>2</sub> and M phases and least sensitive in the G<sub>1</sub> phase.<sup>43</sup> Noncycling cells may be more sensitive than cycling cells. The observation that cells were killed during G<sub>2</sub> suggested an advantage for a continuous infusion, which was not supported by clinical trials.

## CELLULAR PHARMACOLOGY

Bleomycin is taken up by cells slowly and inactivated by an aminohydrolase found in normal and malignant cells.<sup>44</sup> Hydrolase levels are higher in animal species resistant to the pulmonary toxicity of bleomycin and is low in lung and skin, the two organs most susceptible to bleomycin toxicity. Levels in tumor cell lines do not appear to correlate with drug resistance.

## CLINICAL PHARMACOLOGY

Using a 4- to 5-day continuous intravenous infusion, the steady-state concentration is approached approximately 12 hours after initiation of infusion and ranged from 0.132 to 0.312 µg/mL. After an intravenous bolus of 15 U/m<sup>2</sup>, peak plasma concentrations reach 1 to 10 µg/mL, with a rapid two-phase disappearance from plasma with a half-life of elimination of approximately 3 hours. Approximately two-thirds of excretion is renal, and the half-life increases rapidly in patients with a creatinine clearance of less than 25 to 35 mL/min. There is increased pulmonary toxicity with renal insufficiency, but no formal guidelines for dose reduction have been determined. Bleomycin is absorbed rapidly after intramuscular administration, resulting in peak plasma concentrations approximately one-third to one-half of those obtained after rapid intravenous administration. One hour after intramuscular injection, maximum serum levels range from 0.13 to 0.35 µg/mL, with no drug detectable in the serum 24 hours after injection. Absorption after subcutaneous injection has not been clearly defined. Intracavitary administration of bleomycin achieves levels 10- to 22-fold higher than simultaneous plasma levels and is effective in the control of malignant effusions.<sup>45,46,47,48 and 49</sup> Approximately 45% of the intracavitary dose is absorbed into systemic circulation. Bleomycin also has been applied topically.<sup>50</sup> No pharmacologic advantage to intraperitoneal administration has been reported.

## TOXICITY

A test dose of 1 mg of bleomycin is generally administered before a weekly or twice-weekly dose of 5 to 15 U/m<sup>2</sup> because of the risk of hypersensitivity with urticaria, periorbital edema, and bronchospasm. The dose-limiting toxicity of bleomycin is pulmonary fibrosis of uncertain pathogenesis, which occurs in 10% of patients and is more common in patients older than 70 years, with doses of more than 400 U, or in those with a history of chest radiotherapy and in the postoperative period.<sup>51,52,53,54,55,56,57,58 and 59</sup> The onset is usually delayed, and the initial physical examination and chest x-ray may be normal. Eventually, rales, rhonchi, and pleural friction rubs are noted, and abnormal pulmonary function, with decreased lung capacity and increased lung stiffness, is seen. Clinical parameters better predict outcome than pulmonary function studies. Chest x-ray may reveal increased interstitial markings, patchy reticulonodular infiltrates, consolidation, or nodules indistinguishable from metastatic lesions, which may cavitate. Biopsy findings are nonspecific. After the drug is discontinued, reversal may take months, and fibrosis may be only partially reversible and may be fatal. A number of investigational approaches are being evaluated to prevent or reduce the severity of this complication.<sup>54,55,60,61 and 62</sup>

Myelosuppression and immunosuppression are not prominent. Fevers occur in 20% to 50% of patients, occasionally with hyperpyrexia. Mucocutaneous toxicities are common, with mucositis; alopecia; and hyperpigmentation, erythema, induration, hyperkeratosis, and peeling that may progress to ulceration. The digits, hands, joints, and areas of prior radiation or surgery are most affected. Acute arthritis may occur.

## L-ASPARAGINASE

The growth of malignant and normal cells depends on the availability of specific nutrients and cofactors required for protein synthesis. Some nutrients can be synthesized within the cell, whereas others, such as essential amino acids, require exogenous sources. L-asparagine is a nonessential amino acid synthesized by the transamination of L-aspartic acid by a reaction catalyzed by the enzyme L-asparagine synthetase. The ability to synthesize asparagine is notably lacking in malignancies of lymphoid origin. In 1953, Kidd<sup>63</sup> first reported that the growth of transplantable lymphomas of rat and mouse was inhibited by guinea pig serum, and subsequent experiments demonstrated that the responsible factor was L-asparaginase. Subsequent purification from *Escherichia coli* and *Erwinia carotovora* permitted production of large quantities of the enzyme for clinical use. The purified bacterial enzyme has a molecular weight of 133,000 to 141,000 daltons and is composed of four subunits, each with one active site. The enzymes are specific for the L-isomer. Asparaginase catalyzes the conversion of L-asparagine to aspartic acid and ammonia. The enzyme does not enter cells, instead degrading circulating asparagine to aspartic acid, which cannot be converted to asparagine by the cancer cell. In contrast, most normal cells can synthesize asparagine from aspartic acid by induction of asparagine synthetase. This metabolic difference is not absolute, as demonstrated by the toxicity profile of the agent. Resistance occurs through increased expression of the asparagine synthetase gene, which is transcriptionally silent in most tissues and leads to increased enzyme synthesis in response to a decrease in intracellular L-asparagine levels.<sup>64</sup> Resistance may also be mediated by the formation of asparaginase antibodies that alter asparaginase pharmacokinetics.

## CLINICAL PHARMACOLOGY

L-asparaginase is administered either intravenously or intramuscularly. The intramuscular route produces peak blood levels 50% lower than the intravenous route, but the former may be less immunogenic and is more commonly used. Three preparations of L-asparaginase are in clinical use. The most widely used is derived from *E coli*, and an *Erwinia* preparation is available for patients who develop hypersensitivity to the *E coli*-derived agent. The usual doses are 6000 IU/m<sup>2</sup> three times weekly for 3 to 4 weeks, or daily doses of 5000 to 20,000 IU/m<sup>2</sup> for 10 to 20 days. The optimal dose and schedule are unknown. Intermittent schedules with less frequent administration are associated with reduced efficacy and increased anaphylaxis. An *E coli* preparation modified by the covalent attachment of polyethylene glycol (PEG) has a prolonged half-life, thus permitting lower doses and less frequent administration.<sup>65</sup> The approved dose of PEG-asparaginase is 2500 IU/m<sup>2</sup> every 14 days, either intravenously or intramuscularly.

L-asparaginase concentration in plasma is proportional to a total dose up to 200,000 IU/m<sup>2</sup> and falls with a primary half-life of 14 to 22 hours after administration. Blood levels of the *E coli* enzyme are detectable for 1 to 2 weeks after a single dose, and concentrations of L-asparaginase fall below 1 mmol within minutes of enzyme injection and remain low for 7 to 10 days after completion of therapy. The half-life is independent of the dose administered, disease status, renal or hepatic function, age, or gender. The pharmacokinetics of asparaginase depend on the preparation.<sup>66,67</sup> and <sup>68</sup> With *E coli*-derived enzyme, the t<sub>1/2</sub> (1.14 to 1.35 days) administered by the intramuscular route is the same irrespective of dose (2500 or 25,000 IU/mL) or with repeated doses. Peak serum levels are reached in 24 to 48 hours and are no longer detectable in serum by 10 to 14 days. Extremely low levels are found in the urine at 24 hours, suggesting clearance of L-asparaginase by mechanisms other than urinary excretion. Cerebrospinal fluid levels disappear rapidly. The serum t<sub>1/2</sub> for *Erwinia* is 0.65 days, and enzyme was no longer detectable by 7 days. This value is shorter than the *E coli* preparation, although similar schedules are often used. The serum t<sub>1/2</sub> of PEG-modified L-asparaginase as an initial dose was 5.73 days, which is significantly longer than after subsequent doses.<sup>66</sup>

Patients who experience a hypersensitivity reaction to *E coli* asparaginase have a decreased t<sub>1/2</sub> subsequently with PEG asparaginase.<sup>66,69</sup> Serum L-asparaginase activity is undetectable in the week after an anaphylactoid reaction. And even a "silent" anaphylactoid reaction to *E coli* may result in neutralizing antibodies and reduced drug efficacy.<sup>70</sup>

## TOXICITIES

L-asparaginase has no effect on bone marrow function. Hypersensitivity is the most serious toxicity, and it occurs in fewer than 10% of patients. It is manifested by urticaria, nausea, vomiting, and chills, and less often by a serum sickness-like reaction or by anaphylaxis with hypotension, laryngospasm, and cardiac arrest, which is fatal in fewer than 1% of patients. Reactions generally occur during the second week of treatment or later, and they mandate a change to another preparation. The risk of hypersensitivity is greater when the drug is used as a single agent than with concurrent immunosuppressive agents (steroids, 6-mercaptopurine), at doses higher than 6000 IU/m<sup>2</sup>/d administered by the intravenous route and with repeated courses of treatment. Neither skin testing nor antibody levels have been sufficiently predictive. The PEG formulation is the least immunogenic<sup>71,72</sup> and may be more cost-effective.<sup>73</sup> The development of an allergic reaction does not appear to compromise the efficacy of the agent.<sup>74</sup>

Decreased protein synthesis leads to reduced albumin and serum lipoprotein concentrations. A reduction in vitamin K-dependent clotting factors, a fall in fibrinogen levels, and decreased platelet aggregation to collagen may lead to bleeding. Decreases in antithrombin III, proteins C and S, and increased endogenous thrombin generation are associated with venous thrombosis and embolism.<sup>75,76,77,78,79,80</sup> and <sup>81</sup> Other toxic effects include confusion, aphasia, stupor, or coma in 25% to 33% of patients<sup>82,83</sup>; hyperlipidemia<sup>84,85</sup>; and abnormal liver enzymes with fatty metamorphosis. L-asparaginase is contraindicated in patients with a history of pancreatitis because of the risk of acute pancreatitis.<sup>86</sup>

## AMIFOSTINE

Amifostine is a phosphorylated aminothiols prodrug analogue of cysteamine. It was developed by the Walter Reed Army Medical Institute (thus the military code name WR-2721) during the cold war as part of a classified research project to identify an agent that would protect military personnel from radiation in the event of nuclear war. Amifostine was found to afford greater protection against radiation than more than 4000 other compounds screened. Nevertheless, the army terminated development of this compound in 1988 because of its poor oral bioavailability and the prohibitive nausea, vomiting, diarrhea, and abdominal cramps noted with the oral formulation.

When administered intravenously, the pharmacokinetics (PK) of amifostine varies somewhat with dose.<sup>87</sup> The clearance from plasma is rapid (distribution and elimination phases in humans of t<sub>1/2a</sub>, less than 1 minute; t<sub>1/2b</sub>, 8.8 minutes), with a plasma half-life of 1 minute and almost all drug cleared by the plasma within 10 minutes. Bioavailability from the subcutaneous route is high but variable.<sup>87,88</sup>

Amifostine is dephosphorylated at the tissue level to its active metabolite, the free thiol WR-1065, by membrane-bound alkaline phosphatase. WR-1065 is rapidly taken up by cells and is thought to be the major cytoprotective metabolite. WR-1065 protects normal cells by acting as a free radical scavenger and by hydrogen donation to repair damaged target molecules.<sup>89,90</sup>

Preclinical studies with amifostine suggested that the agent could protect normal tissues from radiation and chemotherapy toxicity without protecting tumors.<sup>91,92,93,94,95,96</sup> and <sup>97</sup> Phosphorylation of the aminothiols contributes substantially to the selective uptake of WR-1065 by normal kidneys, bone marrow, heart, and salivary glands compared with tumor tissues. Several explanations have been postulated for this preferential uptake, such as that concentrations of alkaline phosphatase are higher in normal tissues compared with malignant tissues. The hypovascular, hypoxic nature of tumors results in anaerobic metabolism and a low interstitial pH, which are associated with a low rate of prodrug activation by alkaline phosphatase.

Separate phase I trials of amifostine were conducted in conjunction with radiotherapy or chemotherapy. A true maximum tolerated dose was not identified in either setting, but the recommended dose ranges from 740 mg/m<sup>2</sup> to 910 mg/m<sup>2</sup>.<sup>98,99,100</sup> and <sup>101</sup> No clear therapeutic advantage to the higher doses has been determined.<sup>100,102,103</sup> Drug-related toxicity appears to correlate with the duration of the infusion.<sup>104</sup>

## CHEMOTHERAPY-RELATED NEPHROTOXICITY

Amifostine has been evaluated for its ability to prevent chemotherapy-related nephrotoxicity, especially that induced by cisplatin.<sup>100,101</sup> and <sup>102,105</sup> In the only phase III trial, Kemp et al.<sup>106</sup> randomized 242 women with advanced ovarian cancer to six cycles of chemotherapy, with or without amifostine, 910 mg/m<sup>2</sup>, before each cycle. The severity of renal toxicity was reported to be lower in the group receiving amifostine. Fewer patients discontinued therapy on the amifostine arm because of toxicity. The response rates and survival durations were comparable between the two arms. However, the doses of cisplatin used in this study are higher than the dose currently recommended, and this regimen is less commonly used than other less nephrotoxic programs.

## NEUROLOGIC TOXICITIES AND OTOTOXICITY

Several small phase II studies and one phase III trial suggest that amifostine may offer modest protection against the neurologic toxicities of cisplatin, but with no effect on ototoxicity.<sup>101,105,106</sup>

## NEUTROPENIA AND THROMBOCYTOPENIA

Various phase I, II, and III trials suggest a myeloprotective effect from amifostine. Glover et al.<sup>103</sup> conducted a phase II trial of amifostine in combination with cyclophosphamide with 21 patients used as their own controls; 90% had an improved white blood cell count with the second course of cyclophosphamide compared with the first course. Whether these findings are clinically meaningful is questionable.<sup>103,106,107</sup> In a study conducted by the Cancer and Leukemia Group B,<sup>108</sup> patients with solid tumors were treated with high-dose cyclophosphamide with amifostine alone or with amifostine and granulocyte-macrophage colony-stimulating factor. No

additional protection was noted with the combination.

Preliminary phase I data suggest less thrombocytopenia in patients treated with carboplatin and amifostine.<sup>109</sup> However, the aggregate data from subsequent studies provide less support for clinically meaningful benefit.<sup>108,110,111,112 and 113</sup>

## ADDITIONAL OBSERVATIONS

Limited data suggest that amifostine may modulate the cardiotoxicity of doxorubicin and the pulmonary toxicity of bleomycin.<sup>54,55,114</sup>

## RADIOPROTECTION

Amifostine has been evaluated in combination with radiation therapy or combined modality treatment for patients with head and neck and lung cancers.<sup>111,115,116,117,118,119,120,121,122,123 and 124</sup> The suggestion has been made of a reduction in esophagitis in lung cancer patients and less xerostomia and loss of taste with amifostine, but with no clear impact on mucositis or salivary gland function.<sup>117,118 and 119</sup> There is no clear radioprotective effect in patients with rectal cancer.<sup>98,125</sup>

## TOXICITIES

The major toxicities associated with amifostine include nausea and vomiting, hypotension, hypocalcemia, and allergic reactions. The onset of nausea and vomiting is generally within 15 to 30 minutes of the start of the infusion, and they resolve spontaneously. Pretreatment with dexamethasone and a 5-hydroxytryptamine receptor antagonist is recommended.

Hypotension is a potentially serious side effect. It is generally systolic, lasting 5 to 15 minutes, without central nervous system, renal, or cardiovascular consequences. Administration issues that influence the frequency and severity of hypotension include patient hydration, infusion duration, position of patient, and antiemetic pretreatment. Patients should not be receiving agents that potentiate the potential for hypotension, and the drug should not be administered to patients who cannot be without antihypertensive medications for at least 24 hours. Dehydrated patients should not receive the drug until the problem has been corrected. Patients should be hydrated before administration of amifostine. Patients should remain supine or reclining during amifostine therapy.

Hypocalcemia is clinically significant in approximately 1% of patients and can be managed with oral calcium carbonate and vitamin D. The drug has been used successfully to treat hypercalcemia.<sup>126</sup>

Allergic reactions occur in fewer than 1% of patients and are successfully treated with diphenhydramine.

## DRUG ADMINISTRATION

Amifostine should be administered over 15 minutes, 5 to 30 minutes before cytotoxic chemotherapy. The patient should be well hydrated and in a reclining position, with frequent blood pressure monitoring. The recommended dose with radiation therapy is 200 mg/m<sup>2</sup>/d, as a slow intravenous push over 3 minutes, 15 to 30 minutes before each radiation fraction. Bolus schedules have been studied as well.<sup>127</sup>

## MYELOYDYSPLASTIC SYNDROMES

Amifostine stimulates hematopoiesis in animal models, and in *in vitro* studies it stimulates the formation of hematopoietic progenitors from myelodysplastic syndrome bone marrow.<sup>128</sup> In a phase I/II study,<sup>129,130</sup> the drug was administered at doses of 100, 200, or 400 mg/m<sup>2</sup> three times per week, or 740 mg/m<sup>2</sup> weekly for 3 weeks. Hematologic improvement was observed in 83% of patients with the thrice-weekly schedule, including either an increase in neutrophils or a reduction in red blood cell transfusion requirements. More than 40% of patients had a rise in their platelet counts. Acceleration to acute myeloid leukemia was noted in several patients with RAEB-T (refractory anemia with excess of blasts in transformation). In a subsequent multicenter trial,<sup>131</sup> there was single or multilineage improvement in 35%. A poor response rate was reported using a continuous schedule of eight uninterrupted thrice-weekly doses of 300 to 450 mg/m<sup>2</sup>.<sup>132</sup> The role of this agent in myelodysplastic syndrome is being elucidated.

## RECOMMENDATIONS FOR THE USE OF AMIFOSTINE

Based on a careful review of the data, the American Society of Clinical Oncology made the following recommendations regarding the use of amifostine<sup>133</sup>:

- It may be considered for the reduction of nephrotoxicity in patients receiving cisplatin-based chemotherapy.
- Although it may be considered for the reduction of neutropenia in patients receiving alkylating agents, chemotherapy dose reduction or growth factor use should be considered as an alternative to the use of amifostine.
- Present data are insufficient to recommend the use of amifostine for protection against thrombocytopenia or the routine use of amifostine to prevent cisplatin-associated neurotoxicity or ototoxicity. Similarly, the data were felt to be insufficient to support the use of amifostine for the prevention of paclitaxel-associated neurotoxicity.
- The use of amifostine may be considered to decrease the incidence of acute and late xerostomia in certain patients undergoing fractionated radiation therapy in the head and neck region, although the present data are insufficient to recommend the use of amifostine to prevent radiation therapy-associated mucositis.

### RATIONALE FOR INVESTIGATION OF INTERFERONS: DIRECT REGULATION OF CELL GROWTH, DIFFERENTIATION, ANTIGEN EXPRESSION; INDIRECT EFFECTS MEDIATED THROUGH MODULATION OF THE HOST IMMUNE RESPONSE

The interferons (IFNs) are a complex family of inducible natural host proteins that have been traced in phylogeny to prevertebrate species. The physical and chemical immunologic and biologic differences among the IFNs have served as a basis for speciation of these molecules, long before the knowledge of intracellular signaling pathways that have been more recently elucidated was known.<sup>1,2</sup> These intercellular pathways activated by the IFNs (signal transducers and activators of transcription)<sup>3,4</sup> are triggered by a large number of signaling polypeptides, but are activated in different patterns by different signaling polypeptides, to induce precise cellular responses in mammalian (as well as insect and slime mold) cells, demonstrating critical roles in different phases of cell biology. Disruption of the STAT genes in the mouse has shown roles in viral/bacterial defense (STAT 1).<sup>5,6</sup> Early lethality has been reported for STAT 2 and 3 lesions, whereas disruption of TH1 has been identified as a consequence of disruption of STAT 4,<sup>7,8</sup> and TH2 function has been assigned to STAT 6.<sup>9,10</sup> and <sup>11</sup> The role of IFN-induced gene regulation in many diverse tissues is likely to account for the effects of IFNs on a variety of neoplastic, viral, and angiogenic conditions in which IFN therapeutic activity has been clinically observed since the 1980s.

The IFNs have been empirically tested as therapies for a multitude of hematologic and solid neoplasms, demonstrating therapeutic benefits in more than a dozen cancers, leading to regulatory approval in multiple countries across the world. This chapter reviews the biology and preclinical effects of the IFNs, discussing the multiple mechanisms of potential relevance to cancer and the therapeutic advances that have been made with IFNs as single agents and combined with chemotherapy, radiotherapy, and other biologic agents, including vaccines, particularly as these relate to the solid tumors.

#### INTERFERONS OF TYPE I: INTERFERON- $\alpha$ , - $\beta$ , - $\tau$ , AND - $\omega$

Human IFN- $\alpha$  comprises a complex array of subspecies, each of approximately 165 to 166 amino acids encoded by a superfamily of closely related genes located with the IFN- $\alpha$  and - $\beta$  genes on the short arm of human chromosome 9 that are variably modified by posttranslational glycosylation.<sup>12,13</sup> and <sup>14</sup> In the human, 14 nonallelic IFN- $\alpha$  genes and four pseudogenes are clustered together with genes for IFN- $\alpha$ . A variable mixture of IFN- $\alpha$  species is induced in leukocytes and other host cells by a range of stimuli classically including virus or nucleic acids. The biologic effects of the many subspecies are overlapping in large part, despite differences in relative antiviral, antiproliferative, antigen-modulating, and immunomodulating effects to be discussed later in this chapter.<sup>15,16</sup>

IFN- $\alpha$  and - $\beta$  bind with high affinity (dissociation constant of  $10^{-10}$  to  $10^{-12}$  mol/L) to a single receptor of 110 kD specified on chromosome 21,<sup>17,18</sup> ranging in density from 100 to 10,000 receptors per cell. A range of cellular processes induced by IFNs follow the production of a new set of proteins, after binding and internalization. Knowledge of the events that occur after binding of IFN to its receptor has advanced significantly.<sup>1,19,20</sup> and <sup>21</sup> A multimeric transcription activator ISGF3 is stimulated to translocate to the nucleus, where it binds *cis* to the IFN response element of DNA and induces genes that make up the array of IFN-stimulated genes.<sup>21,22,23,24</sup> and <sup>25</sup> The cytoplasmic and nuclear components of the transcription-activating factor ISGF3 associated with IFN- $\alpha$  are activated, such that ISGF3- $\gamma$  (the component of the complex specifically recognizing the ISRE) and ISGF3- $\alpha$  (which contains three polypeptides activated specifically on phosphorylation) interact and translocate to the nucleus without the requirement of protein synthesis to activate the IFN response element.

#### INTERFERON-BINDING RECEPTOR OF TYPE II: INTERFERON- $\gamma$

IFN- $\gamma$  binds a receptor that is discrete from that bound by type I IFNs. Evidence for two classes of receptors, one with low ( $10^{-6}$  mol/L) and one with high ( $10^{-11}$  mol/L) affinity, has been reported.<sup>26</sup> The *in vitro* and *in vivo* immunomodulatory activity of IFN- $\gamma$  in experimental animals as well as the human has been one of the most potent of all IFNs,<sup>27</sup> leading to expectations that IFN- $\gamma$  would also be the most therapeutically active of all IFNs against cancer. Trials of IFN- $\gamma$  in patients with advanced metastatic melanoma and renal cell carcinoma, as well as adjuvant trials in patients with a high risk of relapse, have been conducted, but have not shown therapeutic effects equivalent to the IFN- $\alpha_2$  molecule. Reasons for this may relate to effect on antigen presumption and the proteasome complex.

The pleiotropism of the IFNs has posed significant challenges in their quantification and the definition of mechanism of action. The specific activity of various IFN preparations may be expressed in terms of differing functions (e.g., antiviral, antiproliferative, differentiating, effector cell activating, antigen augmenting, and enzyme inducing). Antiviral activity has been accepted as the basis of IFN standardization, although it is far from clear that this function is related to the effects of IFN- $\gamma$  in cancer therapy. Units of antiviral activity determined against reference standards of the Center for Biologics (Washington, DC) are commonly used to quantify IFN- $\alpha$  and - $\beta$ , but recombinant IFN- $\gamma$  and newer polyethylene glycol (PEG) bound forms of IFN- $\alpha_2$  are generally reported in terms of mass. The various species, subspecies, and molecular variants (muteins) of IFNs argue for adoption of functional standardization in terms of alternative mechanisms relevant to antitumor activity for clinical trials.

#### MECHANISMS RELEVANT TO ANTITUMOR ACTION

The pleiotropic actions of IFNs may be separated into several categories that are useful in analyzing preclinical and clinical data, as summarized in [Table 20.1-1](#). Direct effects of the IFNs include antiproliferative and differentiating effects that may be demonstrated against fresh melanoma tissues or cultured cell lines *in vitro*. Effects have been designated as *composite* that result in alterations in tumor cell surface antigen expression without direct effect on tumor cell growth, invasion, and metastasis. These effects may permit host recognition and response *in vivo*. Each of three major categories of IFN effects that are potentially relevant to melanoma has been studied in some detail and may provide a basis for understanding the outcome of therapeutic trials (as discussed). Indirect effects of the IFNs are those that are mediated by the host immune system, including the cellular elements such as the large granular lymphocyte or natural killer (NK)/lymphokine-activated killer cell, macrophage/dendritic cell, neutrophil, and T and B cells.<sup>28,29,30</sup> and <sup>31</sup>

Effect	Composite (Tumor Cell Indirect)	Indirect (Immune)	Indirect (Tumor)
Antiproliferative	Major histocompatibility complex class I and II surface antigens	Synergistic growth factor activation	Indirectly
Modulating	Increased expression of surface antigens	Macrophage-monocyte lineage cell	
Initial	Adhesion molecules Intercellular adhesion molecule-1	Large granular lymphocyte F1L expression Major histocompatibility complex class II expression Antigen-specific effector molecules T cell B cell	

**TABLE 20.1-1.** Pleiotropy of Interferons: Direct, Composite, and Indirect Effects

## DIRECT EFFECTS ON TUMOR CELL PROLIFERATION AND ENZYME AND SIGNALING PATHWAYS

The actual mechanism(s) responsible for the antitumor action of IFNs in human cancer remain uncertain. Nonrecombinant IFN- $\alpha$  and - $\beta$  and recombinant subspecies of IFN- $\alpha_2$ , - $\beta$ , and - $\gamma$  have been evaluated *in vitro* for their antiproliferative activity against cultured and fresh solid tumor cells. These demonstrate comparable growth-inhibitory activity, and one may draw the general observations that (1) there exists a direct dose-response tumor-inhibiting relationship for each species; (2) there is considerable heterogeneity among different tumors regarding sensitivity to inhibition; and (3) solid tumors are generally sensitive to IFNs *in vitro* if exposed to high levels (greater than 500  $\mu$ /mL) of IFN- $\alpha_2$ . Molecular pathways of IFN signaling have been defined, allowing analysis of the proximate intracellular pathways of action, which may prove more informative than the measurement of IFN-induced enzymes such as oligoadenylate synthetase, and more distal effects such as induction of major histocompatibility complex (MHC) antigen expression. Studies of cultured *in vitro* tumor cells have suggested acquired defects in the STAT signaling pathway and the absence of STAT that may be associated with IFN resistance. By contrast, studies of human tumor tissues *in vivo* have revealed the constitutive activation of STAT pathways and nuclear correlation of STAT, in melanocytic nevi tissues of patients untreated with IFN as well as in solid tumor tissues (squamous carcinoma of the upper aerodigestive tract). The analysis of signal transduction intermediates of the IFNs in tumor cells of patients undergoing therapy with the IFNs is now feasible. The prospective evaluation and correlation of these intermediate end points of IFN action with clinical evidence of response, progression, or both will be of interest in future trials.<sup>32</sup>

### Enzyme Induction

A number of enzyme pathways are activated after induction of the IFN response element, including some that have been evaluated in clinical trials. These include 2'5' oligoadenylate synthetase (2'5' oligo-As) and protein kinase (p67).<sup>33</sup> Two molecular forms of 2'5' oligo-As of 33 kD and 110 kD have been identified differing in subcellular localization and activation requirements.<sup>34,35</sup> The role of the different forms of 2'5' oligo-As as in relation to antitumor effects of IFNs has yet to be established. Indoleamine 2,3, dioxygenase is induced by IFNs in a dose- and time-dependent fashion; this enzyme alters tryptophan metabolism<sup>36</sup> and with xanthine oxidase generates superoxides that may relate to both therapeutic and toxic effects of IFN, as well as depression of cytochrome P-450 enzymes levels.<sup>37,38</sup> Neopterin production induced by IFN- $\gamma$  may provide an additional biochemical tool for the analysis of intermediate effects of IFN- $\gamma$  *in vivo*.

### Antiproliferative Effects of Interferons in Combination with Chemotherapy and Other Biologic Agents In Vitro

The presence of additive or synergistic effects of chemotherapeutic agents has been examined with IFNs *in vitro* using isobologram plots to compare various combinations for synergistic, additive, or subadditive effects against tumor cells.<sup>39</sup> Although synergism and additive effects have been identified with some combinations<sup>40,41,42,43,44</sup> and negative interactions<sup>45</sup> for others, there is no compelling evidence that these *in vitro* effects have been useful in the development of therapeutic regimens for the clinic.

IFN- $\gamma$  has been shown to potentiate apoptotic cell death and DNA fragmentation induced by tumor necrosis factor (TNF),<sup>46</sup> whereas IFN- $\alpha$  and - $\gamma$  potentiate the tumor-cytotoxic activity of TNF in clonogenic stem cell assays.<sup>46</sup>

### Differentiation In Vitro and In Vivo

Differentiative and growth regulatory or apoptotic effects of the IFNs have become focal points of interest in multiple solid and hematopoietic neoplasms. A number of adhesion molecules, growth factors, and receptors have been identified in the process of malignant progression that are subject to IFN regulation. The receptor-ligand pairs may serve as paracrine or autocrine growth-stimulating circuits<sup>47,48</sup> that may be interrupted at various stages. IFN- $\alpha$  and retinoic acid inhibit epidermal growth factor receptor expression, and retinoids as well as IFNs are under study as potential inhibitors of progression.

## COMPOSITE (ANTIGENIC) ANTITUMOR MECHANISMS: MODULATION OF MELANOMA-ASSOCIATED CELL SURFACE ANTIGENS

The antitumor effects of IFNs have been attributed to their effects on cell surface antigens of several tumors. The histocompatibility complex is among the most consistent and sensitive targets of the IFNs. It is well established that MHC class I antigens are inducible by type I IFNs, whereas MHC class II antigens are the target of type II IFNs (IFN- $\gamma$ ).<sup>49,50,51,52,53,54</sup> *In vivo* studies have suggested an even broader pleiotropy type of the IFNs than *in vitro*, in which induction of both MHC class I (ABC) and II (DR, DP, DQ) antigens have been reported with IFN- $\alpha_2$ .<sup>55,56</sup>

IFNs modulate the expression of many cell surface molecules, not all of which have been assigned physiologic functions, and a number of which play roles in the progression from neoplastic to invasive neoplastic disease.<sup>51,57,58,59,60</sup>

The clinical implications of altered MHC antigen expression relate to their pivotal function in intercellular immunologic recognition and communication at multiple levels. Antigen presentation to T cells by Langerhans'/dendritic cells of the macrophage monocyte lineage and B cells is associated with the expression of MHC class I and II antigens, adhesion molecules, and costimulating molecules (B7.1/7.2, CD80, CD86). Antitumor effects of IFNs may thus occur through MHC class I and II antigens even if the tumor antigens recognized by the immune system are not themselves up-regulated.<sup>61,62</sup> Decreased susceptibility to NK cells is associated with induction of class I major histocompatibility antigen expression,<sup>63,64</sup> and IFN- $\gamma$  protects human tumor cells that are otherwise susceptible to NK cell lysis within hours.<sup>65,66</sup>

The induction of MHC class I and II antigens by IFNs may increase the immunogenicity of tumor cells used for vaccination, outweighing effects on susceptibility to NK/lymphokine-activated killer effector cells in experimental models.<sup>67,68</sup> Thus, induction of increased MHC class I and II tumor cell surface antigen expression may account for the enhanced efficacy of host T-cell-mediated immunity or tumor cell elimination by means of a composite mechanism, irrespective of the modulation of effector cell functions. To date, studies have not resolved these issues in human clinical trials.

## INDIRECT IMMUNOMODULATORY EFFECTS

### Natural Killer, Macrophage, and Dendritic Cells

The macrophage is a key target of IFN- $\gamma$ , which was earlier described as macrophage activating factor<sup>69,70</sup> and<sup>71</sup> (see Table 20.1-1). The large granular lymphocyte known as the *NK cell* is a well-recognized target of the type I and II IFNs.<sup>72,73</sup> Clinical relevance of the effects of IFNs on NK activity has been sought for many years, both *in vitro* and *in vivo* for IFN- $\alpha$ , - $\beta$ , and - $\gamma$ . NK activity measurements performed in the context of multiple trials has depended on assay conditions, effector cell manipulation, and the delay from blood-drawing to assay (*rest period*). To date, no convincing evidence of a relationship between NK cell activity *in vivo* and the therapeutic activity of IFNs in patients with solid tumors has been documented.<sup>74,75,76,77</sup> Antibody-dependent cellular cytotoxicity of peripheral blood lymphocytes is

mediated in part by NK cells and augmented *in vitro* and *in vivo* by IFN- $\alpha$ , as well as interleukin-2 (IL-2).<sup>78</sup> As trials of antitumor antibodies are further developed, the optimization of NK activity and antibody-dependent cellular cytotoxicity with IFNs, IL-2, as well as IL-12, and other newer biologic agents will continue to be important.

The dendritic cell, a central antigen-presenting cell, is influenced by multiple cytokines, including granulocyte-macrophage colony-stimulating factor, IL-4, IL-12, and IFN- $\alpha$ . The immunomodulatory effects of IFN- $\alpha$  may thus be due to altered numbers or functional capacities of dendritic cells,<sup>79</sup> although studies *in vivo* during IFN therapy have yet to be performed to evaluate this potential mechanism.

### T Cell

Specific T-cell-mediated immunity has been implicated as the basis of antitumor effects of the IFNs in many solid tumors. Durable complete responses have been reported in multiple clinical trials of IFN- $\alpha$  for chemotherapy-refractory solid tumors, including renal cell carcinoma and melanoma. Shifts in T-cell subsets (CD4 to CD8 ratio increased) have been correlated with clinical antitumor response to IFN- $\alpha$  and - $\gamma$ .<sup>80,81,82,83,84,85,86,87,88</sup> IFN- $\alpha$  modulates mixed leukocyte reactions *in vitro*,<sup>89</sup> and the modulation of specific cytotoxic T-cell immune responses to solid tumors by IFN- $\alpha_2$  remains a leading hypothetical basis for the durable antitumor effects observed clinically with IFN- $\alpha_2$  in melanoma, renal cell carcinoma, and other solid tumors. This is prospectively being evaluated in the context of current trials for several solid tumors.<sup>29,30,90,91,92,93,94,95</sup> The prognostic importance of CD4+ T-cell infiltrates in predicting response of melanoma and other solid tumors has been suggested by Hakansson et al.<sup>87</sup> and is now being tested prospectively as a means to select a more IFN-responsive population. The definition of both MHC class I-restricted and MHC class II (DR)-restricted epitopes recognized by CD4+ T cells in melanoma, renal cell carcinoma/H/N cancer, and other solid tumors adds a new dimension to the expanse of CD8+ T-cell-defined MHC class I-restricted epitopes for analysis of IFN-modulated effector functions.<sup>96</sup>

In preclinical systems, Belardelli and Gresser et al.<sup>97,98,99</sup> have shown that IFN prevents the outgrowth of experimental murine tumors that does not correlate with the tumor cell susceptibility to direct tumor growth inhibition by IFN. This effect depends critically on the presence of an intact immune system in the host and particularly the CD4 T cell. Tumor response suggesting that tumor regression induced by IFN in this system is dependent on immunologic effects of IFN on the tumor and host.

### B Cell

IFN- $\gamma$  increases production of IgG2a and decreases that of IgG3, IgG1, IgG2b, and IgE by human B cells.<sup>100</sup> Several tumor vaccines have been evaluated in conjunction with IFN- $\alpha_2$  to evaluate the immunomodulatory role (and possible inhibitory effects) of IFN- $\alpha_2$  administered together with or following GM2 vaccine (Eastern Cooperative Oncology Group trial E2696: GMK, Progenics, Tarrytown, NY). The results of these trials have established the feasibility of this combination and the absence of inhibitory interactions between ganglioside GM2 vaccination and high-dose IFN- $\alpha_2$  in regard to serologic IgM and IgG response and pave the way for IFN combinations in other disease settings.

The specific effects of IFN- $\alpha$ , - $\beta$ , and - $\gamma$  on specific immune function against autologous solid tumors have not been examined due to the complexity of measuring immune responses to autologous tumor cell surface antigens in clinical trials. Analyses of specific immune responses to tumor-associated antigens will be essential to interpret therapeutic responses to IFN, much as it is critical to the analysis of an array of vaccine trials underway for many solid tumors.

## ROLE OF INTERFERON- $\gamma$ AS A MEDIATOR OF CLINICAL EFFECTS OF OTHER CYTOKINES

IFN- $\gamma$  induction by IL-2 and IL-12 has been documented *in vivo* in humans.<sup>101,102</sup> Ambient levels of 1 to 7 U/mL have been demonstrated after continuous intravenous infusion of IL-2 and are likely to be a major component of the dose-limiting toxicity of IL-2.<sup>102,103</sup> The IFN- $\gamma$  induced during therapy with IL-2, IL-12, and other cytokines may play a role in therapeutic as well as toxic effects of a number of biologic agents.

## DENDRITIC CELL MODULATION

A cell that has taken center stage and is central to antigen presentation is the dendritic cell. The antiangiogenic actions of the IFN- $\alpha$  cell<sup>104</sup>; this cell, regulated by a series of cytokines, including granulocyte-macrophage colony-stimulating factor, IL-4, IL-12, and IFN- $\alpha$ , has the ability to promote T-cell immune responses in naive subjects.

IFN- $\alpha$  is one of the earliest antiangiogenic agents established in clinical trials in experimental and human systems. Angiogenesis associated with tumor progression<sup>105</sup> is a logical mechanism for evaluation, although direct evidence of a role for antiangiogenic effects of IFNs in the clinical therapy of human solid tumors has yet to be documented. The observation that IFN- $\alpha$  is able to cause regression of hemangiomas of childhood remains a clinical foundation for the exploration of antitumor antiangiogenic effects of IFN in malignant neoplasms.<sup>106</sup> A balance between proangiogenic (basic fibroblast growth factor) and antiangiogenic (IFN- $\alpha$ ) effects has been proposed on the basis of preclinical studies that may have implications for the optimal administration of IFN- $\alpha$  in bladder cancer, ovarian cancer, and melanoma, among other solid tumors.<sup>107,108</sup>

## CLINICAL EVALUATION

### TOXICITY AND PHARMACOKINETICS OF THE INTERFERONS

#### General

The clinical toxicity of the different species of IFNs involves a similar range of target organs, although the relative components of toxicity differ from species to species and in the human from individual to individual<sup>109,110</sup> (Table 20.1-2). Acutely, a flu-like constitutional syndrome with fever, chills, headache, malaise, myalgias, arthralgias, and fatigue occurs in the majority of patients and diminishes over time with continued daily or alternate-daily administration. For this reason, therapy is best tolerated in many patients at bedtime. Low back pain and headache with severe rigors have been associated with IFN- $\alpha$  in particular. Metabolic alterations in the blood lipid profile have been noted with hypertriglyceridemia, and elevated low-density lipoprotein is seen due to inhibition of lipoprotein lipase.<sup>111</sup> IFN- $\alpha$  may depress the plasma cholesterol in 15% to 40% of patients, with a parallel decrement in both high- and low-density cholesterol, without alteration of very low-density lipoproteins.<sup>112,113,114</sup> Long-term toxicity of IFN consists in constitutional flu-like symptoms compounded by anorexia, weight loss, and fatigue. These late toxicities are the result of dysgeusia, low-grade fever, and nutritional compromise and may be difficult to differentiate from the appearance of thyroid dysfunction or other endocrine pathology on the basis of autoimmune processes associated with IFN- $\alpha$  (as for IL-2). Neuropsychiatric toxicity ranges from mild cognitive deficits to frank depression and psychosis (see [Neurologic Effects](#), later in this chapter).

Acute/Subacute	Chronic
<b>Symptoms</b>	
Fever, chills	Anorexia
Headache	Dysgeusia
Myalgia	Fatigue
Nausea/vomiting	Depression
Diarrhea	
<b>Signs</b>	
Hyperthermia	Weight loss
Tachycardia	Alopecia
Anemia	Hypothyroidism
Neutropenia	
Rash	
<b>Rarer</b>	
Rhabdomyolysis	Nephrotic syndrome
Subacute hepatic necrosis	

TABLE 20.1-2. Toxicities of Interferons

## **Hematologic Effects**

Hematologic toxicities of the IFNs include leukopenia and, less frequently, thrombocytopenia and anemia; infections are a recognized complication of the leukopenia, but bleeding complications have been rare. Diminished colony-forming capacity and hypocellularity have been noted in the bone marrow, which are rapidly reversible on withdrawal of IFN.<sup>115,116</sup>

## **Hepatic Effects**

Hepatotoxicity observed at high doses frequently includes elevated circulating transaminase enzyme levels that are dose related and reversible on withdrawal of the agent, without evidence of cholestasis. Rarely, subacute hepatic necrosis and cholestatic liver failure with death have been observed when IFN has been administered in the face of hepatotoxicity with hyperbilirubinemia or a history of antecedent viral or alcoholic liver disease. Careful observation of hepatic function generally permits the avoidance of such problems, with treatment modification according to signs and symptoms of toxicity.<sup>29,117</sup> Indeed, after the initial report of two cases of fatal hepatotoxicity of high-dose IFN in the pivotal E1684 adjuvant trial for high-risk melanoma,<sup>118</sup> the confirmatory intergroup trial E1690 was completed without any instance of life-threatening hepatotoxicity, and the only two toxic fatalities noted were cardiovascular and cerebrovascular, occurring with low-dose IFN.

## **Cardiac and Renal Effects**

Cardiovascular, renal, and CNS toxicity are less common. Supraventricular tachyarrhythmias noted with the IFNs may be direct effects or the consequence of fever or nutritional and fluid imbalances. Complex conduction disturbances have been observed with IFN-g, including bradycardia with high-grade heart block.<sup>93</sup> Cardiotoxicity is increased among elderly patients and patients with underlying heart disease or prior exposure to cardiotoxic agents, but the mechanism has not been defined.<sup>119,120</sup> Hypotension occurs through at least two separate mechanisms: acute hypotension, occurring 1 to 2 hours after administration of IFNs, may be related to peripheral vasodilatation and responds to fluid repletion or rarely may require pressors. Hypotension during chronic administration of IFNs is related to subclinical low-grade fever with insidious fluid losses, anorexia, dysgeusia, and diminished fluid intake. Proteinuria is the most common renal manifestation of the IFNs and is generally reversible on withdrawal of IFN.<sup>121,122,123and124</sup> Rarely, interstitial nephritis and nephrotic syndrome have been reported with IFN-a and -g.<sup>119,125</sup>

## **Neurologic Effects**

CNS toxicity associated with global changes in mentation is often subtle. The cognitive dysfunction induced by IFN may be documented in formal testing, but is often more apparent to family and friends of patients.<sup>126</sup> Stupor and coma with diffuse slowing of the electroencephalographic pattern have infrequently been reported and are reversible on discontinuation of IFN.<sup>120,127</sup> Mild peripheral neuropathy has also been noted, with paraesthesia and slowing of nerve conduction velocity. Most recently, reversible retinal microvascular toxicity has been noted during studies of IFN-a administered for macular degeneration, which may indicate the need for ophthalmologic evaluation of patients with visual changes during IFN-a therapy in other settings.<sup>128</sup>

## **Musculoskeletal Effects**

Rhabdomyolysis has rarely been reported in association with IFN-a<sub>2</sub> at high dosages.<sup>129</sup> However, the significance and even the attribution of such occurrences is difficult to resolve at this time, as this complication has been reported as early as the first week into IFN-a<sub>2</sub> therapy in postoperative patients in whom it is difficult to exclude other contributory factors. Although monitoring for elevations in creatine phosphokinase enzymes has been suggested, this has not been adopted in practice because of the rarity of the event and the early occurrence of the event, which would preclude use of laboratory values to monitor treatment and supportive care.

## **PHARMACOLOGY AND DOSAGE**

### **Recombinant Interferon of the First Generation**

The maximum tolerated dose for IFN-a lies between 10 and 20  $\mu\text{m}^2$  daily and 50  $\mu\text{m}^2$  on alternating days for periods of weeks to months, regardless of subspecies. The half-life of IFN-a<sub>2</sub> is 6 hours in the blood and has allowed alternate-daily schedules of outpatient administration by intramuscular and subcutaneous routes. The maximum tolerated dose for IFN-a varies according to the industrial preparation used, schedule, and route; acceptable absorption and activity have been reported with IFN-g administered intravenously or intramuscularly.<sup>130,131</sup> Early pharmacokinetic studies of IFN-a<sub>2</sub> have demonstrated that peak levels at 5  $\mu\text{m}^2$  obtained by the intravenous route do not reach 100  $\mu\text{mL}$ , whereas by the intramuscular and subcutaneous routes generally adopted for therapy they remain under 50  $\mu\text{mL}$ . By contrast, the administration of doses of 20  $\mu\text{m}^2$  (or 36  $\mu\text{m}^2$  in early pharmacodynamic studies) achieves serum levels approaching 10,000  $\mu\text{mL}$ .<sup>132</sup> This difference in the pharmacodynamics and peak levels has been the focus of considerable interest, as the positive results of trials using the intravenous administration of 20  $\mu\text{m}^2$  have shown the first survival benefits in melanoma, whereas lower dosages administered by alternative routes have yielded antitumor effects in terms of delayed recurrence (during therapy) without significant survival prolongations.

### **Recombinant Interferons of the Second Generation**

A second generation of recombinant IFN-a<sub>2</sub> therapy is currently unfolding, with intense exploration of linear polyethylene glycol-conjugated IFN-a<sub>2b</sub> (PEG-Intron, Schering Plough Corporation, Kenilworth, NJ) and larger branched chain formulations of IFN-a<sub>2a</sub> (Pegasys, Roche Laboratories Inc., Nutley, NJ) entering multicenter trials in the United States, Canada, and Europe. The half-life of these species is substantially prolonged, allowing twice weekly and weekly administration, with concentration time products that are significantly higher than can be achieved with the first-generation recombinant IFN-a<sub>2</sub> species as initially formulated, regardless of route. Clinical studies, accompanied by more sophisticated molecular laboratory corollaries, are under way in the context of these trials in leukemia (chronic myelogenous leukemia), solid tumors (melanoma, renal cell carcinoma), and viral diseases (hepatitis).

## **ANTIBODIES**

The development of anti-IFN neutralizing serum antibodies has been correlated with loss of toxicity and antitumor effects in chronic myelogenous leukemia. The role of anti-IFN antibodies appears to vary with the disease state as well as the species of IFN used. In representative series, antibodies have been detected in from 0% to 5% of subjects after 2 to 6 months of therapy<sup>133,134</sup> without demonstrable adverse consequences for therapeutic effects in patients with most solid tumors to date. Strategies to reduce the immunogenicity and increase the likelihood of tolerance to recombinant IFN-a have included the initial use of intravenous, as opposed to subcutaneous or intramuscular, routes and continuous as opposed to interrupted schedules. Despite the delayed release and depot-like behavior of polyethylene glycol-bound IFN-a<sub>2</sub>, the immunogenicity of polyethylene glycol-bound IFN formulations appears to be less than that of the parent recombinant IFN-a<sub>2</sub> species.

## **CLINICAL EFFICACY OF INTERFERONS ADMINISTERED SYSTEMATICALLY**

Nonrecombinant IFN-a was initially brought to clinical trial against several solid tumors in 1978, when the American Cancer Society began a series of trials of buffy coat leukocyte IFN produced by Cantell with the Finnish Red Cross. These trials were limited by the extremely short supply of the agent (the trials lasted for only 6 weeks) from which no firm conclusions can be drawn. The trials served as an important impetus for the pharmaceutical industry to begin commercial production of IFN-a, as well as IFN-b, -g, and other biologic agents, using recombinant DNA technology. The large-scale production of IFNs by recombinant DNA technology enabled the first systematic evaluation of appropriate dose, route, and schedule of IFN-a<sub>2</sub>, as well as the other major subspecies of IFN-a, -b, and -g.

Phase II trials have documented the antitumor activity of recombinant IFN-a<sub>2</sub> in many solid tumors as documented elsewhere in this volume. [Table 20.1-3](#) lists the applications of IFN-a that have received approval by the U.S. Food and Drug Administration in the United States.<sup>80,109,134,135,136,137,138,139,140and141</sup> General principles that can be drawn from this experience are that the hematologic neoplasms appear to respond to lower dosages than the solid tumors and to respond on the basis of direct effects that are either antiproliferative, prodifferentiative, or proapoptotic. The mechanism for IFN-a<sub>2</sub> antitumor activity in solid tumors appears to be indirect, as the result of antigenic modulation (MHC), modulation of host immune responses (CD4/CD8 T cell), or both, or antigen presentation (dendritic cell), although vascular

effects may also be implicated.

Role	Solid Tumors	Hematologic Neoplasms
Advanced disease	Kaposi's sarcoma	Hairy cell leukemia
	Renal cell carcinoma*	Chronic myeloid leukemia
	Melanoma <sup>a</sup>	Non-Hodgkin's lymphoma
	Carcinoid	T cell
Postoperative adjuvant setting	Ovarian cancer	B cell
	Melanoma stage II and III	
	Bladder carcinoma	

<sup>a</sup>With vinblastine chemotherapy.  
<sup>\*</sup>With polychemotherapy and interleukin-2 greater than 50% response; alone, 10% response; and 5% complete.

**TABLE 20.1-3.** Efficacy of Interferon- $\alpha_2$  in Human Cancer

## REGIONAL THERAPY WITH INTERFERON- $\alpha$

Intralesional administration of IFN- $\alpha$ <sup>142</sup> at 6 to 10 Mu twice or three times weekly has been used for refractory solid tumors such as melanoma,<sup>143</sup> but offers little advantage over systemic therapy. Regional *in-transit* disease of the extremity is an infrequent manifestation of melanoma that continues to be studied with hyperthermic isolated limb perfusion using combinations of chemotherapy (melphalan) and two cytokines (TNF, together with IFN-g). IFN-g was given for the original theoretical purpose of modulating TNF receptor expression for subsequent isolated limb perfusion with TNF. The role of IFN-g in this combination is debated, but the reported response rates of 90% with the original combination have been confirmed by investigators in the United States<sup>144,145</sup> and the Netherlands.<sup>146,147</sup> TNF given alone at comparable doses has shown only brief and limited antitumor activity,<sup>148</sup> suggesting that melphalan, or melphalan and IFN-g, may be critical to the therapeutic effects of the triple combination. Fraker and colleagues are undertaking a controlled study of isolated limb perfusion that will allow more definitive conclusions.<sup>144,149</sup>

## COMBINATIONS

### *Phase II Trials of Combinations of Biologic Agents: Types I and II, Interferon- $\alpha_2$ Plus Interferon-g*

Combinations of IFNs of types I and II (IFN- $\alpha_2$  or -b, and -g, respectively) have been of theoretical interest, given the potential synergism of IFNs interacting through the two separate classes of IFN receptor. The modulation of receptors for IFN- $\alpha_2$  by IFN-g and elucidation of signal transduction pathways through which IFN-g and IFN- $\alpha$  act at a molecular level<sup>22</sup> provide a further impetus for exploration of combined IFN therapy. The molecular synergism of IFN-g and IFN- $\alpha$  through signal transducer and transcriptional activators of IFN summarized by Darnell is currently under investigation with IFN- $\alpha_2$  and IL-12 (an inducer of IFN-g).<sup>19,21,22,23,24and25,150,151and152</sup>

Clinical studies of combinations of IFN- $\alpha$  and -g have previously followed two strategies: concurrent and sequenced administration. Increased toxicity without apparent therapeutic benefit was seen with concurrent regimens,<sup>153,154,155and156</sup> whereas sequenced regimens have improved therapeutic and immunomodulatory activity in renal cell carcinoma.<sup>85,157</sup>

### *Modulation of Antitumor and Immunologic Effects of Interferons by Biologic Agents, Cytotoxic Drugs, and Nonsteroidal Antiinflammatory Drugs*

The pleiotropic effects of IFN- $\alpha_2$  include the induction of a variety of feedback mechanisms of immunosuppression that may be associated with prostaglandins for which nonsteroidal antiinflammatory drugs might be of benefit. In addition, it has been hoped that these agents might alleviate some of the significant constitutional toxicity and flu-like symptoms of IFN therapy.

Miller et al.<sup>158</sup> have conducted a randomized controlled trial of indomethacin with IFN- $\alpha_2$ , demonstrating neither clinical nor immunologic untoward interactions. Dexamethasone has been assiduously avoided in most trials of IFN- $\alpha$ , -b, and -g as a consequence of its potent immunosuppressive effects. IFN- $\alpha$  has been used with corticosteroids for multiple myeloma and lymphoma, diseases in which corticosteroids have an established role. Corticosteroids abrogate the benefit of IFN in experimental animals, and it appears prudent to avoid corticosteroids during IFN- $\alpha_2$  therapy for solid tumors.<sup>158,159</sup>

### *Combinations of Interferon- $\alpha$ and Retinoids*

Broad interest exists in the potential applications of retinoids for therapy and prevention of squamous carcinomas of aerodigestive tract skin, carcinoma of the cervix, and other epithelial neoplasms. There have been unexpected and dramatic clinical responses of acute promyelocytic leukemia with the retinoids, and this disorder is associated with a lesion in the chromosomal region coding for the retinoic acid receptor. The retinoic acid receptors exhibit sequence homology with the corticosteroid hormone receptor superfamily, suggesting that both may function through the regulation of gene transcription, although the mechanism and optimal combination of retinoids and IFN- $\alpha$  have not been established.<sup>160,161and162</sup>

### *Combined Modality Therapy*

Given the differing presumed mechanisms and nonoverlapping toxicities of cytotoxic chemotherapy and IFN regimens available for hematologic neoplasms and solid tumors as well as the lack of a survival effect of previous combination chemotherapy,<sup>163</sup> the combination of chemotherapy and IFN- $\alpha_2$  has been an obvious one. The combination has shown mixed results.<sup>164,165,166,167,168,169,170and171</sup> The Eastern Cooperative Oncology Group has tested combinations of tamoxifen, IFN- $\alpha$ , or both versus dacarbazine in a factorial two-by-two study that demonstrates a lack of any advantage of IFN (high-dose) (or hormonal combination therapy with tamoxifen) over standard chemotherapy in melanoma.<sup>172</sup> Combinations of IFN- $\alpha$  and chemotherapy have suggested improved duration of response in myeloma<sup>173</sup> and non-Hodgkin's lymphoma.<sup>174,175</sup>

In melanoma, combination chemotherapy has been found to induce complete responses in a small fraction (less than 5%), and IL-2 has been shown to achieve a durable complete response in 6%.<sup>176</sup> IFN- $\alpha_2$  with IL-2 and combination chemotherapy has been associated with complete responses in more than 10%, and overall complete and partial responses in more than 50% of patients in multiple single-institution trials, leading to exploration of the role of IFN- $\alpha_2$  plus IL-2 with cisplatin, vinblastine, and dacarbazine, as opposed to polychemotherapy alone, in the current intergroup E3695 trial for metastatic melanoma.<sup>177,178</sup>

A number of regimens have evaluated the role of IFN- $\alpha_2$  in combination with complex cisplatin-based polychemotherapy regimens, with or without IL-2. These regimens have generally exacted greater toxicity than the binary regimens, requiring hospitalization for administration of IL-2 when administered by continuous intravenous infusion or high-dose bolus schedules.<sup>179,180and181</sup>

More complex regimens using multiple cytotoxic agents, IFN- $\alpha_2$ , and IL-2 have been reported from multiple centers in the United States and Europe.<sup>177,178</sup> Regimens known collectively as biochemotherapy have consistently achieved response rates greater than 50% with complete response in 10% or greater, at the cost of significant toxicity and hospitalization for metastatic melanoma. Intergroup study E3695 of the Eastern Cooperative Oncology Group and Southwest Oncology Group is evaluating whether IL-2 as a continuous infusion at high dosage for 4 days and IFN- $\alpha_2$  at a daily dosage of 5  $\mu$ /m<sup>2</sup> subcutaneously prolongs the survival of patients

with metastatic melanoma over cisplatin, vinblastine, and dacarbazine polychemotherapy.

The application of IFN as systemic adjuvant therapy is currently focused on melanoma, in which the precision of prognostic assessment for regional lymph node disease has advanced substantially. The risk category of patients with nodal metastasis defined using sentinel node mapping has improved substantially. <sup>182</sup>

Melanoma risk may be categorized as very high, high, intermediate, and low, according to 5-year relapse and mortality. The prognosis of clinically localized primary melanoma may be estimated rather precisely by the Breslow depth of primary tumor invasion (in millimeters) at the site of origin, the presence or absence of ulceration, and sentinel lymph node status. The poor prognosis for cure for deep or ulcerated primary disease, or node-positive patients has provided the rationale for postoperative adjuvant therapy of these categories of high-risk patients. <sup>183,184</sup>

## ADJUVANT TRIALS OF INTERFERON- $\alpha_2$ IN MELANOMA

On the basis of the antitumor activity of IFN- $\alpha_2$  in metastatic melanoma and the gradient of response with patients having the smallest size and number of metastases exhibiting the highest response rates, multiple trials of IFN- $\alpha_2$  for prevention of melanoma relapse were commenced in the United States and international cooperative groups during the 1980s. The three largest and most mature studies of IFN- $\alpha_2$  conducted to date adopted similar entry criteria, including patients with deep (T4) primary lesions or pathologically proven involvement of regional lymph nodes. The groups that have undertaken these studies were the Eastern Cooperative Oncology Group, North Central Cancer Treatment Group, and the World Health Organization.

### **Eastern Cooperative Oncology Group**

E1684 accrued 287 patients between 1984 and 1990, was unblinded and reported to the American Society of Clinical Oncology in 1993 <sup>185</sup> at 5 years of median follow-up, and published in 1996 at 6.9 years median follow-up. This trial used an aggressive therapy of 1 year's duration, 20  $\mu\text{m}^{-2}$  intravenously daily for 5 days a week for 1 month, then 10  $\mu\text{m}^{-2}$  subcutaneously t.i.w. for the balance of the year with IFN- $\alpha_{2b}$  or observed as the reference standard of care. Risk groups were defined by lymph node pathology (reviewed in all cases) and stratified to allow the analysis of therapeutic effect in homogeneous groups of patients whose susceptibility to this therapy was postulated to be potentially related to tumor burden and disease extent. <sup>186,187</sup>

The analysis of treatment effect for high-dose IFN- $\alpha_{2b}$  on relapse for the overall trial revealed a highly significant reduction of relapse rate ( $P_2 = .004$ ) and a significant survival benefit in the intention-to-treat analysis ( $P_2 = .046$ ). A Cox multivariate analysis demonstrated significant improvement in the disease-free and overall survival ( $P = .001$  to  $.01$ ) and estimated the relative improvement in continuous relapse-free survival to be 50%.

The median interval to relapse with IFN- $\alpha_{2b}$  adjuvant therapy was prolonged from 0.9 to 1.6 years, whereas the median survival of treated patients has been prolonged from 2.62 to 3.78 years. A retrospective quality-adjusted analysis of time spent without symptoms or toxicity (Q-TWiST) study has been conducted in the context of this trial. <sup>188,189</sup> After 84 months, the group of patients receiving IFN- $\alpha_{2b}$  gained a mean of 8.9 months quality-adjusted time without relapse ( $P = .03$ ) and 7 months of overall survival time ( $P = .02$ ) compared with the observation group.

Economic analyses of the E1684 regimen <sup>190,191 and 192</sup> projected incremental cost comparable with other accepted adjuvant therapies of breast and colorectal cancer. This therapy has been approved for resected high-risk melanomas by regulatory authorities across North and South America, Europe, and Australia.

To confirm and extend the preliminary results of the E1684 trial, the two intergroup trials were initiated: E1690, comparing the high-dose regimen of IFN- $\alpha_{2b}$  with a low-dose regimen of 3  $\mu\text{m}$  subcutaneous IFN- $\alpha_{2t}$  three times a week, which accrued 642 patients between 1990 and 1995, with 608 evaluable at 52 months' median follow-up, as the study was recently reported. An improvement in relapse-free survival for the high-dose IFN- $\alpha_{2t}$  was noted that is significant ( $P_2 = .03$  by Cox analysis) only for high-dose IFN- $\alpha_{2t}$ . Neither the high-dose arm nor the low-dose arm showed an improvement in overall survival, as compared with observation, in this trial, which included a substantial fraction (25%) who had deep primary melanoma, most of whom were not surgically and pathologically staged at elective lymph node dissection (as had been mandated in the first trial E1684). Postrelapse salvage surgery was feasible in these patients, followed by extensive use of IFN in patients who had relapsed after initial assignment to observation. The systematic and unbalanced pursuit of IFN salvage therapy in observation patients, more than IFN-assigned patients ( $P = .004$ ), was associated with prolonged survival that may have confounded efforts to detect differences between survival of those who were assigned originally to high-dose IFN, not observation. The World Health Organization trial 16 of low-dose IFN showed no significant survival or relapse-intense prologation in a study of similar size. <sup>193</sup> Most recently, the intergroup E1694 trial has been concluded, in which the overall survival and relapse-free survival benefit of the high-dose E1684 IFN $\alpha_2$  1 year regimen, with  $P = .009$  and  $P = .0015$ , in the largest study of high-dose IFN $\alpha_2$  conducted to date ( $n = 880$ ).

### **Vaccine: Interferon Contributions as Adjuvant Therapy for Melanoma**

The attractiveness of vaccines for melanoma is broad and theoretically compelling, although no randomized controlled trial of vaccine has yet shown benefit in melanoma. Eastern Cooperative Oncology Group trial E2696 has tested the anti-GM2 antibody IgG and IgM response induced by the vaccine alone, in comparison with the vaccine combined with or followed by IFN- $\alpha_{2b}$  at high dosage as in E1684/E1690. This trial has been completed and analyzed, demonstrating no significant inhibition of the immunogenicity of the GMK vaccine in terms of anti-GM2 antibody immunoglobulin G and immunoglobulin M. <sup>194</sup> Thus, it is reasonable to consider the combined use of vaccine, and high-dose IFN- $\alpha_{2b}$  in future adjuvant trials, as any vaccine has been demonstrated to be of benefit in appropriate randomized controlled trials, alone.

#### INTRODUCTION

Interleukin-2 (IL-2) is the first agent available for the treatment of metastatic cancer that functions solely through the activation of the immune system. Originally described as a growth factor for activated T cells, IL-2 was subsequently found to exert multiple effects on cellular immune function and to induce tumor regression in mice. Subsequent clinical trials in patients with renal cell carcinoma and malignant melanoma demonstrated sufficient efficacy to establish IL-2 as a U.S. Food and Drug Administration (FDA)-approved treatment for both of these malignancies.

#### ISOLATION, CHARACTERIZATION, AND CLONING OF INTERLEUKIN-2

In 1976, Morgan et al.<sup>1</sup> demonstrated the existence of a growth factor present in the conditioned medium of lectin-stimulated human peripheral blood mononuclear cells that could sustain indefinitely the *ex vivo* proliferation of human T cells. This initial report was followed in short order by the isolation, biochemical characterization, and, ultimately, the cloning of what was then termed *T-cell growth factor*.<sup>2,3</sup> Subsequently designated *IL-2*, this factor was shown to be a 15-kD polypeptide made up of 153 amino acids, the first 20 of which form a signal sequence that is proteolytically cleaved during secretion. Natural IL-2 is glycosylated, although the attachment of sugar moieties is not essential for biologic activity. The molecule has cysteine residues at positions 58, 105, and 125, the first two of which form an intramolecular disulfide bridge. The third cysteine is not essential for biologic activity and can be replaced with alternative amino acids to minimize polymerization and increase shelf life. Crystallographic analysis indicates that IL-2 is a spherical molecule comprised of six  $\alpha$  helical regions.

#### INTERLEUKIN-2 RECEPTOR

The various biologic effects of IL-2 are the result of the binding of the lymphokine to specific surface receptors.<sup>4</sup> As with IL-2 itself, the expression of high-affinity IL-2 receptors is induced as a result of signaling through the T-cell antigen receptor. With the exception of a minor population of memory T cells that presumably were activated *in vivo* by a prior antigen exposure, freshly isolated peripheral blood T cells do not constitutively express high-affinity IL-2 receptors.<sup>5</sup>

The high-affinity IL-2 receptor consists of three distinct subunits designated the  $\alpha$ ,  $\beta$ , and  $\gamma$  chains ( Fig. 20.2-1). The  $\alpha$  chain<sup>6</sup> is a 251 amino acid polypeptide with a large extracellular domain, a transmembrane span, and a short 13-residue cytoplasmic tail. The extracellular domain of this protein binds IL-2 with low affinity. The cytoplasmic domain of this receptor has no known biologic function and is dispensable for IL-2–induced signaling.

**FIGURE 20.2-1.** The high-affinity interleukin-2 receptor and associated signaling pathways. The cytoplasmic domains of the  $\beta$  and  $\gamma$  chains contain several tyrosines that, when phosphorylated, provide docking and activation sites for numerous downstream kinases that affect cell proliferation, gene expression, and cell motility. GTPases, guanosine triphosphatases; JAK, Janus kinase; PI3K, phosphoinositide 3 kinase; STAT, signal transduction and activators of transcription.

The IL-2 receptor  $\beta$  chain has a 214 amino acid extracellular domain, a transmembrane motif, and a large 286-residue cytoplasmic tail.<sup>7</sup> In contrast to the cytoplasmic domain of the  $\alpha$  chain, that of the  $\beta$  chain is essential for IL-2 signaling. The IL-2 receptor  $\beta$  chain has paired cysteines at two sites within the extracellular domain and a perimembrane WSXWS motif characteristic of the members of an enlarging cytokine receptor superfamily that includes the receptors for IL-3, IL-4, IL-6, IL-7, granulocyte-macrophage colony-stimulating factor, prolactin, erythropoietin, and growth hormone.

The  $\gamma$  chain is a novel 64-kD protein that physically associates with the  $\beta$  chain. Like the  $\beta$  chain, the  $\gamma$  chain is a member of the cytokine receptor superfamily.<sup>8</sup> These two together bind IL-2 with intermediate affinity. When cotransfected along with the complementary DNAs of the  $\alpha$  and  $\beta$  chains, the complementary DNA encoding the  $\gamma$  chain yields a high-affinity IL-2 receptor that transduces signals and is internalized in response to IL-2 binding. More recent studies have demonstrated that this receptor chain is shared by the receptors for several lymphokines, including IL-4, IL-7, IL-9, and IL-15, as well as IL-2.<sup>9</sup> Mutations in the gene encoding this receptor chain account for most, if not all, cases of X-linked severe combined immunodeficiency.<sup>10</sup> Using antibodies against these receptor chains, resting T cells were found to constitutively express low levels of the IL-2 receptor  $\gamma$  chain, but not the  $\alpha$  or  $\beta$  chains. All three chains are up-regulated as a result of antigenic stimulation. Resting natural killer cells constitutively express the  $\beta$  chain, and both the  $\alpha$  and  $\gamma$  chains are induced in these cells by exposure to IL-2 or IL-12.<sup>11</sup>

#### INTERLEUKIN-2 –ACTIVATED SIGNALING PATHWAYS

The binding of IL-2 to its receptor induces the tyrosine phosphorylation of numerous cellular proteins, including the IL-2 receptor  $\beta$  chain itself. Because all three chains of the IL-2 receptor lack intrinsic tyrosine kinase activity, these events must be transduced through kinases that physically associate with the cytoplasmic domains of the receptor subunits (see Fig. 20.2-1). Indeed, the *src* family member p56<sup>lck</sup> has been shown to associate with the  $\beta$  chain, and its kinase activity is augmented by IL-2.<sup>12</sup> IL-2 also induces the recruitment and subsequent tyrosine phosphorylation of the adapter protein *Shc* to the IL-2R  $\beta$  chain. This particular association is thought to be largely responsible for the activation of p21<sup>ras</sup> and the downstream mitogen-activated protein kinases *erk-1* and *erk-2* in response to

IL-2.<sup>13</sup> The IL-2 receptor  $\gamma$  chain is also essential for IL-2–induced signaling, because T-cell lines expressing the  $\alpha$  and  $\beta$  chains and a mutant version of the  $\gamma$  chain lacking the C-terminal 68 residues fail to express the protooncogenes *c-fos*, *c-jun*, and *c-myc* when stimulated with IL-2.<sup>14</sup>

In addition to the association with *src* family tyrosine kinases, both the  $\beta$  and  $\gamma$  receptor chains associate with members of the Janus kinase family of tyrosine kinases.<sup>15</sup> Janus kinase family member JAK3 associates with the C-terminus of the IL-2 receptor  $\gamma$  chain, and both JAK1 and JAK2 associate with the  $\beta$  chain. JAK1 has been shown to bind to a specific serine-rich domain present in the membrane-proximal region of the  $\beta$  chain. Janus kinases activate various members of the signal transduction and activators of transcription (STAT) family of transcription factors. The binding of IL-2 to its receptor results in the activation of STAT1, STAT3, and STAT5 in T cells, and an additional member, STAT4, in natural killer (NK) cells.<sup>16</sup>

## IN VITRO EFFECTS OF INTERLEUKIN-2

IL-2 was originally isolated based on its ability to induce the growth of previously activated T cells.<sup>1</sup> In addition to its proliferative effects, IL-2 induces the synthesis of an array of secondary cytokines, such as IL-1, tumor necrosis factor (TNF), IL-6, and lymphotoxin.<sup>17</sup> Several of these secondary cytokines are detectable in the circulation of cancer patients receiving IL-2 immunotherapy (see later, [Toxicity of High-Dose Interleukin-2 Administration](#)) and are thought by many investigators to contribute to the side effects of IL-2.<sup>18</sup>

The biologic effect of IL-2 arguably most pertinent to its use as an antitumor agent may be its ability to enhance the cytolytic activity of antigen-specific cytotoxic T lymphocytes and NK cells.<sup>19,20</sup> The biochemical basis for this enhanced cytolytic function is currently unclear, but it is thought to be due in part to the increased expression of genes encoding the lytic components of cytotoxic granules (e.g., perforin, granzymes) as well as adhesion molecules (lymphocyte function-associated antigen 1) that facilitate the binding of activated leukocytes to tumor endothelium and the tumor cells themselves. In addition to increasing the HLA-restricted cytolytic activity of cytotoxic T lymphocytes for cells expressing a particular antigen and that of NK cells for susceptible tumor cell targets, IL-2 markedly diversifies the range of target cells susceptible to killing by these effectors.<sup>21,22</sup> Indeed, human peripheral blood lymphocytes exposed only to high concentrations of IL-2 without prior exposure to tumor cells are able to kill virtually all tumor cell lines and most freshly isolated tumor cells *in vitro*, regardless of the particular HLA class I alleles expressed by the target cell. Some nontransformed cells, in particular cultured endothelial cells, are similarly susceptible to IL-2–primed peripheral blood lymphocytes in isotope release assays.<sup>23</sup> The cells responsible for this HLA-unrestricted killing in response to IL-2 have been termed *lymphokine-activated killer* (LAK) cells.<sup>21,22</sup> LAK cells appear to be a mixture of activated NK cells and CD3+/CD8+ cytotoxic T cells, the relative contributions of which depend on the duration of culture in IL-2 and whether human peripheral blood lymphocytes or murine spleen suspensions are used as a LAK cell source. As described below, these *ex vivo*–activated LAK cells featured prominently in the early clinical trials carried out with IL-2 in cancer patients.

## PRECLINICAL STUDIES WITH INTERLEUKIN-2 IN TUMOR-BEARING MICE

The results of the *in vitro* studies demonstrating that IL-2 could enhance the cytolytic activity of NK cells and tumor-specific cytotoxic T cells suggested that systemically administered IL-2 might induce tumor regression in tumor-bearing mice. IL-2 has since undergone extensive evaluation as an antitumor agent in a variety of murine tumor models. IL-2 has been used alone, in combination with other cytokines, and in conjunction with the adoptive transfer of various *ex vivo*–activated lymphoid preparations to eradicate a wide range of local and metastatic tumors. Early studies demonstrated that IL-2 used alone could reduce or eliminate pulmonary metastases from methylcholanthrene-induced sarcoma and melanoma cell lines and that this antitumor effect was strictly dependent on the dose of IL-2 administered.<sup>24</sup> In another early study, IL-2 was able to cure 50% of mice inoculated with FBL-3 leukemia cells.<sup>25</sup> In this study, mice cured of leukemia by IL-2 were resistant to the subsequent inoculation of the same tumor cell line, suggesting that IL-2 treatment had effectively immunized the tumor-bearing mice against this particular tumor. In more recent studies in which mice were immunized with dendritic cells pulsed with tumor lysates, the concurrent systemic administration of IL-2 was shown to enhance the efficacy of the vaccine.<sup>26</sup>

In several studies, the effects of IL-2 could be enhanced by the concurrent administration of LAK cells generated by culturing splenocytes *ex vivo* in IL-2–containing media.<sup>27</sup> Mice bearing hepatic micrometastases from poorly immunogenic MCA-105 or MCA-102 sarcomas or MCA-38 adenocarcinoma cells, for example, were highly responsive to treatment with the combination of IL-2 and LAK cells but were unresponsive to LAK cells alone and only partially responsive to IL-2.

Lymphocytes present within tumor infiltrates are presumably enriched for effector cells capable of killing tumor cells.<sup>28</sup> When isolated and tested *in vitro* for cytolytic activity against autologous tumor cells, these tumor-infiltrating lymphocytes (TILs) are 50- to 100-fold more potent than IL-2–activated splenocytes (LAK cells). This apparent superiority was also evident *in vivo*. The infusion of  $2 \times 10^6$  TILs with IL-2, for example, completely eradicated the pulmonary metastases of mice previously inoculated with MCA-105 sarcoma cells.<sup>29</sup> As many as  $2 \times 10^8$  LAK cells were required for a comparable effect.

## CLINICAL APPLICATIONS OF INTERLEUKIN-2

The potent immunomodulatory and antitumor effects of IL-2 in the *in vitro* experiments and preclinical animal tumor models described in the previous two sections prompted the rapid movement of IL-2 into the clinical setting. Early clinical trials involving the brief administration of modest doses of purified, cell-derived IL-2 produced only transient fever and lymphopenia, but no sustained ill effects or tumor responses.<sup>30</sup> Because preclinical trials had shown that tumor responses were dose-dependent and maximal when IL-2 was combined with LAK cells, the advent of recombinant IL-2 led quickly to a series of trials using higher doses of IL-2, with and without LAK cells.

## CLINICAL INVESTIGATIONS INVOLVING HIGH-DOSE INTERLEUKIN-2

Investigators at the National Cancer Institute (NCI) Surgery Branch developed a regimen that involved the administration of high-dose intravenous bolus IL-2.<sup>31,32</sup> In this regimen, IL-2 [aldesleukin (Proleukin); Cetus/Chiron, Emeryville, CA] was administered at 600,000 to 720,000 IU/kg intravenously every 8 hours on days 1 to 5 and 15 to 19 of a treatment course. A maximum of 28 to 30 doses per course was administered; however, doses were frequently withheld for excessive toxicity. Treatment courses were repeated at 8- to 12-week intervals in responding patients. During initial studies, patients underwent daily leukaphereses on days 8 to 12, during which large numbers of lymphocytes were obtained to be cultured in IL-2 for 3 to 4 days to generate LAK cells; these LAK cells were then reinfused into the patient during the second 5-day period of IL-2 administration.

This high-dose IL-2 regimen, with or without LAK cells, produced overall tumor responses in 15% to 20% of patients with metastatic melanoma or renal cell cancer in clinical trials conducted at either the NCI Surgery Branch or within the Cytokine Working Group (formerly the Extramural IL-2 and LAK Working Group).<sup>32,33,34</sup> Complete responses were noted in 4% to 6% of patients with each disease and were frequently durable. Rare responses, usually partial and of shorter duration, were also noted in patients with either Hodgkin's or non-Hodgkin's lymphoma,<sup>35</sup> or non–small cell lung, colorectal, or ovarian carcinoma.<sup>36</sup> Randomized and sequential clinical trials comparing IL-2 plus LAK cells with high-dose IL-2 alone did not show sufficient benefit for the addition of LAK cells to justify their continued use.<sup>37,38,39</sup> The quality and durability of tumor responses to this high-dose IL-2 regimen led to IL-2 receiving FDA approval for the treatment of metastatic renal cell carcinoma in 1992 and metastatic melanoma in 1998.<sup>40,41</sup>

## TOXICITY OF HIGH-DOSE INTERLEUKIN-2 ADMINISTRATION

The utility of high-dose IL-2 has been limited by toxicity, many features of which resemble bacterial sepsis. Side effects are dose-dependent and largely predictable and rapidly reversible. Common side effects include fever, chills, lethargy, diarrhea, nausea, anemia, thrombocytopenia, eosinophilia, diffuse erythroderma, hepatic dysfunction, and confusion.<sup>42,43</sup> Myocarditis also occurs in approximately 5% of patients. IL-2 therapy also commonly produces a “capillary leak syndrome,” leading to fluid retention, hypotension, early adult respiratory distress syndrome, prerenal azotemia, and, occasionally, myocardial infarction. As a consequence of these side effects, few patients are able to receive all of the proposed therapy. IL-2 also has been shown to produce a neutrophil chemotactic defect that predisposes patients to infection with gram-positive and, occasionally, gram-negative bacteria.<sup>44,45</sup> Early high-dose IL-2 studies were associated with 2% to 4% mortality, largely related to infection or cardiac toxicity.<sup>46,47,48,49</sup> The routine use of antibiotic prophylaxis, more extensive cardiac screening, and more judicious IL-2 administration have greatly enhanced the safety of this therapy; since 1990, the mortality rates at experienced treatment centers have been less than 1%<sup>46</sup> (Table 20.2-1). Nonetheless, the considerable toxicity of the high-dose IL-2 regimen has continued to limit its application to highly selected patients with excellent performance status and adequate organ function treated at medical centers with considerable experience with this approach.

Adverse Event <sup>a</sup>	1985 Incidence (%)	1997 Incidence (%)
Hypotension	81	31
Diarrhea	92	12
Neuropsychiatric toxicity	19	8
Line sepsis	18	4
Pulmonary complications	12	3

<sup>a</sup>720,000 IU/kg every 8 hours.  
<sup>b</sup>With patient selection and experience in managing side effects, high-dose recombinant interleukin-2 is safe. No treatment-related deaths in 809 consecutive patients.  
<sup>c</sup>Incidence of grade 3-4 adverse events has been greatly reduced.  
Data from ref. 46.

**TABLE 20.2-1.** Safety of High-Dose Intravenous Bolus Recombinant Interleukin-2 Therapy <sup>a</sup>: The National Cancer Institute Experience <sup>b</sup>

Laboratory studies have suggested that IL-2 toxicity appears to be mediated, at least in part, by the release of secondary cytokines such as TNF- $\alpha$ , IL-1, and IL-6 and the generation of nitric oxide.<sup>47,48and49</sup> Nonetheless, attempts to block the toxicity of IL-2 by the co-administration of selective inhibitors of the biologic effects of these secondary cytokines have been largely unsuccessful to date.<sup>50,51and52</sup>

### MANAGEMENT OF PATIENTS RECEIVING HIGH-DOSE INTERLEUKIN-2

The management of patients undergoing high-dose IL-2 therapy begins at the time of patient selection. This therapy should be limited to patients without significant cardiac disease (prior myocardial infarction, angina, congestive heart failure, or serious cardiac arrhythmias). Patients older than age 40 years should have a normal cardiac stress test. In addition, patients should have no evidence of central nervous system metastases; adequate pulmonary, renal, and hepatic function (forced expiratory volume in 1 second of more than 2 L, serum creatinine less than 1.6 mg/dL, serum bilirubin less than 1.5 mg/dL); and good performance status (Eastern Cooperative Oncology Group scale, 0 or 1).

Concomitant therapy typically includes acetaminophen and indomethacin to prevent rigors and fever, H<sub>2</sub> blockers to prevent gastritis, and prophylactic antibiotics to prevent catheter-related infections. Patients should also receive antiemetics, antidiarrheals, and skin care on an as-needed basis. Steroids should be avoided because they interfere with immune activation. Patients typically require fluid administration to support their blood pressure. Hypotension unresponsive to fluid administration is treated with intravenous dopamine hydrochloride and, when necessary, intravenous phenylephrine hydrochloride. Sodium bicarbonate administration is often necessary to keep the serum HCO<sub>3</sub> concentration higher than 18 mEq/L. Severe toxicities, such as hypotension requiring multiple pressor agents, confusion, cardiac arrhythmias or myocarditis, metabolic acidosis, or dyspnea, are usually managed by withholding doses of IL-2. Once these problems resolve, treatment usually can be resumed (omitted doses of IL-2 are not replaced).

With careful patient selection and judicious treatment of toxicity, most patients can safely receive an adequate amount of high-dose IL-2; however, because of the unusual nature and potential severity of these side effects, the use of this therapy by inexperienced physicians and nurses should be discouraged.

### LOWER-DOSE OR ALTERNATIVE INTERLEUKIN-2 REGIMENS

Because of the significant toxicity associated with high-dose intravenous bolus IL-2 regimens and the expense involved with the necessary hospitalization and intensive monitoring, various investigators have attempted to establish active regimens using lower doses of IL-2. In these regimens, IL-2 was administered either by lower-dose intravenous bolus, continuous intravenous infusion, or subcutaneous injection in an effort to maintain or enhance antitumor effects while decreasing toxicity. [Table 20.2-2](#) lists a variety of the more commonly used lower-dose IL-2 regimens.<sup>53,54,55,56,57,58and59</sup>

Regimen	IL-2 Dose	IL-2 Schedule	Clinical Setting
High-dose IV bolus IL-2	600,000-720,000 IU/kg	IV q8h days 1-5, 15-20	ICU-like
Continuous infusion IL-2	18 MIU/m <sup>2</sup> /d	CV infusion days 1-5, 15-20	ICU-like
Low-dose IV bolus IL-2	720,000 IU/kg	IV q8h days 1-5, 15-20	Ward
Subcutaneous IL-2	250,000 IU/kg/d	SC days 1-5, 15-20	Outpatient
Intermediate IL-2	18 MIU/m <sup>2</sup> /d	CV infusion 1-5	Ward
	18 MIU/m <sup>2</sup> /d	CV infusion 1-5	
	18 MIU/m <sup>2</sup> /d	CV infusion 1-5	
	45 MIU/m <sup>2</sup> /d	CV infusion 1-5	
Thalidomide IL-2	18 MIU/d	CV infusion 1-5-20	Outpatient

CV, continuous intravenous; ICU-like, intensive care unit or specialized unit capable of providing blood pressure support.

**TABLE 20.2-2.** Commonly Used Treatment Regimens of Interleukin-2 (IL-2) Alone

The maximum tolerated dose for IL-2 when administered by a 5-day (120-hour) continuous infusion was shown to be 18 MIU/m<sup>2</sup>/d or only approximately one-fifth the total amount of IL-2 tolerated by intravenous bolus IL-2 regimens.<sup>53</sup> Although continuous infusion IL-2 regimens were shown to produce response rates similar to the high-dose intravenous bolus IL-2 regimen, the toxicity was also generally comparable.<sup>53,54and55</sup> Other regimens, such as those using lower doses of IL-2 administered either by intravenous bolus or subcutaneous injection, are much better tolerated, enabling treatment to be provided in a routine ward or even an outpatient setting. The side effects are generally limited to the flu-like symptoms and constitutional symptoms already described, allowing treatment to be provided safely, even to patients with more limited cardiac, pulmonary, and renal function. These regimens have produced roughly comparable response rates in patients with renal cell carcinoma; however, the quality and durability of these responses have yet to be shown to be comparable to the responses observed with high-dose intravenous regimens.<sup>56,57</sup> Lower-dose IL-2 regimens have been largely inactive in patients with metastatic melanoma.<sup>60</sup>

### BIOLOGY AND PHARMACOKINETICS OF INTERLEUKIN-2

Although only the recombinant IL-2 manufactured by Chiron (Proleukin) is currently FDA approved for clinical use, several different IL-2 preparations have been used in clinical trials. These preparations differ in potency and, in some instances, biologic activity. By convention,<sup>60</sup> the following conversion factors are used: 1 Cetus unit = 6 IU; 1 Hoffman-LaRoche unit = 1 Biologic Response Modifier Program = 2.6 IU. It has become apparent, however, that many other differences may exist between these preparations<sup>61</sup> and, therefore, these simple conversions may not be entirely valid.

Yang et al.<sup>56</sup> examined the pharmacokinetics of IL-2 (Proleukin) administered to patients with advanced renal cell carcinoma on three distinct treatment regimens ([Fig. 20.2-2](#)). Patients undergoing treatment with high-dose intravenous IL-2 (720,000 IU/kg) achieved peak serum concentrations of 4680  $\pm$  1188 IU/mL shortly after the first injection. Subsequent clearance was biphasic, with an initial half-life of 12.6  $\pm$  5.4 minutes and a terminal half-life of 1.6  $\pm$  0.4 hours. Patients receiving low-dose intravenous IL-2 (72,000 IU/kg) exhibited peak levels of 486  $\pm$  198 IU/mL after the first injection, with a similar clearance pattern and rates. Those patients receiving IL-2 administered subcutaneously at a dose of 250,000 IU/kg had peak serum levels of 61  $\pm$  34 IU/mL 2 to 3 hours after the injection, with a half-life of 5.3  $\pm$  1.9 hours. Levels in excess of 18 IU/mL were maintained between injections in patients receiving either the high-dose intravenous or the subcutaneous regimen cited, but not the low-dose intravenous regimen. The relationship of these differing pharmacokinetic profiles to the biologic and antitumor effects of IL-2 remains to be determined.

**FIGURE 20.2-2.** Examples of pharmacokinetic studies on representative patients with metastatic renal cell carcinoma measuring biologically active serum interleukin (IL)-2 levels after the first administration of recombinant IL-2 at (A) 720,000 IU/kg by intravenous bolus, (B) 72,000 IU/kg by intravenous bolus, or (C) 250,000 IU/kg by subcutaneous injection. (From ref. 56, with permission.)

## ATTEMPTS TO IMPROVE ACTIVITY OF INTERLEUKIN-2-BASED THERAPY

A number of approaches have been tried in an effort to improve the activity of IL-2–based therapy. These are listed in Table 20.2-3. Although preclinical laboratory and animal studies provided a strong rationale for the clinical investigations involving the combination of IL-2 and interferon- $\alpha$  (IFN- $\alpha$ ),<sup>62</sup> and early clinical studies appeared promising,<sup>63</sup> subsequent clinical trials have not shown superiority for this combination relative to high-dose IL-2.<sup>64,65</sup> Nonetheless, combinations of low-dose IL-2 with IFN have been developed that can be administered safely in an outpatient setting, and they appear to possess sufficient antitumor activity to enable them to be considered by many as an alternative to high-dose IL-2.<sup>67,68</sup> In addition, low-dose IL-2 and IFN regimens have been better able to accommodate the addition of other potentially active agents, such as chemotherapy or cellular therapy.

Combination with other cytokines
Interferon- $\alpha$
Interferon- $\gamma$
Tumor necrosis factor
Interleukin-4
Interleukin-12
Combinations with monoclonal antibodies
Tumor antigen target
T-cell activation antigen target
Combinations with vaccines
Nonspecific tumor derived
HLA-restricted peptide
Dendritic cell based
Combinations with adoptive immunotherapy
Lymphokine-activated killer cell
Tumor-infiltrating lymphocytes
CD8-selected tumor-infiltrating lymphocytes
Interleukin-2–based biochemotherapy
5-Fluorouracil based
Cisplatin/dacarbazine based
Expansion to other diseases
Adjuvant therapy

**TABLE 20.2-3.** Approaches to Improve the Activity of Interleukin-2

Efforts to combine IL-2 with other potentially active cytokines, such as IFN- $\gamma$ , TNF, and IL-4, have been largely unsuccessful to date,<sup>70</sup> whereas clinical trials involving combinations of IL-2 and IL-12 are ongoing. Likewise, combinations of IL-2 with a variety of monoclonal antibodies directed either against tumor antigens (GD2 or GD3 gangliosides) or T-cell activation antigens (CD3) have been disappointing.<sup>71</sup> Although IL-2 and TIL combinations were extremely promising in animal tumor models, results of human investigations with this approach have been mixed. Although preliminary studies involving IL-2 and TILs in melanoma or IL-2/IFN and selected CD8+ TILs in renal cell carcinoma produced encouraging response rates, selection bias could not be excluded as an explanation.<sup>72,73</sup> A randomized trial of low-dose IL-2, with or without CD8+ TILs, in patients with metastatic renal cell carcinoma produced a disappointingly low response rate for both treatment arms<sup>75</sup>; a similar study has yet to be performed in patients with metastatic melanoma.

Despite their limited therapeutic utility, TILs have proven to be a valuable tool for identifying melanoma-associated tumor regression antigens.<sup>76</sup> Extensive research at the NCI Surgery Branch and elsewhere has identified HLA-restricted melanocyte lineage–specific antigens that are recognized by the cellular immune system in patients exhibiting a response to IL-2–based therapy.<sup>77</sup> Active immunization trials with immunodominant peptides derived from these tumor regression antigens have produced some encouraging results.<sup>78,79</sup> For example, vaccination with a mutated version of the *gp100* peptide antigen, together with high-dose IL-2, produced tumor responses in more than 40% of patients.<sup>80</sup> Confirmatory trials examining either a variety of schedules of peptide vaccination and IL-2 administration or comparing this combination to high-dose IL-2 alone are currently under way. In addition, trials examining combinations of similarly HLA-restricted antigens or antigen-presenting cells pulsed with these peptides together with IL-2 have been initiated.

Another promising approach has involved the combination of IL-2–based immunotherapy and cytotoxic chemotherapy—so called biochemotherapy. Efforts in renal cell cancer patients have focused on the addition of 5-fluorouracil–based chemotherapy,<sup>79</sup> whereas in melanoma, investigations have primarily examined IL-2 together with cisplatin- and dacarbazine-based cytotoxic chemotherapy.<sup>81,82</sup> Response rates as high as 40% in patients with renal cell carcinoma and 50% to 60% in patients with metastatic melanoma have been reported with these regimens. These encouraging results from multiple phase II trials and metaanalyses<sup>83,84</sup> await confirmation in ongoing large-scale phase III clinical trials. If biochemotherapy proves superior to chemotherapy alone in either disease, it might conceivably provide a rationale for examining IL-2–based biochemotherapy regimens in other 5-fluorouracil– or cisplatin-sensitive malignancies. In addition, these or other approaches mentioned here might show sufficient activity in the metastatic setting to justify their being examined in the high-risk adjuvant setting in which tumor burden and associated immune suppression may be less and, consequently, the potential for clinical impact may be greatly enhanced.

#### INTRODUCTION

There are many hormonal agents used in the treatment of patients with cancer. The primary use of these agents is in hormonally responsive cancers such as breast, prostate, or endometrial carcinomas. Other uses for some hormonal therapies include paraneoplastic syndromes, such as carcinoid syndrome, or symptoms caused by cancer, including anorexia. This chapter discusses the major hormonal agents for such therapy, first with a general overview of their use in practice, then with more detailed pharmacologic information regarding them.

#### SELECTIVE ESTROGEN RECEPTOR MODULATORS

##### TAMOXIFEN

Tamoxifen is most frequently used in the adjuvant treatment of women with resected breast cancer. There is general consensus, at present, that tamoxifen should be continued for 5 years. Tamoxifen is also used for treating patients with metastatic breast cancer if their disease has characteristics that would suggest hormonal responsiveness.<sup>1,2</sup> In addition, tamoxifen has undergone prospective evaluation as a potential breast cancer chemoprevention drug.<sup>3</sup> The study reported that tamoxifen decreased the incidence of breast cancer by approximately 50%. Nonetheless, this treatment has not been widely used to date in clinical practice for several reasons, including: (1) the vast majority of treated patients do not get benefit; (2) there is not yet any significant effect on patient survival; (3) the economic cost of the drug is high; (4) toxicities occur from this drug; and (5) the findings of this study have not been confirmed by two ongoing European trials (which underwent interim analyses).

The standard dose of tamoxifen is 20 mg. The long terminal half-life of the drug indicates that this can be given once daily. Tamoxifen is among the least toxic antineoplastic agents. Randomized, placebo-controlled trials have demonstrated that it does not cause any more gastrointestinal symptoms than placebo. The most prominent toxicity from tamoxifen is hot flashes, which affect approximately one-half of women. These hot flashes are of varying intensity and varying duration. Tamoxifen-induced hot flashes appear to increase over the first 3 months of therapy and then plateau.<sup>1</sup> They appear to be more prominent in women with a prior history of hot flashes or a prior history of using estrogen replacement. They can be ameliorated by the concurrent use of low doses of megestrol.<sup>4,5</sup>

The estrogenic properties of tamoxifen are responsible for both beneficial and deleterious side effects. The most prominent deleterious one, endometrial cancer, is increased approximately threefold in incidence over the general population. It has not yet been determined if progestins can prevent this toxicity of tamoxifen as they do with estrogen treatment. Beneficial estrogenic effects from tamoxifen include a decrease in total cholesterol,<sup>6,7</sup> a suggestion of decreased cardiovascular disease,<sup>8</sup> and a preservation of bone density in postmenopausal women.<sup>9,10</sup> In premenopausal women, tamoxifen appears to have a negative effect on bone density.<sup>11</sup> Although most patients do not complain of vaginal symptoms, a few complain of vaginal dryness, whereas others have increased vaginal secretions with a resultant vaginal discharge. An uncommon effect from tamoxifen is retinal toxicity. This has usually been associated with high drug doses or prolonged drug use.<sup>12</sup> Tamoxifen may predispose to thromboembolic phenomena, especially if used with concomitant chemotherapy. Depression has also been described, but this association with tamoxifen is not clear. Although liver cancers have been noted in laboratory animals, there is no clear-cut association between tamoxifen and liver cancers in humans.

##### Pharmacology

The chemical structure of tamoxifen is shown in [Figure 20.3-1](#). It acts by blocking estrogen stimulation of breast cancer cells, inhibiting both translocation and nuclear binding of the estrogen receptor. This alters transcriptional and posttranscriptional events mediated by this receptor.<sup>13,14</sup> *In vivo*, tamoxifen activity is complicated by the potential actions of the metabolite *trans*-4-hydroxy-tamoxifen, which is a potent antiestrogen. Tamoxifen has agonistic, partial agonistic, or antagonistic effects depending on the species, target, or end points that have been assessed. Other effects that have been attributed to tamoxifen include inhibition of the conversion of estrone sulfate to estradiol,<sup>15</sup> inhibition of protein kinase C,<sup>16</sup> and reversal of multidrug resistance.<sup>17,18</sup>

FIGURE 20.3-1. Structure of tamoxifen.

Resistance to tamoxifen develops with resultant recurrence or progression of metastatic breast cancer.<sup>19</sup> Several mechanisms for this resistance have been proposed.<sup>20,21</sup> At each step of the signal transduction pathway with which tamoxifen interferes, there is potential for an alteration in response. Tamoxifen binds to the estrogen receptor, and subsequent translocation of this complex to the nucleus and binding to the estrogen response element occur. This binding prevents transcriptional activation of estrogen-responsive genes. Decreased tamoxifen metabolism to the potent antiestrogen *trans*-4-hydroxy-tamoxifen and increased metabolism to estrogenic compounds such as metabolite E have been proposed as possible mechanisms of resistance.<sup>22,23,anc24</sup> In some cases resistance occurs after loss of estrogen receptor-positive cells.<sup>25,26</sup> Although estrogen receptor mutation has been suggested as a mechanism of resistance, two groups have found little evidence for such changes in the estrogen receptor.<sup>27,28</sup> Phosphorylation of the estrogen receptor can mediate the hormone binding, DNA binding, and ultimately transcriptional activation. Alterations in this phosphorylation mediated by changes in protein kinase A and C could lead to resistance. Finally, modifications of the estrogen-response element such as sequence alteration or element duplication may lead to binding of the tamoxifen-estrogen receptor complex with increased transcription of the estrogen-response genes. At present, the primary mechanisms of tamoxifen action remain unknown, and further studies are needed.

The carcinogenic potential of tamoxifen has been recognized in rat studies<sup>29,30,anc31</sup> and in humans.<sup>32</sup> Although the mechanism of these carcinogenic effects is not understood, it has been proposed that generation of reactive intermediates that bind covalently to macromolecules underlies the process. Such reactive intermediates have been demonstrated *in vitro*.<sup>33,34,anc35</sup> In addition, induction of covalent DNA adducts in rat livers treated with tamoxifen has been reported.<sup>36</sup> Both constitutive and inducible cytochrome P-450 enzymes have been implicated in the formation of metabolites with tamoxifen,<sup>37,38</sup> and the flavine-containing monooxygenase has been implicated in the formation of the N-oxide of tamoxifen. Reactive intermediates from such metabolic steps are being evaluated for their carcinogenic potential *in vitro* and *in vivo*.

The pharmacokinetics of tamoxifen have not been fully elucidated despite clinical use of the drug for more than 20 years. The oral bioavailability is not known. Results from animal studies suggest that the drug is well absorbed.<sup>39</sup> Oral administration of [<sup>14</sup>C]tamoxifen results in only 30% of radioactive material detectable in feces and approximately 11% in urine.<sup>40</sup> Whereas oral absorption may be good, first-pass metabolism may significantly alter exposure *in vivo*. The metabolic pathway of tamoxifen outlined in Figure 20.3-2 is dependent on the cytochrome P-450 3A subfamily-mediated demethylation and hydroxylation (possibly by an as yet undetermined cytochrome P-450 isoenzyme) followed by glucuronidation and biliary excretion. 4-Hydroxy-tamoxifen, which exists as two stereoisomers, is a potent antiestrogen<sup>41</sup> as the *trans*-isomer, but is much less potent as the *cis*-isomer.<sup>42,43</sup> The predominant species in serum are N-desmethyl-tamoxifen and N-desdimethyl-tamoxifen whereas 4-hydroxy-tamoxifen and 4-hydroxy-N-desmethyl-tamoxifen and metabolite Y, which are more hydrophilic, are found in lower concentrations. Metabolism affects the actions of tamoxifen because the hydroxylated metabolites have higher affinity for the estrogen receptor than the parent compound.<sup>44</sup> Tamoxifen is 98% bound to human serum albumin.<sup>45,46</sup>  $\alpha_1$ -acid glycoprotein binding by tamoxifen may have an impact on its clinical activity because the presence of  $\alpha_1$ -acid glycoprotein in tissue cultures abolishes the inhibitory effect of tamoxifen and toremifene on P glycoprotein.<sup>17</sup>

FIGURE 20.3-2. Tamoxifen metabolism.

Peak plasma levels of tamoxifen ( $C_{max}$ ) are seen 3 to 7 hours after oral administration. Assuming an oral bioavailability of 30%, the volume of distribution has been calculated to be 20 L/kg, and plasma clearance ranges from 1.2 to 5.1 L/h.<sup>60</sup> The terminal half-life of tamoxifen has been reported to range between 4 and 11 days.<sup>47,48</sup> The elimination half-life of tamoxifen increases with successive doses.<sup>47,49</sup> This finding is consistent with tamoxifen inhibition of its own metabolism. The drug's distribution in tissues is extensive. Levels of the parent drug and metabolites have been reported to be higher in tissue than in plasma in animal studies.<sup>50,51</sup> Reports of tamoxifen concentrations 10- to 60-fold higher than plasma concentrations in liver, lung, brain, pancreas, skin, and bone have appeared.<sup>52,53</sup> Concentrations of tamoxifen in pleural, pericardial, and peritoneal effusions approach those in plasma, with effusion to serum ratios ranging between 0.2 and 1.0. These findings are consistent with the large calculated volume of distribution. Elevated levels of tamoxifen with biliary obstruction have been reported.<sup>54</sup>

Tamoxifen has been reported to interact with coumadin,<sup>55,56,57,anc58</sup> digitoxin,<sup>59</sup> and medroxyprogesterone.<sup>58</sup> Lien et al.<sup>60</sup> have reported that tamoxifen serum concentrations and those of metabolites Y, 4-hydroxy-tamoxifen, 4-hydrox-N-desmethyl-tamoxifen, N-desmethyl-tamoxifen, and N-desdimethyl-tamoxifen are markedly reduced after aminoglutethimide administration. The mean increase in tamoxifen clearance was 249% when administered with aminoglutethimide. Each of these clinical drug interactions is consistent with an effect at the level of cytochrome P-450 3A. Inasmuch as progestational agents, such as megestrol acetate, are cytochrome P-450 3A substrates, these agents may also alter tamoxifen metabolism and ultimately elimination. This indicates that administration of tamoxifen to individuals taking medication dependent on cytochrome P-450 3A metabolism may alter drug levels extensively, and careful consideration of this should be made when prescribing tamoxifen.

## TOREMIFENE

Toremifene, an agent similar to tamoxifen, is thought to be a more pure antiestrogen. It has become available in the United States for the treatment of patients with metastatic breast cancer. A randomized comparison of toremifene and tamoxifen in metastatic breast cancer suggested that these two medications were equivalent.<sup>61</sup> Clinical trials in postmenopausal women with metastatic breast cancer concluded that there is major cross-resistance between tamoxifen and toremifene.<sup>62,63</sup>

### Pharmacology

Toremifene is an antiestrogen with a chemical structure that differs from that of tamoxifen by the substitution of a chlorine for a hydrogen atom that is retained when toremifene undergoes metabolism.<sup>64</sup> Like tamoxifen, toremifene is metabolized by cytochrome P-450 3A.<sup>65</sup> Toremifene and its 4-hydroxylated metabolite both bind to the estrogen receptor.<sup>66</sup> Although the oral bioavailability has not been defined, toremifene's oral absorption appears to be good. The time to peak plasma concentrations after oral administration ranges from 1.5 to 6.0 hours,<sup>67</sup> with the terminal half-lives for toremifene and one metabolite, 4-hydroxy toremifene, being 5 to 6 days.<sup>68,69</sup> The apparent clearance is 5.1 L/h. The terminal half-life for the major metabolite, N-desmethyltoremifene, is 21 days.<sup>70</sup> Time to reach plasma steady-state concentrations is 1 to 5 weeks. Plasma protein binding is more than 99%. As with tamoxifen, toremifene tissue distribution in rats has been studied and found to be extensive and in high concentrations. Consistent with this is the high apparent volume of distribution, 958 L. Seventy percent of the drug is excreted in feces as metabolites. Studies in patients with impaired liver function secondary to alcoholic cirrhosis and in patients on anticonvulsants known to induce cytochrome P-450 3A have been undertaken.<sup>71</sup> Those patients with hepatic dysfunction had decreased clearance of toremifene and N-desmethyl-toremifene, whereas those patients on anticonvulsants had an increased clearance. Interestingly, toremifene appears to be less carcinogenic than tamoxifen in preclinical models.<sup>35,71,72</sup>

## RALOXIFENE

Raloxifene is an estrogen agonist and antagonist that was initially developed as an anti-breast cancer agent. Initial studies were not promising regarding this approach, but large placebo-controlled randomized studies have reported that this drug does retard osteoporosis in women at risk for such. These studies demonstrated an apparent reduction in breast cancer in treated women, leading to the development of a second-generation breast cancer chemoprevention trial in which it will be compared with tamoxifen in high-risk postmenopausal women. Although this drug is relatively well tolerated, it can produce hot flashes. A potential

advantage for raloxifene over tamoxifen is that it does not appear to induce endometrial cancer.

## Pharmacology

Raloxifene is partially estrogenic in bone<sup>73</sup> and lowers cholesterol.<sup>74</sup> It is antiestrogenic in mammary tissue<sup>75,76</sup> and uterine tissue.<sup>77</sup> The mechanism whereby raloxifene exerts tissue-selective effects is not clear. Several hypotheses have been proposed. Coactivators and corepressor proteins are involved in the transcription complex when estrogen receptor is bound. There may be differential distribution of these coactivators or corepressors, which are responsible for the changes in estrogenicity seen in tissue. The discovery of a second estrogen, estrogen receptor- $\beta$ , with 55% homology between it and estrogen receptor- $\alpha$  raises the possibility that there is a differential expression of these two estrogen receptors in different tissue.<sup>78</sup> This presence of two forms of the receptor also raises the possibility that there are different downstream effectors when one or the other estrogen receptor is activated.<sup>79,80</sup>

The pharmacokinetics of raloxifene have been studied principally in postmenopausal women.<sup>81,82,83and84</sup> Pharmacokinetic parameters of raloxifene show considerable interindividual variation. Limited information is available on the pharmacokinetics of raloxifene in individuals with hepatic impairment, renal impairment, or both.

Raloxifene is rapidly absorbed from the gastrointestinal tract. Because raloxifene undergoes extensive first-pass glucuronidation, oral bioavailability of unchanged drug is low. While approximately 60% of an oral dose is absorbed, absolute bioavailability as unchanged raloxifene is only 2%. However, systemic availability of raloxifene may be greater than that indicated in bioavailability studies because circulating glucuronide conjugates are converted back to the parent drug in various tissues.

Following oral administration of a single 120- or 150-mg dose of raloxifene hydrochloride, peak plasma concentration of raloxifene and its glucuronide conjugates are achieved at 6 and 1 hours, respectively. Plasma concentrations of raloxifene's glucuronide conjugates exceed those of the parent drug, and the time to achieve maximum concentrations of the drug and glucuronide metabolites depends on the extent and rate of systemic interconversion and enterohepatic circulation. Following oral administration of radiolabeled raloxifene, less than 1% of total circulating radiolabeled material in plasma represents parent drug.

Area under the curve (AUC) for plasma concentration-time of raloxifene following a single dose is the same as the AUC following multiple doses of the drug. Increasing the dose of raloxifene hydrochloride over a range of 30 to 150 mg results in a slightly less than proportional increase in the AUC of raloxifene. Administration of raloxifene with a standardized high-fat meal increases the raloxifene peak plasma concentration by 28% and AUC by 16%, when compared with administration on an empty stomach, but does not result in clinically important changes in systemic exposure.

Results of a single-dose study in patients with cirrhosis of the liver (Child-Pugh class A) and total serum bilirubin concentrations of 0.6 to 2.0 mg/dL indicate that plasma raloxifene concentrations correlate with serum bilirubin concentrations and are 2.5 times higher in such individuals compared with individuals with normal hepatic function. In postmenopausal women receiving raloxifene in clinical trials, plasma concentrations of raloxifene and the glucuronide conjugates in those with renal impairment (i.e., estimated creatinine clearance values as low as 23 mL/min) were similar to values in women with normal renal function.

Distribution of raloxifene into body tissues and fluids has not been fully characterized. Raloxifene and raloxifene 4'-glucuronide have been detected in saliva following oral administration of radiolabeled drug. In studies in rats given radiolabeled raloxifene 6-glucuronide, the liver contained the highest concentration of radioactivity, followed by serum, lung, and kidney. While bone and the uterus contained relatively low concentrations of radiolabeled metabolite, 24% of the radioactivity in bone, 14% in the uterus, and 23% in the liver represented raloxifene. Results of this study indicate that the conversion of metabolite to parent drug occurs readily in a variety of tissues including the liver, lung, spleen, kidney, bone, and uterus. The apparent volume of distribution following oral administration of single doses of raloxifene hydrochloride, 30 to 150 mg, is 2348 L/kg, suggesting extensive tissue distribution. The volume of distribution is not dose dependent over a dosage range of 30 to 150 mg daily.

Raloxifene and its monoglucuronide conjugates are more than 95% bound to plasma proteins. Raloxifene binds to albumin and a  $\gamma$ -acid glycoprotein.

Raloxifene undergoes extensive first-pass metabolism to the glucuronide conjugates raloxifene 4'-glucurone, 6-glucuronide, and 6,4'-diglucuronide. Metabolism of raloxifene does not appear to be mediated by cytochrome P-450 enzymes, since metabolites other than glucuronide conjugates have not been identified.

The plasma elimination half-life of raloxifene at steady state averages 32.5 hours (range, 15.8 to 86.6 hours).

Raloxifene is excreted principally in feces as unabsorbed drug and via biliary elimination as glucuronide conjugates, which subsequently are metabolized by bacteria in the gastrointestinal tract to the parent drug. Following oral administration, less than 0.2% of a raloxifene dose is excreted as parent compound and less than 6% as glucuronide conjugates in urine.

## MEDROXYPROGESTERONE AND MEGESTROL

Medroxyprogesterone and megestrol are 17-OH-progesterone derivatives differing in a double bond between C6 and C7 positions in megestrol. Megestrol has been most commonly used as a hormonal agent for patients with advanced breast cancer; usually at a total daily dose of 160 mg/d. It has also been used frequently for the treatment of hormonally responsive metastatic endometrial cancer, at a dosage of 320 mg/d. In addition, dosages of 160 mg/d are occasionally used as a hormonal therapy for prostate cancer.<sup>85</sup> Megestrol has also been extensively evaluated for the treatment of anorexia-cachexia related to cancer or acquired immunodeficiency syndrome.<sup>86,87,88and89</sup> Various dosages ranging from 160 to 1600 mg/d have been used. Prospective studies have demonstrated dose-response relationship with doses up to 800 mg/d.<sup>90</sup> Low dosages of megestrol (40 mg/d) have been shown to be an effective means of reducing hot flashes in women with breast cancer and in men who have undergone androgen ablation therapy.<sup>5</sup> Although megestrol historically had been commonly administered four times per day, the long terminal half-life supports that once per day dosing is reasonable.

Megestrol is a relatively well-tolerated medication, with its most prominent side effect being appetite stimulation and resultant weight gain. While this may be a beneficial effect in patients with anorexia-cachexia, it can be an important problem in patients with breast or endometrial cancers. Another side effect of megestrol acetate is the marked suppression of adrenal steroid production by suppression of the pituitary-adrenal axis.<sup>91</sup> While this appears to be an asymptomatic state in the majority of patients, reports suggest that this adrenal suppression can cause clinical problems in some patients.<sup>92</sup> This drug has been abruptly stopped for decades without recognizing untoward sequelae in patients, and it seems reasonable to continue this practice. Nonetheless, if Addisonian signs or symptoms develop after drug discontinuation, corticosteroids should be administered. Furthermore, if patients receiving megestrol have a significant infection, experience trauma, or undergo surgery, then corticosteroid coverage should be administered. There may be a slight increased incidence of thromboembolic phenomena in patients receiving megestrol alone.<sup>90</sup> This risk appears to be higher if megestrol is administered with concomitant cytotoxic therapy.<sup>93</sup> There are conflicting reports regarding megestrol causing edema.<sup>94</sup> If it does, it is generally minimal and easily handled with a mild diuretic. Megestrol may cause impotence in some men.<sup>95</sup> The incidence of this is controversial, although it is generally agreed that this is a reversible situation. Megestrol can cause menstrual irregularities, the most prominent of which is withdrawal menstrual bleeding within a few weeks of drug discontinuation.<sup>5</sup> Although nausea and vomiting have been attributed as a toxicity, there are good data to demonstrate that this drug has antiemetic properties.<sup>86,88,93</sup> In terms of magnitude, megestrol appears to decrease both nausea and vomiting in advanced-stage cancer patients by approximately two-thirds.

Medroxyprogesterone has many of the same properties, clinical uses, and toxicities as megestrol acetate. It is not used commonly in the United States, but has been used more in Europe. Medroxyprogesterone is available in 2.5- and 10.0-mg tablets and in injectable formulations of 100 and 400 mg/L. Dosing for treatment of metastatic breast or prostate cancer is 400 mg/wk or more and for metastatic endometrial cancer, 1000 mg/wk or more. Smaller injectable or daily oral doses have been used for controlling hot flashes.

## PHARMACOLOGY

The exact mechanism of antitumor effect of medroxyprogesterone and megestrol is unclear. These drugs have been reported to suppress adrenal steroid synthesis,<sup>96</sup> suppress estrogen receptor levels,<sup>97</sup> alter tumor hormone metabolism,<sup>98</sup> enhance steroid metabolism,<sup>99</sup> and directly kill tumor cells.<sup>100</sup> In addition to this, progestins may influence some growth factors,<sup>101</sup> suppress plasma estrone sulfate formation, and, at high concentrations, inhibit P glycoprotein.

The oral bioavailability of these progestational agents is unknown, although absorption appears to be poor for medroxyprogesterone relative to megestrol.

The terminal half-life for megestrol is approximately 14 hours<sup>102,103</sup> with a  $t_{max}$  of 2 to 5 hours after oral ingestion.<sup>104</sup> The AUC for a single megestrol dose of 160 mg is between 2.5- and 8-fold higher than that for single-dose medroxyprogesterone at 1000 mg. Of the radioactive dose of megestrol, 50% to 78% is found in the urine after oral administration, and 8% to 30% in the feces. Three glucuronide metabolites of megestrol have been identified in the urine: megestrol hydroxylated in the 2 position and the 6-methyl position, or both. They account for only 5% to 8% of the radioactive dose administered.

Metabolism and excretion of medroxyprogesterone have been incompletely characterized. In humans, 20% to 50% of a [3H] medroxyprogesterone dose is excreted in the urine and 5% to 10% in the stool following intravenous administration.<sup>105,106,107and108</sup> Metabolism of medroxyprogesterone occurs via hydroxylation, reduction, demethylation, and combinations of these different reactions.<sup>109</sup> The major urinary metabolite is a glucuronide. Less than 3% of the dose is excreted as unconjugated medroxyprogesterone in humans. Clearance of medroxyprogesterone has been reported to range between 27 and 70 L/h.<sup>108</sup> The initial volume of distribution is between 4 and 8 L in humans. The mean terminal half-life is 60 hours. The  $t_{max}$  for medroxyprogesterone occurs 2 to 5 hours after oral administration.

Medroxyprogesterone appears to be concentrated in small intestine, colon, and adipose tissue in human autopsy studies.<sup>110</sup> Drug interactions of medroxyprogesterone have been reported with aminoglutethimide, which decreases plasma medroxyprogesterone levels.<sup>111</sup> Medroxyprogesterone may reduce the concentration of the N-desmethyl-tamoxifen metabolite concentration. Progestational agents also may increase plasma coumadin levels.<sup>112</sup> These reports are consistent with cytochrome P-450 3A being the site of interaction.

## AROMATASE INHIBITORS

### AMINOGLUTETHIMIDE

Aminoglutethimide was the first clinically used aromatase inhibitor. When it became available, it was used to cause a *medical adrenalectomy*. A 32% response rate in metastatic breast cancer<sup>113</sup> has been reported. Aminoglutethimide is infrequently used for treating metastatic breast cancer because there are other available hormonal treatments with less toxicity. Aminoglutethimide has also occasionally been used to try to reverse excess hormone production by adrenocortical cancers.<sup>114</sup>

For treatment of metastatic breast cancer before other aromatase inhibitors became available, aminoglutethimide commonly was started at a dose of 250 mg/d, increasing doses every couple of days to twice a day, then three times a day, and sometimes four times a day. Replacement hydrocortisone was often started at 100 mg/d for a week and then decreased to 40 mg/d. Aminoglutethimide doses less than 500 mg/d did not require corticosteroid replacement.<sup>115</sup> For suppression of hormone production by adrenocortical cancers, doses may be increased to 2 g/d.

Toxicities most frequently associated with aminoglutethimide are lethargy, orthostatic hypertension, nausea, vomiting, hypothyroidism, reversible agranulocytosis, and rash.<sup>116,117</sup> The rash is generally self-limited and usually disappears despite the continuation of aminoglutethimide. However, a severe rash leading to a Stevens-Johnson syndrome can occur.

### Pharmacology

Aminoglutethimide (Fig. 20.3-3) suppresses postmenopausal estrogen synthesis by inhibiting the conversion of circulating androgens into estrogens. Androstenedione is peripherally converted to estrone by cytochrome P-450 aromatase. Estrone can be further converted to estradiol by the enzyme, hydroxysteroid dehydrogenase. Aromatase inhibitors block estrogen production in postmenopausal women or oophorectomized premenopausal women by 90% inhibition of peripheral conversion of androstenedione to estrone, whereas ovarian estrogen synthesis is maintained by gonadotropin release in the premenopausal women with intact ovarian function. Another biochemical effect of aminoglutethimide includes the inhibition of several enzymes in adrenal steroid synthesis, which may lead to mineralocorticoid deficiency.<sup>118,119</sup> Aminoglutethimide effect on adrenal steroid synthesis is complex.<sup>120</sup> Suppression of circulating plasma cortisol may occur,<sup>121</sup> but a compensatory increase in pituitary corticotropin (previously adrenocorticotrophic hormone) levels may overcome this suppression. Because aminoglutethimide is a competitive inhibitor of aromatase, increased adrenal steroid synthesis may compete with aminoglutethimide at the level of the aromatase. Concomitant replacement doses of hydrocortisone addresses both potential effects on adrenal steroid synthesis. Aminoglutethimide is administered as a racemic mixture with different biologic effects.<sup>121</sup> The *d* form is the more potent inhibitor of adrenal steroid synthesis and aromatase activity. The pharmacokinetic characteristics of the separate enantiomers have not been characterized. Aminoglutethimide is absorbed well, with 80% to 98% of a radioactive dose recovered in the urine within 72 hours. Only 1% of the drug is excreted unchanged in the feces. Of the administered aminoglutethimide dose, 12% to 20% is excreted unmetabolized in the urine, and 3% to 7% is excreted as the N-acetyl-aminoglutethimide.<sup>122</sup> The  $C_{max}$  occurs 0.5 to 4.0 hours after oral administration in fasting patients. The clearance of the drug ranges from 1.5 to 6.0 L/h with a mean of 3 L/h. The volume of distribution is 66 to 70 L. Aminoglutethimide undergoes acetylation<sup>123</sup> and is cleared more rapidly in fast acetylators [half-life ( $t_{1/2}$ ) = 12.6 hours] than in slow acetylators ( $t_{1/2}$  = 19.5 hours). After 7 days of treatment, the half-life in slow acetylators decreased from 19.5 to 14.3 hours and in fast acetylators, from 12.6 to 8.6 hours. This was associated with an increased apparent systemic clearance of chronically administered aminoglutethimide and indicates autoinduction of this drug's metabolism.<sup>122,124</sup> Lønning and associates<sup>125</sup> have reported a decrease in volume of distribution on repeated dosing, which may also contribute to the decreased terminal half-life. Aminoglutethimide is approximately 25% bound to plasma proteins. Little is known about aminoglutethimide tissue distribution in humans. The erythrocyte to plasma concentration ratio is 0.83:1. Aminoglutethimide induces mixed function oxidases, enhancing the metabolism of coumadin, dexamethasone, theophylline, and digitoxin. Also, aminoglutethimide has been reported to decrease concentrations of progestational agents and tamoxifen.<sup>60,99</sup> These drug interactions implicate cytochrome P-450 3A in aminoglutethimide metabolism. The increased clearance of progestational agents and tamoxifen in the presence of aminoglutethimide makes the interpretation of studies that combine this aromatase inhibitor with tamoxifen or progestins difficult. Alterations in the blood levels of antiestrogen or progestational agents may have decreased their contribution to any therapeutic benefit.

FIGURE 20.3-3. Structure of aminoglutethimide.

A series of second-generation aromatase inhibitors have been synthesized and many are undergoing clinical trials. These include rogletimide, formestane, fadrozole, letrozole, exemestane, vorozole, and anastrozole.<sup>120,126,127</sup>

### LETROZOLE AND ANASTROZOLE

Letrozole and anastrozole are available in the United States for women with metastatic breast cancer. These second-generation aromatase inhibitors have basically replaced aminoglutethimide for breast cancer given their better toxicity profile. Headaches were the most common toxicity in a phase I trial.<sup>128</sup> It is not necessary to give replacement doses of corticosteroids as was previously done with aminoglutethimide. Letrozole and anastrozole appear to be similar drugs in clinical practice. Randomized trials have demonstrated that they are better hormonal agents for treating tamoxifen-resistant breast cancer than is megestrol acetate.

Letrozole is a nonsteroidal aromatase inhibitor with a high specificity for inhibition of estrogen production. Letrozole is 180 times more potent than aminoglutethimide as an inhibitor of aromatase *in vitro*. Aldosterone production *in vitro* is inhibited by concentrations 10,000 times higher than those required for inhibition of estrogen synthesis.<sup>129,130</sup> In a normal male volunteer study, letrozole was shown to decrease estradiol and serum estrone levels to 10% of baseline with a single 3-mg dose. In phase I studies,<sup>131,132</sup> letrozole caused a significant decline in plasma estrone and estradiol within 24 hours of a single oral dose of 0.1 mg. Following 2 weeks of treatment, the blood levels of estradiol, estrone, and estrone sulfate were suppressed 95% or more from baseline. This continued over the 12 weeks of therapy. There was no apparent alteration in plasma levels of cortisol and aldosterone with letrozole or following corticotropin stimulation.<sup>131</sup> In postmenopausal women with advanced breast cancer, the drug did not have any effect on follicle-stimulating hormone (FSH), luteinizing hormone (LH), thyrotropin (previously thyroid-stimulating hormone), cortisol, 17-a-hydroxyprogesterone, androstenedione, or aldosterone blood levels.<sup>128,133,134</sup>

Anastrozole is an aromatase inhibitor that is 200-fold more potent than aminoglutethimide.<sup>135</sup> No effect on the adrenal glands has been detected. In human studies, the  $t_{max}$  is 2 to 3 hours after oral ingestion.<sup>136</sup> Elimination is primarily via hepatic metabolism, with 85% excreted by that route and only 10% excreted unchanged in urine. The main circulating metabolite is triazole after cleavage of the two rings in anastrozole by N-dealkylation. Linear pharmacokinetics have been observed in the dose range of 1 to 20 mg and do not change with repeat dosing. The terminal half-life is approximately 50 hours and steady-state concentrations are achieved in approximately 10 days with once a day dosing and are three to four times higher than peak concentrations after a single dose. Plasma protein binding is approximately 40%.<sup>137</sup> Anastrozole 1 mg and 10 mg daily inhibits *in vivo* aromatization by 96.7% and 98.1%, respectively, and plasma estrone and estradiol levels were suppressed 86.5% and 83.5% regardless of dose.<sup>138</sup> Thus, 1 mg of anastrozole achieves near maximal aromatase inhibition and plasma estrogen suppression in breast cancer patients.

## VOROZOLE

Vorozole is another aromatase inhibitor that is not currently available for clinical use, but is undergoing clinical trial evaluation.

### Pharmacology

Vorozole, a racemic mixture of (+) and (–) enantiomers, is approximately 1000 times more effective than aminoglutethimide in the inhibiting human placental aromatase. The aromatase inhibitory activity is primarily due to the (+) enantiomer.<sup>139</sup> This drug does not appear to affect cytochrome P-450–dependent cholesterol synthesis, cholesterol side-chain cleavage, 7-a-hydroxylation of cholesterol, or 21-hydroxylase.<sup>140</sup> In rat ovarian, testicular, and adrenal cell cultures, vorozole affects progesterone, androgen, and glucocorticoid production at concentrations at least 1000 times greater than that required to inhibit aromatase.<sup>139,141</sup> In initial human studies, doses of 5 mg of the racemic mixture of vorozole resulted in 94.4% inhibition of peripheral aromatization, and, in healthy male volunteers, a single dose of the racemic mixture lowered plasma estradiol levels to the detection limits of the assay between 4 and 8 hours after drug administration. Johnston and associates<sup>142</sup> reported a similar inhibition of plasma estradiol, estrone, and estrone sulfate with no significant effect on aldosterone, testosterone, androstenedione, 17-a-hydroxyprogesterone, or thyroid-stimulating hormone. Vorozole is rapidly absorbed, with peak plasma concentrations obtained 1 hour after oral intake. Peak plasma concentrations and AUC of vorozole increase proportionately with the dose. Vorozole displays a biphasic disposition curve with a mean terminal half-life ranging from 4.7 to 7.5 hours. The total body clearance ranges from 6.1 to 11.8 L/h in a single dose study in normal healthy male volunteers.<sup>143</sup>

## GONADOTROPIN-RELEASING HORMONE ANALOGUES

Gonadotropin-releasing hormone (GnRH) analogues result in a *medical orchiectomy* in men and are used as a means of providing androgen ablation for metastatic prostate cancer.<sup>144</sup> Because the initial agonist activity of GnRH analogues can cause a *tumor flare* from temporarily increased androgen levels, concomitant use of the antiandrogen, flutamide, has been used to prevent this effect. GnRH analogues can also cause tumor regressions in hormonally responsive breast cancers<sup>145</sup> and have recently received U.S. Food and Drug Administration approval for treatment of metastatic breast cancer in premenopausal women. Emerging data suggest that these drugs may be useful as adjuvant therapy of premenopausal women with resected breast cancer.<sup>146</sup>

The primary toxicities of GnRH analogues are secondary to the ablation of sex steroid concentrations and include hot flashes, sweating, and nausea.<sup>147</sup> These symptoms can be reversed with low doses of progestational analogues.<sup>5</sup>

GnRH analogues available for clinical use include goserelin<sup>148,149</sup> and leuprolide.<sup>150</sup> Both are available in depot intramuscular preparations to be given at monthly intervals. The recommended monthly dose of leuprolide is 7.5 mg and for goserelin is 3.6 mg. There are also longer acting depot preparations that only need to be administered every 3 months.

### PHARMACOLOGY

Analogues of the decapeptide GnRH<sup>149,150and151</sup> have been synthesized by modifications of position 6 in which the L-glycine has been exchanged for a D-amino acid and the C-terminal amino acid has been either replaced by an ethylamide or substituted for a modified amino acid. These changes increase the affinity of the analogue for the GnRH receptor and decrease the susceptibility to enzymatic degradation. There is an amino acid structure of GnRH with the substitutions for leuprolide and goserelin. Initial administration of these compounds results in stimulation of gonadotropin release. However, prolonged administration has led to profound inhibition of the pituitary-gonadal axis.<sup>152</sup> Plasma estradiol and progesterone are consistently suppressed to postmenopausal or castrate levels after 2 to 4 weeks of treatment with goserelin or leuprolide.<sup>153,154and155</sup> These drugs are administered intramuscularly or subcutaneously in a parenteral sustained-release microcapsule preparation because parenteral administration of the parent drug otherwise is associated with rapid clearance. The GnRH analogues are metabolized in the liver, kidney, hypothalamus, and pituitary gland by neutral peptidase cleavage of the peptide bond between the tyrosine in the 5 position and the amino acid in position 6, and a postproline cleaving enzyme that cleaves the peptide bond between proline in the 9 position and the glycine-NH<sub>2</sub> in the 10 position. Substitutions at the glycine 6 position and modification of the C-terminal make these analogues more resistant to this enzymatic cleavage.

Leuprolide is approximately 80 to 100 times more potent than endogenous GnRH. It induces castrate levels of testosterone in men with prostate cancer within 3 to 4 weeks of drug administration after an initial sharp increase in LH and FSH. The mechanisms of action include pituitary desensitization following reduction in pituitary GnRH receptor-binding sites and possibly a direct antitumor effect in estrogen receptor-positive human breast cancer cells.<sup>150</sup> The depo form results in a dose rate of 210 µg of leuprolide per day. Peak concentrations of the depo form that are achieved at approximately 3 hours after drug administration have been reported to range between 13.1 and 54.5 µg/L. There appears to be a linear increase in the AUC for doses of 3.75, 7.5, and 15.0 mg in the depo form. The parenteral bioavailability of subcutaneously injected leuprolide is 94%. The volume of distribution ranges from 27.4 to 37.1 L. In human studies, leuprolide urinary excretion as a metabolite was the primary route of clearance.

Goserelin is approximately 100 times more potent than the naturally occurring GnRH. Like leuprolide, it causes stimulation of LH and FSH acutely, and with subsequent administration, GnRH receptor numbers decrease and the pituitary becomes desensitized with decreasing LH and FSH levels. Castrate levels of testosterone are achieved within 1 month. In women, goserelin inhibits ovarian androgen production, but serum levels of dihydroepiandrosterone sulfate, and to a lesser extent androstenedione, are preserved. *In vitro*, goserelin has demonstrated antitumor activity in estrogen-dependent MCF-7 human breast cancer cells and LNCaP-2 prostate cancer cells. The drug is released at a continuous mean rate of 120 µg/d in the depo form, with peak concentrations in the range of 2 to 3 µg/L achieved. The mean volume of distribution in six patients has been reported to be 13.7 L,<sup>156</sup> consistent with extracellular fluid volume. Goserelin is principally excreted in the urine, with a mean total body clearance of 8 L/h in patients with normal renal function. The total body clearance is reduced by approximately 75%, with renal dysfunction and the elimination half-life increased two- or threefold. However, dose adjustment for renal insufficiency does not appear to be necessary. The 5 to 10 hexapeptide and the 4 to 10 hexapeptide were detected in urine in animal studies.<sup>157</sup> The terminal half-life of goserelin is approximately 5 hours after subcutaneous injection. Protein binding is low, and no known drug interactions have been documented.

## ANTIANDROGENS

### FLUTAMIDE

The antiandrogen flutamide is used in men with metastatic prostate cancer either as initial therapy, combined with GnRH analogue administration, or when the

metastatic prostate cancer is unresponsive despite androgen ablation therapy. The recommended dosage is 250 mg orally three times a day. In patients whose prostate cancer is growing despite flutamide use, stopping flutamide can clearly cause a flutamide-withdrawal response.

The most common toxicity seen with flutamide is diarrhea with or without abdominal discomfort. Gynecomastia, which can be tender, frequently occurs in men who are not receiving concomitant androgen ablation therapy.<sup>158</sup> Flutamide can rarely cause hepatotoxicity, a condition that is reversible if detected early, but can also be fatal.<sup>159</sup> There is no accepted clinically recommended testing schedule to screen for flutamide-induced hepatotoxicity other than being aware of this phenomenon and testing for liver function if hepatic symptoms develop.

### **Pharmacology**

Flutamide is a pure antiandrogen with no intrinsic steroidal activity.<sup>160</sup> Flutamide's mechanism of action is as an androgen-receptor antagonist. This binding prevents the dihydrotestosterone binding and subsequent translocation of the androgen-receptor complex into the nuclei of cells. Because it is a pure antiandrogen, it acts only at the cellular level with no progestational effects. Administration by flutamide alone leads to increased LH and FSH production and a concomitant increase in plasma testosterone and estradiol levels. Plasma protein binding of flutamide ranges between 94% and 96%, and for 2-hydroxy-flutamide, its major metabolite ranges between 92% and 94%. When the drug is administered three times a day, steady-state levels are achieved by day 6. The steady-state  $C_{max}$  is 112.7 ng/L and occurs at approximately 1.13 hours after drug administration. The steady-state  $C_{max}$  is between three and five times higher than after the first dose. The elimination half-life at steady state is 7.8 hours. 2-Hydroxy-flutamide achieves concentrations 50 times higher than the parent drug at steady state and has a potency equal to or greater than that of flutamide.<sup>160</sup> The mean  $C_{max}$  averaged 1719 ng/mL at steady state and was achieved 1.9 hours after drug administration. The elimination half-life for the metabolite is 9.6 hours. The high plasma concentrations of 2-hydroxyflutamide, as compared with flutamide, suggest that the therapeutic benefits of flutamide are mediated primarily through its active metabolite.<sup>161</sup>

### **BICALUTAMIDE (CASODEX)**

Casodex is another nonsteroidal antiandrogen that has been approved by the U. S. Food and Drug Administration for use in the United States. The recommended dose is one 50-mg tablet per day. One randomized trial reported that Casodex compared favorably with flutamide in patients with advanced prostate cancer.<sup>162</sup> Casodex appears to be relatively well tolerated and is associated with a lower incidence of diarrhea than is flutamide.

### **Pharmacology**

Casodex<sup>163,164</sup> has a binding affinity to the androgen receptor in the rat prostate that is four times greater than that of 2-hydroxy-flutamide. *In vivo*, Casodex caused marked inhibition of growth of accessory sex organs in rats with a potency five to ten times greater than flutamide. Unlike flutamide, Casodex did not cause a significant increase in LH or testosterone in rats. Casodex bioavailability in humans has not been defined. The drug has a long plasma half-life of 5 to 7 days such that the drug may be administered on a weekly schedule. Pharmacokinetics of the drug showed a dose-dependent increase in mean peak plasma concentrations, and the AUC increased linearly with dose. The half-life of Casodex in humans was approximately 6 days, and the drug clearance was not saturable at plasma concentrations up to 1000 ng/mL. Daily dosing of the drug led to an approximately ten-fold accumulation after 12 weeks of administration. In contrast to rats, serum concentrations of testosterone and LH increased significantly from baseline at all dose levels tested in humans. Whereas serum FSH concentrations remained essentially unchanged, the median serum estradiol concentrations increased significantly.<sup>165</sup>

### **NILUTAMIDE**

Nilutamide represents the third variation of antiandrogens available for use in patients with prostate cancer. Although it may be less expensive than the other antiandrogens, it has two unique toxicities, night blindness and pulmonary toxicity, which limit its utility.

### **Pharmacology**

Nilutamide<sup>166,167</sup> is a newer nonsteroidal antiandrogen that has a high bioavailability with moderate plasma protein binding. It is extensively metabolized with less than 2% of parent drug administered isolated in urine over 5 days. Oxidation of a methyl group forms two stereoisomeric metabolites whose pharmacokinetics and pharmacodynamics are not characterized. Sixty-two percent of oral drug is eliminated in the urine as metabolites. The terminal half-life varies from 38 to 59 hours. Steady-state levels are achieved in 2 to 4 weeks with 150 mg given twice a day with approximately a twofold accumulation of drug over that time.

### **FLUOXYMESTERONE**

Fluoxymesterone is an androgen that has been used in women with metastatic breast cancer who have hormonally responsive cancers and who have progressed on other hormonal therapies such as tamoxifen, an aromatase inhibitor, and megestrol acetate. The usual dose is 10 mg given twice daily. Although the overall response rate is low for fluoxymesterone used in this clinical situation,<sup>168</sup> there are some patients who have substantial antitumor responses lasting for months or even years.

Toxicities associated with fluoxymesterone are those that would be expected with an androgen: hirsutism, male-pattern baldness, voice lowering (hoarseness), acne, enhanced libido, and erythrocytosis. Fluoxymesterone can also cause elevated liver function test results in some patients and rarely has been associated with hepatic neoplasms.

### **PHARMACOLOGY**

Fluoxymesterone is a chlorinated synthetic analogue of testosterone with potent androgenic and anabolic activity in humans. Limited pharmacologic information is available on this agent. Colburn,<sup>169</sup> using a radioimmunoassay, studied two subjects after a single oral administration of a 50-mg dose. Peak serum concentrations were achieved between 1 and 3 hours after administration, with the average peak concentrations being 335 ng/mL. By 5 hours after drug administration, serum levels had declined to approximately 50% of the peak concentration. Urinary excretion of a 10-mg dose can be detected for 24 hours; and at least 6-hydroxy, 4-ene, 3<sup>b</sup>, and 11 hydroxy metabolites of fluoxymesterone have been detected.<sup>170</sup>

### **DIETHYLSTILBESTROL AND ESTRADIOL (ESTRACE)**

Diethylstilbestrol (DES) used to be the primary hormonal therapy for postmenopausal metastatic breast cancer. Randomized comparative trials demonstrated that it had a similar response rate as tamoxifen.<sup>171,172</sup> However, based on these trials, DES use was supplanted by tamoxifen primarily because DES has more toxicity. DES is occasionally used in metastatic breast cancer patients who have hormonally sensitive cancers that have failed to respond to multiple other hormonal therapies. The usual dose in this situation is 15 mg/d (either as a single dose or as divided doses). DES was also used as androgen ablation therapy in men with metastatic prostate cancer.<sup>173</sup> Doses of approximately 3 mg/d result in testosterone levels that are seen in an anorchid state.

In women, DES may cause a number of toxicities. One of the most common is nausea and vomiting. It also can cause breast tenderness and a darkening of the nipple-areolar complex. DES increases the risk of thromboembolic phenomenon, and this may result in life-threatening complications. In men, DES results in increased thromboembolic events and mortality, thus limiting its use. It also causes painful gynecomastia. Although breast irradiation before DES administration appears to prevent this toxicity, it does not appear to help if it is given after the toxicity develops.

DES has not been clinically available in the United States in recent years but similar antitumor effects and toxicities are seen with Estrace, 1 mg orally three times a day.

### **PHARMACOLOGY**

DES disposition studies in humans have been limited.<sup>174</sup> In animal studies, the oral absorption is approximately 20%. The drug undergoes hepatic metabolism and is excreted as dienestrol and hydroxydienestrol in urine.<sup>175</sup> The parent compound has been detected in feces. After administration of a radioactive dose of DES,

approximately 40% of the drug was found in urine in the first 24 hours, with 87% of this being in the form of glucuronides. The peak plasma concentrations were achieved approximately 20 hours after ingestion and the terminal half-life for the radioactivity ranged between 2 and 3 days.

Estrace is a micronized form of estradiol. The pharmacology of estradiol has been extensively described in other texts. [176,177](#)

## OCTREOTIDE

Octreotide is a somatostatin analogue that has revolutionized the therapy of carcinoid syndrome and other hormonal excess syndromes associated with some pancreatic islet cell cancers and acromegaly. Response rates are high and, on average, last for several months, sometimes for years. Occasionally, antitumor responses temporarily related to octreotide are seen with these tumors. Octreotide is being investigated as a potential therapy for other cancers such as breast or pancreas, but is not recommended for routine treatment of these tumors. Finally, octreotide appears to help to alleviate 5-fluorouracil-induced severe diarrhea in some patients. [178,179](#)

Octreotide can be administered intravenously or subcutaneously. Initial doses of 50 µg are given two to three times on the first day. The dose is titrated upward with a usual daily dose of 300 to 450 µg/d for most patients. At times, doses up to 1500 µg/d have been given. A depot preparation is available, allowing doses to be administered at monthly intervals. Octreotide is generally well tolerated overall. It appears to cause more toxicity in acromegalic patients, with such problems as bradycardia, diarrhea, hypoglycemia, hyperglycemia, hypothyroidism, and cholelithiasis.

### Pharmacology

Octreotide is an 8 amino acid synthetic analogue of the 14 amino acid peptide somatostatin. [21](#) Octreotide has a similar high affinity for somatostatin receptors as does its parent, with a concentration that inhibits the receptor by 50% (IC<sub>50</sub>) in the subnanomolar range. Octreotide inhibits insulin, glucagon, pancreatic polypeptide, gastric inhibitory polypeptide, and gastrin secretion. It has a much longer duration of action than the parent compound because of its greater resistance to enzymatic degradation. Its absorption following subcutaneous administration is rapid, and bioavailability is 100% after subcutaneous injection. Peak concentrations of 4 µg/L after a 100-µg dose occur within 20 to 30 minutes of subcutaneous injection and are 20% to 40% of the corresponding intravenous injection. Both peak concentration and AUC for octreotide increase linearly with dose. The total body clearance in healthy volunteers is 9.6 L/h. Hepatic metabolism of octreotide accounts for 30% to 40% of the drug's disposition, and 11% to 20% is excreted unchanged in the urine. The volume of distribution ranges between 18 and 30 L and the terminal half-life is reported to be between 72 and 98 minutes. Sixty-five percent of the drug is protein bound primarily to the lipoprotein fraction. [180,181](#) Because of the short half-life, classic octreotide is administered subcutaneously two or three times per day. [182](#) A slow-release form of octreotide, designed for once per month administration, is now evaluable. [183](#)

## INTRODUCTION

Chemotherapy treatment of certain tumors (notably germ cell cancers and neuroblastoma) is occasionally associated with persistence of residual tumors that on biopsy reveal only differentiated cells. These clinical observations, combined with *in vitro* data that morphologic differentiation can be induced in many cancer cell lines, have led to a resurgence of interest in the concept of induced cytodifferentiation as a means of cancer treatment. The identification of drugs that can induce an irreversible commitment to terminal differentiation (and consequently programmed cell death) has yielded some noteworthy successes.

## RETINOIDS

Retinoids, which are natural or synthetic derivatives of vitamin A (retinol), induce cellular differentiation, suppress carcinogenesis, or inhibit proliferation of a number of cell lines, including epithelial cancers, melanoma, neuroblastoma, leukemia, germ cell, bone, and breast cancers.<sup>1</sup> These findings have generated widespread interest in these agents for cancer treatment and prevention. Several retinoids (all- *trans* retinoic acid [RA] and 9-*cis* RA) are normally found in plasma at nanomolar concentrations. Most retinoids bind to nuclear proteins that are RA receptors (RARs).<sup>2,3</sup> Cofactors, called *retinoid X receptors* (RXRs),<sup>4</sup> dimerize with RARs (Fig. 20.4-1), as well as receptors for thyroid hormone, vitamin D, and peroxisome proliferation activators. These receptor dimers bind specific DNA segments within target genes known as *retinoid response elements*. Activation of the receptor requires binding of its ligand, which then regulates transcription in part via recruitment of histone acetyltransferases.<sup>5</sup> Importantly, nonactivated receptors have important roles in silencing basal transcription of target genes via interaction with nuclear corepressor proteins that recruit histone deacetylases.<sup>6</sup>

**FIGURE 20.4-1.** Metabolism of all-*trans* retinoic acid (RA). RA enters the cell by simple diffusion or by conversion from retinol (vitamin A) that has been absorbed from the gastrointestinal tract, bound in circulating form to retinol-binding proteins (RBP), and rebound intracellularly to cellular retinol-binding proteins (CRBP). RA can be immediately metabolized on binding to cellular retinoic acid-binding proteins (CRABP) and oxidized by cytochrome P-450 enzymes located in smooth endoplasmic reticulum. Alternatively, RA (or its isomers) enter the cell nucleus and bind to retinoic acid receptors (RARs) or retinoid X receptors (RXRs). On dimerization of these receptors (i.e., formation of a RAR-RXR heterodimer or RXR-RXR homodimer), RA-activated receptors bind with high affinity to specific DNA segments [the retinoic acid response element (RARE)] and effect messenger RNA (mRNA) transcription. Ultimately, the retinoid response is mediated by primary target genes, by interference with other transcription factors, or by control of certain posttranscriptional actions. (From ref. 1, with permission.)

## ALL-TRANS RETINOIC ACID

The most striking success of the clinical application of differentiation therapy has been in acute promyelocytic leukemia (APL)<sup>7</sup> (see [Chapter 46.2](#)) where all-*trans* RA induces complete remission in a high proportion of patients with APL. Resistance to all- *trans* RA in a previously untreated patient is exceptionally rare, and failure is almost exclusively because of early death.<sup>7,8</sup> In APL, reciprocal translocations between the long arms of chromosomes 15 and 17 result in a fusion between genes that encode a RAR (RAR-*a*) and a transcription factor known as PML.<sup>9,10</sup> The resulting fusion protein, PML-RAR-*a*, blocks myeloid differentiation at the promyelocyte stage, which is relieved by pharmacologic (but not physiologic) concentrations of all- TRANS RA.

The initial response to all- *trans* RA in APL is associated with induced differentiation of leukemic cells.<sup>11</sup> This process is obvious, both in the bone marrow and in the peripheral blood, with the appearance of cells that are intermediate in maturation between promyelocytes and neutrophils. Prominent features of these intermediate cells are indented nuclei, loss of azurophilic granularity, and nuclear and cytoplasmic vacuolation.<sup>7</sup> Cell surface immunophenotyping of the neoplastic cells shows progression from a pattern of immature antigen expression at presentation toward the appearance of mature granulocytic markers during remission.<sup>11</sup>

The plasma half-life of all- *trans* RA is approximately 40 minutes,<sup>12</sup> and continuous dosing induces a progressive decrease in the plasma drug concentration.<sup>13</sup> Remissions induced by all- *trans* RA in patients with APL who do not receive additional anticancer therapy are brief and average 3 to 5 months in duration.<sup>14</sup> The mechanisms of clinically acquired retinoid resistance may be multifactorial,<sup>15</sup> but point mutations in the ligand-binding domain of the PML-RAR-*a* have been described in a few patients.<sup>16</sup> Combined sequential treatment programs that use all- *trans* RA (with or without chemotherapy) for induction, followed by anthracycline-based chemotherapy for consolidation, have yielded a two- to threefold increase in the proportion of patients cured of this disease.<sup>17,18and19</sup> Further administration of all- *trans* RA as maintenance therapy during the first year of remission makes a further, albeit modest,<sup>8,17</sup> contribution to relapse-free survival. Regrettably, the high single-agent activity of all- *trans* RA observed in APL has not been replicated in other neoplastic diseases.

## 13-CIS RETINOIC ACID

Of all retinoids, 13- *cis* RA has undergone the most extensive clinical examination; however, the single-agent activity of this drug in established cancer is quite limited. In the hematologic cancers, modest single-agent activity has been observed in patients with cutaneous T-cell lymphoma (mycosis fungoides)<sup>20,21</sup>; however, responses are usually partial and limited in duration. Studies of 13- *cis* RA in patients with myelodysplastic syndromes<sup>22,23</sup>; chronic myelocytic leukemia<sup>24</sup>; germ cell cancer and

neuroblastoma<sup>25,26</sup>; and carcinomas of the head and neck, lung, and bladder<sup>27,28and29</sup> have had negative results. Modest activity has been observed in patients with epidermoid skin cancers, alone and in combination with interferon- $\alpha$ .<sup>30,31and32</sup>

The drug has also been explored as a means of cancer prevention, either as primary (to prevent an initial cancer) or secondary (to reduce the risk of recurrence) therapy. Treatment with 13-*cis* RA (1 to 2 mg/kg/d for 3 months) in heavy tobacco users reverses oral leukoplakia,<sup>33</sup> a known precursor to squamous carcinoma of the oral cavity. Because this dose causes considerable mucocutaneous toxicity, follow-up studies have used a high-dose induction course followed by a lower dose (0.5 mg/kg/d) maintenance program.<sup>34</sup> However, the duration of the clinical response is frequently brief, and most patients relapse when the drug is withdrawn. In an important preliminary study, adjuvant treatment with 13-*cis* RA (1 mg/kg/d) in patients who had undergone primary surgical excision, radiation treatment, or both for head and neck cancer significantly reduced the incidence of second primary tumors of the aerodigestive tract.<sup>35</sup> However, a large randomized multicenter study has not confirmed these findings.

## OTHER RETINOIDS

The natural ligand of the RXRs is 9-*cis* RA, an isomer of all-*trans* RA<sup>36</sup> (see Fig. 20.4-1). Because 9-*cis* RA also binds to RARs, this property as a receptor pan-agonist suggested potentially broad biologic effects. Early clinical trials of 9-*cis* RA showed activity comparable with all-*trans* RA in APL, but the drug has not reversed clinically acquired retinoid resistance in this disease.<sup>37</sup> Toxicity of the two compounds has also been similar (see [Adverse Effects of Retinoids](#), later in this chapter).<sup>38,39</sup> The drug was recently approved for topical use in patients with Kaposi's sarcoma related to acquired immunodeficiency syndrome. A number of relatively selective retinoid receptor agonists have also been synthesized<sup>39</sup> and are under active development. In contrast, fenretinide (N-[4-hydroxyphenyl], Retinamide) is a synthetic retinoid whose receptor has not yet been identified, but that has exhibited some chemopreventive activity against carcinomas of the breast, prostate, oral cavity, and bladder.<sup>40</sup> A large Italian study showed that fenretinide did not reduce the incidence of contralateral breast cancer, although an unexpected reduction of ovarian carcinoma was observed.<sup>41</sup> Fenretinide lowers serum retinol levels, which can cause temporary night blindness.<sup>42</sup>

## ADVERSE EFFECTS OF RETINOIDS

Retinoids share many common side effects ([Table 20.4-1](#)). Most reactions are relatively mild; however, serious and occasionally fatal reactions have occurred. Headache that occurs several hours after drug ingestion is the most common side effect of all-*trans* and 9-*cis* RA.<sup>7,38,43,44</sup> This effect is less prominent with 13-*cis* RA in which mucositis is the most common reaction. Although narcotics are occasionally required, mild analgesics generally control the headaches, and tolerance to this effect develops within the first week of dosing. Pseudotumor cerebri has been documented in several patients (especially children)<sup>44</sup> who have required treatment with lumbar punctures and high-dose corticosteroids.

Organ System	Adverse Effects
General	Headache, malaise, fatigue, weight gain, dry skin, itching, flaking, nasal stuffiness, xerostomia, cheilitis, hypercalcemia, hypertriglyceridemia, hypercholesterolemia, acute pancreatitis, fetal malformation (usually craniofacial abnormalities)
Cardiovascular	Hypertriglyceridemia, hypercholesterolemia
Respiratory	Pseudotumor cerebri, pleural or pericardial effusions
Neurological	Pseudotumor cerebri
Renal	Hypercalcemia
Other	Leukocytosis, bone pain, genital ulcerations, mucositis

**TABLE 20.4-1.** Adverse Clinical Effects of the Retinoids

Dry skin, itching, flaking, nasal stuffiness, xerostomia, and cheilitis are relatively common with both all-*trans* and 13-*cis* RA. These reactions have been managed with topical lubricants and moisturizing agents, but some patients may require a decrease in drug dose. Genital ulcerations have been observed with all-*trans* RA. Bone pain occurs in 10% to 20% of APL patients receiving all-*trans* RA.<sup>7</sup> Like headache, this effect tends to occur early, remits with continued therapy, but can be quite severe, requiring parenteral narcotics for relief. Although bone pain is less common with 13-*cis* RA, protracted treatment with that agent has caused formation of bone spurs on vertebral bodies and the calcaneus.<sup>45</sup> Hypercalcemia has been reported with many RA isomers.<sup>46</sup>

Hypertriglyceridemia has been observed with all-*trans* RA, 9-*cis* and 13-*cis* RA, and also with RXR-selective agonists<sup>7,38</sup>; hypercholesterolemia is less striking. Cardiovascular consequences specifically related to hyperlipidemia have not yet been described, although acute pancreatitis has been reported.<sup>38</sup> These complications may assume increasing importance as retinoids are used in more patients for extended periods. Hepatic toxicity, usually manifested by a transient increase in serum transaminase, alkaline phosphatase, or bilirubin, is a well-known side effect of all retinoids. Generally, this reaction occurs during the first several weeks of therapy and reverses after the drug is stopped. As with vitamin A itself,<sup>47</sup> retinoids are exceptionally potent teratogens, but this reaction is more important during treatment of nonmalignant conditions. The risk of fetal malformation (usually craniofacial abnormalities) appears to be highest in the first trimester and quite low in the third trimester.<sup>48,49</sup>

Leukocytosis (peripheral blood leukocytes greater than or equal to 10,000 cells/mm<sup>3</sup>) occurs in approximately one-half of APL patients treated with all-*trans* RA<sup>50</sup> who do not receive concurrent cytotoxic chemotherapy. This finding is usually the first clinical sign of a biologic response. Cytotoxic therapy specifically directed toward lowering the leukocyte count is not required; however, patients who present with leukocyte counts greater than or equal to 5000 cells/mm<sup>3</sup> should be treated with full-dose chemotherapy (including an anthracycline) rather than low-dose chemotherapy (e.g., hydroxyurea or cytosine arabinoside), as the latter can trigger the onset of a lethal coagulopathy.<sup>50</sup>

More than one-half of patients with APL treated with all-*trans* RA experience the *RA syndrome*, a disorder characterized by fluid retention, weight gain, respiratory distress, radiographic pulmonary infiltrates, hectic fever, and pleural or pericardial effusions.<sup>51</sup> Leukocytosis is frequently but not invariably associated with this syndrome, and chemotherapy does not reduce the risk of this problem.<sup>8,17,50,51and52</sup> Early recognition of the syndrome before the onset of dyspnea (especially fever or weight gain) is critical. These signs should prompt immediate treatment with corticosteroids (dexamethasone, 10 mg intravenously every 12 hours for 3 or more days), which halts progression of the syndrome in most patients. RA need not be discontinued, but recurrence of the syndrome is common, requiring an additional course of corticosteroids.

## ARSENIC TRIOXIDE

After a resurgence of interest owing to studies in China,<sup>53,54</sup> intravenous arsenic trioxide has been shown to induce complete remissions in a high proportion of patients with APL.<sup>55</sup> In APL, the drug is given intravenously as a 1- to 2-hour infusion at a dose of 0.15 mg/kg once per day until visible evidence of leukemic cells has been eliminated from the bone marrow. The duration of treatment in relapsed patients has ranged from 12 to 60 days, with a median of approximately 32 days.<sup>55,56</sup> Recovery of the peripheral leukocyte and platelet counts usually follows cessation of drug therapy. One or more additional treatment courses, each of a fixed duration of 25 cumulative days, is usually started approximately 3 weeks after discontinuing the initial series of infusions. These later infusions have been administered on a weekdays-only schedule without any apparent decrease in efficacy to date.

Arsenic trioxide has proved surprisingly potent in APL; indeed, the proportion of patients who achieve a molecular remission (as manifest by a negative reverse transcriptase–polymerase chain reaction result for the PML-RAR- $\alpha$  rearrangement) considerably exceeds that of patients on all-*trans* RA.<sup>56</sup> In APL, the drug is associated with induction of partial nonterminal differentiation, degradation of the PML-RAR- $\alpha$  fusion protein, and caspase activation.<sup>56</sup> The drug is currently being studied in other conditions and in different dosing schedules.<sup>57,58</sup>

When administered in the low-dose daily schedule described previously, the drug has generally been well tolerated. Fatigue is common. Lightheadedness during the infusion can be ameliorated by increasing its duration. A characteristic maculopapular skin eruption over the neck and torso occasionally occurs that resolves on discontinuation of the drug. Arsenic can cause peripheral neuropathy when administered for prolonged periods or higher doses, and severe neuropathic reactions, including quadriparesis,<sup>59</sup> have been reported from overdosage. Prolongation of the QT interval may occur, which may require treatment with parenteral potassium and magnesium supplements, especially in patients after amphotericin B therapy. APL patients treated with arsenic trioxide may also develop leukocytosis and the RA syndrome.<sup>60</sup> Management of these problems is identical to that described previously.

## HISTONE DEACETYLASE INHIBITORS

The enzymatic addition of acetyl groups to histones, nuclear proteins closely associated with DNA, is known to have a permissive effect for messenger RNA transcription.<sup>61</sup> Histone hyperacetylation may induce site-specific conformational relaxation of tightly coiled DNA that facilitates binding of transcription factors.<sup>62</sup> Conversely, histone deacetylation has been linked to gene repression, and a number of oncogenes (as well as normal genes) silence transcription by recruiting histone deacetylases.<sup>63,64</sup> Furthermore, a link between gene methylation, a recognized mechanism of transcriptional repression, and histone deacetylation has now been established<sup>65</sup> (Fig. 20.4-2). Thus, DNA demethylation and inhibition of histone deacetylation offer potential targets for anticancer therapy. Azacytidine is the best-studied agent that induces demethylation, and the drug has shown modest single-agent activity in patients with various myelodysplastic syndromes.<sup>66</sup> Trichostatin A is the prototypic inhibitor of histone deacetylase,<sup>67</sup> but the agent has not been used clinically. In addition to the drugs noted in the following sections, other inhibitors include the trapoxins,<sup>67</sup> depudecins,<sup>68</sup> and depsipeptides.<sup>69</sup>

**FIGURE 20.4-2.** Mechanism of transcriptional repression by DNA methylation and histone deacetylation. In a transcriptionally inactive state, DNA is tightly coiled around core histones in the nucleosome. To activate transcription, the compact inactive nucleosome must undergo conformational relaxation, which may facilitate the binding of transcription factors (TF). Chromatin relaxation is associated with histone acetylation by histone acetyltransferases (HAT). A variety of normal DNA-binding proteins or oncogene products can complex with other proteins, and these complexes recruit histone deacetylases (HDACs), which cleave acetyl groups from histones, thereby preventing chromatin relaxation and blocking gene transcription. Treatment with a HDAC may prevent such cleavage, thereby yielding a loose accessible nucleosome whose DNA is then accessible for gene activation and transcription. Last, gene methylation (Me) in the promoter region has long been known to suppress gene activation in cancer. These two processes (i.e., gene methylation and histone deacetylation) have now been linked by the discovery of a protein (MeCP2) that forms a bridge between HDAC and methylated DNA. Inhibition of both processes may be required in cases wherein inhibition of only one process is insufficient to activate the target gene.

## BUTYRATES AND OTHER FATTY ACIDS

Butyric acid induces differentiation in various cell lines,<sup>70</sup> but high concentrations (0.3 mM) have been required to reliably induce these effects. Butyrates have been widely studied as a treatment for thalassemia<sup>71</sup> and certain hyperammonemic states in children.<sup>72</sup> Several clinical studies have suggested that sodium phenylbutyrate has little single-agent activity in patients with advanced cancer or myelodysplasia.<sup>73,74</sup>

Histone deacetylase was shown to mediate transcriptional repression in APL,<sup>75,76and77</sup> as well as other cancers.<sup>78,79,80,81,82and83</sup> One report has shown that sodium phenylbutyrate reversibly induced histone hyperacetylation in leukemic cells and induced a complete remission in a child with retinoid-resistant APL when used in combination with all-*trans* RA.<sup>84</sup> Studies have suggested that these drugs act synergistically to induce cytodifferentiation,<sup>85,86</sup> and this combination is currently undergoing additional clinical testing. The major side effects of sodium phenylbutyrate are fluid overload and central nervous system depression, including transient somnolence and confusion.

Phenylbutyrate exhibits pleiotropic effects, and the agent is a prodrug for phenylacetate,<sup>87</sup> which promotes *in vitro* differentiation of certain cell lines.<sup>88</sup> High doses of phenylacetate itself (250 to 550 mg/kg/d) have been used clinically<sup>89</sup> with low single-agent activity in malignant gliomas<sup>90</sup> and prostate cancer.<sup>91</sup> Tributyrin is a major constituent of dietary butterfat, which yields three molecules of butyrate after hydrolysis. The relatively high butyrate concentrations that are achievable in the colon have suggested a potential chemopreventive utility for colon cancer.<sup>92</sup>

## HYBRID POLAR COMPOUNDS

Certain hybrid polar compounds have broad *in vitro* activity as differentiating agents. The prototype compound of this class, hexamethylene bisacetamide,<sup>93</sup> has required relatively high concentrations (1 to 5 mM). Renal insufficiency, central nervous system toxicity, and thrombocytopenia were dose-limiting in early studies,<sup>94</sup> but some responses were observed in patients with myelodysplastic syndromes using 10-day infusion schedules.<sup>95</sup> Newer synthetic derivatives have more potent activity than hexamethylene bisacetamide, and several are potent inhibitors of histone deacetylase.<sup>96</sup>

## VITAMIN D

1,25-Dihydroxyvitamin D<sub>3</sub>, the active form of the hormone, facilitates differentiation in a variety of cell types.<sup>97</sup> Vitamin D receptors have been identified in a variety of cell types.<sup>98,99</sup> Circumstantial evidence has suggested that vitamin D can decrease the incidence of some tumor types.<sup>100,101</sup> Vitamin D decreases growth of leukemia,<sup>102,103</sup> breast,<sup>104</sup> colon,<sup>105</sup> and prostate<sup>106</sup> cancer cell lines. In HL60 cells, vitamin D induces differentiation into monocytes and macrophages,<sup>107</sup> unlike retinoids and dimethyl sulfoxide, which induce granulocytoid differentiation.

Few clinical trials of vitamin D have been conducted. Several responses were observed in a study of patients with myelodysplastic syndromes treated at a dose of 2 mg/d, but intolerable hypercalcemia proved limiting.<sup>102</sup> New analogues of vitamin D<sub>3</sub> have become available that retain differentiating activity while causing minimal effects on calcium metabolism.<sup>108,109</sup>

## CYTOKINES AND OTHER PROTEINS

Colony-stimulating factors induce a variety of responses in their target cells, including a commitment to terminal differentiation.<sup>110</sup> Both granulocyte colony-stimulating factor (filgrastim) and granulocyte-macrophage colony-stimulating factor (sargramostim) have been studied clinically. Neither agent has proved dramatically effective in either myelodysplastic syndromes or acute myeloid leukemias; however, mature populations of granulocytes and monocytes can be regularly increased in many patients, sometimes with clinical benefit (e.g., reduced infectious complications).<sup>111</sup>

#### INTRODUCTION

Antibody-based therapeutics are coming of age. Antibodies have provided an important means to exploit the capacity of the immune system to specifically recognize and direct antitumor responses. Antibody therapy studies were among the earliest attempts to explicitly target cancers based on the structural and biologic properties that distinguish neoplastic cells from their normal counterparts. Although the early clinical studies yielded inconsistent and often disappointing clinical results, more recent work has identified a number of important and useful applications for antibody-based cancer therapy. Unconjugated antibodies directed against the lymphocyte antigen CD20 have significant clinical activity in patients with low-grade lymphomas.<sup>1</sup> The U.S. Food and Drug Administration (FDA) has approved one of these antibodies, rituximab, for clinical use. Radioimmunoconjugates directed against CD20 demonstrate significant clinical activity in patients with chemotherapy-pretreated lymphomas as well.<sup>2,3</sup> A chemoimmunoconjugate containing an anti-CD33 antibody and calicheamicin has impressive activity in acute myelogenous leukemia (AML).<sup>4</sup> Finally, the anti-HER2/*neu* antibody trastuzumab has single-agent activity in metastatic breast cancer and potentiates the antitumor effects of Taxol chemotherapy.<sup>5,6</sup> This antibody also received FDA approval for clinical use. These results provide ample evidence that a number of strategies using unconjugated antibodies or antibody conjugates carrying toxic payloads, such as radiation or chemotherapy agents, have clinical benefits. At this time, the mechanisms underlying the clinical benefits of rituximab and trastuzumab are not understood, but both antibodies mediate antibody-dependent cellular cytotoxicity (ADCC) *in vitro* and may do so in the clinical setting as well.<sup>7</sup>

Antibodies are produced by B cells. These proteins arise in response to exposure to a variety of structures, termed *antigens*, as a result of a series of recombinations of V, D, and J germline genes. Somatic hypermutation occurs with each subsequent exposure to the antigen and introduces further variation that can increase binding affinity or alter target antigen specificity. The resulting proteins exhibit selective targeting of a variety of potential antigens and can direct the clearance or immune recognition of such antigens. Various isotypes of antibodies have specialized functions [e.g., immunoglobulin A (IgA) molecules play important roles in mucosal immunity, and IgE molecules are involved in anaphylaxis]. IgG molecules are most commonly used as the working backbones of current therapeutic monoclonal antibodies (MABs).

Before 1975, the ability of antibodies to specifically target immunogens for therapeutic applications was inconsistently exploited because the available antibody preparations were derived from polyclonal antisera obtained from immunized animals. The advent of hybridoma technology by Kohler and Milstein<sup>8</sup> made it possible to produce large quantities of antibodies with high purity and monospecificity for a single binding region (epitope) on an antigen.

#### IMMUNOGLOBULIN STRUCTURE: STRUCTURAL AND FUNCTIONAL DOMAINS

IgG antibodies are comprised of two identical light chains and two identical heavy chains. The variable region contains hypervariable regions, or complementarity determining regions (CDRs), in which the antigen-contact residues reside. Antibodies achieve diversity due to variations in the amino acid sequences of the CDRs resulting from the VDJ recombinations and somatic hypermutations previously described. The Fc domain is composed of the CH2 and CH3 regions of the antibody's heavy chains. This portion of the antibody mediates its effector functions, transport across cellular barriers, and biologic half-life. The different isotypes of immunoglobulins are defined by the structure and function of their Fc domains. The types of immune effector cells that interact with IgG and the results of the interactions are dictated by cellular Fc receptor expression patterns. Developments in the field of molecular biology have led to the production of a wide variety of novel antibody-based targeting structures (Fig. 20.5-1). These include chimeric human-murine antibodies with human constant regions and murine variable regions,<sup>9</sup> humanized antibodies in which murine CDR sequences have been grafted into human IgG molecules and entirely human antibodies derived from human hybridomas and more recently from transgenic mice expressing human immunoglobulin genes.<sup>10</sup> Additionally, a large number of recombinant immunoglobulin-based structures have been produced from the variable or constant domains of antibodies. These range in size from CDR-based peptides<sup>11</sup> to bispecific antibodies (BsAb) with dual antigen specificities. Some of the more promising structures include monovalent single-chain Fv (scFv), derived from murine hybridomas<sup>12,13</sup> and<sup>14</sup> or phage-display libraries,<sup>15,16</sup> and multivalent dimeric Fv [(scFv)<sub>2</sub>],<sup>17</sup> diabodies,<sup>18,19</sup> triabodies,<sup>20</sup> and minibodies.<sup>21</sup> This technology also has resulted in the creation of a number of antibody-based fusion proteins designed to target cytokines [e.g., interleukin (IL)-2] to the tumor.<sup>22</sup>

## FACTORS REGULATING ANTIBODY-BASED TUMOR TARGETING

Although great progress has been made since initial treatment trials of MAB therapy, a number of obstacles to treatment efficacy have been identified in preclinical studies and in clinical trials. It is not surprising that obstacles have been identified for a concept that attempts to introduce an unprecedented degree of targeting specificity while using large proteins whose sizes greatly exceed those of conventional pharmaceuticals. It should be emphasized that the identification of obstacles is not a reason for discouragement, but rather is a necessary prelude to the cycles of molecular and strategy refinements that are inherent in the development of any new therapeutic modality.

### IMPAIRED DISTRIBUTION AND DELIVERY OF ANTIBODY TO TUMOR SITE

IgG molecules are large proteins of approximately 150 kD in mass; most chemotherapy agents have a molecular weight of less than 1 kD. Accordingly, MABs would be expected to have significantly slower kinetics of distribution and severely limited tissue penetration properties as compared to small molecules. Indeed, nonuniform uptake of systemically administered antibody is generally observed in biopsied specimens of solid tumors. Although inhomogeneous tumor antigen expression can be a factor, physiologic barriers to MAB penetration bear the greatest responsibility for the limited distribution of MABs within a tumor mass. Heterogeneous tumor blood supply limits uniform antibody delivery to tumors, and elevated interstitial pressures in the centers of tumors oppose inward diffusion.<sup>23</sup> Furthermore, the relatively large transport distances in the tumor interstitium combine with the above factors to increase the time required for these large macromolecules to reach target cells. For example, the diffusion of an intact IgG molecule into a solid tumor is limited to 100  $\mu\text{m}$  in 1 hour, 1 mm in approximately 2 days, and 1 cm in approximately 7 to 8 months.<sup>24</sup> These physiologic barriers pose substantial obstacles to antibody penetration in the majority of solid tumors and bulky lymphomas. Thus, it can be anticipated that the therapy of patients with large tumors using MABs will be compromised. These concepts also hold true for potentially cytotoxic leukocytes to accumulate at tumor sites; as a result, physiologic barriers can represent a major limitation to the effective clinical exploitation of ADCC.

The poor tumor penetration of MABs has been addressed by using the smaller antibody-based constructs and fragments (discussed earlier in [Immunoglobulin Structure: Structural and Functional Domains](#)). As shown in [Figure 20.5-1](#), commonly used antibody-based structures include  $F(ab')_2$  [fragment (of IgG) after digestion with the enzyme pepsin], Fab [fragment (of IgG involved in) antigen binding], and scFv molecules. These derivative structures usually exhibit binding affinity for target antigen that is of the same order of magnitude as the intact parental immunoglobulin. These molecules exhibit systemic clearance that accelerates with decreasing size. In general, the smaller molecules have the advantages of improved tumor penetration, rapid systemic clearance, and improved specificity of tumor targeting during the terminal phases of elimination. These advantages are counterbalanced by decreased quantitative tumor targeting.<sup>25,26</sup> The ideal size of tumor-targeting antibodies will most probably depend on the intended therapeutic application. When prolonged inhibition of a tumor-associated function is intended, larger molecules with slow clearance might be preferred, whereas the administration of a highly potent immunotoxin might be facilitated if the molecule is small and rapidly clears from normal organs.

### TUMOR ANTIGENS

The properties of the tumor antigen can be a major factor in regulating the success or failure of antibody-based therapies. Heterogeneity of antigen expression by tumor cells can restrict the percentage of cells that can be reliably targeted by antibodies. This is manifested not only as the presence or absence of antigen on a cell, but also by the degree of its expression on a given cell. The density of antigen expression may be a critical determinant of therapeutic effect for a variety of antibody-based applications. The ultimate fate of a cell surface antigen (e.g., whether it is shed from the membrane or internalized) can also impact on the degree of targeting and therapeutic efficacy of an antibody. For example, large concentrations of shed antigen in the tumor microenvironment may saturate the antibody's binding sites and prevent binding to the cell surface. In contrast, a rapidly internalized antigen may deplete the quantity of cell surface MABs capable of initiating ADCC or cytotoxic signal transduction events. Finally, additional obstacles relate to the tumor specificity of the targeted antigens. Antibody targets may be *tumor-associated* or *tumor-specific*. Tumor-associated targets have most frequently been identified and typically are oncofetal antigens or overexpressed growth factor receptors with extracellular membrane domains. Tumor-associated antigens usually are relatively overexpressed on tumor cells but are found to a lesser extent on normal cellular counterparts and by other normal cells. Potential consequences of targeting this class of antigens with toxic immunconjugates can include decreased targeting specificity and unacceptable normal tissue cytotoxicity. Tumor-specific antigens that exhibit high levels of expression limited to malignant tissue are both highly desirable and rare. Typically, these antigens arise as a result of unique genetic recombinations that are the cause or consequence of oncogenic transformation. Examples of tumor-specific antigens include clonal immunoglobulin idiotypes expressed on the surface of B-cell lymphomas<sup>27</sup> and tumor-specific mutations, such as the epidermal growth factor receptor (EGFR)-VIII deletion mutant of the EGFR that is present in a small proportion of tumors, including glioblastoma and non-small cell lung carcinoma.<sup>28,29</sup> The advent of new techniques for identifying genetic abnormalities in malignancies will no doubt uncover numerous tumor-specific mutations, some of which will provide accessible protein targets for antibody therapy.

### IMMUNOLOGIC RESPONSES TO MONOCLONAL ANTIBODIES

The initial clinical trials of MABs used murine proteins produced by hybridoma technology. Treatment with murine MABs and their derivatives often induces human antimouse antibody (HAMA) responses within 2 to 3 weeks after the initial infusion. These responses, which are directed to any portion of the antibody, can impair targeting and accelerate MAB clearance. The induction of HAMA has precluded the continued successful application of MAB therapy in several instances.<sup>30</sup> Considerable effort has been expended to overcome HAMA by creating human or nearly human antibodies (discussed earlier in [Immunoglobulin Structure: Structural and Functional Domains](#)) or by suppressing the human immune response to the mouse MAB. As a result, the majority of the MABs currently entering the clinic bear human or humanized structures.

Although the field of antibody therapy is progressing beyond murine MABs and their associated drawbacks, analysis of the HAMA responses in clinical trials has led to the development of a novel therapeutic strategy. Although most of the HAMAs generated during these immune responses recognize conserved sequences, a small percentage of the antibodies are specific for the idiotypic or hypervariable sequences that comprise the active binding site of the antibody. Some of these antiidiotypic antibodies mimic the original antigen completely enough to be capable of inducing an immune response that is capable of reacting with the original tumor antigen.<sup>31</sup> Stimulation of this "idiotypic network," originally postulated by Jerne,<sup>31</sup> offers some specificity advantages when compared with immunization strategies that directly make use of the tumor antigens.

### UNCONJUGATED ANTIBODIES

#### ANTIBODY-DEPENDENT CELLULAR CYTOTOXICITY

In the process of ADCC, the antibody Fab domains engage tumor antigen and the Fc domain binds to cellular Fc receptors to bridge effector and target cells. This bridging induces effector cell activation and natural killer (NK) cell-mediated cytotoxicity or phagocytosis by neutrophils, monocytes, or macrophages.<sup>10</sup>

In addition to rituximab and trastuzumab, many other antibodies have been clinically tested to exploit their ADCC properties, but without consistent clinical benefit in the setting of advanced disease.<sup>32</sup> ADCC continues to be a potent *in vitro* phenomenon that should provide a powerful antitumor mechanism, if it can be replicated or mimicked in the *in vivo* setting. Advances in the understanding of human Fc receptor and T-cell receptor structures and functions have made it possible to refine antibody-directed cellular activation strategies, particularly given the improved flexibility afforded by antibody engineering techniques. Human Fc $\gamma$  and Fc $\alpha$  receptors can trigger cellular cytotoxicity,<sup>33,34</sup> and <sup>35</sup> as can elements of the T-cell receptor/CD3 complex,<sup>36,37</sup> CD28 on T cells,<sup>38</sup> and CD44 on NK cells.<sup>39</sup> It is now possible to create a wide variety of recombinantly produced antibody binding site-based targeting proteins, including IgG,  $F(ab')_2$ , Fab, and scFv formats, with an equally formidable choice of approaches to create multimeric, monospecific, or bispecific binding proteins. The affinity properties of the binding sites can be manipulated through chain-shuffling or site-directed mutagenesis.<sup>40</sup> The HAMA response can be circumvented by the production of chimeric antibodies or by the use of human antibodies prepared by fusion techniques or from human phage display libraries.<sup>41</sup>

### BISPECIFIC ANTIBODIES

In the years since the pioneering work of Segal and colleagues,<sup>42</sup> numerous BsAb targeting tumor antigens and effector cell trigger molecules have been developed and shown to redirect cellular cytotoxicity. For example, BsAb can target tumor antigens and human effector cell trigger molecules on T cells via CD3/TcR<sup>39,40,42</sup> and

CD28.<sup>41</sup> BsAb directed against FcγRI<sup>36</sup> trigger tumor cytotoxicity by neutrophils, monocytes, and macrophages. BsAb targeting FcγRIII<sup>37,43</sup> promote tumor lysis by macrophages and NK cells, and BsAb targeting CD44<sup>42</sup> promote tumor cytotoxicity by NK cells. Typically, BsAb promote *in vitro* cytotoxicity at low concentrations and have been shown to cause either growth delays or tumor regressions in appropriate animal models.<sup>44,45</sup> and <sup>46</sup> These properties have led to the testing of several BsAb in human clinical trials.

Several early reports of CD3-directed BsAb suggested possible applications in glioblastoma<sup>46</sup> and ovarian cancer.<sup>47</sup> However, subsequent trials of a number of intact CD3-directed BsAb have yielded few objective responses, and treatment has been limited by toxicities reminiscent of the first-dose effect seen with OKT3 antibody therapy. The first-dose effect is characterized by the release of massive amounts of cytokines, such as tumor necrosis factor-α (TNF-α). Treatment with an F(ab')<sub>2</sub> anti-CD3 BsAb, which is bereft of Fc domains and Fc domain-dependent cellular cross-linking properties, also has led to toxicities at low BsAb doses. This finding indicates that the engagement of some T-cell activating molecules on circulating T cells can produce unacceptable dose-limiting toxicity.<sup>48</sup> A series of clinical trials used the BsAb 2B1, a murine IgG that is dually specific for extracellular domain epitopes on the human tumor antigen HER2/*neu* and the human Fc receptor FcγRIII. Whereas therapy with 2B1 yielded a handful of objective responses, BsAb-induced cross-linking of Fc receptors on circulating leukocytes led to massive cytokine release and associated toxicities. 2B1-promoted antigen presentation led to the induction of anti-HER2/*neu* antibodies, but only in patients treated with 2B1 doses exceeding the ultimate maximum tolerated dose.<sup>49,50</sup>

The clinical experience with the MDX-210 BsAb provides a useful additional perspective to the results previously described. MDX-210 targets the same epitope on HER2/*neu* as does 2B1, and it targets human FcγRI on neutrophils and mononuclear phagocytes. In contrast to 2B1, MDX-210 is a chemically conjugated F(ab')<sub>2</sub>. Because it lacks an Fc domain, MDX-210 cannot activate leukocyte Fcγ receptors in the absence of tumor antigen engagement. Like 2B1, MDX-210 is a potent mediator of *in vitro* cytotoxicity and phagocytosis. Because much higher doses of this BsAb can be given safely in comparison with 2B1, monomeric FcγRI engagement may have different consequences than do FcγR aggregation or CD3 engagement.<sup>51</sup> Like 2B1, MDX-210 therapy leads to antigen presentation and the induction of anti-HER2/*neu* antibodies. Again, as with 2B1, clinical responses have been seen with BsAb targeting FcγRI, and the results obtained with MDX-210 indicate that the Fc domain of a BsAb is not required for Fc receptor-dependent antigen presentation.

## PROMOTION OF TUMOR INFLAMMATION

A number of strategies can be considered to promote selective tumor inflammation. Experiences with systemic cytokines have shown that the selectivity of effects at tumor sites is usually low, as evidenced by work with high-dose IL-2.<sup>52</sup> With IL-2 and other cytokines, such as TNF-α, toxicities caused by systemic leukocyte activation have limited the doses that can safely be administered. Several groups have attempted to address this fact by producing immunocytokines, which are composed of engineered antibodies fused to cytokines. Antibody/IL-2 fusion proteins have exhibited promising preclinical results.<sup>25,53</sup> However, a potential limitation to this strategy is that these large (e.g., greater than 150-kD) proteins will have relatively prolonged half-lives. As a result, functionally intact IL-2 will circulate predominantly in the vasculature, leading to systemic leukocyte activation that at least partially offsets any targeting advantages conferred by the antibody binding property. Less progress has been reported regarding the creation of antibody-targeted vasoactive or chemotactic conjugates or fusion proteins. Conjugates containing antibody binding sites and F-M-L-P<sup>54</sup> and RANTES<sup>55</sup> have been reported but have not undergone extensive preclinical testing or clinical trials.

Several antibodies that have been used clinically are capable of fixing serum complement, and this mechanism of action has been postulated to be relevant to the *in vivo* mechanisms of action of antibodies directed against gangliosides and against CD20 as well, as discussed in the section on [Antiganglioside Antibodies](#).

## GROWTH FACTOR RECEPTOR SIGNALING PERTURBATION

Antibodies directed against selected growth factor receptors, such as the EGFR, directly inhibit the growth of receptor-bearing tumors *in vitro* and *in vivo*, and they synergize with a number of antineoplastic agents. EGFR is overexpressed on many cancers. The receptor and its ligands, EGF and TGF-α, act in an autocrine loop to stimulate the growth of breast cancer cells. *In vitro*, some anti-EGFR antibodies have been shown to inhibit the binding of the receptor ligands.<sup>56,57</sup> Antibodies that block the binding of EGFR ligands limit receptor activation by tyrosine kinases and inhibit growth of normal fibroblasts,<sup>58</sup> as well as tumor cells in culture.<sup>59</sup> Also, combining anti-EGFR antibodies with cisplatin leads to a significant decrease in the IC<sub>50</sub> (concentration that inhibits 50%) of cisplatin,<sup>60</sup> and cures of established tumors are seen when anti-EGFR antibodies are combined with cisplatin<sup>61</sup> or doxorubicin.<sup>62</sup> *In vitro* and *in vivo* studies also have suggested anti-EGFR antibodies may lead to terminal differentiation of squamous cell carcinoma cells, with accumulation of cells in G<sub>0</sub> to G<sub>1</sub> phases of the cell cycle and expression of cell surface markers, such as involucrin and cytokeratin-10.<sup>63</sup>

The anti-EGFR antibody MAB225 blocks *in vitro* phosphorylation of the EGFR and induces receptor internalization, as occurs with binding of the natural ligand.<sup>64</sup> However, receptor processing is slower with antibody engagement than with natural ligand engagement.<sup>65</sup> Smaller bivalent F(ab')<sub>2</sub> and univalent Fab forms of this antibody also inhibit growth and decrease receptor phosphorylation, although the bivalent form is superior to the monovalent form.<sup>66</sup> Because the smaller fragments lead to tumor regressions, the efficacy of antibody therapy is not dependent on ADCC, as these smaller fragments lack the Fc portion of the antibody required for ADCC. Rather, the efficacy of this antibody is due to its ability to inhibit binding of the natural ligand, limit receptor phosphorylation, and thus downstream signals, and induce receptor internalization.

The chimeric form of MAB225, C225, has been evaluated *in vitro* and *in vivo* in hormone-sensitive and hormone-refractory prostate cancer.<sup>67</sup> EGF is a strong chemoattractant for prostate cancer cells. Blocking the EGFR receptor with C225 *in vitro* results in decreased migration of prostate cancer cells in a dose-dependent manner due to decreased phosphorylation of the EGFR.<sup>68</sup> This antibody also has been shown to lead to cell-cycle arrest and decreased proliferation of prostate cancer cells.<sup>69,70</sup> The binding of C225 to the EGFR results in multiple events leading to a decrease in proliferation and, possibly, decreased metastatic potential in prostate cancer. Preclinical animal models also have suggested a potential therapeutic role for anti-EGF antibodies in combination with radiation therapy for the treatment of gliomas.<sup>71</sup> Other studies have demonstrated increased efficacy with topotecan,<sup>72</sup> antisense oligonucleotides targeting CRIPTO<sup>73</sup> and protein kinase A,<sup>74</sup> and Trastuzumab.<sup>75</sup> C225 also has been shown to have antiangiogenic properties.<sup>76</sup>

C225 has been tested in phase I studies in recurrent head and neck cancer in combination with cisplatin. Four of seven patients exhibited clinical responses.<sup>77</sup> The safety of C225 in combination with radiation therapy has been documented in head and neck carcinoma in preliminary reports.<sup>78</sup>

ICR62, a rat monoclonal IgG, has been shown *in vitro* to block binding of the ligands of EGFR, inhibit growth of tumor cell lines that overexpress EGFR, and to cause differentiation of malignant cells to a normal phenotype. This antibody was evaluated in a phase I trial of patients with squamous head and neck and lung cancer. Evidence was found of localization of antibody to tumor sites at doses of 40 to 100 mg, accompanied by the development of anti-rat antibodies.<sup>79</sup> Another anti-EGFR antibody, RG 83853, has been used to treat patients with non-small cell lung cancer and head and neck cancer in a phase I setting. In this study, patients received up to 600 mg/m<sup>2</sup> by continuous infusion over 5 days without significant toxicity.<sup>80</sup> Saturation of at least 50% of the EGFR was noted at doses of 200 mg/m<sup>2</sup> or more. EGFR-expressing tumor cells demonstrate increased sensitivity to chemotherapy<sup>81</sup> and to radiation therapy<sup>82</sup> in the presence of EGF. In two of five patients with pre- and posttherapy biopsies of tumor, evidence was found for increased tyrosine kinase activity of EGFR, providing a rationale for combined modality therapy.

Similar strategies have been developed for MAB directed against another member of the EGFR family, the HER2/*neu* (c-erbB-2) receptor, as discussed later in the section [Breast Cancer](#). It has been shown that intracellular antibodies can interfere with the expression of proteins that are critical for the maintenance of the neoplastic phenotype. For example, Curiel and coworkers<sup>83</sup> have packaged the gene for an anti-c-erbB-2 antibody in viral vectors and infected c-erbB-2-expressing tumor cells *in vitro* and *in vivo*. The infected cells express the encoded antibody, which is engineered to contain signals for its retention in the endoplasmic reticulum of the target cells. This approach efficiently inhibits c-erbB-2 expression and exhibits potent antitumor activity in preclinical models.<sup>83</sup>

## ANTIIDIOTYPE ANTIBODIES

MAB can be used as the basis for creating tumor vaccines by inducing the idiotypic network. The antigen-combining site of each antibody, the idiotype, is a unique, clonally derived structure that stimulates the production of a series of host antibodies, some of which bind to the idiotype. Accordingly, an idiotype-containing antibody (i.e., Ab1) that binds to a tumor antigen induces the production of antiidiotype antibodies (i.e., Ab2).<sup>36</sup> Ab1 can be used to immunize mice and create Ab2-secreting hybridomas. The resulting Ab2, a portion of which contains a surrogate tumor epitope recognized by the Ab1, can be used to immunize patients, leading to the production of anti-antiidiotype antibodies (i.e., Ab3) that in part bind to the tumor epitope against which the Ab1 was directed. Based on this idiotypic network put forth by Lindenmann and Jerne,<sup>31</sup> various investigators have created antiidiotypic antibodies to serve as vaccines.<sup>84,85</sup> and <sup>86</sup> Antiidiotype antibody strategies that mimic a

number of tumor antigens have been generated and are under investigation as cancer vaccines. This approach offers the practical advantages of an abundant supply of highly purified immunogen that stimulates an immune response against carefully defined tumor antigen epitopes. This approach may be preferable to immunization with tumor antigens, because the immune response to the whole antigen may include reactivity with epitopes on the antigen that are shared by other structures that are not selectively expressed by tumors.

Results are available for several clinical trials of antiidiotypic antibodies. Herlyn and colleagues<sup>87</sup> treated 30 patients with advanced colorectal carcinoma with serial injections of polyclonal goat antibody induced by immunizations with murine 17-1A MAB. Six patients experienced brief clinical responses, and all 30 developed antibodies directed against the immunizing goat antibody.<sup>87</sup> Mittelman and colleagues<sup>88</sup> treated 15 patients with metastatic melanoma using a murine antiidiotypic MAB directed against an antibody recognizing a high-molecular-weight human melanoma-associated antigen. Seven of these patients developed Ab3, and three patients exhibited partial responses (PRs) to therapy.<sup>88</sup> Similar findings have been observed using antibodies directed against the carcinoembryonic antigen (CEA) system.<sup>89</sup> It is noteworthy that these strategies induce not only the desired immunologic responses, but also possess clinical activity in some patients with advanced solid tumors. If these results hold up with further testing, this general strategy will merit testing in the adjuvant, high-risk setting.

An antiidiotypic antibody, created using an antibody directed against the gp72 antigen, has been used to treat patients with advanced colorectal cancer,<sup>90</sup> as well as rectal cancer patients in an adjuvant setting.<sup>91</sup> The antibody 105AD7 was produced by fusion of plasma cells from patients treated with an anti-gp72 antibody 791T/36 with EL41, a mouse-human heterohybrid. The 105AD7 hybridoma was found to produce a human IgG1 that bound to the binding site of the 791T/36 antibody. In 13 patients with metastatic colorectal cancer treated with the vaccine, survival was 12 months as compared to 4 months for patients in a contemporary control cohort; the significance of this increase in survival is unknown because this was not a prospectively randomized study. *In vitro* immunologic correlates demonstrated evidence of cellular responses as indicated by lymphocyte proliferation to gp72-expressing tumor cells and IL-2 production. In the adjuvant setting, six patients were vaccinated preoperatively. In a follow-up study, the immunologic responses and progression-free survival rate in patients were superior in patients who received a 100- $\mu$ g versus a 200- $\mu$ g dose of vaccine.<sup>92</sup>

Foon<sup>89,93</sup> has evaluated an anti-idiotypic vaccine strategy for CEA expressing tumors. The antiidiotypic antibody 3H1 was derived from a murine antibody that targets a highly restricted epitope of CEA, which is not found on normal adult tissues or hematopoietic cells. Patients with advanced colorectal cancer treated with 3H1 injections developed both humoral and cellular responses against CEA.<sup>89</sup> This response was not abrogated by concurrent chemotherapy.<sup>93</sup> An ongoing phase II randomized study is evaluating 3H1 plus granulocyte-macrophage colony-stimulating factor (GM-CSF), or alum-precipitated 3H1 antibody with GM-CSF, in patients with stage II or stage III colorectal cancer. This trial is the first to evaluate an antibody as a vaccine in the adjuvant setting. Patients were found to have a cellular, but not a humoral, response to the immunization.

The impact of antiidiotypic vaccines remains to be clarified. Most of the vaccines use nonhuman antibodies for the vaccine, which may help stimulate an immune response against the antibody. However, as has been seen with intravenously administered antibodies, multiple administrations of the antiidiotypic vaccine may be limited by the immune response against the constant regions of the antibody (e.g., HAMA response). Also, although *in vitro* data supporting the induction immune responses have been demonstrated, no clear evidence exists for the induction of clinically meaningful responses. Clinical trials with various antibodies have demonstrated antiidiotypic cascades after therapy.<sup>53</sup> There are also examples of antibodies with specificity for the tumor antigen that are being used as vaccines.<sup>94,95</sup> and<sup>96</sup> The infused antibody may allow for *in vivo* immunization, and the induction of these antiidiotypic antibodies may serve to amplify the antigenic stimulus to the immune system. For example, ovarian and breast cancer patients receiving high-dose chemotherapy followed by stem cell transplantation have been immunized with Theratope STn-KLH, an antibody directed against a MUC-1 epitope. Eleven of 26 patients developed STn-specific T-cell responses.<sup>97</sup> It remains to be determined if such responses are components of therapeutic responses.

## IMMUNOCONJUGATES

The use of antibodies as “magic bullets” has captured the scientific and public imagination for some time. In contrast to the immunologically oriented strategies already described, antibodies used in immunoconjugates are designed to provide targeting specificity to cytotoxic processes. The toxic payloads used in clinically tested immunoconjugates have included catalytic toxins, chemotherapy agents, and radionuclides.

## RADIOIMMUNOCONJUGATES

To a large extent, both immunotoxins and drug immunoconjugates kill by single-cell mechanisms. Thus, less opportunity exists for the destruction of “innocent bystander” antigen-negative tumor cells at the tumor site. Radioimmunoconjugates address this potential deficiency by virtue of the long track lengths of many of the commonly used radionuclides, so that toxic effects can extend over several cell diameters from the radiation source. Most radioimmunoconjugates do not require internalization to be effective, and the cytotoxic effects do not require the presence of an intact, functional immune system. Radioimmunotherapy (RIT) has been the most extensively studied immunoconjugate treatment strategy and has been the source of several exciting clinical results, particularly in the treatment of chemotherapy-refractory lymphomas. In the past, most RIT studies used iodine 131, but improvements in chelation technology have enabled the study of yttrium 90 conjugates.<sup>90</sup> Y is preferred because of its long track length, high-energy  $\beta$ -emissions, lack of volatility, and the relative ease and safety of its conjugation to antibodies and subsequent patient administration.

Early studies of RIT have shown that partial, short-lived clinical responses can be achieved in some patients with advanced, solid tumors. Hematologic neoplasms are more responsive than are solid tumors. Bone marrow suppression is the common dose-limiting toxicity of RIT. The HAMA response can limit the use of multiple rounds of RIT in some patients. Lymphomas and leukemias remain the most sensitive tumor targets for RIT, presumably because of their intrinsic sensitivity to radiation and the relatively good access of radioimmunoconjugates to the malignant cells that comprise these neoplasms. Patients with hematologic neoplasms are less likely to mount HAMA responses and frequently can be re-treated with MAB.

## IMMUNOTOXINS

One approach to immunoconjugates involves coupling MAB (or fragments) to highly lethal cellular toxins. A number of plant and bacterial catalytic toxins have been used, but most clinical trials to date have been conducted using immunotoxins containing either the plant toxin ricin or the bacterially derived *Pseudomonas* exotoxin. These toxins require transport and intracellular processing to exert their effects and, generally, act by inhibiting protein synthesis via interruption of ribosomal elongation factor-2. Toxins of this type are extremely efficient and potent and usually contain two chains. One chain facilitates cell binding and intracellular transport, whereas the other chain is responsible for the catalytic activity of the toxin. Substituting an antibody binding domain for the cell binding chain of the toxin creates immunotoxins. The antibody specificity directs the cellular targeting of the catalytic chain of the toxin. Immunotoxins have been prepared by chemical conjugation of antibodies or their fragments to the catalytic toxin chains, or by the creation of recombinant fusion proteins linking either Fab or sFv antibody fragments to native or modified catalytic toxin chains. Nanomolar concentrations of immunotoxins are capable of eradicating tumor cells *in vitro*, and low doses are extremely effective in preclinical animal models.

Clinical trials have been performed using immunotoxins in patients with breast cancer, ovarian cancer, colorectal cancer, melanoma, and lymphoproliferative disorders. In a landmark study, Vitetta and colleagues<sup>98</sup> treated 14 patients with B-cell lymphoma using an anti-CD22 MAB conjugated to ricin A chain and observed clinical responses in five patients. In a separate study, patients with B-cell lymphomas were treated using a continuous infusion of an immunotoxin composed of an anti-CD19 MAB conjugated to whole ricin with a blocked B chain, so that the toxin's entrance into cells was conferred solely by the antibody binding specificity. In 34 patients with B-cell neoplasms, two complete and three PRs were noted.<sup>99</sup>

The results of trials in patients with solid tumors have been less impressive. Toxicities have limited the doses of immunotoxins that have been used, and such dose limits must be overcome before the full therapeutic benefit of this highly potent therapy approach can be obtained. These toxicities include vascular leak syndrome, fevers, rigors, malaise, occasional hepatotoxicity, rhabdomyolysis, and rare but potentially devastating central nervous system effects. These effects are thought to arise from unintended uptake of the toxins by normal cells and can be caused by low levels of targeted antigen expression by such cells, or by poorly understood nonspecific uptake. Further improvements in toxin selection and design, coupled with more knowledgeable selections of tumor antigen targets and the development of recombinant antibody-based proteins, are likely to address many of the impediments to effective therapy that have been observed to date.<sup>100</sup> It may prove more difficult to overcome the potent human antitoxin immune response that these plant or bacterial proteins elicit. However, overcoming this response is necessary to permit multiple cycles of therapy.

## CHEMOIMMUNOCONJUGATES

One of the major potential advantages of immunotoxins is that such toxins work catalytically, so that the antitumor effects can be amplified *in situ*. Paradoxically, the potent toxicity of these molecules may make it difficult to identify an appropriate therapeutic window that permits efficacy within the tolerable host range. An alternate strategy is to use antibody-based targeting to deliver conventional chemotherapy agents to tumor sites. These molecules have well-understood pharmacology and can be administered safely in native form, so that it should be feasible to administer high, tumor-cytotoxic doses of antibody-conjugated agent within acceptable host toxicity ranges. For example, promising preclinical results were obtained using the immunoconjugate BR96-doxorubicin, with exceptional activity *in vitro* and in a variety of preclinical rodent models.<sup>101</sup> This agent has been examined in a series of phase I clinical trials, and the dose-limiting toxicity was gastritis, possibly related to the Fc domain of the intact IgG BR96 molecule.<sup>102</sup> More recently, highly potent calicheamicin-antibody conjugates have been tested in leukemia and other cancers and are undergoing clinical evaluation.<sup>103,104</sup>

## THERAPEUTIC APPLICATIONS

### HEMATOLOGIC MALIGNANCIES

Initial studies using antibodies directed against B-cell determinants showed that the passive administration of these antibodies led to clearance of circulating tumor cells and rare objective clinical responses.<sup>105</sup> In a series of landmark studies, Levy and colleagues<sup>106</sup> prepared customized antibodies reactive with a given lymphoma patient's idiotype that was uniquely expressed on the surface of the malignant B-cell clone. Each patient's idiotype served as a tumor-specific signature that could be targeted by a customized MAB. The procedures for preparing such antibodies for each patient were laborious, but approximately 50% of treated patients experienced significant clinical responses, with some patients achieving durable complete remissions.<sup>106</sup> The addition of chemotherapy agents, interferon (IFN), or other cytokines did not appreciably improve treatment outcomes. Effective therapy had to overcome circulating lymphoma idiotype proteins that diverted antibodies from their cellular targets, and resistance to therapy resulted in part from the emergence of idiotype-negative variants. The mechanisms underlying responses to these antibodies have not been completely elucidated, but may include mechanisms such as ADCC and perturbation of signal transduction through idiotype engagement.<sup>107</sup> Because of the immunosuppression of lymphoma patients, relatively few patients developed HAMAs that interfered with repeated therapeutic antibody administration. This exciting approach was very cumbersome, because it required the generation of patient-customized reagents. These results could not be replicated by using antibodies that recognize shared idiotypes expressed by a large proportion of lymphoma patients.<sup>108</sup> Despite this set of impediments, these important observations have informed much of the subsequent work in this field.

Other antibodies directed against B-cell surface determinants have been developed and clinically tested. For example, Lym-1 recognizes an HLA-DR10 determinant and promotes ADCC. Clinical trials with this antibody have shown interesting response profiles in low-, intermediate-, and high-grade lymphoma, respectively.<sup>109</sup>

### CAMPATH-1

The CAMPATH-1 antibody has specificity for CD52, a glycopeptide that is highly expressed on T and B lymphocytes. It has been tested as a therapeutic agent for chronic lymphocytic and promyelocytic leukemias, as well as other non-Hodgkin's lymphomas, and as a means to deplete T cells from allogeneic transplantation grafts. One-half of the patients with fludarabine-resistant chronic lymphocytic leukemia or B-prolymphocytic leukemia exhibited clinical responses to CAMPATH-1.<sup>110</sup>

A phase II multicenter study of CAMPATH-1H in previously treated patients with low-grade non-Hodgkin's lymphomas has been reported.<sup>111</sup> Fifty patients with relapsed or refractory disease were treated with 30 mg of CAMPATH-1H three times weekly for up to 12 weeks. Infection, anemia, and thrombocytopenia were common, and myocardial infarction occurred in a patient with a prior history of angina and congestive heart failure. A 16% PR rate and a 4% complete response (CR) rate were reported, for an overall response rate of 20%. Responses were short in duration, with a median time to progression of 4 months. Patients with mycosis fungoides responded more frequently and had a longer time to progression (10 months) than did patients with low-grade non-Hodgkin's lymphoma (4 months). Treatment was associated with reactivation of herpes simplex, oral candidiasis, *Pneumocystis carini* pneumonia, cytomegalovirus pneumonitis, pulmonary aspergillosis, disseminated tuberculosis, and seven cases of pneumonia and septicemia.

CAMPATH-1 has been used to deplete T cells from allogeneic transplantation grafts in patients with hematologic malignancies.<sup>112,113</sup> The initial study suggested that the addition of CAMPATH-1 can significantly decrease graft rejection and graft-versus-host disease compared with conventional therapy. However, the frequency of graft rejection and graft failure may be higher. A retrospective review of patients with acute lymphocytic leukemia or AML who underwent allogeneic transplantation with CAMPATH-1-purged marrow suggested no impact on the graft-versus-leukemia effect, because no increase in leukemia relapse was found.<sup>114</sup> Additionally, the development of Epstein-Barr virus-related lymphoproliferative disorders was decreased in allogeneic transplantation patients who had T-cell depletion with CAMPATH-1 therapy compared with other methods of T-cell depletion (e.g., E-rosettes or other MABs).<sup>115</sup> CAMPATH-1 eliminates B cells within the graft, thus eliminating a potential reservoir of Epstein-Barr virus or targets for subsequent infection.

### Anti-CD20 Antibodies

The testing and evaluation of the chimeric anti-CD20 antibody, IDEC-C2B8, also known as *rituximab*, has led to significant excitement within the field.<sup>116,117</sup> Rituximab was the first antibody therapy approved by the FDA for use in treating human malignancy. Other anti-CD20 antibodies had demonstrated responses of low-grade non-Hodgkin's lymphomas; however, therapy was limited because of the induction of HAMAs. By reducing immunogenicity through the substitution of human for murine constant domain sequences, rituximab allows for the safe administration of multiple doses of therapy. The phase I study that set out to determine the maximum tolerated dose used four weekly infusions.<sup>119</sup> Thrombocytopenia and B-cell lymphocytopenia were observed. The lymphocytopenia persisted for 3 to 6 months. Six of 18 patients (33%) demonstrated PRs. Phase II studies using the maximum tolerated dose, 375 mg/m<sup>2</sup>, confirmed the efficacy of this therapy, demonstrating 46% and 48% response rates in two separate studies.<sup>118,119</sup> Although the numbers of circulating B cells were reduced by therapy, no changes were documented in serum immunoglobulin levels. Bacterial and viral infections were seen in patients with relapsed indolent lymphomas, but in contrast to the CAMPATH-1 experience, treatment with rituximab did not result in significant morbidity due to infections. However, patients with small lymphocytic B-cell lymphoma had lower response rates, likely related to the lesser expression of CD20 on these tumor cells. A different multiinstitutional phase II study using a 375-mg/m<sup>2</sup> dose for eight weekly treatments in low-grade or follicular non-Hodgkin's lymphoma with relapsed or primary refractory disease also demonstrated minimal toxicity, with an overall response rate of 57%.<sup>120</sup>

In another phase II trial, 54 patients with relapsing or refractory diffuse large B-cell lymphoma, mantle cell lymphoma, or other intermediate- or high-grade B-cell non-Hodgkin's lymphomas were treated.<sup>121</sup> The study randomized patients to either eight weekly treatments of 375 mg/m<sup>2</sup> intravenous rituximab, or to 375 mg/m<sup>2</sup> rituximab intravenously in week 1 followed by seven weekly intravenous infusions of 500 mg/m<sup>2</sup>. Five CRs and 12 PRs were observed, for an overall response rate of 31%; no evidence of superiority of either treatment regimen was demonstrated. Patients with refractory disease and those with histologies other than diffuse large B-cell lymphoma appeared to have lower response rates.

Peak levels of circulating antibody inversely correlate with pretreatment B-cell counts and the bulk of tumor.<sup>121,122</sup> Greater numbers of peripheral lymphocytes or larger tumor bulk serve as an antigen sink and therefore remove antibody from the circulation. For patients with bulky disease, future consideration of a higher antibody dose or a greater number of cycles may be warranted, because patients with lower serum antibody concentrations have had statistically significant lower response rates. In some patients with circulating blood tumor cells, however, rituximab therapy has induced an infusion-related syndrome characterized by fever, rigors, thrombocytopenia, tumor lysis, bronchospasm, and hypoxemia requiring discontinuation of the antibody infusion. Symptoms typically resolve with supportive care, and patients may continue further therapy without sequelae.<sup>122</sup> Another case report has documented rapid tumor lysis in a patient with B-cell chronic lymphocytic leukemia with a pretreatment lymphocytosis of more than 100 × 10<sup>9</sup> cells per liter.<sup>123</sup>

Rituximab therapy rarely selects for the emergence of an antigen-negative population of tumor cells. This phenomenon has been documented in a patient with a follicular mixed small and large cell lymphoma treated with rituximab after progression through multiple chemotherapy regimens.<sup>124</sup>

Rituximab has been tested in conjunction with chemotherapy.<sup>125</sup> Preclinical data have shown this antibody can sensitize chemotherapy-resistant cell lines to the cytotoxic effects of chemotherapy.<sup>126</sup> Forty patients with low-grade or follicular B-cell non-Hodgkin's lymphoma received six cycles of the cyclophosphamide,

doxorubicin, vincristine, and prednisone (CHOP) regimen every 21 days, with six infusions of rituximab at a dose of 375 mg/m<sup>2</sup> given before, during, and after the completion of chemotherapy. Thirty-eight patients received therapy, with three patients not completing treatment because of intercurrent infections (n = 2) and patient choice (n = 1). The overall response rate was 95% (38 of 40) with a 55% CR and a 40% PR, with fewer CRs noted in patients with bulky disease. Median response duration and time to progression had not been reached after more than 29 months of follow-up. Seven of eight patients initially positive for the bcl-2 translocation became negative for the translocation by polymerase chain reaction assay after therapy; this finding has not been seen previously with CHOP chemotherapy alone. <sup>127</sup>

Unconjugated antibodies directed against CD20 and other B-lymphocyte antigens have exhibited exciting and clinically important antitumor activity in patients with low-grade lymphomas (Table 20.5-1).<sup>128</sup>

**TABLE 20.5-1.** Antibody Therapy of B-Cell Lymphomas: Selected Results

### Radiolabeled Antibodies

Press and colleagues<sup>2,129</sup> used high, marrow-ablative RIT doses in patients with biodistributions that predicted favorable tumor dosimetry within tolerable host toxicity ranges in the setting of autologous bone marrow transplantation. In a group of 42 patients with chemotherapy-refractory lymphomas, 24 had favorable biodistributions and 19 received high-dose RIT. A remarkable 84% of these patients experienced complete remissions, and an additional 11% had partial remissions. More recent updates suggest that many of the complete remissions are durable, with a 62% progression-free survival rate at 2 years. Preliminary studies in patients with AML suggest that RIT may be useful as a conditioning regimen before bone marrow transplantation.<sup>130</sup>

These exciting results illustrate the potential of RIT in appropriately selected patients, and they certainly contradict any pessimism regarding the role of antibody-based targeted therapeutics in the management of cancer. Further advancements in antibody design, chelation chemistry, choice of radioligand, and selection of appropriate candidates and clinical setting for therapy can be safely predicted to expanded indications for antibody-based RIT in the treatments of patients with hematologic neoplasms.

<sup>131</sup>I-B1 (anti-CD20) treatment has caused 50% and 79% CR rates for patients with chemotherapy-refractory B-cell lymphoma treated with low-dose nonmyeloablative<sup>3,131</sup> and high-dose ablative<sup>2,132</sup> RIT followed by autologous transplantation, respectively. The median CR duration of a single nonmyeloablative dose was 16.5 months. Patients were pretreated with unlabeled anti-CD20 to enhance the targeting of <sup>131</sup>I-B1 to tumor by prolonging blood and whole body radioisotope clearance through the saturation of nonspecific binding sites, nonmalignant B cells, and other potential antigenic sinks.<sup>3</sup> CD20 antigen does not internalize after antibody binding, allowing for extended retention of intact <sup>131</sup>I-B1 at the targeted cell. Minimal myelosuppression was observed in all patients treated at nonmyeloablative doses.<sup>3,134</sup> Toxicity in the high-dose trials<sup>2,132</sup> was modest compared to total body irradiation. The myeloablative doses delivered less than 27.25 Gy to dose-limiting normal organs. Further dose escalation was limited by cardiopulmonary toxicity. Sixty percent of patients have developed elevated thyroid-stimulating hormone levels, and 2 of 29 patients have developed second malignancies (bladder and colon cancer) several years after therapy. Acute leukemias or myelodysplastic syndromes have been documented at a median of 42 months after therapy.<sup>132</sup> Responses have been attributed to the tumoricidal effects of the MAB itself and to the selective delivery of irradiation by the radiolabeled MAB. The murine anti-CD20 antibody C2B8, which was chimerized to create rituximab, has been conjugated to <sup>90</sup>Y, and the resulting radioimmunoconjugate has shown impressive antitumor activity in patients with chemotherapy-refractory B-cell lymphomas.<sup>133</sup>

Therapy with <sup>131</sup>I Lym-1 in phase I/II clinical trials has shown significant antitumor activity as well. Low-dose fractionated treatment of 30 patients (25 with non-Hodgkin's lymphoma, five with chronic lymphocytic leukemia) resulted in three CRs and 14 PRs.<sup>134</sup> At the nonmyeloablative maximally tolerated dose of 100 mCi/m<sup>2</sup>, 11 of 21 patients exhibited clinical responses.<sup>135</sup>

CD33 is expressed on most myeloid leukemic blasts and leukemic progenitor cells. This tumor-associated antigen is also present on committed normal myelomonocytic and erythroid progenitor cells and is expressed at low levels on early hematopoietic stem cells. M195, a murine anti-CD33 MAB, has been used to deliver therapeutic doses of <sup>131</sup>I in combination with busulfan or cyclophosphamide to eliminate residual leukemia before bone marrow transplantation.<sup>136</sup> More recently, a humanized form of M195, HuM195, has been radiolabeled and used as a single agent in the treatment of AML and chronic myeloid leukemia. In these studies, 8 of 12 patients treated with <sup>90</sup>Y-conjugated MAB and 13 of 18 patients treated with bismuth 213-conjugated MAB exhibited minor responses.<sup>137,138</sup>

### Other Approaches

CD15 and CD33 have been used as targets in AMLs.<sup>139,140</sup> PM-81, or MDX-11, is an IgM with specificity for CD15.<sup>133</sup> It was evaluated before induction therapy in patients with AML. The number of peripheral blasts decreased transiently. Two patients at the highest dose level, 1.5 mg/m<sup>2</sup>, had grade 4 toxicities of hypotension or rhabdomyolysis. Unconjugated HuM195 recognizes CD33.<sup>142</sup> Patients with persistent disease after chemotherapy were treated with daily infusions 4 days a week for 2 weeks. One of ten patients had a CR. More recently, this antibody has been conjugated to a recombinant form of gelonin, a single-chain plant catalytic toxin that inactivates the 60S ribosomal subunit.<sup>141</sup> *In vitro* experiments using HuM195-rGel with CD33-expressing AML cell lines, as well as primary cultures of human AML blasts, demonstrated effective cell killing. There was also enhanced killing of AML blasts after exposure to HuM195-rGel for 24 hours followed by freeze thawing of cells compared with freeze thawing alone. This approach may have applicability in purging autologous bone marrow products for transplantation, particularly because CD33 is not expressed on stem cells.<sup>142</sup>

Anti-Tac is a MAB that recognizes the IL-2 receptor. Infection with human T-cell leukemia virus type I can result in the development of adult T-cell leukemia. The majority of leukemic blasts in adult T-cell leukemia have been found to express large numbers of IL-2 receptor. Waldmann and colleagues<sup>143</sup> reported on the use of anti-Tac for treatment of patients with adult T-cell leukemia. Of 19 treated patients, four PRs, two CRs, and seven mixed responses were reported. Responding patients also demonstrated a lowering of elevated calcium levels. The Tac receptor can be shed in the serum and decrease the available unbound anti-Tac antibody available for binding at the tumor site.<sup>143</sup> However, the antibody can be exchanged from soluble Tac to tumor-bound Tac.<sup>144</sup> This antibody may have therapeutic potential in other hematologic disorders, such as T- and B-cell leukemia, myelogenous leukemia derived from monocytes and granulocytes, hairy cell leukemia, Hodgkin's disease, and histiocytic and mixed cell diffuse lymphoma, all of which overexpress IL-2 receptors.

## SOLID TUMORS

### Breast Cancer

HER-2/*neu* (c-erbB-2), a member of the EGFR family, has been targeted for antibody therapy because it is overexpressed on 25% of adenocarcinomas. Recombinant human MAB (rhuMAB) HER-2<sup>145</sup>, also known as *trastuzumab*, is a humanized antibody derived from 4D5, a murine MAB that recognizes HER-2/*neu*. In a phase II trial in women with metastatic breast cancer, Baseglia and associates<sup>5</sup> reported an objective response rate of 11.6%, with responses seen in the liver, mediastinum, lymph nodes, and chest wall metastases. Patients typically received ten or more treatments with the antibody, and none developed an antibody response against trastuzumab.<sup>5</sup> Cobleigh and coworkers<sup>146</sup> treated 222 women with metastatic breast cancer, finding an objective response rate of 16%. The median response duration

was 9.1 months with a median overall survival rate of 13 months, which is superior to results reported for second-line chemotherapy in metastatic breast cancer. <sup>146</sup>

Preclinical data with trastuzumab suggested enhanced clinical activity in combination with cisplatin chemotherapy. A phase II study in patients with chemotherapy-refractory breast cancer that overexpressed HER2/ *neu* has been completed. <sup>147</sup> Nine of 37 assessable patients achieved a PR, and nine additional patients exhibited a minor response or stable disease. The median response duration was 3.3 months. Toxicities were largely attributable to cisplatin. No evidence was found for cisplatin-related alteration of antibody pharmacokinetics.

A large, randomized, phase III trial comparing cytotoxic chemotherapy alone or with trastuzumab (anti-HER-2/ *neu*) has been completed. <sup>148</sup> Patients receiving initial therapy for metastatic breast cancer were treated with doxorubicin or epirubicin and cyclophosphamide, or with paclitaxel if they had received an anthracycline in the adjuvant setting. Patients were randomized to receive chemotherapy alone or in combination with weekly antibody therapy. The addition of trastuzumab improved response rates for combination therapy from 42.1% to 64.9% for the anthracycline-based regimens and from 25.0% to 57.3% for the taxane regimen. Myocardial dysfunction seen with anthracycline therapy was observed with increased frequency in patients receiving antibody alone <sup>149</sup> or with doxorubicin or epirubicin, and therefore trastuzumab is not recommended in combination with anthracyclines.

### Colorectal Cancer

Ep-CAM is a glycoprotein normally found on the basolateral surface of the nonsquamous epithelium of the lung, gastrointestinal tract, pancreas, ovary, kidney, sweat glands, biliary tract, and thymus. Most recently it has been detected in prostatic intraepithelial neoplasia and prostatic adenocarcinoma. 17-1A, a murine antibody that targets an extracellular epitope of this antigen, has undergone extensive clinical trials in metastatic colorectal cancer and pancreatic cancer as a single agent, <sup>150,151,152,153</sup> and <sup>154</sup> or in combination with GM-CSF <sup>155</sup> or IFN-g. <sup>156</sup>

The therapeutic administration of 17-1A also has been shown to induce potentially effective antiidiotypic antibodies <sup>157,158</sup> and <sup>159</sup> with increased titers when GM-CSF was coadministered with the 17-1A. <sup>160</sup> T-cell responses against antiidiotypic epitopes have been demonstrated by *in vitro* proliferation assays, IFN-g production, and *in vivo* delayed-type hypersensitivity responses. <sup>161</sup> In a small study of ten patients, those with T-cell proliferation against antiidiotypic antibodies demonstrated clinical responses, contrasting with patients without a T-cell response who had no clinical response. <sup>159</sup>

Initial phase I studies with 17-1A demonstrated occasional responses in metastatic cancers of the gastrointestinal tract after only one intravenous dose of antibody. Therapy was well tolerated, with mild side effects of nausea, vomiting, or diarrhea. Phase II studies in colon and pancreatic cancers were less encouraging ( [Table 20.5-2](#)). The overall lack of efficacy seen in these studies may have resulted from the large tumor burden or the associated immunosuppression seen in these patients with metastatic disease.

Phase	Dose and Schedule	Disease	Number of Patients	Response	Reference
I	15-300 mg IV	MetG	4	1 CR	Steele <sup>150</sup>
I	15-300 mg IV	MetG	30	3 CR	Steele <sup>151</sup>
I	60 mg IV + 100 dermohenge	Pancreas	16	2 PR	Sal <sup>152</sup>
I	60 mg IV	Pancreas	25	4	Sal <sup>153</sup>
I	300 mg IV six times	Pancreas	26	1 PR	Waller <sup>154</sup>
II	60 mg IV day 1 + GM-CSF days 2-8	Colorectal	30	2 CR	Aggeler <sup>155</sup>
II	150 mg IV day 1 + IFN-g days 1-3	Colorectal	10	None	Waller <sup>156</sup>
II	150 mg IV day 1 + IFN-g days 1-3	Pancreas	30	1 CR	Trapp <sup>157</sup>
II	300 mg IV + 1, day 10 mg IV yohimbine	Dukes' Colorectal	20	Improved PR and OS	Rehder <sup>158</sup>

CR, complete response; PR, disease-free survival; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN-g, interferon-gamma; OS, overall survival; PR, partial response.

TABLE 20.5-2. Selected 17-1A Clinical Trials

Riethmuller and colleagues <sup>162</sup> have evaluated 17-1A in the adjuvant setting in patients with colorectal cancer. Patients with lymph node–positive cancers were randomized to observation or to therapy with 17-1A for 5 months. After 5 years, the death rate in the 17-1A group was 36% versus 51% in the observation group. <sup>162</sup> The decreased death rate persisted at 7 years—43% versus 63%. <sup>163</sup> This result translated to a 30% reduction in death ( $P = .04$ ) and a 27% reduction in recurrence ( $P = .03$ ). This study has been criticized for the higher than expected death rate in the observation group and the lack of adjuvant chemotherapy. Currently, a clinical trial is comparing 17-1A to observation in patients with lymph node–negative cancers. Another ongoing study is evaluating lymph node–positive colorectal cancer patients, randomizing patients to standard adjuvant chemotherapy alone or in conjunction with 17-1A. These trials will define the role of this antibody therapy in the adjuvant setting. If the encouraging outcomes of the original randomized study are confirmed, it will signify a paradigm shift. In this new paradigm, high objective response rates in patients with metastatic disease will not be required to provide an activity signal that warrants testing in the adjuvant setting when the agent involved acts to stimulate immune responses.

### Ovarian Cancer

The majority of patients with ovarian cancer relapse even after receiving adjuvant chemotherapy and even when they present with limited disease. RIT using HMFG1, which recognizes a polymorphic epithelial mucin, has been evaluated in patients with stage Ic to IV ovarian cancer after standard chemotherapy. <sup>164</sup> The radiolabeled antibody was given once as an intraperitoneal injection. Compared with a retrospective matched control group, the estimated survival at 10 years was superior for the patients treated with RIT. Further prospective studies are needed to confirm this initial observation.

### Antiganglioside Antibodies

Significant promise has been associated with MAB directed against ganglioside antigens in patients with melanoma and neuroblastoma. <sup>165,166</sup> and <sup>167</sup> In these trials, the induction of complement-mediated cytotoxicity has been suggested as a possible mechanism of response. Gangliosides have a limited distribution within the body and normally can be found only on peripheral nerves at low densities. In contrast, gangliosides (GD2) are overexpressed on melanomas, neuroblastomas, osteosarcoma, and small cell lung cancers. Antibodies targeting gangliosides have unique toxicities resulting from peripheral nerve tissue targeting, and treatment is associated with severe pain, often requiring narcotic analgesia. Long-term neurologic deficits have been observed, although rarely. Murray et al. <sup>167</sup> treated 18 patients who demonstrated GD2 tumor expression by prior radionuclide imaging using the murine MAB 14.G2a. Toxicities included pain, fever, hyponatremia, paresthesias, and postural hypotension. Treatment with the anti-GD2 ganglioside antibodies 3F8 and Ch14.18 has been associated with lesser toxicities, although pain during infusion has been described. All studies have demonstrated responses in patients with neuroblastoma. Cheung and colleagues <sup>168</sup> have evaluated 3F8 in metastatic neuroblastoma, observing PRs as well as long-term, unmaintained remissions and survivals of 79 to 130 months. More recently, this group reported on the use of 3F8 in patients with metastatic disease treated in conjunction with chemotherapy at the time of relapse. <sup>169</sup> Two-thirds of patients with occult disease had evidence of response after 3F8 treatment. One-third of the patients are progression-free 40 to 130 months after completion of therapy. Treatment with 3F8 antibody, alone or radiolabeled, has not resulted in the selection of GD2-negative tumor clones. Ongoing studies with 3F8 are evaluating its effectiveness as a consolidation therapy after bone marrow transplantation.

The human chimeric antibody Ch14.18 has been tested in neuroblastoma and osteosarcoma. <sup>168,169</sup> The first study <sup>168</sup> reported on nine patients with previously treated stage IV neuroblastoma. Pain in the abdomen and joints controlled by intravenous morphine defined the maximally tolerated dose of 50 mg/m<sup>2</sup>. Two patients with bone and paravertebral disease had complete remissions lasting 2 months and more than 14 months, respectively. Two other patients with bone and adrenal metastases had PRs, and one other patient had a minor response of an adrenal metastasis. These results were essentially replicated in a second phase I trial, <sup>169</sup> in which five of seven patients with metastases to bone marrow had evidence of minor to CRs in the bone marrow as assessed by repeated bone marrow biopsies. This agent also has been used as consolidation therapy after bone marrow transplantation following high-dose chemotherapy and <sup>131</sup>I-metaiodobenzylguanidine with encouraging preliminary results. <sup>170</sup>

GD3 ganglioside has been targeted by the R24 antibody, which promotes ADCC and complement deposition. Therapy with R24 has induced occasional tumor regressions in patients with metastatic melanoma.<sup>171</sup> Soiffer and associates<sup>172</sup> reported on a trial in metastatic melanoma combining IL-2 at both high and low doses with R24. Treatment was limited by IL-2-related toxicities, particularly catheter-related infections. Treatment led to the expansion and activation of NK cells and T lymphocytes. In spite of this *in vitro* immune activation, only one PR was observed.

IFN- $\alpha$  given in an adjuvant setting may decrease the risk of melanoma recurrence in patients free of disease after the resection of lymph node-positive primary disease. The combination of IFN- $\alpha$ , R24, and IL-2 was studied in patients with metastatic melanoma.<sup>173</sup> Patients were treated with R24 by continuous intravenous infusion, followed by approximately 3 weeks of therapy with IL-2 and IFN- $\alpha$ . The cytokine therapy was designed to enhance the proliferation and cytotoxicity of T lymphocytes infiltrating melanoma lesions after R24 MAB therapy. However, pre- and posttreatment biopsies of these lesions showed no evidence of augmentation in the composition or biologic features of the effector cell population after the combination therapy in comparison with cytokine or MAB therapy alone. No objective tumor responses were observed. M-CSF also has been administered in combination with R24.<sup>174</sup> In this study, M-CSF was given as a 14-day continuous intravenous infusion, adding R24 on days 6 to 10. Three of 19 treated patients had a minor tumor response in metastases to the breast, liver, and lymph nodes. In yet another study evaluating combination therapies with R24, treatment combining R24 and GM-CSF demonstrated increased ADCC *in vitro* after therapy.<sup>175</sup> Two PRs were seen in 20 patients treated. Similar results have been obtained with ch14.18.<sup>176,177</sup>

## FUTURE DIRECTIONS

The initial clinical studies using antibodies and their derivatives have identified a number of applications that promise to make significant impacts in the management of patients with cancer. Patience was required to acquire the results, understand the reasons for disappointment or success, and refine the treatment strategies to obtain results that provide legitimate causes for encouragement. These promising results represent the most advanced clinical antibody therapy programs, but a wealth of innovative strategies using recombinantly prepared antibody molecules with novel effector functions are in earlier stages of clinical evaluation. Some of these approaches, such as modulating growth factor receptor functions or inducing immune responses using BsAb, show considerable promise and are expected to add to the list of novel agents available for the treatment of malignancies in which previously conventional therapeutic strategies have proven inadequate.

In the past, antibody development has focused on identification of targets on the cancer cell itself. There are now an increasing number of targets in the extracellular matrix and local tumor environment. The most developed approach targets the vascular endothelial growth factor, a mediator of tumor neovascularization. An antibody-targeting tenascin, a class of extracellular matrix proteins, has been tested in a RIT trial in patients with primary or metastatic brain tumors.<sup>178</sup> Antibodies against osteoclast integrins can prevent osteoclastic bone resorption.<sup>179</sup> Such approaches offer additional causes for optimism about antibody-based therapeutics.

mice.<sup>27,28,29,30,31,32,33,34,35,36,37,38,39,40</sup> and <sup>41</sup>

Three decades after publication of the hypothesis that tumors are angiogenesis-dependent, elegant proofs continue to be published. Two such studies appeared in 1999. One of these is a gene knockout experiment.<sup>42</sup> Mice deficient in one allele of *Id1* and two alleles of *Id3* are unable to mount an angiogenic response to 100 million inoculated tumor cells. The tumors take, but remain dormant and nonangiogenic and do not metastasize. Placental angiogenesis is unaffected. In a second experiment, human cancer cells are transfected with thrombospondin-1 and/or thrombospondin-2, both of which inhibit angiogenesis. The transfected cells are then inoculated into immunodeficient mice.<sup>43</sup> Tumor growth is inhibited in direct proportion to the level of thrombospondin secreted. Tumor cell apoptosis is inversely proportional to tumor angiogenesis (i.e., apoptosis increases as angiogenesis decreases). Tumor cell proliferation, however, is independent of angiogenesis and apoptosis (Fig. 20.6-2).

**FIGURE 20.6-2.** Transfection of squamous cell carcinoma cells by thrombospondin-1 (TSP-1), thrombospondin 2 (TSP-2), or both. PCNA, proliferating cell nuclear antigen. (From ref. 43, with permission.)

## MICROVASCULAR ENDOTHELIAL CELLS CONTROL A TUMOR'S SUPPLY OF OXYGEN, NUTRIENTS, AND GROWTH FACTORS

### Oxygen and Nutrients

Virtually every cell in the body lives adjacent to a capillary endothelial cell, or at least a distance no greater than the oxygen diffusion limit of 100 to 200  $\mu\text{m}$ .<sup>20</sup> This arrangement permits *perfused* vessels to deliver oxygen and nutrients and to remove catabolites over short distances. This proximity of tissue cells to microvessels is accomplished by at least three common configurations and some rare configurations (Fig. 20.6-3). One category includes cells such as pancreatic islet cells, fat cells, and certain skeletal muscle cells, which are surrounded by two or more microvessels. A second category includes hepatic cells and cells of other solid organs. Each hepatic cell abuts a microvessel on one side and another hepatocyte on the other side. Epithelial cells exposed to the environment make up a third category (e.g., keratinocytes in the skin; mucosal cells in the gastrointestinal tract and bladder; and cells that line a wide variety of ducts, such as those in the breast or prostate). These cells exist in an avascular compartment (e.g., epidermis) separated from underlying microvessels (e.g., in the dermis) by a basement membrane. The basal cells lying on the basement membrane are closest to the microvessels beneath it and receive oxygen and nutrients across a short distance defined by the limits of oxygen diffusion (100 to 200  $\mu\text{m}$ ). However, the cells in the upper layers lie beyond the oxygen diffusion limit and are undergoing apoptosis. In contrast, tumor cells form multiple layers that encircle a microvessel until these cell layers (three to six or more), reach the absolute limits of oxygen diffusion. In the outermost cell layer, tumor cells are completely anoxic and are dying. This has been quantified by infrared spectroscopy in transparent skin chambers in experimental animals.<sup>20</sup> A gradient of tumor cell proliferation also is present in these multiple layers. The highest rate of proliferation is found in tumor cells closest to the microvessel.<sup>19</sup> Tumor cells may continue to proliferate and die in this *in situ* configuration, but they cannot expand the tumor mass beyond 0.2 to 2.0 mm until they have induced endothelial cell migration, proliferation, and sprout formation.<sup>44,45</sup> Therefore, a general rule is that any expansion of tumor mass beyond a microscopic size is dependent on two cell compartments growing in tandem: tumor cells and microvascular endothelial cells.

**FIGURE 20.6-3.** Common patterns of normal tissue cells (A,B,C) illustrating how they are apposed to capillaries in comparison to tumor cells (D).

### Growth Factors and Antiapoptotic Factors

Endothelial cells not only guard the entry of oxygen and nutrients as well as the exit of catabolites, these cells also elaborate mitogens and survival factors for tumor cells. This *paracrine* activity of microvascular endothelial cells includes the mobilization of basic fibroblast growth factor (bFGF), platelet-derived growth factor, insulin-like growth factor-1 and -2, and cytokines such as interleukin-6 and granulocyte-macrophage colony-stimulating factor. At least 20 paracrine factors are known to be produced by vascular endothelial cells.<sup>46,47,48,49,50,51</sup> and <sup>52</sup>

Antiangiogenic therapy can cause either arrest or regression of growing blood vessels,<sup>39,53</sup> which would shut down the supply of endothelial-derived paracrine factors and contribute to tumor cell apoptosis. In an *in vitro* experiment, the withdrawal of insulin-like growth factor-1 from *myc*-dependent lymphoma cells caused them to undergo apoptosis.<sup>54</sup> Because one microvascular endothelial cell can support up to 5 to >100 tumor cells, antiangiogenic therapy directed solely against endothelial cells is amplified in contrast to conventional chemotherapy, which attacks tumor cells directly.<sup>55,56</sup>

## ANTIANGIOGENIC THERAPY OPERATES OVER A WIDE THERAPEUTIC WINDOW

In animal studies and in human clinical trials, antiangiogenic therapy generally has fewer side effects than conventional cytotoxic chemotherapy. Endostatin, for example, showed no detectable side effects in tumor-bearing animals. At this writing, no significant side effects have been reported during the first 6 months of a phase I clinical trial of endostatin in five cancer centers.

### Turnover Times of Endothelium in a Tumor Bed versus Endothelium in Other Regions of the Vasculature

One reason for this predicted lack of toxicity in antiangiogenic therapy is that, under normal conditions, vascular endothelial cells, which form a monolayer of approximately 1000  $\text{m}^2$ , are not dividing. Their turnover time is more than 1000 days.<sup>57,58</sup> In contrast, bone marrow cells and mucosal cells in the gastrointestinal tract are among the most rapidly proliferating cells in the body. Bone marrow cells undergo approximately 6 billion cell divisions per hour, and the entire bone marrow is turned over in 5 days. During ovulation and in wound healing, microvascular endothelial cells may grow almost as rapidly as bone marrow cells, but for short periods (days). During tumor angiogenesis, microvascular endothelial cells undergo sustained rapid proliferation that persists for as long as the tumor is present. In [Figure](#)

20.6-4, proliferation rates of cells in various human tissues are plotted as turnover times on the horizontal axis. Relative size of tissue mass is plotted on the vertical axis. The tissues turning over most rapidly, in descending order, are gut mucosa, bone marrow, and skin. Cancer of the esophagus (depicted in blue) contains a subset of tumor cells that are rapidly cycling, as well as tumor cells with slower cycling times and some tumor cells that are not cycling. Conventional cytotoxic chemotherapy targets proliferating cells in a tumor but is limited by coincidental injury to normal tissues according to their individual proliferation rates. Rapidly cycling tissues succumb first, then more slowly cycling tissues, as cytotoxic therapy continues.

**FIGURE 20.6-4.** Turnover times of various tissues plotted against tissue mass. (From ref. 58, with permission.)

A second limitation of conventional cytotoxic therapy is that only a small fraction of tumor cells are in cycle when chemotherapy is administered (e.g., in human prostate cancer, fewer than 2% of cells are in cycle).<sup>59</sup> After these cells are killed, they may be replaced by cycling cells. Thus, repeated therapy is required, followed by intervals off of the drug to recover bone marrow and gut. In contrast, antiangiogenic therapy, which either selectively or specifically targets the microvascular endothelial cells in a tumor bed, restricts growth of all tumor cells, regardless of their cycling state.

#### **Differences in Specificity of Angiogenesis Inhibitors**

Because a drug is an angiogenesis inhibitor *per se* does not guarantee its freedom from side effects. Certain synthetic small molecules designed to inhibit an angiogenic target (such as a receptor for an angiogenic factor), may induce side effects that are related to the structure of the molecule and not to its antiangiogenic function.

The more specifically that an angiogenesis inhibitor targets growing endothelial cells to the exclusion of resting endothelium or other cell types, such as smooth muscle or fibroblasts, the less is the risk of side effects. Although the pharmaceutical industry generally prefers to develop small synthetic molecules instead of proteins as therapeutic anticancer agents, certain proteins are advantageous because they inhibit angiogenesis specifically. Endostatin is an example. This 20-kD internal fragment of the carboxy-terminus of collagen XVIII is one of the most highly specific and least toxic of the known angiogenesis inhibitors.<sup>37,39,60</sup> Doses of endostatin that produce tumor dormancy or tumor regression have no effect on pregnant mice. Normal babies are born and their growth is not delayed by treating them with endostatin (R. Rohan and R. D'Amato, personal communication, 1998). Furthermore, wound healing is not delayed by endostatin (J. Marler, personal communication, unpublished data, 1999). Therefore, endostatin is not only a specific angiogenesis inhibitor, but it also appears to be a selective inhibitor of tumor neovascularization. Not all angiogenesis inhibitors are free of effects on healing wounds. For example, the fumagillin analogue TNP-470 slows tumor growth by approximately 65% to 75% in a wide variety of tumor-bearing mice,<sup>28</sup> but it also delays wound healing by at least 15% to 17%.<sup>61</sup> In addition, it causes 5% weight loss.

#### **Differences in Types of Angiogenesis Generated by the Host**

Why should tumor and wound vessels respond differently to a specific angiogenesis inhibitor such as endostatin? A possible explanation is that these two types of neovascular beds may be controlled in part by different ratios of certain endothelial regulatory proteins, such as the angiopoietins. Angiopoietin-1 is a 70-kD ligand that binds to a specific tyrosine kinase expressed only on endothelial cells, called *Tie2* (also called *Tek*).<sup>62,63,64,65</sup> and <sup>66</sup> (A ligand for *Tie1* has not been elucidated.) Like vascular endothelial growth factor (VEGF), angiopoietin-1 is an endothelial cell-specific growth factor. Angiopoietin-1 is not a direct endothelial mitogen *in vitro*, but it induces endothelial cells to recruit pericytes and smooth muscle cells to appose themselves to the wall of a microvessel. This process can convert a capillary vessel to a venule. Pericyte and smooth muscle recruitment are mediated by endothelial production of platelet-derived growth factor-BB (and probably other factors) when *Tie2* is activated by angiopoietin-1.<sup>67</sup> In mice that overexpress angiopoietin-1 in the skin, increased vascularization is noted.<sup>65</sup> The vessels are significantly larger than normal and the skin is reddened. The vessels are not leaky and no skin edema is present, in contrast to dermal vessels of mice overexpressing VEGF. In transgenic mice expressing both angiopoietin-1 and VEGF in the skin, dermal angiogenesis is increased in an additive manner, but the vessels do not leak.<sup>68</sup> This model closely approximates angiogenesis in healing wounds (i.e., relatively nonleaky vessels coated by pericytes and some perivascular smooth muscle cells). In contrast, tumor vessels are leaky and thin-walled with a paucity of pericytes. Angiopoietin-2 blocks the *Tie-2* receptor on endothelial cells,<sup>66</sup> which initiates a chain of events so that pericytes and smooth muscle cells are repelled. Angiopoietin-2 is produced by vascular endothelium in a tumor bed, but a putative "angiopoietin-inducing factor" from tumor cells is unknown. Nevertheless, tumor vessels remain as thin "endothelial-lined tubes," even though some of these microvessels reach the diameter of venules. Angiopoietin-2 and VEGF acting together increase angiogenesis. However, if VEGF is antagonized or withdrawn at this point, endothelial cells may undergo apoptosis and new microvessels can regress.<sup>68</sup> In summary, endostatin may regress tumor neovascularization that is under the control of angiopoietin-2, but it may have little or no effect on wound neovascularization regulated by angiopoietin-1.

#### **Differences in Angiogenic Response at Different Sites in the Host**

In animals, it has been shown that the same tumor type may elicit different intensities of angiogenesis when implanted at different sites in the body. For example, subcutaneous tumors implanted on the dorsum between the scapulae may grow at four times the rate of tumor implanted more caudally between the iliac crests.<sup>69</sup> Human colon cancers implanted subcutaneously (in immunodeficient mice) do not become neovascularized and remain dormant at a microscopic size. In contrast, when these tumors are transplanted to the surface of the colon, they become neovascularized and grow to a large size.<sup>70</sup> This tumor uses bFGF as its major angiogenic mediator but is unable to induce angiogenesis in the subcutaneous position because of high levels of interferon- $\beta$  in the keratinocytes, which is not found in the colon wall. Interferon- $\beta$ , like its commercially available relative interferon- $\alpha$ , down-regulates bFGF messenger RNA and protein production by colon cancer cells,<sup>70</sup> thus acting as a natural suppressor of any angiogenesis mediated by bFGF. In this experiment, the colon cancer cells lacked a receptor for bFGF. If these findings apply to patients, metastases in different sites (e.g., lung vs. bone), may respond differently to a given dose of angiogenesis inhibitor. Conversely, different doses of inhibitor may be required for inhibition of metastases at different organ sites.

#### **Genetic Differences in Host Angiogenic Response**

D'Amato and Rohan in our department of surgery at Children's Hospital, Boston, demonstrated that certain strains of mice (e.g., 129/SvImJ) produce an intense angiogenic response to the same dose of an angiogenic protein (bFGF) that induces a low angiogenic response in mice of a different genetic background (SJL/J).<sup>71</sup> At least a tenfold difference is seen between the high and low responders, with other strains of mice responding in the middle range ( Fig. 20.6-5).

**FIGURE 20.6-5.** Genetic heterogeneity of angiogenesis in different genetic strains of mice. bFGF, basic fibroblast growth factor. (From ref. 71, with permission.)

### TOTAL ANGIOGENIC OUTPUT OF A TUMOR MAY DETERMINE ITS RESPONSE TO ANTIANGIOGENIC THERAPY

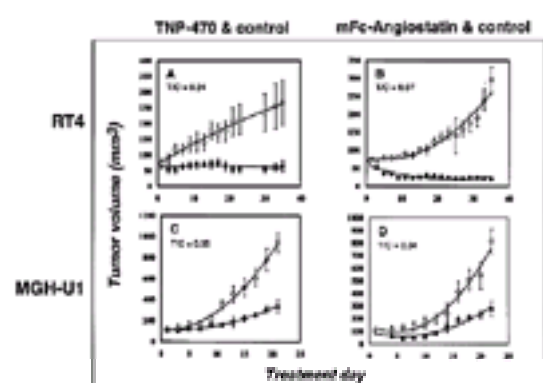

When taken together, the experimental findings cited above indicate that the total angiogenic output of a tumor may be a sum of (1) the balance of positive and negative angiogenic regulators that the tumor cells generate, (2) the genetic heterogeneity of angiogenic responsiveness in the host, and (3) the angiogenic heterogeneity at the tumor site. If these results are extrapolated to cancer patients, metastases in one site (e.g., lungs) may respond to a given angiogenesis inhibitor before metastases at another site (e.g., bone) in the same patient. Furthermore, two patients with the same tumor type may respond differently to a given dose of an angiogenesis inhibitor. Therefore, in principle, optimal therapeutic efficacy would be achieved by administering antiangiogenic therapy at a dose that would match the total angiogenic output of the tumor. In practice, however, it is not currently feasible to determine the total angiogenic output of a tumor. Therefore, those angiogenesis inhibitors that have little or no side effects could possibly be increased to whatever dose level causes a tumor response (i.e., stable disease or tumor regression).

### ANTIANGIOGENIC THERAPY MAY BYPASS ACQUIRED DRUG RESISTANCE

The genetic instability and high mutation rate of tumor cells is responsible, in part, for the frequent emergence of acquired drug resistance with conventional cytotoxic anticancer therapy. However, vascular endothelial cells, like bone marrow cells, are genetically stable and have a low mutation rate. Therefore, Kerbel <sup>72</sup> proposed a hypothesis in 1991 that antiangiogenic therapy would be a strategy to bypass drug resistance. Subsequently, my laboratory validated this concept in tumor-bearing mice treated with endostatin.<sup>39</sup>

### ANTIANGIOGENIC THERAPY IS INDEPENDENT OF TUMOR CELL CYCLE

Conventional cytotoxic chemotherapy is generally cell cycle-dependent. Indolent tumors with a low percentage of cycling tumor cells are more refractory to cytotoxic chemotherapy than are rapidly growing tumors. This property is thought to explain the high efficacy of chemotherapy in fast-growing mouse tumors compared to the relatively low efficacy in adult human tumors, with success against pediatric tumors viewed as somewhere in between. It has been widely assumed that antiangiogenic therapy would be similar to chemotherapy. Experimental studies, however, reveal just the opposite. Slowly growing tumors in mice require lower doses of antiangiogenic therapy to bring them to dormancy than do faster growing tumors, which require higher doses ( Fig. 20.6-6).<sup>73</sup>

**FIGURE 20.6-6.** The effect of antiangiogenic therapy on slowly growing (RT4) (A,B) versus rapidly growing (MGH-U1) (C,D) human bladder cancer in mice.

Furthermore, during tumor inhibition by antiangiogenic therapy, tumor cell proliferation usually remains unchanged from the pretreated state. <sup>14,44</sup> When mice bearing drug-sensitive tumors were treated with cyclophosphamide on a “conventional” schedule, tumor cell proliferation was significantly decreased <sup>74</sup> (see [Cytotoxic Chemotherapy May Be Angiogenesis Dependent](#), later in this chapter). However, when the same tumor was made highly resistant to cyclophosphamide, the tumor cell proliferation rate did not decrease, despite the fact that tumors regressed under an “antiangiogenic” schedule of the same drug.

### MICROVESSEL DENSITY IS A USEFUL PROGNOSTIC INDICATOR BUT MAY NOT BE A USEFUL INDICATOR OF EFFICACY OF ANTIANGIOGENIC THERAPY

The first quantitative method for histologic grading of tumor angiogenesis was reported by Steven Brem and colleagues <sup>75</sup> from my laboratory in 1972. They correlated neovascularization in human brain tumors with tumor grade. It was not until 13 years later that a second report describing histologic quantification of tumor angiogenesis was published.<sup>76</sup> This report was followed 3 years later by the first report of the use of tumor vascularity as a prognostic marker (cutaneous melanoma).<sup>77</sup> In 1991, Noel Weidner and I used specific antiendothelial antibodies to highlight tumor vasculature and showed that microvessel density was a prognostic marker for human breast cancer.<sup>78</sup> Since then, the majority of reports (52 different studies) have confirmed that microvessel density is a powerful and often an independent prognostic indicator for many different types of human cancer. However, other reports fail to show that microvessel density is a prognostic indicator (seven studies), especially for certain types of tumors. Many of the negative reports may be methodological. Others may result from poorly understood biologic differences, such as the possible coexistence of angiogenesis inhibitors and stimulators in certain tumors. Gasparini and Harris <sup>79</sup> analyzed the variables in quantitation of tumor angiogenesis in histologic sections, and they have summarized the reports up to 1999. These reports are also summarized in tabular form. <sup>4</sup> The basis of the prognostic value of quantifying the areas of highest microvessel density (“hot spots”) in a tumor may be that these areas represent the most angiogenic clones of tumor cells. Such clones have the highest probability of being angiogenic metastases.

However, because microvessel density of a tumor is a prognostic marker for the risk of metastasis or death of a patient does not necessarily make it a useful indicator of efficacy of antiangiogenic therapy. Microvessel density is largely determined by intercapillary distance, which itself is governed by the thickness of the cuff of tumor cells surrounding a microvessel (50 to 200  $\mu\text{m}$ ). In experimental animals, microvessel density may remain constant as a tumor is regressing under antiangiogenic therapy. Despite ongoing capillary dropout in a shrinking tumor mass, residual tumor cells can assemble around the remaining microvessels, thus leaving the microvessel density relatively unchanged. Furthermore, microvessel density may not distinguish between certain benign and malignant tumors. For example, normal human pituitary has a higher microvessel density than a pituitary adenoma, which has a higher microvessel density than a pituitary carcinoma.<sup>80</sup> One explanation of this apparent paradox is that, in most normal tissues, the perivascular cuff is usually one or two cells thick. In some normal tissues, therefore, intercapillary distance is small, leading to a high microvessel density. In contrast, in many tumors the perivascular cuff thickness increases as tumor cells adapt to lower oxygen tension and survive at an increasing distance from the nearest open capillary. The cuff thickness of a murine breast carcinoma (MCA-IV) reaches 100  $\mu\text{m}$  or more, which approaches the limit of oxygen diffusion.<sup>81</sup> For other tumors, such as breast carcinoma, microvessel density is significantly higher in the cancer than in normal breast.<sup>78,82</sup> In certain animal tumors, angiogenic output appears to exceed the growth capacity of the tumor cells so that treatment with an angiogenesis inhibitor initially induces a significant decrease in microvessel density as tumor growth is inhibited or arrested. Because all of these variables are not fully understood, it may

not be prudent at this time to use microvessel density as a surrogate marker for efficacy of antiangiogenic therapy.

### STABLE DISEASE OR TUMOR DORMANCY CAN BE SUSTAINED BY BLOCKED ANGIOGENESIS

Increasing evidence shows that experimental tumors can be maintained at a stable size or at a microscopic dormant size by uninterrupted antiangiogenic therapy or by blocked angiogenesis.<sup>35,36</sup> and <sup>37,39,42,43</sup> For the purpose of this chapter, *stable disease* may be defined as tumor that has stopped expanding but is grossly visible or radiologically detectable. A definition of *tumor dormancy* is nonexpanding tumor that can be detected only microscopically. In either event, recruitment of new vessels is sufficiently restricted that tumor cells surviving on residual vessels exist in a steady state of proliferation and apoptosis that prohibits further expansion of tumor mass, regardless of whether it is a primary tumor or a metastasis. It is too early to say whether prolonged stable disease or durable tumor dormancy can be achieved by antiangiogenic therapy in cancer patients. Nevertheless, it may be prudent to include these states as possible end points in clinical protocols for antiangiogenic therapy. A close approximation to tumor dormancy in experimental animals may be the regression of a recurrent giant cell tumor of the mandible by interferon- $\alpha$  administered at a low dose of 3 million units per day for 1 year.<sup>83</sup> Interferon- $\alpha$  is an angiogenesis inhibitor by virtue of its ability to block overproduction of bFGF.<sup>53,70</sup>

### LEUKEMIA IS ANGIOGENESIS DEPENDENT

The conventional wisdom has been that, because leukemia is regarded as a liquid tumor, it does not require angiogenesis. However, in children with newly diagnosed untreated acute lymphoblastic leukemia, bone marrow biopsies revealed a six- to sevenfold increase in microvessel density in the leukemic marrows in contrast to control bone marrows from children undergoing staging evaluations at the time of diagnosis of solid tumor.<sup>84</sup> Microvessels in leukemic bone were surrounded by a perivascular cuff of tumor cells not unlike solid tumors. This configuration was best observed by confocal microscopy. bFGF was approximately sevenfold higher in the leukemic children than in controls. Interestingly, acute myeloid leukemia in adults is also associated with intense bone marrow neovascularization.<sup>85,86,87</sup> and <sup>88</sup> Cellular levels of the angiogenic factor VEGF are abnormally elevated and provide an independent predictor of outcome.<sup>89</sup> The myeloproliferative diseases polycythemia vera, chronic myelocytic leukemia, and myelofibrosis also have significantly increased neovascularity.<sup>90</sup> The close configuration of bone marrow cells and microvessels may permit a two-way paracrine pathway between vascular endothelial cells, which can release granulocyte colony-stimulating factor<sup>52</sup> (a mitogen for bone marrow cells), and bone marrow cells, which release bFGF (a mitogen for vascular endothelial cells).<sup>91</sup>

These results show that leukemia (and other proliferative diseases of the bone marrow) are angiogenic. They do not, however, prove that leukemia is angiogenesis dependent. The first experimental evidence in support of this concept is by Browder and colleagues,<sup>74</sup> who demonstrated that L1210 leukemia can be eradicated by an antiangiogenic schedule of chemotherapy, but not by the conventional schedule of maximum tolerated dosing. Unpublished preliminary data by Browder suggests that endostatin, a specific angiogenesis inhibitor, can significantly prolong survival of mice bearing murine leukemias.

These observations provide a conceptual basis for the potential future use of angiogenesis inhibitors in leukemia, perhaps first in patients for whom all conventional therapy has been unsuccessful, and later as an adjunct to conventional therapy.

### CLINICAL PATTERNS OF METASTASIS PRESENTATION MAY BE ANGIOGENESIS DEPENDENT

Cancer metastases may present at least four common clinical patterns and one rare pattern (Fig. 20.6-7). These clinical observations have previously been unrelated to each other, but we can now propose that they may all be explained on the basis of angiogenic principles.<sup>92</sup>

At first diagnosis:		Recurrence of metastases	
Primary Tumor	Metastases		
I	+	○	months
II	+	+	
III	○	+	years
IV	+	○	
V	+	+	(Metastases regress when primary tumor removed: renal carcinoma, rare.)

FIGURE 20.6-7. Clinical presentation of metastases.

1. The patient whose metastases appear a few months after surgical removal of a primary tumor may have undergone a decrease in a circulating angiogenesis inhibitor that was generated by the primary tumor. A murine Lewis lung carcinoma that generates angiostatin is a model of this type of clinical presentation.<sup>35</sup>
2. When metastases are already present at the first diagnosis of a primary tumor (i.e., parallel tumor growth), the primary tumor may have lost or down-regulated its ability to generate a circulating angiogenesis inhibitor and therefore is incapable of suppressing distant metastases. The experimental analogue would be a subline of Lewis lung carcinoma that has lost the ability to generate angiostatin.<sup>35</sup>
3. When metastases present in the absence of a primary tumor (i.e., a pattern known as the *occult primary*),<sup>93</sup> this finding may be similar to mice in which tumor cells are injected intravenously and are allowed to take as lung metastases before a primary tumor is implanted subcutaneously.<sup>94</sup> In this experiment, growth of the subcutaneous tumor appears to be inhibited by the extensive metastatic growth. However, it has not yet been ascertained whether the inhibition was mediated by a circulating inhibitor. In a patient presenting with this metastatic pattern, the total mass of metastases would need to expand faster than the primary tumor to produce sufficient quantities of circulating angiogenesis inhibitor that could suppress the primary tumor.
4. The patient whose metastases do not appear until years after removal of the primary tumor may harbor dormant metastases that are not angiogenic for many years but eventually switch to the angiogenic phenotype. This is more than just speculation, because we have developed an animal model that behaves exactly in this way. The surgical removal of a B-16 melanoma from C57Bl/6 mice leaves numerous viable lung metastases of approximately 0.1 to 0.2 mm diameter that are nonangiogenic and do not expand further throughout the life of the animal. However, the microscopic metastases can be stimulated to grow by trauma to the lung or by transplanting a piece of lung to the subcutaneous tissue of another mouse (M. O'Reilly, unpublished data, 1998).
5. A rare event is for metastases to disappear completely or to undergo partial regression after removal of a renal cell carcinoma. An animal model that most closely resembles this clinical pattern is V2 carcinoma in the rabbit. Lung metastases grow in parallel with a primary tumor in the thigh. However, lung metastases regress after the primary is completely resected (H. Verheul, R. D'Amato, and D. Panigrahy, unpublished data, 1998). This finding does not appear to be an immune reaction, because fresh tumor can be successfully grown in the same rabbit. One explanation may be that the metastases were dependent on high production of a circulating angiogenic factor(s), such as the high tissue levels of bFGF that have been found to correlate with high mortality in renal cancer.<sup>95</sup>

By describing these patterns of metastatic presentation in patients, I have tried to provide a possible unifying mechanism to explain them. The experimental evidence for the animal models is discussed in more detail by Holmgren et al.<sup>14</sup> It must be emphasized that the similarity of such animal models to human patterns of metastatic presentation does not prove that the human patterns are based on the same angiogenic principles as the animal models. However, this arrangement of the human metastatic patterns will hopefully stimulate other investigators to find additional clinical or experimental evidence to support or refute the general hypothesis. Thus, the heuristic value of Figure 20.6-7 is its potential inclusion in the design of clinical trials of angiogenesis inhibitors. These observations also provide an alternative to the widely held assumption that tumor cells in a dormant microscopic tumor are not cycling and remain in  $G_0$ . In fact, dormant animal tumors with blocked angiogenesis maintain a high apoptosis rate balanced by a high proliferation rate in the tumor cells.<sup>14</sup>

### CYTOTOXIC CHEMOTHERAPY MAY BE ANGIOGENESIS-DEPENDENT

Conventional cytotoxic chemotherapeutic drugs target tumor cells, but the effect of these drugs on microvascular endothelial cells has received little attention until the 1990s. Baguley et al.<sup>96</sup> demonstrated in 1991 that vinblastine caused more than 90% necrosis of drug-resistant solid tumors within hours but had no direct effect on the tumor cells as demonstrated when the cells were grown as ascites. In 1992, Steiner showed that vincristine, vinblastine, doxorubicin, mitoxantrone, and etoposide

had short-term antiangiogenic activity in the chick embryo.<sup>97</sup> Also, *in vitro* antiendothelial effects have been reported for cyclophosphamide,<sup>98</sup> 5-fluorouracil,<sup>99</sup> and mitomycin C.<sup>95,100</sup> Short-term *in vivo* antiangiogenic effects have been reported for paclitaxel,<sup>101,102</sup> and 103 6-methylmercaptopurine,<sup>104</sup> tegafur,<sup>105</sup> 9-amino-20(S)-camptothecin,<sup>106</sup> topotecan,<sup>106</sup> and combretastatin A-4.<sup>107,108</sup>

The question was raised by Browder as to why those cytotoxic chemotherapeutic agents with antiangiogenic activity still induced acquired drug resistance. Specific angiogenesis inhibitors do not usually induce drug resistance.<sup>39,72</sup> Vascular endothelial cells, like bone marrow cells, do not develop drug resistance, in part because of their low mutation rate. Browder hypothesized that the usual dose-schedule regimen for chemotherapeutic agents is not conducive to sustained blockade of angiogenesis. Conventional chemotherapy is traditionally administered at maximum tolerated doses followed by an extended treatment-free interval to permit recovery of hematopoietic progenitors and gastrointestinal tract mucosa. Browder proposed, however, that *during this off-therapy interval, microvascular endothelial cells in the tumor bed could also resume growth and nourish tumor recurrence*. Virtually all animal experiments show that antiangiogenic therapy is most successful when it is given over short intervals (e.g., daily or every other day) without off-therapy gaps. Browder demonstrated that 5-fluorouracil and 6-mercaptopurine are nearly devoid of antiangiogenic activity when given as bolus injections, but they reveal potent antiangiogenic efficacy when the same dose is given as a continuous infusion.<sup>74</sup>

He further showed that a standard cytotoxic agent, cyclophosphamide, can be administered to animals bearing Lewis lung carcinoma at a dose and schedule that is optimized for more sustained apoptosis of *endothelial* cells but not of tumor cells. This was named the *antiangiogenic schedule*. The *conventional schedule* is a maximum tolerated dose administered every other day for three doses followed by 21 days off-therapy to rescue bone marrow. The antiangiogenic schedule consists of a lower dose administered every 6 days. A drug-sensitive Lewis lung carcinoma became drug resistant on the conventional schedule and killed all mice, but it was eradicated on the antiangiogenic schedule. No detectable tumor was detected after 657 days, when the animals reached the end of their natural lifespan. When the tumor was made drug resistant before therapy, the antiangiogenic schedule suppressed tumor growth three times more effectively than the conventional schedule. When an angiogenesis inhibitor, TNP-470, was added at a dose 86% lower than its effective dose alone, the drug-resistant tumor was eradicated in 84% of mice.<sup>74</sup> This finding is provocative because TNP-470 alone, even at its full dose, slows Lewis lung carcinoma by only 65% and cannot cause regression. Thus, a cytotoxic chemotherapeutic agent administered in an antiangiogenic dose schedule can more effectively control tumor growth in mice, whether or not its tumor cells are drug resistant, an improvement that has come from using new logic for an old drug. In summary, the new logic is that the antiangiogenic properties of certain conventional cytotoxic agents are not revealed unless the drugs are administered frequently, without a prolonged off-therapy period. Frequent administration requires lower doses. Klement et al.<sup>109</sup> in Robert Kerbel's laboratory have demonstrated this new logic with a different experimental system. For a commentary on antiangiogenic chemotherapy, see Hanahan et al.<sup>110</sup> They showed that continuous low-dose therapy with vinblastine and an antibody to VEGF receptor-2 induced sustained regression of neuroblastoma without overt toxicity. No evidence of acquired drug resistance was found throughout the 6 months' course of treatment.

When taken together, these results in mice may help to explain why some patients who are receiving long-term maintenance or even palliative chemotherapy continue to have stable disease beyond the time that the tumor cells would have been expected to develop drug resistance. However, because conventional schedules of combination chemotherapy have led to profound increases in the survival of children with cancer and have improved the survival of adults with certain types of cancer, we do not believe that these clinical protocols should be changed for the sake of increasing the antiangiogenic efficacy of any given drug.<sup>74</sup> Formal clinical trials with patients whose tumor has become refractory to conventional chemotherapy or radiotherapy will be necessary to find an optimum antiangiogenic dose and schedule and to demonstrate whether it is an improvement over conventional chemotherapy dose schedules.

## CLINICAL TRIALS OF ANGIOGENESIS INHIBITORS

At this writing, 20 angiogenesis inhibitors produced by the biotechnology and pharmaceutical industry are in clinical trial for patients with advanced metastatic cancer, and seven are in phase III trials (see [Fig. 20.6-1](#)).

Three general strategies have been used to develop these inhibitors. A target molecule in the angiogenic pathway is identified and then is counteracted by a synthetic inhibitor or by an antibody (e.g., an antibody to the angiogenic factor VEGF or its receptor). A second approach is to identify antiangiogenic activity in a drug previously used for a different effect. Examples are thalidomide and interferon- $\alpha$ . Slamon showed that Herceptin has antiangiogenic activity in addition to its direct antitumor effect on breast cancer cells: It interferes with the activity of at least three angiogenic proteins produced by breast cancer cells (D. Slamon, Plenary Address before the American Association of Cancer Research, San Francisco, April 2000). A third approach is to discover specific endogenous angiogenesis inhibitors that are already in the circulation or in matrix. In fact, several of these are internal fragments of larger proteins that have different functions. Some examples are thrombospondin-1, a 140-kD protein under the control of p53<sup>111</sup>; angiostatin, a 38-kD fragment of plasminogen<sup>35</sup>; endostatin, a 20-kD fragment of collagen XVIII<sup>37</sup>; pigment epithelium-derived factor, a 50-kD serine protease inhibitor<sup>112</sup>; antiangiogenic antithrombin III, a 53-kD cleaved or latent conformation of the 58-kD antithrombin III<sup>40</sup>; restin, a 22-kD internal fragment of collagen XV<sup>113</sup>; canstatin, a 24-kD fragment of the  $\alpha_2$ -chain of type IV collagen<sup>114</sup>; and maspin, a 42-kD gene product of normal breast epithelium, also under the control of p53 and silenced during breast cancer progression.<sup>115,116</sup> A longer list would include SPARC (secreted protein acidic and rich in cysteine),<sup>117</sup> VEGI (vascular endothelial cell growth inhibitor),<sup>118</sup> IP-10 (interferon- $\gamma$ -inducible protein-10),<sup>119</sup> interleukin-18,<sup>120</sup> and 16-kD prolactin.<sup>121</sup>

The angiogenesis inhibitors operate by quite different mechanisms, which reveal that multiple pathways in the angiogenic process are vulnerable to attack.<sup>4</sup> As of this writing, it is too soon to say which of the angiogenesis inhibitors currently in clinical trial will receive U.S. Food and Drug Administration approval. However, because angiogenesis inhibitors can be added to chemotherapy, radiotherapy, immunotherapy, or gene therapy, as well as to each other, there is likely to be a future need for a group of angiogenesis inhibitors from which physicians can choose. The eventual possibility also exists that antiangiogenic therapy may be used as long-term maintenance therapy, like tamoxifen, to reduce the risk of recurrences.

## INTRODUCTION

Clinical trials are experiments to determine the value of treatments. There are two key components to the experimental approach. First, results rather than plausible reasoning are required to support conclusions. Second, experiments should be prospectively planned and conducted under controlled conditions in order to provide definitive answers to well-defined questions. Comparing the survival rates (based on tumor registry data) of prostate cancer patients treated with surgery to those of patients receiving radiotherapy is an example of an observational study, not a clinical trial. In an observational study, the investigators are passive observers. Treatment assignments, staging workup, and follow-up procedures are out of the control of the investigators and are conducted with no considerations about the validity of the subsequent attempt at comparison. The statistical associations resulting from such studies are, consequently, a weak basis for causal inferences about relationships between the treatments administered and the outcomes observed. Treatments usually are selected on the basis of subjective assessment of the prognosis of the patient, specialties of the physician, and various diagnostic evaluations. Unknown patient selection factors generally are more important determinants of patient outcome than are differences between treatments.

Observational studies are generally the only feasible approach for epidemiologic assessment of disease etiology. Acute observations in poorly structured therapeutic settings can also lead to the development of valuable ideas that can be tested in the laboratory and in clinical trials. However, observational studies rarely are satisfactory substitutes for clinical trials. <sup>1,2</sup> and <sup>3</sup> As pointed out by MacMahon and Pugh<sup>4</sup>:

“Only a minority of statistical associations are causal. . . . Once a statistical association has been demonstrated, how can it be determined whether or not it is causal. . . . The most satisfactory procedure is a direct experiment. . . . The evaluation of the causal nature of a relationship, in the absence of direct experiment, is neither easy nor objective. . . . The field of cancer therapy is replete with examples of new modalities that were taken up with enthusiasm and proved worthless only after they had resulted in many years of futile cost and suffering.”

Clinical trials require careful planning. The first result of the planning process is a written protocol. Typical subject headings for the protocol are shown in [Table 21.1-1](#). The protocol should define treatment and evaluation policies for a well-defined set of patients. It also should define the specific questions to be answered by the study and should directly justify that the number of patients and the nature of the controls are adequate to answer these questions. Some clinical trials are really only guidelines for clinical management supplemented by lofty objectives with no scientific meaning and no realistic chance of providing a reliable answer to a well-defined medical question. Such studies do not warrant the expenditure of limited clinical research dollars and represent a disservice to the patients who may be willing to undergo some inconvenience in order to contribute to the welfare of future patients. In this section, we attempt to provide information that will help to avoid such clinical trials.

## PHASE I CLINICAL TRIALS

The objective of a phase I trial is to determine a dose that is appropriate for use in phase II trials. Patients with advanced disease that is resistant to standard therapy are included in such trials, but it is important that the patients have normal organ function.

There are several different types of phase I trials. The most common is the phase I trial of a new cytotoxic drug. Such studies usually are performed by starting with a low dose not expected to produce serious toxicity in any patients. A starting dose of one-tenth the lethal dose (expressed as milligrams per square meter of body surface area) in the most sensitive species usually is used. <sup>5</sup> The dose is increased for subsequent patients according to a series of preplanned steps. Dose escalation for subsequent patients occurs only after sufficient time has passed to observe acute toxic effects for patients treated at lower doses. Cohorts of three to six patients are treated at each dose level. Usually, if no dose-limiting toxicity (DLT) is seen at a given dose level, the dose is escalated for the next cohort. If the incidence of DLT is 33%, then three more patients are treated at the same level. If no further cases of DLT are seen in the additional patients, then the dose level is escalated for the next cohort. Otherwise, dose escalation stops. If the incidence of DLT is greater than 33% at a given level, then dose escalation also stops. The phase II recommended dose often is taken as the highest dose for which the incidence of DLT is less than 33%. Usually, six or more patients are treated at the recommended

dose.

The dose levels themselves commonly are based on a modified Fibonacci series.<sup>6</sup> The second level is twice the starting dose; the third level is 67% greater than the second; the fourth level is 50% greater than the third; the fifth is 40% greater than the fourth; and each subsequent step is 33% greater than that preceding it. Escalating doses for subsequent courses in the same patient is generally not done, except at low doses before any DLT has been encountered.

There is no compelling scientific basis for the approach just outlined, except that experience has shown it to be safe. Traditional phase I trials have three limitations: (1) They sometimes expose too many patients to subtherapeutic doses of the new drug; (2) the trials may take a long time to complete; and (3) they provide very limited information about interpatient variability and cumulative toxicity. New trial designs have been developed to address these problems. One class of designs, *accelerated titration designs*, permit within-patient dose escalation and use only one patient per dose level until grade 2 or greater toxicity is seen.<sup>7</sup> Doses are titrated within patients to achieve grade 2 toxicity. The analysis consists of fitting a statistical model to the full set of data that includes all grades of toxicity for all courses of a patient's treatment. The model includes parameters that represent the steepness of the dose-toxicity curve, the degree of interpatient variability in the location of the dose-toxicity curve, and the degree (if any) of cumulative toxicity. All these parameters are estimated from the data.

In developing the accelerated titration designs, Simon et al.<sup>7</sup> fit a stochastic model to data from 20 phase I trials of nine different drugs. New data then were simulated using the model with the parameters estimated from the actual trials, and the performance of alternative phase I designs on this simulated data was evaluated. Four designs were evaluated. Design 1 was a conventional design using cohorts of three to six patients with 40% dose-step increments and no inpatient dose escalation. Designs 2 through 4 included only one patient per cohort until one patient experienced dose-limiting toxicity or two patients experienced grade 2 toxicity (during their first course of treatment for designs 2 and 3 or during any course of treatment for design 4). Designs 3 and 4 use 100% dose steps during this initial accelerated phase. After the initial accelerated phase, designs 2 through 4 resort to standard cohorts of three to six patients with 40% dose-step increments. Designs 2 through 4 use inpatient dose escalation if the worst toxicity is grade 0 to 1 in the previous course for that patient.

Only three of the actual trials showed any evidence of cumulative toxicity. The average number of patients required was reduced from 39.9 for design 1 to 24.4, 20.7, and 21.2 for designs 2, 3, and 4, respectively. The average number of patients who had grade 0 to 1 toxicity as their worst toxicity grade over three cycles of treatment was 23.3 for design 1 but only 7.9, 3.9, and 4.8 for designs 2, 3, and 4, respectively. The average number of patients with a worst toxicity grade of 3 increased from 5.5 for design 1 to 6.2, 6.8, and 6.2 for designs 2, 3, and 4, respectively. The average number of patients with a worst toxicity grade of 4 increased from 1.9 for design 1 to 3.0, 4.3, and 3.2 for designs 2, 3, and 4, respectively. Accelerated titration designs appear to be effective in reducing the number of patients who are undertreated, speeding the completion of phase I trials, and providing increased information. These advantages are achieved with some increase in the number of patients experiencing grade 3 and 4 toxicities.

Some phase I trials are very complex in that they involve the simultaneous escalation of two or more drugs. The design of such trials has been discussed by Korn and Simon.<sup>8</sup>

So-called phase IB trials attempt to determine the relationship between dose of a biologic agent and both toxicity and immunologic effect. Such trials often suffer from two flaws. One is that it is assumed that cohorts of three to six patients are sufficient for relating dose to immunologic effects, without consideration of interpatient variability and measurement error of the immunologic assays. The second problem is that there is often little information about what immunologic end points actually are relevant for antitumor effects. Such studies have little potential for producing meaningful information about the dose of a biologic that should be used for subsequent trials.

Some phase I trials attempt to answer comparative questions. For example, should paclitaxel be administered before or after doxorubicin in a two-drug combination? Because of the small sample sizes of phase I trials, the maximum tolerated doses (MTDs) generally are determined imprecisely. This, combined with the nonrandomized nature of such trials, means that reliable comparative conclusions can be expected only if the differences are large.

## PHASE II CLINICAL TRIALS

### PATIENT SELECTION

Whereas phase I trials need not be performed separately by tumor type, this is not the case for phase II trials, because the biologic response of interest is that of the tumor itself. When a drug enters phase II trials, it should be tested in the patient group that is most likely to show a favorable effect but for whom no effective therapy is available. This is best accomplished by patients with maximum performance status and a minimum amount of prior chemotherapy. Full-dose chemotherapy is often impossible in patients debilitated by prior treatment, and lack of chemotherapeutic activity in previously treated patients may not indicate lack of clinical usefulness in earlier disease. This issue was well illustrated by etoposide in small cell lung carcinoma.<sup>9,10</sup> For the less chemosensitive cancers, chemotherapy offers little or no palliative benefit, and initial phase II trials should be conducted in patients with no prior chemotherapy. In more sensitive tumors, such as breast, small cell lung, or ovarian carcinoma or non-Hodgkin's lymphoma, it is desirable to evaluate new drugs in patients with no more than one prior treatment for advanced disease. For very chemosensitive tumors, the window-of-opportunity design sometimes is used, in which patients not previously treated are given one or two courses of a phase II drug and then are switched to a standard combination. In general, agents should be shown to be active in a favorable population of patients before they are given to a less favorable group. Adherence to this principle saves patients with advanced disease from exposure to inactive agents for which the likelihood of toxicity is much greater than the likelihood of benefit.

### TRIALS OF SINGLE AGENTS

There is much confusion about the appropriate objectives of phase II trials. It often is useful to distinguish between phase II trials of single agents and phase II trials of combinations. Both are called *phase II trials* because eligibility is limited to patients with a specific diagnosis and there is no internal control group. For most single-agent phase II trials, however, the objective is simply to determine whether the drug has activity against the tumor type in question. For this objective, response rate is an appropriate end point for evaluating the question posed by the trial. It is important to recognize, however, that tumor response is not a direct measure of patient benefit and, hence, it cannot be assumed that response rate is an appropriate end point for drawing conclusions about treatment efficacy. A treatment that causes partial responses is not necessarily beneficial to the patient, and analyses that demonstrate that responders live longer than nonresponders are invalid for concluding that a treatment extended survival.<sup>11,12</sup> First, responders, by definition, have lived long enough to achieve that status. Second, responders may have more favorable prognostic factors. Finally, treatment may shorten survival of nonresponders while not influencing survival of responders. To demonstrate that treatment extends survival, it must be demonstrated that the treated group as a whole lives longer than an appropriate control group. Phase II trials do not have an internal control group and, hence, drawing conclusions about survival from such trials is very problematic.

A variety of statistical accrual plans and sample size methods that have been developed for phase II trials have been reviewed by Simon.<sup>13</sup> One of the most popular approaches is the optimal two-stage design.<sup>14</sup> A number ( $n_1$ ) of evaluable patients is entered into study in the first stage of the trial. If fewer than a specified  $r_1$  responses are obtained among these  $n_1$  patients, then accrual terminates and the drug is rejected as being of little interest. Otherwise, accrual continues to a total of  $n$  evaluable patients. At the end of the second stage, the drug is rejected if the observed response rate is less than or equal to  $r/n$ , where  $r$  and  $n$  are determined by the design employed.

Tables 21.1-2 and 21.1-3 illustrate some of these optimized designs. To select a design, researchers must specify a target activity level of interest,  $p_1$ , and also a lower activity level,  $p_0$ . The first row of each triplet of optimal designs provides designs with probability  $\alpha$  of accepting drugs worse than  $p_0$  and probability  $\beta$  of rejecting drugs better than  $p_1$ . Subject to these two constraints, the optimal designs minimize the average sample size. The average sample size is calculated at the lower activity level  $p_0$  in order to optimize protection of patients from exposure to inactive drugs. The tables show for each design the optimal values of  $r_1$ ,  $n_1$ ,  $r$ , and  $n$ , the average sample size, and the probability of stopping after the first stage for a drug with activity level  $p_0$ .

TABLE 21.1-3. Simon Two-Stage Phase II Designs for p<sub>1</sub> - p<sub>0</sub> = .15<sup>a</sup>

These tables also show the “minimax” designs, which provide the smallest maximum sample size *n* that satisfies the two constraints just described. Although minimax designs have somewhat larger average sample sizes than do optimal designs, in some instances they are preferable because the small increase in average sample size is more than compensated for by a large reduction in maximum sample size.

The designs shown in Tables 21.1-2 and 21.1-3 are two-stage designs with the potential for early stopping for lack of activity. Other two-stage designs have been described that provide for early termination for inactivity or for early evidence for activity.<sup>15</sup> Also, optimized three-stage designs have been described.<sup>16</sup>

When sufficient numbers of patients and several treatments are available to test, there are advantages to randomized phase II trials.<sup>17</sup> Although phase II trials are not comparative, in selecting the most promising treatment or schedule to pursue, it is advantageous to evaluate the candidates on comparable patients. Table 21.1-4 shows the number of patients per treatment arm required to ensure that the best treatment will have the highest observed response rate. This calculation assumes that the true response probability for the best treatment is 10 percentage points better than for the others. Simon et al.<sup>17</sup> provide similar tables for 15% differences. This selection approach is useful when one treatment will be carried forward and the treatments are similar with regard to cost and toxicity.

TABLE 21.1-4. Number of Patients per Treatment Group for Selecting Better Treatment When True Response Probabilities Differ by 10 Percentage Points<sup>a</sup>

TRIALS OF COMBINATION REGIMENS

Many so-called phase II trials of combination regimens are conducted. The objectives of such trials are often unclear. One reasonable objective is sometimes merely to ensure that the combination is feasible and tolerable when used in a multiinstitution setting before embarking on a phase III trial. Achieving this objective does not require many patients. An alternative objective is to determine whether the new regimen is promising enough to warrant a phase III trial. Achieving this objective requires considerable planning. Consequently, many phase II trials of this type are not adequately planned and analyzed to serve any real scientific objective.

Investigators often do not distinguish between phase II trials of combinations of active agents and phase II trials of new single agents. Consequently, protocols often are written to distinguish between inactivity of the combination (e.g., p<sub>0</sub> = .05 or .10) and some modest level of activity (e.g., p<sub>1</sub> = .20 or .25). Since the drugs being combined are generally already known to be active, this makes little sense. If response rate is the primary end point, then the level of no interest (p<sub>0</sub>) should generally represent the level of activity of the most active single-agent component or the level of activity of previously studied combination regimens (as presumably the new regimen would be considered promising only if it is promising relative to other existing regimens).

With the lower limit of activity, p<sub>0</sub>, defined as described earlier, Tables 21.1-2 and 21.2-3 can be used for the design of phase II trials of combination regimens. One problem with this approach, however, is the uncertainty in specifying a meaningful value of p<sub>0</sub> to be used for trial design and analysis. Because the conclusions of phase II trials of combinations are essentially comparative, it is important that the comparison be based on a prognostically similar group of patients given standard treatment. Hence, the planning of such a trial should include the prospective identification of such a group of patients. Although such historical control comparisons are not considered reliable enough to eliminate the need for phase III trials, if done carefully they will provide better decisions about which new regimens are worthy of phase III evaluation. For comparative trials of response rates using historical controls, appropriate tables for sample size planning are given by Makuch and Simon<sup>18</sup> and are summarized in Table 21.1-5. This table is for achieving 80% power with a one-sided 5% significance level. If the historical control group of 50 patients showed a response rate of 30%, and the target level of improvement is a 50% response rate, then 69 patients should be treated with the experimental regimen. If there were 100 appropriate historical control patients, then only 48 new patients are required. If there were only 30 historical control patients, then 137 new patients are needed for the experimental treatment. If the uncertainty in the level of response achievable with standard treatment is substantial because of the limited number of appropriate historical controls, then it is not efficient to conduct a phase II trial of the new regimen. It would be more efficient to conduct a randomized phase II or phase III trial of the new regimen and the standard treatment.

Difference in Success Rates	No. of Patients Needed (Approximate)

**TABLE 21.1-5.** Number of Patients Needed in an Experimental Group for 80% Power to Detect (One-Sided  $\alpha = 0.05$ ) a Specified Difference in Success Rates

Thall et al.<sup>19,20</sup> have developed Bayesian methods for planning and conducting trials in which the precision in the response probability  $p_0$  is quantified by a “prior probability distribution.” These Bayesian designs provide for continual analysis of results after evaluation of response for each patient. This is difficult logistically for multiinstitution trials but provides a valid statistical basis for the intensive monitoring of cancer center or pharmaceutical industry trials in which patients may be limited or time may be critical. One begins with a prior probability distribution of response for  $p_1$  that is flat over the range 0 to 1. After each patient is evaluated on the experimental regimen, the “posterior probability distribution” for  $p_1$  is updated. This permits calculation of the posterior probability distribution for  $p_1 - p_0$ .

Let  $d$  denote the difference in response probabilities that is of interest. If, at some point during the trial, the posterior probability that  $p_1 - p_0 \geq d$  becomes small—say less than 0.05—one might terminate the trial and conclude that the new regimen is not promising. If, at some point during the trial, the posterior probability that  $p_1 - p_0 \leq -d$  becomes large—say greater than 0.95—one might terminate the trial and conclude that the new regimen appears better than the historical control. In this case, one could continue entry of patients if it were desirable to study the regimen further in a phase II setting.

The trial is designed with a maximum number of patients,  $n_{max}$ , that limits sample size even if neither early termination condition occurs. [Table 21.1-6](#) shows an example of the operating characteristics of a design of this type. In this example, the historical data indicate that the expected response probability for the control regimen is .20 and that the width of the 90% confidence interval around .20 for the true value is approximately 0.20. The table also represents targeting a 20–percentage point improvement in response probability ( $d = 0.20$ ). The maximum sample size is set at 65, and it is assumed that the trial is arbitrarily not terminated before ten patients are evaluated. As can be seen from the table, the median number of patients required is 12 under the null hypothesis that the response probability for the experimental regimen is .20 and is only 13 under the alternative hypothesis. The table also indicates that 75% of the time the trial will terminate by the evaluation of 20 to 22 patients. Bayesian continuing-monitoring phase II designs have also been developed for simultaneously monitoring multiple end points, including efficacy and toxicity. Designs of this type used in actual clinical trials have been illustrated in the work of Thall et al.<sup>19</sup>

$p_1$	Sample Size Percentiles			Probability Reject Regimen	Probability Accept Regimen
	25%	50%	75%		
.20	10	12	20	.92	.07
.40	10	13	22	.15	.83

**TABLE 21.1-6.** Thall-Simon Bayesian Phase II Design

Some investigators and statisticians do not like to use approaches based on explicit comparison to historical controls. Phase II trials of combinations are inherently comparative, however. Going through the exercise of explicitly quantifying the basis of comparison, which these methods require, clarifies beforehand whether the uncertainty in outcome for the control group is so great that a phase II trial is not useful. Phase II trials of combinations are problematic. Only by using methods that provide more careful statistical planning of such trials can we streamline the drug development process.

Many reports in the literature of phase II trials of combination regimens conclude that the treatment is effective. As noted, response rates generally are not a measure of patient benefit. Such reports generally fail to make any meaningful attempt at determining outcome on standard treatment for a prognostically comparable set of patients. Often these trials are not conducted as a prelude to a phase III evaluation, and hence their value to clinical therapeutics is difficult to identify.

For some diseases, it has been noted that combination regimens that produce high response rates in phase II trials do not result in improved survival in phase III trials as compared to standard treatment. This has led to interest in using survival directly as an end point for phase II trials to evaluate the promise of a regimen. In some types of cancer, response rate is difficult to measure, and many patients do not have measurable disease (e.g., brain, ovarian, gastric, and prostate cancer). Dixon and Simon<sup>21</sup> have developed tables for planning historically controlled phase II comparative studies with a survival or time-to-progression end point.

## DESIGN OF PHASE III CLINICAL TRIALS

Good clinical therapeutic research requires asking important questions and getting reliable answers. This chapter attempts to provide guidance on the components necessary for getting reliable answers. As noted earlier in [Trials of Combination Regimens](#), many phase II trials of combination regimens do not provide reliable answers. Some phase III trials, however, do not ask important questions. The most important clinical trials are often the most difficult to conduct.<sup>22</sup> They may involve withholding a treatment established by tradition, potentially transferring patient management responsibility across specialties, standardizing procedures among physicians who believe that their way is best, and sharing recognition with a large group of collaborators.

Phase III trials attempt to provide guidance to practicing physicians to help them make treatment decisions with their patients. Consequently, the trials should provide reliable information concerning end points of relevance to the patients. The major end points for evaluating the effectiveness of a treatment should be direct measures of patient welfare. Survival and symptom control are two such end points. The latter is not routinely used because of the difficulty of measuring it reliably and because it may be influenced by concomitant treatments. As stated, tumor shrinkage usually is not an appropriate end point for phase III trials because it may have little or no relation to patient benefit. Torri et al.<sup>23</sup> performed a metaanalysis of the relationship between difference in response rates and difference in median survivals for randomized clinical trials of advanced ovarian carcinoma. They found that large improvements in response rates corresponded to very small improvements in median survival. Hence, use of response rate as an end point results in giving patients increasingly intensive and toxic therapy with little or no net benefit to them.

It is usually important that the results of phase III trials be applicable to patients seen in the community outside of clinical research settings. This is accomplished by conducting the trials in multiinstitution settings that include community physician participation. The eligibility criteria established for the trial also has a bearing on the generalizability of the conclusions; trials conducted with narrow eligibility criteria tend to be less generalizable. Narrow eligibility criteria also complicate trials logistically. Narrow eligibility criteria tend to require extensive and expensive patient workups and thereby do not facilitate broad participation, especially in an era of closely monitored medical costs. For these and other reasons, there is a trend toward broadened eligibility criteria for phase III clinical trials. In the United Kingdom, many trials are designed using the *uncertainty principle*, an approach that leaves much of the decision making about eligibility to the treating physician. There may be guidelines for eligibility, but the ultimate decision will be made by the treating physician; if he or she is uncertain about which treatment is more appropriate for the

patient, then the patient is eligible.

## RANDOMIZATION

To determine whether a new treatment cures any patients with a disease that is uniformly and rapidly fatal, history is a satisfactory control. Once we leave this setting of complete determinism, however, the definition of an adequate nonrandomized control group becomes problematic. In studies using nonrandomized controls, often diagnostic and staging procedures, supportive care, secondary treatments, and methods of evaluation and follow-up are different for the controls and for the new patients. There is generally differential bias in the selection of patients to be treated resulting from judgments by the physicians, self-selection by the patients, and differences in referral patterns. There may be bias in treatment ineligibility rates. Current patients sometimes are excluded from analysis for not meeting eligibility criteria, not receiving "adequate" treatment, refusing treatment, or committing a major protocol violation. The control group, on the other hand, generally contains all the patients. There may be differences in the distribution of known and unknown prognostic factors between the controls and the current treatment group. Often there is inadequate information to determine whether such differences are present, and current known prognostic factors may not have been measured for the controls. It generally is difficult or impossible to determine whether the controls would have been eligible for the current study and in what way they represent a selection of all eligible patients.

Formation of the control group by random treatment assignment as an integral part of the planned study can avoid most of the systematic biases just mentioned.<sup>24,25,26,27,28</sup> and <sup>29</sup> Randomization does not ensure that the study will include a representative sample of all patients with the disease, but it does help to ensure an unbiased evaluation of the relative merits of the two treatments for the types of patients entered.

It is sometimes said that randomization is unnecessary because matched historical or concurrent controls can be selected. However, matching can be done only with regard to known prognostic factors, and these generally are not sufficient for the construction of prognostically homogeneous groups of patients.<sup>30</sup> Matching with regard to known factors gives no assurance that the distributions of unknown factors are similar between the groups. It also is sometimes said that randomization is not effective in ensuring that the treatment groups are similar with regard to unknown prognostic factors unless the number of patients is large. This is true but reflects a misunderstanding of the purpose of randomization. Randomization does not ensure that the groups are medically equivalent, but it distributes the unknown biasing factors according to a known random distribution so that their effects can be rigorously allowed for in significance tests and confidence intervals. This is true regardless of the study size. A significance level represents the probability that differences in outcome can be the result of random fluctuations. Without a randomized treatment allocation, a "statistically significant difference" may be the result of a nonrandom difference in the distribution of unknown prognostic factors.

Many investigators today see a useful role for both nonrandomized and randomized clinical trials. The nonrandomized format is used for determining which regimens are sufficiently promising for randomized phase III evaluation and for use in clinical settings where outcome is uniformly poor. For major questions of public health importance, unless the treatment effects are huge, the need for reliable answers dictates the use of randomized phase III trials.

Randomization of a patient should be performed after the patient has been found eligible and has consented to participate in the trial and to accept either of the randomized options. A truly random and nondiscernible randomization procedure should be used and implemented by calling a central randomization office staffed by individuals who are independent of participating physicians.

## STRATIFICATION

When important prognostic factors are known for patients in a randomized trial, it is often advisable to stratify the randomization to ensure equal distribution of these factors. This is usually accomplished by preparing a separate randomization list (or set of cards in sealed envelopes) for each stratum of patients. Each list must be balanced so that after each block of four to ten patients within the stratum, the treatment groups contain equal numbers of patients. Within the blocks, the sequence of treatment assignments is random. The stratification factors must be known for each patient at the time of randomization.

It generally is best to limit stratification to those factors definitely known to have important independent effects on outcome. If two factors are closely correlated, only one need be included. Peto<sup>31,32</sup> believes that stratification is an unnecessary complication because adjustment for imbalances of known factors can be made in the analysis. This is true for large trials. Stratification helps to ensure balance for interim analyses when the sample sizes may be limited and provides the medical audience with confidence in the results, which often is not available when depending on complex adjustment methods to deal with prognostic imbalances. Stratification also is a convenient way of specifying *a priori* what are considered the important prognostic factors. Subsequent "subset analyses" can then be limited to the patient subsets determined by the stratification factors.

Many clinical trials use adaptive stratification methods. These methods permit effective balancing by many prognostic factors, although they typically require a computer program for their use. Simon<sup>33</sup> and Kalish and Begg<sup>34</sup> have reviewed the various stratification methods that are available. Kalish and Begg<sup>35</sup> have also studied analytic aspects of adaptive stratification methods.

## SAMPLE SIZE

The protocol for a phase III trial should specify the number of patients to be accrued and the duration of follow-up after the close of accrual when the final analysis will be performed. Methods of sample size planning are based on the assumption that at the conclusion of the follow-up period, a statistical significance test will be performed comparing the experimental treatment to the control treatment with regard to a single primary end point. A statistical significance level of .05 has the following meaning: If there is no true difference in treatment effectiveness, the probability of obtaining a difference in outcomes as extreme as that observed in the data is .05. The significance level does not represent the probability that the null hypothesis is true; it represents a probability of an observed difference, assuming that the null hypothesis is true. Conventional statistical theory ascribes no probabilities to hypotheses, only to data.

A one-sided significance level represents the probability, by chance alone, of obtaining a difference as large as and in the same direction as that actually observed. A two-sided significance level represents the probability of obtaining by chance a difference in either direction as large in absolute magnitude as that actually observed. The two-sided significance level is usually twice the one-sided significance level. Controversy exists over the appropriateness of one-sided or two-sided significance levels. Although this is a somewhat trivial issue, a two-sided significance level of .05 has become widely accepted as a standard level of evidence.

With few patients in the trial, the difference in observed outcomes must be extreme in order to obtain statistical significance. Consequently, the probability of obtaining a statistically significant result may be low even when a substantial true difference in effectiveness exists. The probability of obtaining a statistically significant result when the treatments differ in effectiveness is called the *power* of the trial. As the sample size and extent of follow-up increases, the power increases. The power depends critically, however, on the size of the true difference in effectiveness of the two treatments. Generally, one sizes the trial so that the power is either .80 or .90 when the true difference in effectiveness is the smallest size that is considered medically important to detect.

A number of statisticians have developed useful methods for planning sample size to compare survival curves or disease-free survival curves in phase III trials. [Table 21.1-7](#) demonstrates results that are valid whenever the *hazard ratio*, the ratio of forces of mortality for the two treatment groups, is constant over time.<sup>36,37</sup> The table shows the total number of deaths that must occur in a given cohort to reflect 90% power for detecting a specified reduction in the hazard for the experimental treatment relative to the control treatment. For exponential distributions, the percentage reduction in hazard of death can be expressed as a ratio of median survivals, which is displayed in the second column of [Table 21.1-7](#). For comparing disease-free survival curves, *deaths* should be replaced by *events*, wherein death, disease recurrence, or development of second cancer usually are considered events. The translation of the number of deaths or events required among the number of patients depends on the actual shape of the survival distributions, the rate of accrual, and the duration of follow-up after close of accrual. Generally, however, it is best to specify the time of the final analysis as the time when the specified number of deaths or events are obtained, not in terms of absolute calendar time.

Percentage Reduction in Hazard of Death	Ratio of Median Survival for Exponential Distributions	No. of Total Deaths to Observe*
20	1.25	846
30	1.43	550
33	1.50	527
40	1.67	462
50	2.0	388

\*Total number of deaths in both groups to have power .90 for detecting ratio of median survival. Type I error  $\alpha = .05$  (two-sided).

TABLE 21.1-7. Number of Events Needed for Comparing Survival Curves

In some cases, it may be convenient to think in terms of specifying the smallest medically important improvement—for instance, an increase in the proportion of patients who survive beyond some landmark time, such as 5 years. Tables 21.1-8 and 21.1-9 provide required numbers of patients for clinical trials planned on this basis. This approach is less flexible for studies in which survival or disease-free survival is the end point, as it presumes that all patients will be followed for the landmark time as a minimum. These tables can, however, be used generally for detecting differences in a binary end point, denoted *success rate* in the tables. Table 21.1-8 is for one-sided significance tests, and Table 21.1-9 is for two-sided tests. For comparing treatments, differences of more than 15 percentage points usually are unrealistic.

TABLE 21.1-9. Number of Patients in Each of Two Treatment Groups (Two-Sided Test)

Sample size planning with good statistical power for detecting realistically expected treatment improvements is important. Numerous published “negative” results are actually uninterpretable because the sample sizes are too small.<sup>38</sup> For trials comparing a standard treatment to a more conservative or less invasive therapy, small reductions in effectiveness will be medically important because survival time or cure probability is being traded for convenience or cosmesis. High statistical power for detecting small differences requires large trials. False acceptance of the null hypothesis of equivalence may result in erroneous adoption of a new, more conservative, and less effective therapy. The burden of proof for therapeutic equivalence trials should generally be on showing that results are similar, not on demonstrating that they are different. These trials should be planned using the specialized methods described later in the section [Therapeutic Equivalence Trials](#). If standard frequency methods are used to analyze such trials, rather than the Bayesian methods described in the section [Therapeutic Equivalence Trials](#), confidence intervals rather than statistical significance tests should be used. The confidence interval for the true difference of effectiveness gives a much clearer picture of which differences are consistent with the data. Makuch and Simon<sup>39</sup> and Durrleman and Simon<sup>40</sup> discuss this approach for planning and monitoring therapeutic equivalence trials.

## FACTORIAL DESIGNS

In a two-by-two factorial design, there are actually four treatment groups. The first factor represents two alternative interventions, such as amputation and resection. The second factor represents two other alternatives superimposed on the first factor, such as adjuvant chemotherapy and no chemotherapy. In another example, the first factor might be chemotherapy regimen A or B, and the second factor might be the duration of treatment, 6 or 12 months. Although there are actually four treatment groups, the average effect of each treatment factor can be evaluated using all of the patients and pooling with regard to the other factor (or by accounting for the influence of the other factor in the analysis by stratification, but not by separate analyses for each level of the other factor).<sup>41,42</sup> The usefulness of this analysis of average effects is proportional to whether the comparison between the two levels of one factor depends in any important way on the level of the other factor. If the effects of the two factors do interact, then the analysis of main effects may not be meaningful. Usually, the sample size for a two-by-two factorial trial is computed assuming that there is no interaction between the effects of the factors. This sample size will not provide enough patients to test adequately the assumption of no interaction between the factors. Consequently, the factorial design offers the possibility of answering two questions for the cost of one, but there is a risk of ambiguity in the interpretation of results.<sup>43,44</sup> and <sup>45</sup> For situations in which interactions are unlikely or in which it is unlikely that both factors will have substantial effects, the factorial design can provide a substantial improvement in the efficiency of clinical trials.

The use of a factorial design for a clinical trial is often controversial. Proponents sometimes indicate that factorial designs are ideal for studying interactions. Others have questioned how factorial trials can provide meaningful information about interactions when the trials are sized only to detect main effects. Brittain and Wittes<sup>45</sup> noted that the power for detecting an effect of treatment A is substantially impaired by a negative interaction with treatment B, as compared to an experiment wherein all the patients are randomly allocated to either treatment A or placebo, with no use of treatment B. Consequently, factorial designs often are used only when one can assume with confidence that there will be no interactions between the effects of the factors and can determine sample size on the basis of that assumption.

Simon and Freedman<sup>46</sup> developed a Bayesian method for the design and analysis of factorial clinical trials. Their approach avoids the need to dichotomize one's assumptions that interactions either do or do not exist and provides a flexible approach to the design and analysis of such clinical trials. The Bayesian method encourages the quantification of prior belief about the size of interactions that may exist. Rather than forcing the investigator to adopt one of two extreme positions regarding interactions, it provides for the specification of intermediate positions. The Bayesian approach also avoids a preliminary test of interaction having poor

power.

The Bayesian model suggests that in planning a factorial trial where interactions are unlikely but cannot be excluded, the sample size should be increased by at least 30% as compared to a simple two-arm clinical trial for detecting the same size of treatment effect. This is less extreme than doubling the sample size but is a recommendation that differs greatly from current usage. The 30% figure allows for a 5% prior probability of a medically important, qualitative interaction between the treatment effects.

Factorial designs can also be useful in phase II trials when an internal control is needed. For example, consider the investigation of antiangiogenic agents A and B for patients in partial remission after induction chemotherapy. With a factorial design, there would be four treatment groups. One group would receive neither agent, one would receive A, one group would receive B, and one group would receive both A and B. Patients are randomized to the four groups. For analyzing the effect of A, the time to progressive disease for the two arms that received A are compared to the time to progressive distribution for the two arms that did not receive A. Analyzing the effect of B is performed analogously. The single-arm phase II trial is problematic when the end point is disease stabilization or time to progression. It is easy to come up with a definition of disease stabilization, but just defining it does not make it valid for measurement of treatment effect. Data are needed that demonstrate that such stabilization does not occur in the absence of treatment in a comparable group of patients. This is difficult to do reliably because of the usual difficulties of identifying comparable historical controls and because of special difficulties involved with documenting stabilization or measuring time to disease progression in a consistent manner, comparable to the way it was done with historical controls. Consequently, the use of disease stabilization or time to progression as an end point in single-arm phase II trials is particularly problematic. A better approach is use of the factorial design, because the factorial design is internally controlled for evaluating the effects of the factors and, hence, the use of time to progression is not problematic.

## THERAPEUTIC EQUIVALENCE TRIALS

The objective of a therapeutic equivalence trial is generally to demonstrate that a new treatment is equivalent to a standard therapy with regard to a specified clinical end point. This is contrasted to bioequivalence trials in which the objective is to demonstrate equivalence of serum concentrations of the active moiety. In some cases, investigators would like to demonstrate that the new treatment is effective as compared to no treatment but, because use of a no-treatment arm is not feasible, they attempt to demonstrate therapeutic equivalence to a standard treatment.

Therapeutic equivalence trials are problematic because it is impossible to demonstrate equivalence. If the outcomes for the two treatments are similar, one can only conclude that results are consistent with differences within specified limits.

In conventional trials, rejection of the null hypothesis leads to change in the treatment of future patients. The implications of failure to reject the null hypothesis are more difficult to interpret. Failure to reject the null hypothesis often is interpreted as a demonstration of therapeutic equivalence and grounds for adoption of the new regimen but may merely reflect inadequate sample size or ineffectiveness of the standard treatment for the patients in the clinical trial.

Large sample sizes often are needed for meaningful therapeutic equivalence trials. For example, consider a cancer trial evaluating tumor resection as an alternative to amputation of the organ containing the tumor in a setting in which amputation is the standard therapy known to be curative in a large number of cases. Tumor resection may have clear advantages with regard to quality of life, but few patients would be interested in these advantages unless they were assured that any reduction in the chance of cure would be very small. Hence, the appropriate trial should focus on distinguishing the null hypothesis in which the difference in efficacy is expressed as  $D = 0$  from that in which the difference in efficacy is expressed as  $D = d$ , where  $d$  is very small. Consequently, this trial would have to be very large.

In a therapeutic equivalence trial, there is no internal validation of the assumption that the control treatment  $C$  is actually effective for the patient population at hand. It is not enough for the experimental treatment  $E$  to be therapeutically equivalent to  $C$ ; we want equivalence coupled with the effectiveness of  $E$  and  $C$  relative to no treatment or to whatever was standard before the adoption of  $C$ .

None of the conventional approaches to the design and analysis of therapeutic equivalence trials is satisfactory. These approaches depend on the specification of a minimal difference ( $d$ ) in efficacy that one is willing to tolerate but do not address how  $d$  should be determined. Simon<sup>47</sup> has recently developed a general Bayesian approach to the utilization of information from previous trials in the design and analysis of therapeutic equivalence trials. The effectiveness of the control treatment  $C$  relative to no treatment or to the previous standard before  $C$  was adopted is represented by a parameter  $b$ . We will denote the previous standard by  $P$ . The effectiveness of  $C$  relative to  $P$  will not be known with certainty and may vary among trials. The information about  $b$  is summarized by a prior distribution, which is normal with mean  $\mu_b$  and standard deviation  $s_b$ . The parameter  $g$  represents the effectiveness of the new experimental treatment  $E$  relative to  $P$ . Usually, it is assumed that there is no prior information about  $g$ .

The result of the therapeutic equivalence trial is summarized by a value  $y$ , which estimates the effectiveness of  $E$  relative to  $C$ .

Two major objectives of active controlled trials can be distinguished. The first is to determine whether the experimental treatment is effective relative to  $P$ . This requires explicit use of prior information about outcomes of trials comparing  $P$  to the active control. Meaningful interpretation of active control trials is impossible without consideration of such information. Establishing whether or not the experimental treatment is effective relative to  $P$  is a first requirement. The second objective is to determine whether any medically important portion of the treatment effect for the active control is lost with the experimental treatment. In some cases, this objective is unrealistic because the size of the treatment effect (relative to  $P$ ) for the active control is imprecisely determined.

If there is no prior information about the effectiveness of  $E$  relative to  $P$  ( $g$ ), then after the equivalence trial is completed  $g$  has a posterior normal distribution with mean  $m_b + y$ . This is the expected effectiveness of  $C$  relative to  $P$  plus the estimate of the effectiveness of  $E$  relative to  $C$  based on the therapeutic equivalence trial. The variance of the posterior distribution of  $g$  is  $s_b^2 + s^2$ , where  $s_b^2$  is the variance of the prior distribution of  $b$  and  $s$  is the standard error of  $y$ . The size of the trial may be planned in this case using the result

$$\frac{1.645\sqrt{1+r}+z}{\sqrt{r}} = -0.84$$

where  $z$  is  $m_b/s_b$ , which is the  $z$  value for comparison of the active control  $C$  to  $P$  in the previous trial (or metaanalysis of previous trials), with a positive value of  $z$  corresponding to superiority of  $C$ . The parameter  $r$  represents the ratio of the required sample size of the therapeutic equivalence trial to the effective sample size of the previous trials demonstrating the superiority of  $C$  to  $P$ . When the  $z$  value is 3 (corresponding to a two-sided significance level of .0027 for the effectiveness of  $C$  relative to  $P$ ), the ratio  $r$  equals 1.25, indicating that the therapeutic equivalence trial needs to be 25% larger than the previous trial. If, however, the  $z$  value is only 2 (corresponding to a two-sided significance level of approximately .05), then the ratio  $r$  equals 10, indicating that the therapeutic equivalence trial needs to be ten times as large as the previous trial that established the effectiveness of  $C$ . Consequently, unless the evidence for the effectiveness of  $C$  is highly statistically significant, the therapeutic equivalence trial is not feasible or appropriate.

An important implication of the new approach is that reliable therapeutic equivalence trials are not practical unless evidence of the effectiveness of the control treatment is substantial and consistent. Conventional methods for planning therapeutic equivalence trials often miss this point, because they take the maximum likelihood estimate of the effectiveness of the control treatment as if it were a value known with certainty. This ignores the fact that the degree of effectiveness of the control treatment is known only imprecisely unless the effect is overwhelmingly significant. For example, if the effect is of borderline significance, then the confidence interval for the size of the effect almost includes zero. Consequently, many planned therapeutic equivalence trials, even large multicenter trials, cannot demonstrate clinically relevant objectives. Superiority trials, rather than therapeutic equivalence trials with marginally effective control treatments, are strongly preferred whenever possible.

## ANALYSIS OF PHASE III CLINICAL TRIALS

### INTENTION-TO-TREAT ANALYSIS

One of the important principles in the analysis of phase III trials is called the *intention-to-treat* principle. This indicates that all randomized patients should be included in the primary analysis of the trial. For cancer trials, this has often been interpreted to mean all "eligible" randomized patients. Because eligibility requirements sometimes are vague and unverifiable by an external auditor, excluding "ineligible" patients can itself result in bias. However, excluding patients from analysis

because of treatment deviations, early death, or patient withdrawal can severely distort the results.<sup>32,48,49</sup> Often, excluded patients have poorer outcomes than do those who are not excluded. Investigators frequently rationalize that the poor outcome experienced by a patient was due to lack of compliance to treatment, but the direction of causality may be the reverse. For example, in the Coronary Drug Project, the 5-year mortality for poor adherents to the placebo regimen was 28.3%, significantly greater than the 15.1% experienced by good adherents to the placebo regimen.<sup>50</sup> In randomized trials, there may be poorer compliance in one treatment group than the other, or the reasons for poor compliance may differ. Excluding patients, or analyzing them separately (which is equivalent to excluding them), for reasons other than eligibility is generally considered unacceptable. The intention-to-treat analysis with all eligible randomized patients should be the primary analysis. If the conclusions of a study depend on exclusions, then these conclusions are suspect. The treatment plan should be viewed as a policy to be evaluated. The treatment intended cannot be delivered uniformly to all patients, but all eligible patients should generally be evaluable in phase III trials.

## INTERIM ANALYSES

If statistical significance tests are performed repeatedly, the probability that the difference in outcomes will be found to be statistically significant (at the .05 level) at some point may be considerably greater than 5%. This probability is called the *type I error* of the analysis plan. Fleming et al.<sup>51</sup> have shown that the type I error can be as great as 26% if a statistical significance test is performed every 3 months of a 3-year trial that compares two identical treatments. Many trials are published without stating the target sample size, without indicating whether a target sample size was stated in the protocol, and without describing whether the published analysis represented a planned final analysis or was one of multiple analyses performed during the course of the trial. In such cases, one must suspect that the investigators were not aware of good statistical practices and the dangers of informal multiple analyses. Consequently, the statistical significance reported in such trials must be discounted as uninterpretable.

Interim analyses can be very misleading, and the significance levels of interim analyses cannot be taken at face value. Nevertheless, the random trends often seen in interim analyses can destroy accrual to a clinical trial and interfere with a physician's attempt to state honestly to the patient that there is no reliable evidence indicating that one treatment option or the other is preferable. For these reasons, it has become standard in multicenter clinical trials to have a data-monitoring committee review interim results, rather than having the monitoring done by participating physicians. This approach helps to protect patients by having interim results carefully evaluated by an experienced group of individuals and helps to protect the study from damage that ensues from misinterpretation of interim results. Generally, interim outcome information is available to only the data-monitoring committee. The study leaders are not part of the data-monitoring committee, because they may have a perceived conflict of interest in continuing the trial. The data-monitoring committee determines when results are mature and should be released. These procedures are used only for phase III trials.

A number of useful statistical designs have been developed for monitoring interim results. The simplest is that of Haybittle.<sup>32,52</sup> Interim differences are discounted unless the difference is statistically significant at the two-sided  $P < .0025$  level. If the interim differences are not significant at that level, the trial continues until its originally intended size. The final analysis is performed without regard to the interim analyses, and the type I error is almost unaffected by the monitoring.

Others have developed group-sequential methods for interim monitoring based on a prespecified number of planned interim analyses.<sup>53,54</sup> and <sup>55</sup> The critical  $P$  value for determining whether an interim difference should be judged statistically significant depends on the number of analyses that will be performed during the trial. For a five-stage trial—four interim analyses and one final analysis—the critical  $P$  values are shown in [Table 21.1-10](#).

Analysis Number	Peto et al. <sup>52</sup> O'Brien and Fleming <sup>54</sup> Fleming et al. <sup>53</sup>

Final	.016	.049	.041	.0402

**TABLE 21.1-10.** Nominal Two-Sided Significance Levels for Interim Monitoring Methods That Maintain an Overall Type I Error Level of .05

Extreme treatment differences at an interim analysis are unusual in cancer clinical trials. It is more common to find that interim results do not support the hypothesis that the experimental treatment is substantially better than the control. The method of stochastic curtailment<sup>56</sup> was developed for evaluating such a circumstance. At any interim analysis, the probability of rejecting the null hypothesis at the end of the trial is computed. This probability is calculated as being conditional on the data already obtained and on the assumption that the alternative hypothesis of superiority of the experimental treatment used initially in planning the sample size for the trial is true. If this conditional power is less than approximately 0.20, then the trial may be terminated with acceptance of the null hypothesis. The 0.20 cutoff can be raised substantially to at least 0.40 if this type of interim analysis is performed only a few times during the course of the trial. With stochastic curtailment, interim analyses need not be equally spaced, and the number of interim analyses need not be specified in advance.

Several investigators have developed other designs for early termination of the clinical trial if results are not promising for the experimental treatment.<sup>57,58,59</sup> and <sup>60</sup> For example, [Table 21.1-11](#) shows some of the two-stage designs developed by Thall et al.<sup>59</sup> for clinical trials with dichotomous end points. The first two columns show the hypothesized success rates for the control and experimental treatments. The remaining columns show the first-stage sample size per treatment and the maximum sample size per treatment. In all instances, the clinical trial is terminated after the first stage, and the experimental treatment is rejected as superior, if the one-sided significance level for comparing success rates is no less than approximately .38. If the one-sided significance level is less than .38, then a second stage of patient accrual is conducted to give the maximum sample size per group shown. When the treatments are equivalent, the chance of early termination is generally 60% to 65% with this design.

Success Rate Control	Success Rate Experimental	Power .80		Power .90	
		Stage 1 Sample Size per Treatment	Maximum Sample Size per Treatment	Stage 1 Sample Size per Treatment	Maximum Sample Size per Treatment
0.2	0.35	48	116	75	137

0.5	0.70	35	78	49	106
0.6	0.75	50	128	81	175
0.6	0.80	29	96	42	72

**TABLE 21.1-11.** Two-Stage Early Termination Designs

Schaid et al.<sup>57</sup> and Wieand et al.<sup>61</sup> developed designs for early termination when results are not promising in survival studies. Schaid's design provides for multiple experimental treatment arms, as do the designs of Thall et al.<sup>62,63</sup> Such designs have been reviewed by Simon.<sup>43</sup> Jennison and Turnbull<sup>64</sup> have presented methods for calculating confidence intervals for treatment differences at interim analyses. Such confidence intervals can be useful in deciding when to terminate the trial.

Stochastic curtailment is based on computing the conditional probability of rejection of the null hypothesis calculated under the alternative hypothesis of the trial. <sup>56</sup> The probability is conditioned on the data available at that point but, because the probability is computed under the originally specified alternative hypothesis that the new regimen *E* is superior, stochastic curtailment is conservative. Bayesian biostatisticians have argued that the conditional probability should be computed under a distribution of the treatment difference that itself reflects the data available at that point. That distribution is called the *posterior distribution*. The Bayesian predictive probability is the probability of rejecting the null hypothesis if the trial is continued to its target number of events, conditional on the data available at that point and computed and averaged with regard to a range of hypotheses about the true difference *d* as determined by the posterior distribution of *d* given the data at that point. Computing the posterior distribution of *d*, however, requires specification of a prior distribution for *d* before the trial begins. The need to specify a prior distribution in a satisfactory manner has limited the applicability of Bayesian methods in clinical trials.

Phase III trials are supposed to be definitive and objective; if we could believe the subjective opinions of experts, we would not need to conduct phase III clinical trials. Recently, it has been recognized that a single prior distribution is not necessary for using Bayesian monitoring. It has been found useful to think in terms of one prior distribution of *d* for “enthusiasts” for the experimental regimen *E* and a different prior distribution for “skeptics.” <sup>65</sup> The investigators conducting the trial often are enthusiasts, whereas other investigators or practicing physicians may be more skeptical. If a trial is to terminate early with a claim that *E* is more effective than *C*, then the data from the trial should be strong enough to convince skeptics. On the other hand, if the trial is to terminate early with a claim that *E* is not more effective than *C*, then the data from the trial should be strong enough to convince enthusiasts. Although this is a somewhat oversimplified view (some enthusiasts or skeptics will never be convinced), it serves as a useful basis for interim monitoring. For computing the Bayesian predictive probability of rejection of the null hypothesis at the end of the trial if it is continued, it would be useful to use an enthusiast's prior distribution to ensure that the data are sufficiently compelling.

Stopping trials when the experimental regimen *E* is not appearing more effective than *C* but is not statistically significantly worse than *C* is sometimes controversial. Statisticians tend to want data as definitively as possible. One must also be cautious that with survival or disease-free survival end points, early parts of the survival curve may not reflect latter parts. Another argument for continuing such trials even if it is clear that *E* will not be found to be significantly better than *C* is that additional data will provide narrower confidence intervals for the true difference *d*. The alternative point of view is that it is not appropriate to continue to expose patients to a more toxic and debilitating treatment *E* if the essential outcome of the trial is well assured. Data-monitoring committees are charged with helping to make these difficult judgments. <sup>66</sup>

### SIGNIFICANCE LEVELS, HYPOTHESIS TESTS, AND CONFIDENCE INTERVALS

Medical decision making is complicated, and clinicians frequently misinterpret statistical significance tests in search of clear-cut answers from ambiguous data. A statistical significance level for comparing outcomes represents the probability of obtaining a difference as large as that actually observed if the treatments were actually of equal efficacy and differences occur merely by chance. If differences in either direction as large in absolute value as the one actually obtained are included, the significance level is called *two-sided*. If the probability is calculated only for differences in the same direction as that actually obtained, the significance level is called *one-sided*. Generally, the two-sided significance level is twice the one-sided level.

After significance tests had been used for many years, Neyman and Pearson <sup>67</sup> formalized a mathematical theory of hypothesis testing. In this theory, a study must prespecify a null hypothesis, an alternative hypothesis, and a decision rule for accepting one hypothesis and rejecting the other based on the data obtained. The theory has appealed to clinicians because it simplifies complex medical decision making by providing yes or no answers; either the difference is statistically significant or it is not. The distinction between one- and two-sided decision rules becomes crucial because a one-sided  $P = .05$  is simply nonsignificant if a type I error of .05 based on a two-sided decision rule is prespecified.

The concept of prespecification of hypotheses is important for medical experimentation. However, the accept-reject nomenclature of the Neyman-Pearson theory provides an oversimplified and sometimes misleading interpretation of the data. Significance levels can serve as useful aids to interpretation of results, but quibbling about whether a one-sided  $P = .04$  is significant makes little sense. Significance levels are influenced by sample sizes, and failure to reject the null hypothesis does not mean that the treatments are equivalent. There is no simple index of truth for interpreting results. Some attempt to use the notion of statistical significance in this way, but thorough presentation, skeptical evaluation, and cautious interpretation of results always are required.

Confidence intervals are generally much more informative than are significance levels. A confidence interval for the size of the treatment difference provides a range of effects consistent with the data. The significance level tells nothing about the size of the treatment effect because it depends on the sample size. However, it is the size of the treatment effect, as communicated by a confidence interval, that should be used in weighing the costs and benefits of clinical decision making. Many so-called negative results are actually noninformative, and confidence intervals help to determine when this is the case. Simon <sup>68</sup> has presented a nontechnical discussion of how to calculate confidence intervals for treatment differences with the types of end points commonly used in cancer clinical trials.

### CALCULATION OF SURVIVAL CURVES

Most cancer clinical trials display results by showing survival curves or disease-free survival curves. Survival curves display the probability of surviving beyond any specified time, with time shown on the horizontal axis. In disease-free survival curves, it is the time until recurrence or death that is shown. Other time-to-event distributions can be similarly represented using the same methods. The usual statistical methods are not appropriate for analyzing survival because they ignore the fact that surviving patients have a limited follow-up period after which their survivals are “censored.”

The most satisfactory way of representing such data is to estimate the survival function  $S(t)$ . This function represents the probability of surviving more than *t* time units. Time *t* is measured from diagnosis, start of treatment, or some other meaningful time point. For randomized studies, it is best to measure time from the date of randomization. There are basically two satisfactory methods for estimating  $S(t)$ . The first is the life-table or actuarial method. It frequently is attributed to Berkson and Gage <sup>69</sup> or Cutler and Ederer <sup>70</sup> and is appropriate when the number of patients is large. The other method is the product limit method of Kaplan and Meier. <sup>71</sup> This method is appropriate for any number of patients, but it involves more effort than the life-table method when the number of patients is large.

The first step in the application of either method is the calculation of survival time for all patients. Survival is the duration from the chosen baseline (e.g., date of randomization) until death or date last known to be alive for patients who are not known to have died. To use the life-table method, intervals for the grouping of survival times are determined. The life table, shown in [Table 21.1-12](#), is then filled out. This sample life table is prepared with yearly intervals in the first column. The number of patients alive at the beginning of the interval is entered in column 2. The number who died in the interval is entered in column 4. Patients dying exactly at a time that represents a boundary between two intervals (e.g., 365 days) are considered to have died in the preceding interval (e.g., 0 to 1 year). Column 3 contains the number of patients who are lost to follow-up during the interval or who are alive with maximum follow-up duration included in the interval. These latter patients are referred to as *withdrawn alive* in the conventional life-table terminology. The life-table method assumes that patients lost to follow-up or withdrawn alive during the interval are at risk of death for half of the interval. Hence, column 5, the number alive at the start of the interval minus half the number lost or withdrawn during the interval, represents an approximate number of patients at risk of death during the interval. Column 6 gives the ratio of the number of patients who died during the interval to the number at risk during the interval. Column 7 gives the estimated probability of surviving the interval for patients alive at the start of the interval.

Survival Randomization Time	No. Alive at Beginning of Interval		No. Lost to Follow-up or Withdrawn Alive During Interval		No. Effective Exposed to Risk of Dying During Interval		Population Surviving through End of Interval (i.e., x...x+1)	
	$n_i$	$n_{i+1}$	$l_i$	$w_i$	$r_i$	$r_{i+1}$	$S_i$	$S_{i+1}$

TABLE 21.1-12. Life-Table Method for Estimating a Survival Distribution

Column 8 should be studied carefully, because it provides the life-table estimate of the survival distribution and indicates the logic behind the method. The probability of surviving more than 3 years after randomization, for example, equals the entry in the third row of column 8 (0.50). The logic is as follows: To survive 3 full years, the patients must survive through the first year; and given that they have survived the first year, they must survive the second year; and given that they have survived the second year, they must survive the third year. Consequently, the probability of surviving for at least 3 years is estimated by the product  $P_1 \times P_2 \times P_3$  of factors in column 7. By using this product, the life-table method takes maximal advantage of the mortality experience of patients with limited follow-up. The entry  $S_x$  in column 8, row  $x$ , represents the life-table estimate of the probability of surviving more than  $x$  years from randomization. Computational shortcuts to observe are those for column 8— $S_x = P_x \times S_{x-1}$ —and for column 2— $l_{x+1} = l_x - w_x - d_x$ .

The product limit method of Kaplan and Meier<sup>21</sup> is similar in concept to the life-table method. With the Kaplan-Meier approach, however, the intervals are defined by the actual survival times of patients who have died. Suppose, for example, that the survivals are 3, 3+, 3+, 5, 6, 8+, 8+, 10, 10, and 12+ months, where a plus sign follows survivals for patients still alive. Then the intervals are 0 to 3, 3 to 5, 5 to 6, and 6 to 10 months, as shown in Table 21.1-13. With the Kaplan-Meier method, deaths occur only at the ends of intervals. The entry in column 5 equals  $l_x - w_x$  rather than  $l_x - 2w_x$  for the life-table method. This is because deaths occur only at the ends of intervals here, and the number of patients at risk of death just before the interval end is  $l_x - w_x$ . In the entry  $w_x$  in column 3 for the Kaplan-Meier method, patients who are lost to follow-up or withdrawn alive at the end of an interval are considered not lost or withdrawn until the following interval. These differences between the Kaplan-Meier and life-table methods render the former more appropriate for studies with fewer patients.

Multiple Intervals	No. Alive at Beginning of Interval		No. Lost to Follow-up or Withdrawn Alive During Interval		No. Died During Interval		Effective No. Exposed to Risk of Death During Interval		Population Surviving Through End of Interval		Cumulative Probability Surviving Through End of Interval	
	$l_x$	$l_x$	$w_x$	$w_x$	$d_x$	$d_x$	$l_x - w_x$	$l_x - w_x - d_x$	$l_x - w_x$	$l_x - w_x - d_x$	$S_x$	$S_x$
0-3	10	0	2	0	1	1	8	7	8	7	0.8	0.8
3-5	8	1	1	1	1	1	6	5	6	5	0.67	0.53
5-6	6	0	1	0	1	1	5	4	5	4	0.53	0.40
6-10	5	2	2	1	1	1	3	2	3	2	0.27	0.27

TABLE 21.1-13. Kaplan-Meier Method for Estimating a Survival Distribution

Once the values  $S_x$  have been calculated for the Kaplan-Meier method, they may be graphed with time on the horizontal axis. The graph is a step function that starts at time zero and ordinate 1.0. It drops to value  $S_x$  at time  $x$ , where  $x$  is the time at the right end of an interval. The survival curve corresponding to Table 21.1-14 is shown in Figure 21.1-1. The tic marks are placed on the curve at 3, 8, and 12 months to represent the follow-up times of living patients. The step function can be extended horizontally out to 12 months to represent follow-up of the last patient, but the right-hand end of the curve usually is very imprecisely estimated, and concluding that a plateau exists at the level shown on the curve is often erroneous.

Comparisons	Probability of at Least One "Significant" Difference (%)
1	5
2	9.7
3	14.3
4	18.5
5	22.6
10	40
20	64.1

TABLE 21.1-14. Probability of Obtaining at Least One Statistically Significant ( $P < .05$ ) Difference by Chance Alone in Multiple Comparisons of Two Equivalent Treatments

FIGURE 21.1-1. Example of estimated survival distribution.

For any time  $t$ , the Kaplan-Meier curve is an estimator of the true unknown value of  $S(t)$ . The estimator is approximately normally distributed in large samples. If  $m$  patients remain alive at time  $x$ , the standard error of the estimate can be conservatively estimated<sup>32</sup> as

$$S_x \sqrt{(1 - S_x) / m}$$

The Kaplan-Meier estimate of a survival distribution is based on the assumption that censoring is noninformative, which means that the censoring time is independent of the prognosis of the patient. Most censoring in a randomized clinical trial results from the fact that some patients are alive and still being followed at the time of analysis. This is noninformative censoring. However, if patients are lost to follow-up, if they fail to return to clinic when they are too sick to travel, then the censoring is informative and all the usual methods of survival analysis are invalidated. Consequently, it is essential to obtain follow-up information actively on *all* patients before analysis. If some patients have not been contacted for many months and their status is unknown, that information should be obtained before any analysis is performed. Examining the distribution of time since the last contact for patients not known to have died is a good way to examine the adequacy of follow-up.

The issue of informative censoring also arises in considering end points other than death. For example, one may be attempting to estimate the distribution of time until tumor recurrence in the central nervous system (CNS) in a pediatric leukemia trial. How should one handle patients whose disease recurs in the marrow without

evidence of CNS recurrence? One may be tempted to censor the time to CNS recurrence of such patients at their time of marrow recurrence, but that implicitly assumes that the censoring is noninformative. Because CNS and marrow recurrence may be biologically linked, the assumption of noninformative censoring may not be valid. Other issues of informative censoring can be similarly problematic. Clearly, one should never censor patients because of lack of compliance with therapy, as this can severely bias results.

More extensive, but fairly nontechnical, discussions of statistical methods for the analysis of clinical trial data are given by Anderson et al. <sup>72</sup> and by Harrington and Anderson.<sup>73</sup>

## MULTIPLE COMPARISONS

Table 21.1-14 shows the probability of obtaining one statistically significant ( $P < .05$ ) difference by chance alone as a function of the number of independent comparisons of two equivalent treatments. With only five comparisons, the chance of at least one false-positive conclusion is 22.6%. When the number of end points, interim analyses, and patient subsets are considered in the analysis of clinical trials, these results are disturbing. <sup>74</sup> The comparisons performed in clinical trials are not entirely independent, but this does not have much effect on ameliorating the problem. Fleming and Watelet <sup>75</sup> performed a computer simulation to determine the chance of obtaining a statistically significant treatment difference when two equivalent treatments in six subsets determined by three dichotomous variables are compared. The chance of a statistically significant difference between treatments in at least one subset was 20% at the final analysis and 39% in the final or one of the three interim analyses. Subset analysis, comparison of treatments with regard to multiple end points, and multiple interim analyses are common sources of erroneous conclusions. The primary end point should be defined in the protocol. Subset analyses and analyses with regard to secondary end points should be specified in advance, and statistical significance should be declared only for significance levels much more extreme than the conventional .05. The simplest approach to multiple comparisons is to declare statistical significance only if the  $P$  value is less than  $.05/n$ , where  $n$  denotes the number of comparisons to be made. For example if  $n = 10$ , then .005 should be the threshold for declaring significance for a secondary analysis. The number of comparisons planned in the protocol is represented by  $n$ . Comparisons not preplanned should not be considered significant in any case and represent hypothesis generation to be tested in subsequent trials.

Interaction tests are statistical procedures that test for lack of homogeneity of treatment effect across subsets of patients. A statistically significant interaction should be documented before claiming that treatment effects vary among subsets. Such tests are described by Simon <sup>76,77</sup> and by Gail and Simon.<sup>78</sup>

Generally, it is not valid to adjust the analysis by characteristics measured after the start of treatment (e.g., compliance, dose delivered, toxicity). New approaches to subset analysis and multiple end point analysis using Bayesian methods have been described by Simon et al. <sup>79,80</sup>

## REPORTING RESULTS OF CLINICAL TRIALS

Effective reporting of results is an integral part of good research. Unfortunately, numerous reviews have indicated that the quality of reporting of clinical trial results is poor. <sup>49,81,82</sup> and <sup>83</sup> Pocock et al. <sup>84</sup> concluded that "overall, the reporting of clinical trials appears to be biased toward an exaggeration of treatment differences." Barr and Tannock<sup>48</sup> have given a clear illustration of how this is easily done. Simon and Wittes <sup>85</sup> developed a set of methodologic guidelines for reports of clinical trials, and these guidelines have been adopted by major cancer journals. These nine guidelines are summarized below:

1. Authors should discuss briefly the quality control methods used to ensure that the data (including response assessments) are complete and accurate.
2. All patients registered on study should be accounted for.
3. The study should not have an inevaluability rate of greater than 15% for major end points.
4. In randomized trials, the report should include a comparison of survival and other major end points for all eligible patients as randomized, with no exclusions other than those not meeting eligibility criteria.
5. The sample size should be sufficient to establish or conclusively rule out the existence of effects of clinically important magnitude. For "negative" conclusions in therapeutic comparisons, the adequacy of sample size should be demonstrated by presenting confidence limits for the true treatment differences.
6. The report should indicate the initial target sample size. It should specify how many interim analyses were performed and how the decisions to stop accrual and report results were made.
7. Claims of therapeutic efficacy should not be made based on nonrandomized phase II trials, unless the disease is so rare or the prognosis so poor that properly controlled randomized trials are not possible. In the latter case, nonrandomized trials should use explicit historical controls for which comparability of patients can be thoroughly evaluated. Comparison of survival between responders and nonresponders is not a valid way of establishing therapeutic efficacy. <sup>11,12,86</sup>
8. The patients studied should be adequately described. Applicability of conclusions to the general population of patients should be carefully discussed. Claims of subset-specific treatment differences should be carefully documented statistically as more than the random result of multiple significance testing. <sup>74</sup>
9. The methods of statistical analysis should be described in detail sufficient that a knowledgeable reader could reproduce the analyses if the data were available.

## EPIDEMIOLOGY OF CLINICAL TRIALS

Several authors have pointed out that many of the positive results reported from small trials are expected to be false-positive results. <sup>76,87,88</sup> In 100 trials, suppose that there are 10 in which the experimental treatment is sufficiently better than the control such that there is an 80% chance of the difference being detected in a small or moderate-sized clinical trial. Of these 10 trials, obtaining a statistically significant difference in 8 cases ( $0.80 \times 10$ ) is expected. Of the remaining 90 trials, it is assumed that the treatments are approximately equivalent to the control. We would expect to obtain a statistically significant difference in 5% (4.5) of these cases. Hence, of the 12.5 ( $8 + 4.5$ ) trials that yield statistically significant results, the finding is false-positive in 4.5 or 36% of the cases ( $4.5/12.5$ ). The 36% false-positive result is striking. It depends on the assumption that only 10% of the trials represent important advances, but this assumption does not seem overly pessimistic.

An additional factor to consider is that of publication bias, <sup>89</sup> which denotes the preference of journals to publish positive rather than negative results. A negative result may not be published at all, particularly from a small trial. If it is published, it is likely to appear in a less widely read journal than it would if the result were positive.

These observations emphasize that results in the medical literature often cannot be accepted at face value. It is essential to recognize that "positive" results need confirmation, particularly positive results of small studies, before they can be believed and applied to the general population.

## METAANALYSIS

A metaanalysis is a quantitative summary of research in a particular area. It is distinguished from the traditional literature review by its emphasis on quantifying results of individual studies and combining results across studies. Key components of this approach are to include only randomized clinical trials, to include all relevant randomized clinical trials that have been initiated, regardless of whether they have been published, to exclude no randomized patients from the analysis, and to assess therapeutic effectiveness based on the average results pooled across trials. <sup>90</sup>

Attention is restricted to randomized trials, because the bias from nonrandomized comparisons may be larger than the small to moderate therapeutic effects likely to be present. Including all relevant randomized trials that have been initiated in a geographic area (e.g., the world, or the Americas and Europe) represents an attempt to avoid publication bias. Avoiding exclusion of any randomized patients also functions to avoid bias. Assessing therapeutic effectiveness based on average pooled results is an attempt to make the evaluation on the totality of evidence rather than on extreme isolated reports. In calculating average treatment effects, a measure of difference in outcome between treatments is calculated separately for each trial. For example, an estimate of the logarithm of the hazard ratio can be computed for each trial. A weighted average of these study-specific differences then is computed, and the statistical significance of this average is evaluated. This approach to metaanalysis requires access to individual patient data for all randomized patients in each trial. It also requires collaboration of the leaders of all the relevant trials and is very labor-intensive. Nevertheless, it represents the gold standard for metaanalysis methodology.

A major issue of concern in metaanalyses is whether the individual trials are sufficiently similar to make calculation of average effects medically meaningful. If the therapeutic interventions or control treatments differ too greatly or if the patient populations are too different, then the results may not be medically meaningful as a basis for making treatment decisions for individual patients. Often in cancer therapeutics, the studies will not be identical in their treatment regimens or their patient populations, but they will not be so different as to make the results meaningless. In this case, the metaanalysis may be useful for answering important questions about a class of treatments that the individual trials cannot address reliably. For example, trials evaluating adjuvant treatment of primary breast cancer often are designed to detect differences in disease-free survival, and a metaanalysis is often required to evaluate survival. Similarly, subset analysis can usually be meaningfully evaluated

only in the context of a metaanalysis, because individual trials are not sized for this objective.

Metaanalysis is *not* an alternative to properly designed and sized randomized clinical trials. Some have suggested that one need not be concerned about computing sample size in the traditional ways, as small randomized trials can be pooled for metaanalysis. Because most investigators would prefer to “do their own thing,” this would lead to a proliferation of diverse trials of inconsequential individual size that were too heterogeneous to permit a meaningful metaanalysis. Given that sufficient large, randomized clinical trials of very similar treatment regimens have been conducted, metaanalysis can provide supplemental information about a given class of treatments that is not available from the individual trials.

## INTRODUCTION

Historically, discussions of data management have focused on an inherently manual process. Questions pertaining to data collection form layout, transport of information, and the role of computers were paramount. Now the questions relate to information technology's assumed role in research data management. Data can be collected in real time from study sites worldwide. Data quality can be verified at time of input or collection. The human interface between clinical care data (the hospital-clinic systems) and clinical research data (the subset of clinical data dictated by protocol) can be significantly assisted by the electronic interchange of data between computers. Still, the fundamentals of data management remain fairly constant and can be applied throughout the steps in the clinical trial life cycle. The clinical trial life cycle begins with protocol development and continues through patient recruitment, screening and registration, protocol implementation, and analysis and publication.

## PROTOCOL DEVELOPMENT

Data management begins with the protocol document and the events prescribed in that document. The protocol defines study objectives, patient selection and eligibility, and the temporal sequence of events. Data to be collected must be prospectively identified. Common elements in treatment protocols include a précis or summary of the protocol, schema, protocol objectives, study design, definition of patient population, the protocol intervention, drug information, toxicities and dosage modifications, methods of evaluation against study end points, data collection, and statistical considerations (see protocol outline in [Table 21.2-1](#)).<sup>1,2</sup> Each component has an impact on research data management and defines requirements to be carried out during the study. In fact, data management begins with the process of authoring, reviewing, and approving the protocol document itself. This process often depends on coordination with associate investigators, internal review committees, institutional review boards, and external sponsors. It is often time-consuming and driven by multiple levels of review. Document templates, electronic document routing, electronic signature, and the use of structured text in the protocol-authoring step of the life cycle could mean that protocols can be conducted more quickly with higher-quality information at every level. The National Cancer Institute (NCI) is pursuing development of information systems that may help to evolve this lengthy process into a faster one.<sup>3</sup>

TABLE 21.2-1. Protocol Outline, National Cancer Institute Division of Clinical Sciences, Bethesda, MD

## PHASE OF PROTOCOL

The protocol phase determines the type of data collected to evaluate study end points. Phase I is not disease-specific. Major end points are maximum tolerated dose of the treatment. The data collection will be focused on measurement and categorization of toxicities. The study size will be small, composed of groups (usually fewer than six participants) at each dose level until maximum tolerated dose is reached.

Phase II is tumor- and diagnosis-specific. The major end points are response of the tumor to the intervention. Phase II studies do not require a control group. The data collection will be to evaluate biologic effect and tumor response.

Phase III is disease- and diagnosis-specific, and its major end points are efficacy, survival, and symptom control. Phase III studies yield results that can be generalized to the population. This imposes the need for a dramatically larger sample size and, possibly, randomization of study subjects to create a control group. The implications for data management are huge: To achieve protocol accrual in a reasonable time, phase III studies are usually conducted in multiple centers.<sup>1,4</sup> A coordinating center is responsible for the management and monitoring of study accrual and conduct of the randomization process. Phase IV studies are designed for postmarketing surveillance of approved drugs.

## STUDY OBJECTIVES

This section includes scientific background and defines study. The end points will drive study conduct as well as determine the data required.

## STUDY DESIGN

The study design specifies study population, sample size, enrollment, treatment administration and schema, data collection, and analysis. Each component will require specific data management events or tasks.

The study population is determined by the use of inclusion and exclusion criteria: what patient diagnoses or characteristics are required to participate in the study (inclusion) and which will eliminate someone from participating (exclusion). Data management tasks include the evaluation and recording of these criteria for each prospective patient.

## TREATMENT ADMINISTRATION AND SCHEMA

Treatment administration and schema outline the study intervention and the temporal sequence in which events must occur. The impact on data management is the resultant schedule sequence for data collection. Schedule delays and intervention modification will be described in sufficient detail to render these directives operational.

## PROCEDURAL ISSUES

The protocol should identify procedural issues for the study conduct, such as documentation of eligibility, enrollment and registration procedures, study schedule, and detailed data collection and handling methods. The tools (forms, procedures, computer applications) for data collection will be included, as well as documentation about computerized systems used to handle trial data.<sup>5</sup> All processes, data requirements, sequence of events, data collection instruments, database, and electronic system usage in a study should be identified prospectively as intended, to support only the stated study objectives.<sup>6</sup>

## PATIENT RECRUITMENT, SCREENING, AND REGISTRATION

Once the protocol is approved and ready for patient accrual, the life cycle moves to the step of patient recruitment. The goal here is to apply the study population parameters—inclusion and exclusion criteria—to potential patients. Matching eligibility criteria with a particular patient requires that criteria be expressed in a standard way. As appropriate within the study design, rendering the entrance criteria as nonspecific as possible will facilitate study accrual.<sup>6</sup> An additional challenge is the display of protocol information based on very specific patient characteristics. Without this capability, information may not narrow study choices sufficiently for patients and their physicians to make informed preliminary decisions. For example, one test using the NCI's Physician Data Query protocol search at <http://cancer.net.nci.nih.gov/trialsrch.shtml> to enter a search for breast cancer trials returned 140 trials, but when the search was limited to only phase III trials for stage II breast cancer, the return dropped significantly. To the extent that the patient population specified in the protocol can be expressed via minimal criteria, the study-patient matching can be facilitated.

Prospective registration (before study intervention) ensures that the patient selection process does not bias the results. Given the methodologic issues and the administrative challenges associated with tracking study accrual, an independent registration office or coordinating center is recommended. A common model is for a coordinating center to record patient registration to a study. After registration, notification to the pharmacy allows study agents to be released to the patient. Additionally, randomization assignments can be made by the coordinating center at time of registration, independently of the study team.

## PROTOCOL IMPLEMENTATION

The protocol life cycle approach allows the researcher to reap the benefit of advance planning at the point of protocol implementation ( [Table 21.2-2](#)). Study design and questions drive the collection of research data and the creation of study-specific data management tools,<sup>1</sup> while U.S. Food and Drug Administration (FDA) recommendations and international guidelines define good clinical practices (GCPs) that must be operational in clinical research.<sup>7</sup>

Life Cycle Step	Data Management Tasks
Protocol development	Protocol authoring; document testing, mark-up, and approval; definition of protocol data requirements; study registration (phase, disease, identification of study population)
Patient recruitment	Patient-study matching; information dissemination for patients and for physicians; contact management
Patient screening and registration	Documentation of first patient encounter; collection of demographic information; collection of patient history; eligibility assessment; protocol enrollment registration
Protocol implementation	Protocol-specific data collection forms; reuse of existing patient information (from patient records, laboratory, auxiliary hospital services); automatic grouping of laboratory activities; data elements defined in data dictionary and applied consistently; data dictionary as subject of standards across patients and studies
Analysis and publication	Predefined report formats; unadvised reports; ad hoc query; data printing; data export to external statistical applications

**TABLE 21.2-2.** Data Management for Support of the Protocol Life Cycle

Clinical research data constitute a subset of the patient's medical information, so the requirement in the design of data management tools and processes is to be selective. The desire to capture interesting but unused data will dilute the ability to answer the study's scientific questions and will overwhelm study personnel with unnecessary workloads.

A data management approach that supports the protocol life cycle will reuse elements identified in the concept and protocol documents, maintaining focus on the study design. It also supports minimal redundancy of data entry, using data harmonization to add standardized meaning to terminology. Researchers understand the strength of this approach in their long-term ability to share information with other investigators and to apply the same analytic procedures across protocols, and in their ability to enroll patients and conduct clinical trials across organizational and geographic constraints.

The heart of data management is the effort of personnel using a set of tools and work processes. Processes must support the sophistication of the tools (electronic or paper-based) used and facilitate the collection and entry of clinical research data.

## DATA COLLECTION

Case report forms (CRFs) represent the industry's standard approach that has been adopted by most research institutions for the collection of clinical research data. The CRF is a layout, or template, of the data elements that are to be captured by personnel working with clinical research data. Items may be categorized and grouped in a logical work flow and order.<sup>8</sup> Items collected or abstracted from source documents should be contiguous on the forms,<sup>9</sup> encouraging the capture of complete data sets and lessening the risk of missing elements. Consistency across protocols will be reflected in a similar display of generic items on forms, use of the same coding conventions across studies, and standardized definition of terms across protocols and across forms for a single study. [Figure 21.2-1](#) is an example of a CRF used for collecting a patient's prior therapy information. Notice that acceptable choices for certain categories (prior therapy type and response) are identified at the top of the form, in addition to other specific instructions supplied at the bottom of the form.

Monitoring is a primary means of quality control for clinical research studies. It is an activity performed by the study monitor of a clinical research organization with the formal responsibility of monitoring the conduct of research trials. Monitoring visits can focus on a variety of protocol-centered elements. Data can be inspected for their completeness and comparison to expected values. Values that fall outside the range of acceptance as well as missing values will generate data clarification forms for the submitting organization. The creation of clarifications or data discrepancy reports and the resolution of clarifications with resultant resubmission of corrected and validated data back to the monitoring agency creates a continual loop for process improvement at the organizational level. Monitoring activities can focus on protocol administrative and regulatory aspects, the availability and completeness of standard operating procedures, institutional and regulatory approvals and reviews, and adverse-event reporting or can even compare electronic data entry screens to reports submitted by the institution. <sup>17</sup>

An audit is one means of quality assurance, to assess the quality of the research process, and must be conducted by personnel independent of a clinical trial. <sup>17</sup> While the terms *audit* and *monitoring* often are used interchangeably, most literature conveys the relationship to be many audits or auditing activities within the realm of a monitoring plan.

## ANALYSIS AND PUBLICATION

Data management tasks associated with analysis and publication in the life cycle are centered on data retrieval. An investigator or clinical research team will have predetermined and preformatted views or reports that they use to examine data, producing validated views of the data as important data management tasks. More flexible queries or simple graphic plots may be required. Report creation on an *ad hoc*, as-needed basis is a common requirement. However, producing reports and views of the research data does not in any way replace the efforts of appropriate biostatistical support and analysis. One of the primary data management tasks for this step may be simply exporting clean, validated data in a format requested by the biostatistician.

## INFORMATION TECHNOLOGY

The information technology architecture required to support clinical trials will depend on the research portfolio and the number of studies and centers involved. Supporting a single study can be accomplished using commercially available office automation software, such as desktop database applications or spreadsheets. There are also applications specifically for management of clinical trials well suited for a single trial or a small study portfolio. More common is the clinical trial portfolio of multiple studies coordinated through a cooperative group or a cancer center. In this case, the burden of managing multiple studies and patients at multiple centers increases the challenges, both administratively and from the clinical data collection and management perspectives. Data management tools available over a Web browser can assist the coordination of multicenter trials.

Information technology is the key to producing better information faster and to finding the answers to research questions more rapidly. If we step away from the view of data management as one step in a process and toward the protocol life cycle model, information technology can be more broadly applied and important to the success of the studies.

## BASIC CONCEPTS

To the extent possible, software applications for clinical research should support work processes, not dictate the process. They should provide study-specific display and collection of information. To support ease of use as well as enforce security, research data management systems should render information and functions based on the role of the user. For example, a registered system user would see only the functions appropriate for a role (e.g., data collection, accrual monitoring, audit, report generation). This role should allow access to only those protocols and patients for which there is an appropriate need to know. Rules-based validation must be technologically supported. As studies are conducted in large or multiple institutions, remote data entry can speed data collection and assimilation. This is increasingly being accomplished via Internet-based technologies.

## INTERNET TECHNOLOGIES

Web-based data collection and management for single and multicenter trials is being increasingly used. <sup>14,18</sup> This approach supports the collection and display of complex medical information unconstrained by geographic location. Additionally, it permits display of complex medical information textually or graphically, managed from a central database. <sup>19</sup> Since it can operate from any site that has an Internet connection and a Web browser, it may be the best answer for large randomized multicenter trial data collection and administration. It can be platform-independent and stores system logic and data centrally. <sup>20</sup> Given the match of flexible and almost universally available Internet technology with the requirement for collecting data from multiple sites, use of Web technology will continue to increase exponentially in the next few years. Lowe <sup>14</sup> describes this as a paradigm shift in medicine toward Internet-based solutions for information management. "Perhaps the two most important applications to emerge in the next decade will be Internet-based clinical trials (in which patients and researchers, though geographically distributed, will be linked via secure Internet-based data collection, review and reporting systems) and the Internet-based multimedia electronic medical record." <sup>14</sup>

## DATA CLASSIFICATION

As information is collected from multiple studies, sites, investigators, and the like, the issues of data standards and data classification become more important. If data are to be collected or aggregated across multiple patients at different centers or multiple studies over time, concepts and terms must be expressed with as little ambiguity as possible. While there is still no consensus on national or international standards for medical vocabularies, there are some dominant candidates to consider, depending on the medical concept being described. <sup>21</sup> One example is the NCI Cancer Therapy Evaluation Program's adverse event reporting requirement, which uses Common Toxicity Criteria (CTC) and the Medical Dictionary for Regulatory Activities (MedDRA). Classification of diagnoses, procedures, morphology, and medications are areas in which fairly mature internationally or commercially maintained vocabularies exist.

Realizing that there is much change occurring in classification of medical terminology, there is no guarantee that a standard used today will be the universally accepted standard tomorrow. However, implementation of a current classification standard is highly recommended over using a home-grown standard or no standard at all. Using an existing standard brings a high likelihood that it will be accounted for should a master thesaurus, such as the Unified Medical Language System, become the standard. Whichever particular scheme is used for data classification on one or a group of studies, adherence to the chosen classifications, enforced by a system data dictionary, will ensure consistent use.

## U.S. FOOD AND DRUG ADMINISTRATION RECOMMENDATIONS

The FDA has adopted guidelines for clinical trial computer systems that report data to that agency. <sup>5</sup> While only guidelines, they are a benchmark against which data management systems can be measured. Areas to underscore include a recommendation that standard operating procedures be established for system setup, system maintenance, data collection, data backup and recovery, and data security. Systems should use electronic signatures to verify that persons entering, viewing, or updating data are authorized to do so. This also ensures attribution so that data entered under electronic signature can be tracked back to the person entering or updating the data.

Audit trails allow recreation of the data history. <sup>5</sup> By viewing the audit trail, a user can determine what was recorded at any point in time and who changed the data.

## DATA VALIDATION

Systems should provide validation logic to be applied to data at time of entry or in batch edit, a process that records data that fail built-in validation rules. Validation can be simple range checking or algorithms that alert users when certain conditions are present. One example of this is the application of the NCI Common Toxicity Criteria; the software prompts the user to file an adverse event report based on a laboratory value falling sufficiently out of range. Data corrections or other actions taken at time of entry are enforced in real time, but this may or may not be desirable. If the person entering data does not have the expertise or documentation to answer computer-driven queries, a preferred process would be to record queries centrally and ensure that they be addressed later (i.e., batch edit). Several types of validation can be easily applied in a computer-based system. These include detection of missing data, data artifacts (outside the usual range), data that contradict other data, and data trends (conflicting data from one encounter to the next). <sup>2</sup>

Validation checks for the presence of data in these fields should be displayed to personnel using clear instructions. When using electronic CRFs, data that fail validation attempts should generate a message in natural language that will identify delinquent items.

Simple edit checks can verify that text fields are not filled with numbers or dates, that future dates are detected, and that values fall within specified acceptable ranges. Because it is difficult to apply edit check logic to free text, responses translated into coding lists can help in the application of edit check rules.

Cross-checks can be used in the context of relationships between data points. The value in one field may constrain the entry of a value in another field, so that the content of these fields can be compared. There can also be cross-validation between variables expected to correlate. For example, if the response to "Prior Chemotherapy?" is yes, the CRF may require that details of a chemotherapy treatment regimen be entered on the CRF. Other cross-validation would occur between variables measured on repeated occasions (e.g., lesion measurements on repeated cycle visits) and other context-specific checks.

Double data entry is another form of validation used to minimize data entry. However, double entry procedures may not be sufficient or even necessary for the production of high-quality clinical research data. Day et al. <sup>10</sup> used exploratory data analysis techniques on simulated clinical data measurements and found that while the double entry approach does detect some errors, many others occur during the transcription process that are not detectable by double entry processes. The use of systems with computerized CRFs to enter data directly from source documents also lessens the benefit of a double entry approach. While the double data entry practice may offer some benefit, other methods to validate data integrity and validity should be mandatory.

## DIRECT DATA CAPTURE

Electronic transfer of data from hospital laboratory or other systems into the research data management system is known as *direct data capture*. When direct data capture is used, it can result in higher-quality data through reduction of the errors produced when data are rekeyed. Where this model is used, the data management system must be able to indicate whether and where data have been changed after import. <sup>5</sup>

## SECURITY

Data management systems should control security at the physical and logical levels. *Physical security* applies to controlling and safeguarding the physical computer resources and data storage, enforced via off-site storage of backup data and fire walls that prevent unauthorized access to data and computing resources. *Logical access* refers to those persons who have access to data through the assignment of system-based roles. <sup>5</sup> Spriet and Dupen-Spriet<sup>2</sup> described required security as (1) operational (proper maintenance, virus protection, and proper use); (2) physical (protection against physical harm by fire, water damage, and the like and safeguarding backup data); and (3) malice (protection against theft, piracy, or sabotage). <sup>2</sup>

## SUMMARY

Each step of the clinical trial life cycle creates distinct data management tasks and processes specified during protocol development. Supporting these tasks can be accomplished with manual (paper-based) processes, completely automated with computer systems, or through some combination of both. The model chosen at the organizational level will depend on principles of good clinical practice and quality control need. The acceptance and use of Internet systems is increasing the acceptance of computer systems as data management facilitators. The product of clinical research is data, and proper data management can help to turn the data into information.

## INTRODUCTION

Tobacco addiction ranks as the greatest public health catastrophe of our time. The practice of inhaling cigarette smoke, which gained widespread acceptance only during the twentieth century, has generated devastating cancer outcomes for our society. Specifically, lung cancer, previously rare, has risen to become the leading cancer killer in American men and women.<sup>1,2</sup> Worldwide estimates suggest that the annual deaths attributable to smoking, currently 2.5 million, will rise to 12 million by the year 2050.<sup>3,4</sup> and<sup>5</sup> Future medical historians undoubtedly will recall the 1900s as the Tobacco and Cancer Century.<sup>2</sup>

A healthier twenty-first century requires a societal commitment to reducing and eradicating tobacco addiction. This chapter reviews the impact of tobacco on cancer and individual and societal strategies for tobacco control.

## TOBACCO AND NICOTINE ADDICTION

Tobacco and tobacco smoke contain at least 4000 chemicals, of which 55 are known carcinogens identified by the International Agency for Research on Cancer.<sup>6</sup> The most notable carcinogen classes include polycyclic aromatic hydrocarbons (PAHs), N-nitrosamines, and miscellaneous organic compounds. Of the PAHs, benzo(a)pyrene (BaP) is the most extensively studied lung carcinogen. Of the N-nitrosamines, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) is best known. Metabolic activation of these agents can incite DNA adduct formation, gene mutations, and a sequence of events that can lead to cancer. The balance between detoxification and metabolic activation determines, in part, the susceptibility of smokers to cancer.<sup>6</sup>

Though nicotine in tobacco is itself not carcinogenic, addiction to nicotine exposes the user to carcinogens, which increases the likelihood of cancer. Nicotine addiction fulfills the physiologic, behavioral, and social characteristics of a dependence syndrome.<sup>7</sup> The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders (DSM, third edition)* requires a minimum of three of seven diagnostic symptoms for drug dependency: (1) tolerance, (2) withdrawal, (3) greater use than intended, (4) persistent desire to quit, (5) great amounts of time spent smoking, (6) activities given up or reduced due to smoking, and (7) continued smoking despite knowledge of having persistent physical or psychological problems with the substance.<sup>7</sup> The 1988 Surgeon General's report focused on the concept of nicotine addiction and its clinical ability to produce brief, pleasurable psychoactive effects; its continued use despite known adverse health outcomes; development of tolerance during early usage; and occurrence of withdrawal symptoms on cessation of use.<sup>8</sup> Withdrawal symptoms include nervousness, restlessness, anxiety, impaired cognition, headache, drowsiness, gastrointestinal disturbances, nicotine cravings, increased appetite and weight gain, and anxiety.<sup>7,8</sup> and<sup>9</sup>

## HEALTH EFFECTS

As early as 1928, Lombard and Doering<sup>10</sup> reported higher smoking rates among patients with cancer than among controls. Later, the pioneering epidemiologic work of Doll and Hill,<sup>11</sup> Wynder and Graham,<sup>12</sup> and Hammond and Horn<sup>13</sup> led to further investigations, which culminated in the 1964 U.S. Surgeon General's report on smoking and health.<sup>14</sup> This report concluded that cigarette smoking was the major cause of lung cancer in men and was causally related to laryngeal cancer and oral cancer in men.<sup>14</sup>

In total, more than 60,000 studies and two dozen additional reports of the Surgeon General have confirmed the devastating impact of tobacco use on human health. Tobacco use, causing approximately 30% of all deaths and more than 400,000 deaths annually, is the leading cause of preventable death in this country ( [Fig. 22-1](#)).<sup>1,15,16</sup> Tobacco use kills more Americans each year than do alcohol, cocaine, crack, heroin, homicide, suicide, car accidents, firearms, and the acquired immunodeficiency syndrome (AIDS) combined.<sup>17</sup>

FIGURE 22-1. 430,000 U.S. deaths are attributable each year to cigarette smoking.

Smoking causes more than 85% to 90% of lung cancers, with a clear dose-response relationship between risk and daily cigarette consumption.<sup>18</sup> People who smoke more than a pack of cigarettes per day have a risk that is as much as 20 times that of nonsmokers.<sup>18</sup> In smokers exposed to other carcinogens in the workplace (e.g., pipefitters exposed to asbestos; uranium workers exposed to radon), the risk for lung cancer is raised in a synergistic fashion.<sup>19,20,21 and 22</sup>

Lung cancer is the leading cause of cancer mortality in both men and women. U.S. estimates for 2000 include approximately 157,000 lung cancer deaths. Lung cancer incidence rates vary widely by race and ethnicity, from a high of 73.9 per 100,000 in African Americans to a low of 27.6 among Hispanics.<sup>1</sup> Gender differences exist as well. Male lung cancer incidence rates peaked in 1984 (86.5 per 100,000) and have decreased since then. Similarly, male lung cancer mortality rates peaked in 1990 at 75.2 per 100,000.<sup>1</sup> In contrast, female lung cancer incidence and mortality continue to rise. Of note, in the late 1980s, lung cancer surpassed breast cancer as the leading cause of cancer death among U.S. women.<sup>1</sup> The histologic profile of lung cancer has shifted, with declining rates of squamous cell carcinoma but increasing rates of adenocarcinoma.<sup>23</sup>

In addition, smoking is accepted as the major cause of cancers of the larynx, pharynx, oral cavity, and esophagus, and is a contributory factor in cancers of the pancreas, bladder, kidney, stomach, colon, and uterine cervix and in acute leukemia.<sup>24,25</sup> A synergistic, multiplicative effect appears to exist between smoking and drinking.<sup>26</sup> For example, the risk for developing cancer of the larynx is as much as 75% higher in people who use tobacco and alcohol as compared with people using either substance alone.<sup>24,26</sup>

The use of pipes, cigars, and spit tobacco in its various forms (plug tobacco, loose-leaf tobacco, twist tobacco, and moist snuff) also causes cancers of the oral cavity.<sup>18,24,25,26,27 and 28</sup> Tobacco use is responsible for more than 90% of tumors of the oral cavity among men and 60% among women.<sup>27</sup> Spit tobacco is a significant cause of leukoplakia,<sup>27,28,29 and 30</sup> an abnormal thickening and keratinization of the oral mucosa that is recognized as a precursor of malignancy. Even after cessation of tobacco exposure, the "field cancerization effect" elevates the risk of cancer of the entire epithelium of the upper aerodigestive tract for years.<sup>31</sup>

Other adverse health outcomes from tobacco addiction include increased risks of cardiovascular disease.<sup>32,33 and 34</sup> The Nurses' Health Study found a 2.5-fold increased risk of fatal coronary heart disease and nonfatal myocardial infarction and up to three times the risk of cerebrovascular disease in smokers as compared to nonsmokers. Smoking also contributes to peripheral vascular disease, aortic aneurysm, impotence, Buerger's disease (thromboangiitis obliterans), and skin aging.<sup>32,33 and 34</sup>

Americans spend an estimated \$50 billion annually on direct medical care for smoking-related illnesses.<sup>35</sup> Lost productivity and forfeited earnings due to smoking-related disability account for another \$47 billion per year.<sup>36</sup>

## SMOKING RATES AND TRENDS

With the vigorous promotion of the blended cigarette in the twentieth century, the annual adult per capita consumption of cigarettes has skyrocketed from 54 cigarettes in 1900 to 4345 cigarettes in 1963, the peak of American consumption per individual smoker.<sup>35</sup> Although consumption has declined, approximately 500 billion cigarettes were sold in the United States in 1995.<sup>6</sup> Historically, smoking rates in men have far exceeded those in women, but the gender difference has narrowed as male rates declined and female rates rose.<sup>1,35</sup> Rates for most races and ethnic groups have decreased since 1978, although the rate of decrease recently has ebbed (Fig. 22-2).<sup>37</sup> The tobacco industry's attempts to recruit women range from the American Tobacco Company's advertising campaign, "To keep a slender figure, reach for a Lucky Strike instead of a sweet" (1920s) to Philip Morris's Virginia Slims slogan, "You've come a long way, baby."<sup>38</sup>

**FIGURE 22-2.** Current cigarette smoking among adults, National Health Interview Surveys, United States 1978–1995 aggregate data.

## ADULTS

Approximately 1 billion smokers are found worldwide.<sup>39</sup> According to the 1995 National Health Interview Study, in the United States, nearly 47 million adults (24.7%) currently smoke, either daily (20.1%) or on some days (4.6%).<sup>37</sup> Currently, men (27.0%) are more likely to smoke than are women (22.6%). Among racial and ethnic groups, American Indians and Alaskan natives had the highest prevalence (36.2%), whereas Asian Americans and Pacific Islanders had the lowest (16.6%).<sup>37</sup> Educational level is the most important predictor of smoking prevalence.<sup>9</sup> High school dropouts had the highest prevalence (41.9% and 33.7% for men and women, respectively), whereas college graduates had the lowest (14.3% and 13.7%, respectively).<sup>37</sup>

Since the landmark 1964 Surgeon General's report, overall U.S. smoking prevalence has declined by half, from 50.2% (1965) to 25% (1998), although adult smoking rates reached a plateau in the 1990s.<sup>1</sup> Declines in smoking prevalence were greater among African American, Hispanic, and white men who were high school graduates than among those with less education.<sup>1</sup> In fact, in the United States during 1965 through 1994, smoking prevalence in adults younger than 65 years declined in every demographic category except those with less than 12 years of education.<sup>7</sup>

## CHILDREN, ADOLESCENTS, AND COLLEGE STUDENTS

Tobacco use qualifies as a pediatric disease.<sup>40</sup> Its current prevalence among adolescents (cigarettes, cigars, or smokeless tobacco) is an astonishing 42.7%.<sup>1,41</sup> The 1997 Youth Risk Behavior Survey showed smoking rates for girls and boys as 69.3% and 70.9% for lifetime cigarette use and 34.7% and 37.7% for current cigarette use.<sup>41</sup> Nearly 90% of adult smokers begin smoking by the age of 18 years. Even by grade 9, 67% of children have experimented with cigarettes.<sup>41</sup> It is estimated that of nearly 3000 young people who start smoking each day, 1 in 3 will die prematurely.<sup>42,43</sup> At least 3 million American teenagers smoke regularly.<sup>9</sup>

Numerous surveys document increased smoking among children and adolescents in recent years.<sup>41</sup> The national 1997 Youth Risk Behavior Survey indicated that cigarette smoking prevalence among U.S. high school students increased from 27.5% in 1991 to 36.4% in 1997.<sup>41</sup> This rise occurred in all racial and ethnic groups [e.g., whites (30.9% to 39.7%), African Americans (12.6% to 22.7%), and Hispanics (25.3% to 34.0%)]. In 1997, the prevalence of current cigar use was 22.0%. Monitoring the Future Project data (an analysis of high school seniors from 1976 to 1995) show that the smoking rate among high school seniors (defined as smoking in the past 30 days) rose from 28.3% in 1991 to 34% in 1996, and rates for grades 8 and 10 show similar or larger increases.<sup>43</sup>

Notably, the age of smoking initiation has declined over the past four decades, for both whites (by 2.4 years) and African Americans (by 1 to 3 years). The decline is particularly striking for girls (5.4 years and 4.6 years for whites and African Americans, respectively).<sup>9</sup> Also, half of the nation's 6 million smokeless tobacco users were younger than 21 years, and several national surveys show an increase in prevalence, especially among boys.<sup>9</sup>

Predictors of future tobacco use include a number of behavioral risk factors.<sup>42,43,44,45,46,47 and 48</sup> These factors include the child's own certainty about smoking or not

smoking in the future, low self-image, poor academic career, receptivity to tobacco advertising, peer pressure, and the use of promotional items. <sup>42,43,44,45,46,47,48</sup> and <sup>49</sup> Individual personality traits such as risk taking and deviant behaviors and perceptions of maturity, attractiveness, and independence also play a role in a child's susceptibility to tobacco use. In white youngsters, peer pressure (estimated by the number of friends who smoke) and a low grade point average were important risk factors. Among African Americans, a greater risk-taking attitude was an important predictor of tobacco use. <sup>48</sup> Acculturation or integration into American society is associated with increased smoking by Latin and Asian women. <sup>48</sup>

Tobacco use in children is linked to alcohol and illegal drug use. <sup>44,45</sup> Among boys especially, aggressive or disruptive classroom behavior as early as first grade has been found to predict later tobacco and other heavy drug use, as well as antisocial behavior and criminality. <sup>44</sup> The National Household Study on Drug Abuse from 1985 showed children who smoke are 3 times more likely to drink alcohol, 8 times more likely to smoke marijuana, and 22 times more likely to use cocaine. <sup>48</sup> Children's tobacco and alcohol use also were associated with less effective parenting behaviors in the children's families and with parental use of tobacco and alcohol. <sup>45</sup>

Newer data point to increasing smoking rates among college students. <sup>50</sup> In serial surveys of nearly 15,000 randomly selected college students, Wechsler et al. <sup>50</sup> found that the prevalence of current cigarette smoking rose by 27.8% (from 22.3% to 28.5% during the period 1993 through 1997). Defying earlier trends, 11% of college smokers had their first cigarette and 28% began to smoke regularly at or after age 19 years. Half of current college smokers tried to quit in the previous year; 18% had made five or more attempts to quit. <sup>50</sup>

## CIGARETTE PRODUCT MODIFICATION

In the 1950s, confronted with declining cigarette sales after studies linked smoking to lung cancer, tobacco companies began producing filter-tip brands designed to remove certain smoke components that manufacturers had not heretofore acknowledged to be harmful. <sup>51</sup> Methods used to decrease the tar and nicotine content in cigarettes were filter tips, porous cigarette paper, reconstituted tobacco, and filter-tip ventilation. <sup>52</sup> Today, almost all cigarettes on the market have filters, most with perforations to dilute tar, nicotine, and carbon monoxide, thereby decreasing their delivery to a smoker's lungs. <sup>53</sup> As a result, in 1995, 72.7% of cigarettes delivered no more than 15 mg of tar, as compared to only 3.6% of cigarettes in 1970. <sup>1</sup> Cigarettes contain 6 to 11 mg of nicotine, of which a smoker typically absorbs 1 to 3 mg, irrespective of nicotine yield ratings. To satisfy the level of nicotine needed, smokers modified their smoking behavior by inhaling more deeply and blocking filter vents with their fingers or lips to increase nicotine yield. These behaviors now are suspected to be linked to rising rates of adenocarcinoma of the lung, which currently is the most common type of lung cancer in the United States. <sup>23</sup> Nevertheless, the tobacco industry has continued to suggest health benefits to consumers through the creation and promotion of "light," "ultralight," "mild," "medium," "slim," and "superslim" cigarettes. <sup>25</sup>

## SPIT TOBACCO

Spit tobacco (smokeless tobacco), available as snuff or chewing tobacco, has gained great popularity over the last few decades. <sup>54,55,56,57</sup> and <sup>58</sup> Snuff dipping, the practice of sucking on a pinch of powdered, flavored tobacco in the cavity between gum and cheek, has increased. Consumption of snuff products nearly tripled between 1972 and 1991. <sup>56</sup> The 1997 Youth Risk Behavior Survey documented a 9.3% prevalence of current spit tobacco use among high school students, with 21% of boys ages 11 to 19 defined as experimenters. <sup>57</sup> The consumption of chewing tobacco, which involves a "chaw" held in the inner cheek area, has also increased. <sup>56,58</sup>

Use of both snuff and chewing tobacco requires continual expectoration—hence the term *spit tobacco*. <sup>55</sup> Manufacturers prefer the term *smokeless tobacco*, to imply a safe alternative to smoking. However, the nicotine in snuff is 2 times the dose in cigarettes, whereas the nicotine in chewing tobacco is 15 times that found in cigarettes. <sup>58</sup> Users tend to be white male adolescents aged 18 to 24 years, persons of low socioeconomic status, current cigarette smokers, residents of the southern United States, baseball players, and American Indians. <sup>57</sup>

Spit tobacco can accelerate a litany of destructive oral changes, from local nonmalignant effects (gingival recession, loss of periodontal attachments, periodontal bone and soft tissue destruction, halitosis, tooth staining, tooth abrasion) to leukoplakia and frank oral cancer. Leukoplakia typically occurs on the cheek mucosa, alveolar ridge, and gingiva, where the snuff is placed. In contrast, tobacco chewers tend to have bilateral lesions of leukoplakia, which is associated with a 3% to 6% progression to squamous cell carcinoma. <sup>58</sup>

## CIGARS

Cigar smoke, which contains the same carcinogenic and toxic compounds as cigarettes, also increases risk of cancer, coronary heart disease, and pulmonary pathologic processes. <sup>8,59,60</sup> and <sup>61</sup> Cigar smoking is potentially addictive and is associated with cancers of the oral cavity, larynx, esophagus, and lung. <sup>8,59,61</sup> Reversing a 20-year decline, cigar sales increased by 50% from 1993 to 1997, <sup>61</sup> prompted by industry marketing and the belief that cigars are less dangerous than cigarettes. Young to middle-aged men of high socioeconomic status, teenagers, and women are the groups responsible for the increased consumption of cigars. <sup>60</sup> The overall prevalence of current cigar use among high school students was 22% in 1997. Teenagers most at risk of smoking cigars were male and those students who smoke cigarettes. <sup>60</sup>

## ENVIRONMENTAL TOBACCO SMOKE

The 1986 U.S. Surgeon General's report defined *environmental tobacco smoke* (ETS), also called *secondhand smoke*, as the combination of sidestream smoke (released from a burning cigarette between puffs) and the fraction of mainstream smoke exhaled by the smoker. <sup>62</sup> The more hazardous sidestream smoke has double the amount of nicotine than mainstream smoke and a higher concentration of carcinogens. <sup>62</sup> Most people spend 90% of their time in the two microenvironments of home and work, where ETS exposure usually occurs. <sup>63</sup> Those at greatest risk for harm from ETS are those who live with smokers in homes where smoking is allowed. Levels of serum cotinine, a nicotine metabolite, are increased in nonsmokers who live with smokers and are correlated to the number of cigarettes smoked. <sup>64</sup>

An increasing number of studies have documented the health risks of the nonsmoker exposed to ETS. <sup>62,63,64,65,66,67</sup> and <sup>68</sup> Case-control studies first noted that nonsmoking wives of smoking husbands had increased risk of lung cancer. <sup>64</sup> In 1992, the U.S. Environmental Protection Agency (EPA), in the most thoroughly documented analysis ever undertaken of the effects of exposure to ETS, concluded that secondhand smoke can cause lung cancer in nonsmoking adults and can impair the respiratory systems of children. The EPA classified ETS as a group A carcinogen, a designation reserved for agents such as asbestos. Of 30 studies analyzed in the EPA report, 24 found an increased risk of lung cancer for nonsmoking wives of husbands who smoked, and each of the 17 studies that examined risk based on exposure level reported increased lung cancer among those most exposed. <sup>67</sup>

The EPA report and other ETS studies now attribute approximately 3000 deaths to lung cancer, up to 62,000 deaths to ischemic heart disease, and up to 2700 deaths to sudden infant death syndrome. <sup>67</sup> The 1997 California Environmental Protection Agency Report also notes that ETS is responsible for new cases of low-birth-weight infants (up to 18,600 cases per year), new cases of childhood asthma (up to 26,000 new cases per year), exacerbation of childhood asthma (up to 1 million new cases per year), and bronchitis or pneumonia in children aged 18 months and younger (up to 300,000 cases per year). Workers at great risk for harm from ETS include flight attendants, casino workers, and restaurant and bar workers, among others. <sup>68</sup>

## TOBACCO INDUSTRY ADVERTISING STRATEGIES

Tobacco companies have dedicated considerable resources to corner new markets, because an estimated 3500 Americans quit smoking and an additional 1200 customers die of smoking-related illness each day. During the last two decades, the tobacco industry has nearly quadrupled its marketing expenditures ( [Fig. 22-3](#)). <sup>69,70</sup> The 1994 U.S. Surgeon General's report, "Preventing Tobacco Use Among Young People," summarized the research on the impact of tobacco advertising and promotional activities on youth <sup>71</sup>:

**FIGURE 22-3.** Cigarette advertising and promotion expenditures in the United States have more than quadrupled in 22 years.

- Young people constitute a highly strategic market for the tobacco industry.
- Young people are continuously exposed to cigarette messages through print media and promotional activities.
- Cigarette advertising uses images, not information, to portray the attractiveness of smoking.
- Cigarette advertisements capitalize on the disparity between an ideal and actual self-image, implying that smoking may close the gap.
- Cigarette advertising appears to affect young people's perceptions of the pervasiveness, image, and function of smoking. Such misperceptions increase young people's risk of smoking.

Most adolescents now experiment with tobacco almost as a rite of passage and have high recollection of tobacco industry promotional messages. Nearly 70% of children aged 13 reported at least moderate receptivity to marketing materials, indicating susceptibility.<sup>72</sup> Adolescents and youth are susceptible to image advertising and promotional themes as they seek to find their own identities.<sup>49</sup> One study found 6-year-old children were as likely to identify Joe Camel as they were Mickey Mouse.<sup>73</sup>

In addition, adolescents smoke the most heavily advertised brands.<sup>49</sup> Pierce et al.<sup>49</sup> provided the first longitudinal evidence that tobacco promotional activities are causally related to the onset of smoking. A total of 1752 adolescents who had never smoked and who were not susceptible to smoking when first interviewed in 1993 were reinterviewed in 1996. Nearly 50% progressed toward smoking, by becoming susceptible, by experimenting, or by consuming at least 100 cigarettes. The authors attributed 34% of all adolescent tobacco experimentation in California from 1993 through 1996 to industry promotional activities.<sup>49</sup>

Tobacco marketing strategies include magazine and newspaper advertising, outdoor advertising, sponsorship of sporting events and public entertainment, and distribution of free samples of cigarettes in public places. Promotions and specialty items include mailings and giveaways of multiple packs (buy one, get one free) and coupon reductions for attractive specialty items (such as T-shirts, caps, calendars, and sporting goods).<sup>9,42,74</sup> Surveys have found that half of all adolescent smokers and one-fourth of adolescent nonsmokers owned at least one tobacco promotional item.<sup>42</sup> Tobacco companies also pay retailers for shelf space and engage them to promote point-of-sale advertising, a technique that places the tobacco products in convenient visible (usually self-service) racks and in point-of-purchase displays.<sup>9,42</sup>

One of the first studies to examine systematically the relationship between cigarette brand-specific advertising and youth readership found that youth brands were more likely than adult brands to be advertised in magazines having a higher percentage of young readers (ages 12 to 17 years). The authors recommended that cigarette advertising in all youth magazines be eliminated.<sup>75</sup>

The tobacco industry also uses its considerable financial and legal resources to influence local and national policy.<sup>35,76,77 and 78</sup> Industry magnates frame the increasing public debate about smoking regulations around rights and liberty rather than health, portray adversaries as extremists, and invest millions of dollars in campaign contributions to the leading political parties.<sup>35,76,77,78 and 79</sup> They successfully solicit allies (including advertisers, civil libertarians, and restaurant owners) to help lobby or advance arguments that oppose regulation.<sup>77</sup>

The tobacco industry has generally escaped strong government legislation. Federal legislation, including the Controlled Substances Act (1970), Consumer Product Safety Act (1972), and Toxic Substances Control Act (1976) all exclude tobacco from regulation.<sup>78</sup> The landmark 1965 Federal Cigarette Labeling and Advertising Act, the first federal statute enacting labeling requirements for cigarette packages, contained a federal preemption clause preventing individual states from making laws to regulate tobacco advertising.<sup>78</sup>

## STRATEGIES FOR TOBACCO CONTROL

For decades, the concept of tobacco control focused solely on cessation strategies for individual smokers. More recently, the emphasis has broadened to encompass prevention strategies that stress denormalization of tobacco use for the entire community. Hence, key dimensions now include individual approaches that expand the role of the clinician in smoking cessation services, which include pharmacologic cessation therapies; community and state interventions; policy strategies; tobacco taxes that fund comprehensive statewide tobacco control programs; mass media and counter-advertising; and tobacco litigation and the tobacco settlement.<sup>78</sup>

### INDIVIDUAL APPROACHES

Each year, approximately 20 million (of the 50 million smokers in the United States) try to quit smoking.<sup>79,80 and 81</sup> In addition, 77% of smokers would like to quit, and 65% have made at least one serious attempt at quitting. Yet, studies indicate that one-third relapse after 24 hours and another third relapse after 48 hours.<sup>79,80 and 81</sup> Of all smokers that attempt to quit each year, fewer than 10% are successful. Cigarette smokers who have successfully quit made, on average, seven serious attempts before achieving abstinence.<sup>79,80 and 81</sup>

Even young smokers want to quit.<sup>42,82,83</sup> The 1989 and 1993 Teenage Attitudes and Practice Surveys did show that nearly 75% of 12- to 18-year-olds had seriously thought about quitting smoking; more recent surveys found that 73% of young smokers had tried to quit smoking.<sup>42,82,83</sup>

Smoking cessation restores a chance of living a full, healthy life.<sup>84</sup> Quitting smoking reduces the risk of lung cancer by 50% at 5 years, and by 10 years, lung cancer risk drops almost to the rate for nonsmokers.<sup>35</sup> After a year, mortality from heart disease decreases by half, and by 5 years it equals the rate for nonsmokers.

### CLINICIANS' ROLE

Physicians and health professionals should view smoking cessation as a cornerstone of their practice.<sup>85</sup> Providing a brief physician intervention to all smokers could more than double annual quit rates.<sup>86</sup> Seventy percent of smokers see their doctors at least once annually, thereby granting physicians ample opportunity for smoking cessation counseling.<sup>87</sup> If only one-half of all U.S. physicians gave brief advice to their patients regarding smoking cessation, leading to success in 10%, clinician intervention would account for 2 million new nonsmokers in the United States each year.<sup>88,89</sup>

The Agency for Health Care Policy and Research (AHCPR) smoking cessation guidelines incorporate the National Cancer Institute's (NCI's) four As: ask, advise, assist, and arrange.<sup>85</sup> The physician should *ask* each patient about his or her smoking status; *advise* the patient to stop and educate him or her regarding the long-term health consequences of smoking; *assist* by helping the patient to set a stop date, prescribing pharmacologic interventions, and supplying self-help pamphlets; and *arrange* follow-up.<sup>90</sup> This NCI manual provides good reasons for quitting smoking, targeted to different groups (Table 22-1).<sup>90</sup> Other groups recommend the four Fs: The physician discusses with the patient the *relevance* of a stop-smoking program to health, the smoking *risks*, and the *rewards* of quitting, and continues *repetition* of the stop-smoking message.<sup>91</sup>

Reason	Percentage
Smoking causes cancer	85.0%
Smoking causes heart disease	84.0%
Smoking causes lung disease	83.0%
Smoking causes emphysema	82.0%
Smoking causes chronic bronchitis	81.0%
Smoking causes nicotine addiction	80.0%
Smoking causes premature aging	79.0%
Smoking causes bad breath	78.0%
Smoking causes yellow teeth	77.0%
Smoking causes loss of athletic ability	76.0%
Smoking causes financial drain	75.0%
Smoking causes loss of life	74.0%
Smoking causes harm to others	73.0%
Smoking causes bad taste	72.0%
Smoking causes bad smell	71.0%
Smoking causes bad habits	70.0%
Smoking causes bad example	69.0%
Smoking causes bad luck	68.0%
Smoking causes bad karma	67.0%
Smoking causes bad karma	66.0%
Smoking causes bad karma	65.0%
Smoking causes bad karma	64.0%
Smoking causes bad karma	63.0%
Smoking causes bad karma	62.0%
Smoking causes bad karma	61.0%
Smoking causes bad karma	60.0%
Smoking causes bad karma	59.0%
Smoking causes bad karma	58.0%
Smoking causes bad karma	57.0%
Smoking causes bad karma	56.0%
Smoking causes bad karma	55.0%
Smoking causes bad karma	54.0%
Smoking causes bad karma	53.0%
Smoking causes bad karma	52.0%
Smoking causes bad karma	51.0%
Smoking causes bad karma	50.0%

**TABLE 22-1.** Good Reasons to Stop Smoking

Clinicians should determine and document the tobacco use status of every patient treated in a health care setting.<sup>85</sup> To remind physicians, Fiore<sup>92</sup> has recommended that smoking status be included as part of a routine patient vital sign assessment. Other researchers recommend flagging smokers' charts to ensure necessary smoking interventions (Fig. 22-4).<sup>36</sup> Ahluwalia et al.<sup>93</sup> have found that placing a smoking stamp on patients' charts significantly increases (from 45.6% to 78.4%) the likelihood that a physician will ask patients whether they smoke.

**FIGURE 22-4.** Smoking status included in the vital signs (a proposal by Fiore<sup>92</sup>).

The AHCPR guidelines also stipulate that effective cessation treatments should be offered to every patient who smokes.<sup>85</sup> Brief cessation treatments are effective. At least a minimal intervention should be provided for every patient who uses tobacco.

As described in the AHCPR guidelines, a dose-response relationship exists between the intensity and duration of treatment and its effectiveness.<sup>85</sup> In general, more intense intervention leads to more effective long-term abstinence from tobacco. The success of an intervention also is maximized by proper training and education of physicians and medical students, by increasing the number of modalities used and the number of professionals involved, and by the creation of office-based systems.<sup>36,92,93,94,95</sup> and <sup>96</sup> Although only 2% to 3% of smokers become nonsmokers each year,<sup>81</sup> some studies report that up to 15% of patients seen by trained physicians have quit smoking.<sup>96</sup>

Finally, three particularly effective elements of smoking cessation treatment are (1) nicotine replacement therapy (NRT), (2) social support (clinician-provided encouragement and assistance), and (3) skills training and problem-solving techniques for achieving and maintaining abstinence.<sup>36</sup> Individualizing the message to the patient increases the likelihood for success.<sup>25</sup> Studies have shown that 3 minutes or less of advice increased quit rates from 7.9% to 10.2%.<sup>96</sup> For example, quit rates of 50% to 63% 6 months after a myocardial infarction can increase to 65% to 75% for those patients who received other interventions in addition to physician contact. Blum<sup>25</sup> recommends that physicians ask nonthreatening questions, such as “What brand do you buy?” and “How much do you spend on cigarettes?” The term *inhalation count* can remind a pack-a-day patient that he or she will breathe in as many as 1 million doses of cyanide, ammonia, carcinogens, and carbon monoxide in less than 15 years. To the construction worker, the physician could link smoking cessation to the likelihood of fewer lost paydays, greater physical strength, and greater ability to work. A high school student, unresponsive to discussions of future emphysema and lung cancer, might be more receptive to the cosmetic unattractiveness of yellow teeth, bad breath, loss of athletic ability, or the financial drain of cigarettes (with costs for a pack-a-day smoker in excess of \$1460 a year, calculated at \$4 per pack).<sup>25</sup>

Also, the physician needs to tailor the message to the patient's readiness to change, according to the Prochaska and DiClemente<sup>97</sup> model: precontemplation, contemplation, action, and maintenance. During *precontemplation*, the patient has not considered quitting. During the *contemplation* phase, the patient is thinking about quitting. In the *action* phase, the patient is preparing and attempting to quit, and, during *maintenance*, the patient is avoiding relapse. Patients do not necessarily pass through each stage in orderly fashion; they may skip a stage or regress.<sup>97</sup>

### NICOTINE REPLACEMENT THERAPY

Approximately 300 cessation methods are reported in the literature, ranging from group therapy, hypnosis, and self-help manuals to acupuncture.<sup>25</sup> The introduction of nicotine-based medications in the form of chewing gum or a transdermal patch, combined with counseling, now provides cessation rates roughly double that of a control group (a factor of 1.4 to 2.6) as compared to placebo treatments. However, 70% to 80% of smokers who use these therapies still start to smoke again.<sup>98,99</sup>

By providing a substitute source of nicotine, NRT lessens the withdrawal symptoms associated with quitting and improves the cessation process. As dozens of published studies have demonstrated its efficacy, safety, and utility, the Smoking Cessation Clinical Practice Guideline of AHCPR recommends NRT as a first-line treatment for tobacco dependence “except in the presence of special circumstances.”<sup>85</sup> Most commonly, NRT is used in the form of nicotine (polacrilex) gum [first approved by the U.S. Food and Drug Administration (FDA) in 1984] or the transdermal nicotine patch (FDA-approved in 1991). In 1996, both of these medications became available as over-the-counter products,<sup>79,80</sup> greatly increasing access. In a metaanalysis, Fiore et al.<sup>99</sup> studied 42 randomized controlled trials of nicotine gum, as well as trials with fewer subjects using a transdermal patch and nasal spray inhaled nicotine. From their studies of nearly 18,000 persons, the authors concluded that NRT was effective, either as a sole therapy or as an adjunct to other therapeutic approaches.<sup>99,100</sup> Dosing of nicotine gum should initially be titrated by the level of nicotine dependence and then adjusted if withdrawal symptoms are not relieved. The Fagerstrom Test for Nicotine Dependence (which features such questions as “How soon after you wake up do you smoke your first cigarette?”) helps guide dosing decisions.<sup>81</sup>

Other agents also show promising results. Recent attention has focused on bupropion, an antidepressant, in combination with the nicotine patch. A recent double-blind, placebo-controlled smoking cessation trial found 12-month abstinence rates of 15.6% for placebo, 16.4% for the nicotine patch alone, 30.3% for sustained-release bupropion (Zyban) alone, and 35.5% for bupropion in conjunction with the nicotine patch. Treatment consisted of 9 weeks of bupropion (150 mg/d) for the first 3 days and then 150 mg twice daily.<sup>98</sup>

### COMMUNITY LEVEL AND STATE INTERVENTIONS

The Community Intervention Trial for Smoking Cessation (COMMIT) and the American Stop Smoking Intervention Study for Cancer Prevention (ASSIST), two NCI-funded efforts to change social norms regarding tobacco use in the community, marked a societal shift toward viewing tobacco control as a public health

prevention issue.<sup>101,102,103</sup> and <sup>104</sup> The 4-year COMMIT study involved 11 matched pairs of communities, randomly assigning one community to active intervention while the other served as the control site. The hypothesis was that a community-level, multichannel intervention (involving media, public education, work-site intervention, and other means) would increase quit rates among smokers, particularly heavy smokers. In 1995, the trial concluded with equal smoking prevalence rates in both groups of communities. Although no increase in the quit rates of heavy smokers was documented, a testament to the powerful nature of nicotine addiction, a statistically significant decrease was realized in the smoking rates of the light to moderate smokers in intervention communities.<sup>101,102</sup>

From 1991 through 1999, the NCI (with logistic support from the American Cancer Society) conducted ASSIST, a nonrandomized study. The project funded health departments in 17 states to implement tobacco control programs that included cessation classes, mass media campaigns, and public policy such as clean indoor air campaigns, efforts to prohibit youth access to tobacco products, and tax increases. Though the goal of reducing adult smoking prevalence to 15% by the year 2000 was not reached, the ASSIST initiative helped public health officials to gain valuable knowledge in statewide tobacco control planning and to move toward statewide denormalization of tobacco use.<sup>103,104</sup>

## RESTRICTING YOUTH ACCESS

Preventing youth access to tobacco products should affect youth smoking rates.<sup>105,106</sup> and <sup>107</sup> All states prohibit the sale and distribution of tobacco products to minors under the age of 18. In several dozen states, additional laws prevent youth access by designating enforcement authorities, enforcing license suspension or revocation for sales to minors, banning vending machines in areas accessible to minors, or restricting advertising. However, one study found that even when 82% of merchants complied with laws banning sales to minors, teenagers reported only a small decrease in their ability to purchase tobacco and no decline in its use.<sup>107</sup> More data are needed to verify the effectiveness of reducing sales to minors in actually limiting adolescents' access.

## RESTRICTING SMOKING IN PUBLIC PLACES

Restricting smoking in workplaces has the potential to decrease greatly human exposure to ETS. Data show that in 1994, of 122 million full-time workers in the United States, nearly 100 million worked indoors.<sup>108</sup> The 1994 National Health Interview Survey showed that smoking prevalence of indoor workers was 26%, and 59% of workers (59 million) worked in buildings where smoking was not permitted.<sup>108</sup> A review of 19 studies of the impact of smoke-free workplaces found that almost all reported declines in daily smoking rates and smoking prevalence. Approximately 13% of the national decline in cigarette consumption in the United States between 1988 and 1994 was attributed to smoke-free workplaces.<sup>108</sup>

An ongoing challenge is to guarantee that smoke-free policies have strength at the local level and are not subject to preemption (i.e., legislation that prevents any local jurisdiction from enacting restrictions that are more stringent than the state law). The Centers for Disease Control and Prevention (CDC), by including tobacco control laws and policies as part of their surveillance efforts, note that from 1993 through 1996, the number of tobacco control laws with a preemption provision increased significantly to cover 30 states currently.<sup>109</sup>

## TOBACCO TAXES THAT FUND DEDICATED, COMPREHENSIVE STATEWIDE TOBACCO CONTROL PROGRAMS

Many public health experts regard tobacco taxes to be the single most effective measure for decreasing tobacco consumption.<sup>78</sup> Economic research documents price elasticity (i.e., a 10% increase in cigarette price generally reduces overall consumption by 4%).<sup>110</sup> Studies show that youth, lower-income smokers, young adults, and minority smokers are more likely than others to be encouraged by a price increase to quit smoking.<sup>111</sup> Government has traditionally taxed tobacco to fund government services, but public health professionals support increased taxes on tobacco products to deter consumption. The Canadian tobacco tax experience in the 1980s and early 1990s demonstrated the potential health impact. The combined average federal and provincial tax reached close to \$3.00, pushing the average price per pack to more than \$4.00. As a result, per capita cigarette consumption (adjusted for estimates of tobacco smuggling) dropped by 38% (1982 to 1992).<sup>110,112</sup>

In contrast, among the world's industrialized countries, the United States has one of the lowest cigarette tax rates, with an average combined federal and state tax on cigarettes in 1993 of 53¢ per pack, as compared to countries such as Denmark and Norway, where taxes exceed \$3.00 per pack. U.S. federal cigarette taxes, currently 24¢ per pack, will rise to 39¢ by 2002. Other forms of tobacco such as snuff, chewing tobacco, and pipe tobacco also are taxed.<sup>113</sup>

To some degree, the state's dependence on tobacco production determines the level of state tax, which currently ranges from 2.5¢ in Virginia to \$1.00 per pack in Alaska and Hawaii (nationwide average, 38.9¢ per pack). The cigarette tax-to-price ratio, which assesses the relative contribution of the total (state and federal) taxes to the full price of cigarettes, has declined from 49.8% in 1960 to 29.6% in 1997.<sup>113</sup>

In general, the public is willing to increase tobacco taxes if those extra revenues are earmarked for specific purposes such as health programs.<sup>114</sup> To date, four states—Arizona, California, Massachusetts, and Oregon—have passed tobacco tax initiatives and used the revenue to develop statewide comprehensive tobacco control programs.<sup>115,116</sup> The CDC recently studied state experiences and disseminated best practices for comprehensive tobacco control programs.<sup>117</sup>

## CALIFORNIA

California voters approved a 1988 ballot initiative that increased the state cigarette tax by 25¢, allocating 20% of the revenue to establish a comprehensive statewide tobacco education and prevention program.<sup>118,119</sup> The initiative also funded mass media antitobacco campaigns, assistance to local health agencies for providing technical support and monitoring adherence to antismoking laws, community-based interventions, smoking cessation services (including a statewide quit-smoking telephone hot line), and enhancement of school-based prevention programs.<sup>118,119</sup> As a result, an analysis of per capita cigarette consumption indicated that the start of the California Tobacco Control Program in 1989 was associated with a 50% more rapid rate of decline in cigarette consumption than was seen in the rest of the country. Both the tax increase and the funded tobacco control program contributed to this decline. However, the post-1993 rate of decline, while still significantly more rapid in California than in the rest of the United States (where the decline in consumption halted), slowed to less than one-third of the rate seen in 1989 through 1993. Pierce et al.<sup>120</sup> attributed the slowing to reduced program funding, increased tobacco industry expenditures for advertising and promotion, industry pricing, and political activities.

## MASSACHUSETTS

Massachusetts voters approved a special 25¢ tax that helped to fund the Massachusetts Tobacco Control Program (MTCP).<sup>114</sup> The MTCP had three major goals: to prevent onset of tobacco use by children, to assist smokers in quitting, and to guard against the harm of ETS. Like California's program, the MTCP consisted of funding for local cessation efforts and local coalitions, a statewide quit-smoking telephone hot line, funding of local boards of health, a statewide public awareness and counter-advertising campaign, and comprehensive school-based programs.<sup>121</sup> Adult per capita tobacco consumption in Massachusetts declined by 20% from the program's inception in 1992 through 1996, reflecting a threefold increase over the reduction observed at the national level.<sup>122</sup> The number of cities and towns that have adopted ordinances restricting youth access to cigarette vending machines has doubled. Recently, data showed the prevalence of current smoking among adults in Massachusetts was 19.1% in 1999, down from 23% in 1993, one of the lowest rates in all the 50 states.<sup>123</sup>

## OTHER STATES

Similar results accompanied a successful 1996 ballot measure in Oregon that increased the excise tax by 30¢ per pack of cigarettes. After passage, per capita consumption has declined 11.3% in Oregon, or the equivalent of 200 cigarettes per capita.<sup>124</sup> Arizona's ballot initiative in 1994 raised cigarette prices by 40¢.<sup>116</sup> Funds from a settled Medicaid lawsuit launched the Florida Pilot Program on Tobacco Control, which is credited with sparking significant declines in tobacco use among middle school and public high school students, declines attributed primarily to a youth-oriented, counter-advertising media campaign, community partnerships in all 67 Florida counties, and enhanced enforcement of youth access laws.<sup>125</sup> From 1998 to 1999, the prevalence of cigarette use among middle school students declined from 18.5% to 15.0% ( $P < .01$ ); among high school students, use declined from 27.4% to 25.2% ( $P = .02$ ).<sup>125</sup>

## MASS MEDIA AND COUNTER-ADVERTISING

All the statewide tobacco control programs just cited have incorporated counter-advertising efforts through mass media. Minnesota (1986) and Michigan (1994) also

have initiated limited tax-funded media campaigns.<sup>116</sup> Such efforts counter the tobacco industry's efforts to normalize a lethal product through advertising and promotional cigarette sales. A counter-advertising public health approach aims to reduce tobacco use by deglamorizing and denormalizing use of the product. To be effective, such mass media antismoking campaigns should provide consistent messages from multiple sources, repeatedly and over a long period, and should work in concert with other interventions and policies, with the goal of changing societal norms.<sup>74</sup>

The effects of these counter-advertising media campaigns, especially those in California and Massachusetts, have been striking. Of the California Tobacco Control Program's decline in cigarette consumption, approximately 20% was estimated to be attributable to the media campaign.<sup>74,126,127</sup> One study of California adults who successfully quit smoking (1990 and 1991) found that in 41%, the media counter-advertising campaign had influenced their decision to stop.<sup>128</sup>

The effectiveness of counter-advertising first emerged in 1967 when the Federal Communications Commission invoked the Fairness Doctrine to require broadcasters to air one antismoking message for every three cigarette commercials aired.<sup>74</sup> When such antismoking advertising prompted a decline in per capita cigarette consumption of at least 5%, the tobacco industry then agreed (in 1970) to Congressional legislation to ban all tobacco advertising on television and radio, thereby eliminating the need for free antismoking ads.<sup>74</sup>

Later, research in Vermont and Minnesota showed that community- and school-based interventions highlighted by prominent mass media campaigns could reduce smoking in young persons by up to 40%.<sup>74,129,130</sup> However, such mass media campaigns before 1988 usually occurred on a sporadic basis. Also, institutionalizing counter-advertising campaigns has posed a public health challenge, as funding for such campaigns can be subjected to legislative diversion.<sup>74</sup> Typically, public service announcements on television did not air during prime time and therefore reached smaller audiences.<sup>74</sup>

Goldman and Glantz<sup>131</sup> have concluded that messages challenging social norms are more successful than are those aimed at changing individual behavior to improve health. Focus groups analysis by these researchers found that the most effective themes stressed the tobacco industry's manipulation of young persons, the negative impact of secondhand smoke, and the burden of cigarette addiction. Such advertisements can be controversial yet memorable and, ultimately, effective.<sup>74,131</sup>

## TOBACCO LITIGATION AND TOBACCO SETTLEMENT

Public health lawyers have advocated bringing suits against tobacco companies as a cancer prevention strategy.<sup>132</sup> The last half century of tobacco litigation can be divided into three waves. Wave 1 (1954 through 1973) featured a number of individual lawsuits against an industry that maintained that tobacco products had never been proven to cause disease. The industry claimed that smokers chose to smoke, hence assuming risk for themselves. In essence, the 1965 Federal Cigarette Labeling and Advertising Act, which requires warning labels on all cigarette packaging and labeling, ironically served as a shield from liability. Wave 2 (1983 through 1992) featured *Cipollone v. Liggett Group Inc.*, a suit brought by a smoker and continued by her husband after her death. Although the original jury verdict of \$400,000 favored the plaintiff, it was reversed on appeal and the case finally was dropped after years of litigation.

Wave 3 (1994 to the present) capitalizes on the release of internal industry documents and subsequent industry concessions that tobacco is addictive and causes cancer and that tobacco companies had consciously marketed their products to children. From this ensued an increasing number of individual lawsuits and class action suits. Among the class action suits is *Broin v. Philip Morris*, which was brought on behalf of flight attendants injured by ETS and was settled for \$349 million. The money realized from this suit will establish a foundation for the study of diseases associated with tobacco.<sup>133,134</sup> and *Engle v. R.J. Reynolds* is a suit brought on behalf of addicted and sick smokers in Florida. In the first phase of this massive class action suit, the industry was found liable for punitive damages, with the award potentially in the hundreds of billions of dollars.<sup>136</sup> In addition, in 1999, the Justice Department filed a \$20 billion lawsuit against the nation's tobacco companies to recover federal costs of treating smoking-related illness.

The most notable litigation to date has been lawsuits brought by states' attorneys general against the tobacco industry to recoup Medicaid costs for the treatment of ill smokers.<sup>137,138</sup> In a remarkable turn of events, the major tobacco manufacturers first settled individually with Mississippi, Texas, Minnesota, and Florida at a cost of \$40 billion over 25 years. Then the industry signed a Master Settlement Agreement with 46 state attorneys general in November 1998, agreeing to pay \$206 billion over 25 years in exchange for no future state litigation. Other conditions included some advertising restrictions (e.g., bans on billboard advertisements) and the establishment of a national foundation to reduce teen smoking.

As the twentieth century ends, states are embroiled in historic discussions of how best to spend the settlement money. The Master Settlement Agreement expressly states that parties "have agreed to settle their respective lawsuits and potential claims pursuant to terms which will achieve for the Settling States and their citizens significant funding for the advancement of public health, the implementation of important tobacco-related public health measures, including the enforcement of mandates and restrictions related to such measures, as well as funding for a national foundation dedicated to significantly reducing the use of tobacco products by youth."<sup>138</sup> However, to date, in most states, the debate has been dominated by proposals to fund civic projects such as debt reduction, school construction, teacher retirement funds, prison construction, and sidewalk repair.<sup>137</sup> As the suits were launched and settled for reasons of tobacco and health, the most fitting outcome would be to dedicate such funds to tobacco control and health programs.

## PROPOSED U.S. FOOD AND DRUG ADMINISTRATION REGULATION

Under Commissioner David Kessler, the FDA first investigated whether to regulate nicotine as a drug. The Federal Food, Drug and Cosmetic Act defines a drug as "an article (except for food) intended to affect the structure and function of the body."<sup>135</sup> Universal scientific consensus indicates that nicotine is an addictive drug. Evidence of the intent of the industry had been supported by the release of internal documents showing that tobacco manufacturers knew that nicotine caused significant pharmacologic effects and designed their products to provide pharmacologically active doses.<sup>80,135</sup> In 1996, the FDA proposed strategies to restrict access to tobacco products and advertising to youth. The first step, effected in part in 1997, involved stricter enforcement of laws affecting minors. The remaining proposed steps included banning free samples, restricting advertising within 1000 feet of schools and playgrounds, and limiting to black and white text print advertising in youth publications. The U.S. Supreme Court recently rejected these proposals, saying the FDA had never received authority from congress to regulate tobacco products.<sup>139</sup>

## CONCLUSION

The dawn of the twenty-first century offers us a new opportunity to create a smoke-free society. All health care professionals, and indeed all citizens, can work to achieve this goal and prevent cancer. At the individual level, we must maximize access to cessation services for all smokers and promote further research into improving nicotine replacement therapies and other pharmacologic approaches. Health care professionals can raise awareness and promote cessation with every clinical opportunity. Reducing and even eliminating nicotine from cigarettes is also technically feasible and may hold the future to eradicating the potential for addiction.

On a broader societal level, communities can commit to changing permanently to a nonsmoking social norm. Such efforts include restricting tobacco advertising and promotion to children, prohibiting tobacco access by youth and teenagers, enhancing public education, raising tobacco excise taxes, and controlling tobacco exports. Dedication of tobacco settlement funds to statewide tobacco control programs nationwide can reduce cigarette consumption and promote prevention, as has been done in California and Massachusetts. Key to such comprehensive programs are broad-scale counter-advertising programs that deglamorize tobacco use.

On the legal front, multiple individual and class action suits ultimately may change the tobacco industry's ability to conduct business as usual. In light of the U.S. Supreme Court's decision as to the authority of the FDA to regulate tobacco, we now await study of this issue by the U.S. Congress.

It is hoped that all these combined efforts will cause the decline and prevention of tobacco-related cancers in the new millennium. Medical historians then can mark the end of the so-called Tobacco and Cancer Century and celebrate the beginning of a new smoke-free chapter in public health.

### INTRODUCTION

In recent years, reduction in dietary fat has been at the center of cancer prevention efforts. In the landmark 1982 National Academy of Sciences review of diet, nutrition, and cancer,<sup>1</sup> reduction in fat intake to 30% of calories was the primary recommendation; this objective has been echoed in subsequent dietary recommendations as well.<sup>2</sup>

Interest in dietary fat as a cause of cancer began in the first half of the twentieth century when studies by Tannenbaum and colleagues<sup>3,4</sup> indicated that diets high in fat could promote tumor growth in animal models. In this early work, energy (caloric) restriction also profoundly reduced the incidence of tumors. A vast literature on dietary fat and cancer in animals has subsequently accumulated (reviewed elsewhere).<sup>1,5,6,7</sup> and <sup>8</sup> Dietary fat has a clear effect on tumor incidence in many models, although not in all<sup>9,10</sup>; however, a central issue has been whether this is independent of the effect of energy intake. An independent effect of fat has been seen in some animal models,<sup>5,7,11</sup> but this has been either weak<sup>12</sup> or nonexistent<sup>13</sup> in some studies designed specifically to address this issue.

In the 1970s, the possible relation of dietary fat intake to cancer incidence gained greater attention as the large international differences in rates of many cancers were noted to be strongly correlated with apparent per capita fat consumption.<sup>14,15</sup> Particularly strong associations were seen with cancers of the breast, colon, prostate, and endometrium, which include the most important cancers in affluent countries not caused by smoking.<sup>16</sup> These correlations were observed to be limited to animal, not vegetable, fat.<sup>17</sup> Complementing these correlational observations, studies of populations migrating from low- to high-incidence areas indicated that the migrating groups adopted the cancer rates of the new environment. This provided powerful evidence that the large international differences in cancer incidence were not due to genetic factors and therefore that the high rates of specific cancers in affluent countries were potentially avoidable. Although such evidence did not directly implicate dietary factors, the animal studies noted previously made the area of diet a strong suspect.

A principal limitation of both the international correlational and migrant studies is the potential for confounding; many other differences besides dietary fat exist between the low-fat (less affluent) and high-fat (more affluent) countries. Indeed, the correlations with gross national product are similar to those for fat intake.<sup>15</sup> Among the many factors that differ between low- and high-fat countries, reproductive behaviors, physical activity level, and body fatness are particularly notable and are strongly associated with specific cancers.<sup>18,19</sup> The quality of dietary data used in the international correlations has also been problematic; this information is not based on actual intakes, but rather on estimated production figures.

Despite their limitations, the suggestive findings of at least some animal models as well as the international correlations and migrant studies have clearly indicated the need for more detailed studies in humans. In particular, studies that can control for the confounding influences of lifestyle factors other than fat intake are important. Two general approaches, discussed elsewhere in detail,<sup>20</sup> are available: case-control or cohort epidemiologic studies and randomized trials. Both case-control and cohort studies are dependent on a reasonably valid assessment of dietary intake. Although for some nutrients, biochemical measurements can be used to assess intake, for total fat consumption a useful biochemical indicator does not exist. Since 1980, considerable effort has been given to the development of standardized questionnaires for measuring intake of fat and other dietary factors and numerous studies have been conducted to assess the validity of these methods.<sup>20,21,22</sup> and <sup>23</sup> These investigations have clearly demonstrated that an informative range of fat exists within the populations of the United States and other countries and that standardized food frequency questionnaires can reasonably measure differences among subjects. Although the range of fat intake that can be studied is restricted to the range of diets in the study population, this typically includes both the levels that have often been recommended (less than 30% of energy) as well as more traditional U.S. levels (more than 40% of energy).<sup>24</sup> Moreover, by combining the data from multiple large prospective studies, the range of fat has been extended from less than 20% of energy to more than 45% of energy), which is similar to the current range observed internationally.<sup>25</sup>

In principle, the most definitive approach to evaluate the relation between fat intake and cancer is to conduct a large randomized trial. However, many practical problems exist in conducting such a trial, the most important being the need to maintain a difference in fat intake between the intervention and control groups for many years; the experience of the Multiple Risk Factor Intervention Trial heart disease prevention study and the pilot studies for the Women's Health Initiative<sup>26,27</sup> indicates this may be difficult. Moreover, the necessary duration for such a trial is not known; much evidence suggests that factors acting from childhood through postmenopausal years can influence breast cancer risk. Because trials of cancer prevention require tens of thousands of subjects to be randomized and the costs of instruction in dietary change is high, such studies are extremely expensive; for example, the Women's Health Initiative will cost well over half a billion dollars.<sup>26</sup>

Since 1985 information on fat intake and cancer has grown rapidly and will continue to accrue exponentially as the populations of ongoing cohort studies age and as recently started cohort studies begin to report their findings. In the following sections, current data on the relation of fat intake to cancers of the breast, colon, and prostate are briefly reviewed as these are the cancers for which the current evidence is most abundant.

### FAT AND BREAST CANCER

Breast cancer is the most frequent malignancy among women in Western countries, and incidence rates have been increasing for decades.<sup>28,29</sup> Rates in most parts of Asia, South America, and Africa have been only approximately one-fifth as high as that of the United States,<sup>30,31</sup> but in almost all these areas rates of breast cancer are also increasing. Populations that migrate from low- to high-incidence countries develop breast cancer rates that approximate those of the new host country.<sup>32,33</sup> However, among Japanese immigrants to the United States, not until the second or third generation do rates approach those of the general U.S. population.<sup>34</sup> This slower rate of change for Japanese immigrants may indicate delayed acculturation, although a similar delay in increase is not observed for colon cancer.

A major rationale for the dietary fat hypothesis has been the international correlation between fat consumption and national breast cancer mortality.<sup>15</sup> However, in a study of 65 Chinese counties,<sup>35</sup> in which both dietary assessment and mortality were measured using standardized methods, and per capita fat intake varied from 6% to 25% of energy, only a weak positive association was seen between fat intake and breast cancer mortality. Notably, four counties consumed approximately 25% of energy from fat, yet experienced rates of breast cancer far below those of U.S. women with similar fat intake,<sup>24</sup> thus providing strong evidence that factors other than fat intake account for the large international differences.

Breast cancer incidence rates increased substantially in the United States during the twentieth century, as have the estimates of per capita fat consumption based on food disappearance data.

However, surveys based on reports of individual actual intake, rather than food disappearance, indicate that consumption of energy from fat, either as absolute intake

or as a percentage of energy, has actually declined in the last several decades, <sup>36,37</sup> a time during which breast cancer incidence has increased. <sup>38</sup>

## CASE-CONTROL STUDIES

A number of case-control studies have been performed to investigate the dietary fat effect on breast cancer. The largest study so far is that of Graham et al., <sup>39</sup> who used a food frequency questionnaire to compare the fat intake of 2024 women with breast cancer with that reported by 1463 women controls entering the hospital with benign conditions. Both animal fat and total fat intake were essentially identical in the two groups. The results from 12 smaller case-control studies have been summarized in a metaanalysis by Howe et al., <sup>40</sup> which included 4312 cases and 5978 controls. The pooled relative risk was 1.35 ( $P < .0001$ ) for a 100-g increase in daily total fat intake, although the risk was somewhat stronger for postmenopausal women (relative risk = 1.48;  $P < .001$ ). This magnitude of association, however, could potentially be compatible with biases due to recall of diet or the selection of controls. <sup>41</sup>

## COHORT STUDIES

A substantial body of data from cohort studies is now available to assess the relation between dietary fat intake and breast cancer in developed countries. Because of the prospective design, most of the methodologic biases of case-control studies are avoided. In a pooled analysis of the seven prospective studies with more than 200 cases of breast cancer, which included 337,000 women who developed 4980 incident cases of breast cancer, <sup>25</sup> no overall association was seen for fat intake over the range of less than 20% to greater than 45% of energy (Fig. 23.1-1). A similar lack of association was seen among postmenopausal women only and for specific types of fat. Only among the small number of women consuming less than 15% of energy from fat was a significant association seen; breast cancer risk was elevated twofold in this group. An update of the Nurses' Health Study included 14 years of follow-up, during which 2956 women developed breast cancer. <sup>42</sup> Because repeated assessments of diet were obtained at 2- to 4-year intervals, this provided a particularly detailed evaluation of the fat intake over an extended period in relation to breast cancer risk. For total fat intake, the overall association was weakly inverse and statistically significant. There was no suggestion of any reduction in risk at intakes below 25% of energy. These cohort findings therefore do not support the hypothesis that dietary fat is an important cause of breast cancer.

**FIGURE 23.1-1.** Pooled relative risks and 95% confidence intervals for various levels of energy from fat. A level of 30% to less than 35% of total energy from fat was designated as the reference category. (From ref. 25, with permission.)

Estrogen level in blood has now been established as a factor for breast cancer. <sup>43</sup> Thus, the effects of fat and other dietary factors on estrogen levels are of potential interest. Vegetarian women, who consume higher amounts of fiber and lower amounts of fat, have lower blood levels and reduced urinary excretion of estrogens, apparently due to increased fecal excretion. <sup>44</sup> A metaanalysis has suggested that reduction in dietary fat may reduce plasma estrogen levels, <sup>45</sup> but the studies included were plagued by the lack of concurrent controls, short duration, and confounding by negative energy balance. <sup>46</sup> In a large randomized trial among postmenopausal women with a previous diagnosis of breast cancer, reduction in dietary fat did not affect estradiol levels when appropriately analyzed. <sup>47,48</sup>

## DIFFERENT TYPES OF FAT

In animal mammary tumor models, the tumor-promoting effect of fat intake has been observed primarily for polyunsaturated fats when fed in the presence of high-fat diets containing approximately 45% of energy. <sup>6,49,50</sup> In a metaanalysis of animal studies, monounsaturated fat had no significant effect on mammary carcinogenesis, and the effect of saturated fat was weak. <sup>6</sup>

In several prospective cohort studies, an inverse association between monounsaturated fat and breast cancer has been present. <sup>24,51</sup> This is an intriguing observation because of the relatively low rates of breast cancer in Southern European countries with high intakes of monounsaturated fats due to the use of olive oil as the primary fat. In case-control studies in Spain, Greece, and Italy, women who used more olive oil had reduced risks of breast cancer. <sup>52,53</sup> and <sup>54</sup> Also, olive oil has been protective relative to other sources of fats in several animal studies. <sup>5,6</sup> Further examination is needed of the hypothesis that monounsaturated fats, and perhaps olive oil in particular, may protect against breast cancer.

## FAT AND AGE AT PUBERTY

An earlier age at menarche is an established risk factor for breast cancer. Although the relative risks associated with early menarche are generally modest, usually less than approximately 1.5 for the earliest compared with the latest age groups within a population, this is likely to be due to the limited range of age at menarche within a population. For example, in the United States, the average age is between 12 and 13 years, <sup>55</sup> but in rural China the typical age is approximately 17 to 18 years. <sup>56</sup> Further, the average age at menarche has been declining worldwide for the last 200 years, <sup>55</sup> thus suggesting that increasing breast cancer rates that occur with increasing industrialization are in part due to a decreasing average age at menarche.

For this reason, nutritional factors that influence age at menarche are of particular interest. Nutritional factors have been examined as potential predictors of age at menarche in several prospective cohort studies. Body mass index, height, and weight have consistently been strong determinants of age at menstruation. <sup>57,58</sup> and <sup>59</sup> In the United States, <sup>57</sup> as well as in the Canadian cohorts, <sup>59</sup> no association was found between the fat composition of the diet and occurrence of menarche, but a suggestion of earlier onset with higher fat intake was seen in the German study. <sup>58</sup> Collectively, these studies provide strong evidence that rapid growth rates before puberty play an important role in determining future risk of breast cancer, but that overall energy balance rather than fat intake is most important.

## FAT AND BREAST CANCER SURVIVAL

High intake of dietary fat has been hypothesized to affect survival adversely in patients with breast cancer, in part because of observations that, adjusted for stage, survival is lower in the United States than in Japan. <sup>60</sup> However, obesity has often been associated with adverse survival from breast cancer, which provides an alternative hypothesis as Japanese women tend to be substantially leaner than U.S. women, and other dietary and lifestyle factors have differed substantially between the United States and Japan.

At present, studies of dietary fat intake and survival from breast cancer are few and have substantial limitations. Most were not specifically designed for this purpose, but instead are based on the follow-up of the control series of case-control or cohort studies of breast cancer incidence. Thus, they usually refer to pre-morbid diet assessed either before or at about the time of diagnosis rather than to diet after diagnosis and, moreover, most studies have been small in terms of the failure end points. Mixed results have been seen in the published work; positive associations have been seen in several studies, <sup>61,62,63,64,65</sup> and <sup>66</sup> but not in others. <sup>67,68,69</sup> and <sup>70</sup> In a report from the Nurses' Health Study, <sup>71</sup> fat intake after diagnosis was not significantly associated with survival, but a modest effect could not be excluded. Unexpectedly, higher protein intake was associated with improved survival. A randomized trial has been started to evaluate the effect of a diet low in fat (15% of energy from fat is the dietary goal) on survival of breast cancer patients. <sup>72</sup>

## FAT AND COLON CANCER

In comparisons among countries, rates of colon cancer are strongly correlated with national per capita disappearance of animal fat and meat, with correlation coefficients ranging between 0.8 and 0.9.<sup>15,17</sup> Rates of colon cancer rose sharply in Japan after World War II, paralleling a 2.5-fold increase in fat.<sup>31</sup> Based on these epidemiologic investigations and animal studies, a hypothesis has developed that dietary fat increases excretion of bile acids, which can be converted to carcinogens or promoters.<sup>73</sup> However, more recent evidence from many studies that obesity and low levels of physical activity increase risk of colon cancer risk means that at least part of the high rates in affluent countries previously attributed to fat intake are probably due to sedentary lifestyle.

With some exceptions,<sup>74,75,76</sup> and <sup>77</sup> case-control studies have generally shown an association between risk of colon cancer and intake of fat<sup>76,78,80,81,82,83,84</sup> and <sup>85</sup> or red meat.<sup>86,87,88,89,90</sup> and <sup>91</sup> However, in many of these studies, a positive association between total energy intake and risk of colon cancer has also been observed,<sup>76,78,80,81</sup> and <sup>82,84,85</sup> raising the question of whether it is general overconsumption of food or the fat composition of the diet that is etiologically important. A metaanalysis by Howe of 13 case-control studies found a significant association between total energy and colon cancer, but saturated, monounsaturated, and polyunsaturated fat were not associated with colon cancer independently of total energy.<sup>92</sup>

Prospective cohort studies of colon cancer are less prone to selection and recall bias. Earlier prospective data have shown positive,<sup>93,94</sup> inverse,<sup>95,96</sup> and null associations<sup>97,98</sup> with fat or meat consumption. These studies were limited by small number of cases or crude assessments of diet. More recent cohort studies have largely avoided these limitations ([Table 23.1-1](#)). The Nurses' Health Study showed approximately a twofold higher risk of colon cancer among women in the highest compared with those in the lowest quintile of animal fat intake.<sup>99</sup> In a multivariate analysis of these data, which included red meat and animal fat intakes in the same model, red meat intake remained significantly predictive of risk of colon cancer, whereas the association with animal fat was eliminated. A cohort study from the Netherlands showed a significant direct association between intake of processed meats and risk of colon cancer, but no relationship was observed for fresh meats or overall fat intake.<sup>100</sup> A cohort study in Iowa women also found a direct association with processed meats, although this was not statistically significant.<sup>101</sup> Among a large cohort study of men, a direct association between red meat consumption and risk of colon cancer was seen, but no association was observed with other sources of fat.<sup>102</sup> In this study, no overall relationship existed between total or saturated fat and colon cancer despite a substantial range in fat intake. A similar association was noted for colorectal adenomas in the same cohort of men.<sup>73</sup> In the large American Cancer Society Cohort,<sup>103</sup> little relation was seen between either meat or fat intake and mortality caused by colon cancer, but the dietary questionnaire was brief and of uncertain validity. As noted in [Table 23.1-1](#), other cohort studies have also failed to support an association with fat intake, even though positive associations with red meat were usually observed.

Study	Population	Cases	Relative Risk for High versus Low Intake		
			Energy	Total Fat	Meat
Miles et al., 1989 <sup>99</sup>	88,721 U.S. women	138	1.06	1.88	1.05, beef, main dish; 1.02, processed meat
Beck et al., 1994 <sup>100</sup>	35,214 U.S. women	112	1.06	1.88	1.05, beef, main dish; 1.02, processed meat
Colthart et al., 1994 <sup>101</sup>	138,882 Dutch men and women	103	0.74	1.07	1.17 (per 1 g processed)
Comas et al., 1994 <sup>102</sup>	47,940 U.S. men	309	0.94	1.09	1.02, beef, main dish
Thun et al., 1997 <sup>103</sup>	294,260 U.S. men and women	1,024	—	1.24 (meat)	—
Geertman et al., 1997 <sup>104</sup>	30,220 Norwegian men and women	148	0.70	1.20	1.08 (total fat); 1.07 (meat)
Sporn et al., 1997 <sup>105</sup>	34,727 New York men	188	—	1.08	1.02 (meat)
Yang et al., 1997 <sup>106</sup>	17,028 Taiwanese men	138	—	—	1.01 (total fat)
Singh and Patten, 1997 <sup>107</sup>	32,222 Adventist men and women	137	—	—	1.01 (total fat); 1.01 (meat)

**TABLE 23.1-1.** Large Prospective Studies of Colon Cancer: Energy, Fat, and Meat

The apparently stronger association with red meat compared with fat intake in most recent cohort studies needs further confirmation, but could result if the fatty acids or nonfat components of meat (e.g., the heme iron or carcinogens created by cooking) were the primary etiologic factors. This issue does have major practical implications as current dietary recommendations<sup>104</sup> support the daily consumption of red meat as long as it is lean. Virtually no data exist on the relation of dietary fat to survival from colon cancer.

## FAT AND PROSTATE CANCER

Consumption of animal fat, but not vegetable fat, is strongly correlated with prostate cancer mortality internationally.<sup>15</sup> Associations with fat intake have been seen in many case-control studies,<sup>105,106,107,108,109,110,111,112,113</sup> and <sup>114</sup> but sometimes only in subgroups. In a large case-control study among various ethnic groups within the United States,<sup>115</sup> consistent associations with prostate cancer risk were seen for saturated fat, but not with other types of fat.

The association between fat intake and prostate cancer risk has been assessed in only a few cohort studies ([Table 23.1-2](#)). In a cohort of 8000 Japanese men living in Hawaii, no association was seen between intake of total or unsaturated fat.<sup>116</sup> However, diet was assessed with a single 24-hour recall in this study so the lack of association may not be informative. In a study of 14,000 Seventh-Day Adventist men living in California, a positive association between the percentage of calories from animal fat and prostate cancer risk was seen, but this was not statistically significant.<sup>117</sup> More recently, three large prospective studies have been published. In the Health Professionals Follow-up Study of 51,000 men, a positive association was seen with intake of red meat and total and animal fat, which was largely limited to aggressive prostate cancers.<sup>118</sup> No association was seen with vegetable fats. In another cohort from Hawaii, increased risks of prostate cancer were seen with consumption of beef and animal fat.<sup>119</sup> In contrast, no relation was seen between intakes of either total or saturated fat and incidence of prostate cancer in a large Dutch cohort.<sup>120</sup>

Study	Population	Cases	Relative Risk for High versus Low Intake	
			Total Fat	Saturated Fat
Seeman et al., 1989 <sup>116</sup>	8000	174	0.9	1.0
Mills et al., 1989 <sup>117</sup>	14,000	180	—	1.4 (animal fat)
Comazzi et al., 1995 <sup>118</sup>	52,000	125	1.8	1.6
				(aggressive cases)
Le Marchand et al., 1994 <sup>119</sup>	30,516	199	—	1.6 (animal fat)

**TABLE 23.1-2.** Prospective Studies of Dietary Fat and Prostate Cancer Risk

Although further data are desirable, the evidence from international correlations, case-control, and cohort studies provides some support for an association between consumption of fat-containing animal products and prostate cancer incidence. This evidence does not generally support a relation with intake of vegetable fat, which suggests that either the type of fat or other components of animal products are responsible. Some evidence also suggests that animal fat consumption may be most strongly associated with aggressive prostate cancer, which suggests an influence on the transition from the widespread indolent form to the more lethal form of this malignancy. No data are available on fat intake in relation to the probability of survival after the diagnosis of prostate cancer.

## OTHER CANCERS

Rates of other cancers that are common in affluent countries, including those of the endometrium and ovary, are, of course, also correlated with fat intake internationally. Although these have been studied in a small number of case-control investigations, consistent associations with fat intake have not been seen.<sup>121,122,123,124,125,126,127,128,129</sup> and <sup>130</sup> In a prospective study among Iowa women,<sup>131</sup> no evidence of a relation between fat intake and risk of endometrial cancer was observed. Positive associations have been hypothesized between fat intake and risks of skin cancer<sup>132</sup> and lung cancer, but relevant data in humans are limited.

## SUMMARY

Based largely on the results of animal studies, international correlations, and a few case-control studies, great enthusiasm developed in the 1980s that modest reductions in fat intake would have a major effect on breast cancer incidence. However, as the findings from large prospective studies have become available, support for this relationship has weakened considerably. For colon cancer, the associations seen with animal fat internationally have been supported in numerous case-control and cohort studies. However, more recent evidence has suggested that this might be explained by factors in red meat other than simply its fat content. Further, the importance of physical activity and leanness as protective factors against colon cancer indicates that international correlations probably overstate the contribution of diet to differences in colon cancer incidence. At present, the available evidence most strongly suggests an association between animal fat consumption and risk of prostate cancer, particularly the aggressive form of this disease. As with colon cancer, the possibility remains that other factors in animal products contribute to risk.

Despite the large body of data on dietary fat and cancer that has accumulated since 1985, any conclusions should be regarded as tentative because we are dealing with disease processes that are poorly understood, but that are likely to take many decades to develop. As almost all of the reported literature from prospective studies is based on less than 15 years of follow-up, further evaluation of the effects of diet earlier in life and at longer intervals of observation will be needed to understand fully these complex relationships. Nevertheless, persons interested in reducing their risk of cancer could be advised, as a prudent measure, to minimize their intake of foods high in animal fat, particularly red meat. Such a dietary pattern is also likely to be beneficial from the standpoint of cardiovascular disease. On the other hand, unsaturated fats (with the exception of *trans* fatty acids) reduce blood low-density lipoprotein cholesterol levels and risk of cardiovascular disease<sup>133</sup> and little evidence suggests that they adversely affect cancer risk. Thus, efforts to reduce unsaturated fat intake do not appear to be warranted at this time and may have adverse effects on cardiovascular disease. As excess adiposity adversely affects risks of several cancers and cardiovascular disease, balancing calories from any source with adequate physical activity is extremely important.

## INTRODUCTION

The hypothesis linking high intakes of dietary fiber with reduced risk of colorectal cancer in humans was advanced in the early 1970s by Burkitt, who observed that certain chronic diseases common to westernized societies, including colon cancer, diverticular disease, gallstones, and ischemic heart disease, were rare among African populations whose diets consisted predominantly of high-fiber foods.<sup>1</sup> Since that time, a compelling body of epidemiologic evidence, experimental data, and clinical research has found that diets high in fiber, grains, cereals, and fresh vegetables and fruits are associated with reduced risk of several cancers, including cancers of the colon, rectum, and breast, and possibly with lowered risk for additional cancers of the alimentary canal (mouth, esophagus, pharynx, stomach) and other hormone-sensitive cancers (ovarian, endometrial, and prostate cancers).<sup>2,3,4,5,6,7,8 and 9</sup>

Despite a substantial body of research suggesting that diets high in fiber-rich foods protect against certain cancers, results from epidemiologic and animal studies investigating the effect of dietary fiber on cancer risk are not entirely consistent.<sup>6,9,10,11 and 12</sup> The type or source of fiber consumed, temporal nature of consumption (current versus past intake), overall eating patterns, familial predisposition to certain cancers, cancer site, and other nutrients found in high-fiber foods (e.g., folate; antioxidants such as vitamins C and E and selenium; and phytochemicals such as carotenoids, phytoestrogens, organosulfides, and isothiocyanates) may all influence cancer risk.<sup>5,8,10,13</sup> Also at issue are the complexities of fiber and the lack of standardized analytical methods for extracting and quantifying the fiber content of food; the differential effects of the various types of fiber on gut physiology; the effect of storage, processing, and food preparation on the physical and chemical nature of fiber; the lack of comprehensive food composition data on types of dietary fiber and total fiber; and problems with dietary assessment methods, such as recall bias.<sup>14,15</sup> Inconsistencies in animal studies may be related to the species and strain of animal used; the type (i.e., an initiator versus promoter) and amount of carcinogen administered; the type and amount of fiber; the overall composition of the animal's diet; the timing of administration of fiber, in relation to the carcinogenic process; and the length of the study.<sup>16</sup>

## SOURCES AND TYPES OF DIETARY FIBER

Dietary fiber is a heterogeneous mixture of complex, plant-based carbohydrates that are resistant to digestion by human intestinal enzymes. High-fiber foods include whole grains, vegetables, fruits, beans, nuts, and seeds (Table 23.2-1). The skins of many vegetables and fruits and the bran layers of grains also are good sources of fiber. Components of dietary fiber in plant foods vary with plant species, stages of maturity, and parts of the plant. Further, although one or two types of fiber may predominate in a particular food, most plants contain a variety of fiber types or components. Grains, roots, green leafy vegetables, legumes, and some fruits such as apples contain high levels of cellulose and hemicelluloses. Another component of fiber, lignin, is found in the walls of plant cells and increases as the plant matures. Most fruits contain pectin, but citrus fruits and apples contain the highest amounts of this fiber component.

TABLE 23.2-1. Dietary Fiber Content of Commonly Consumed Vegetables, Fruits, and Whole-Grain Products

The two primary types of fiber are categorized as soluble and insoluble, according to their degree of solubility in water.<sup>5,17</sup> Fibers also are described in terms of their fermentability characteristics (Table 23.2-2). Soluble fibers attract water, form a gel during digestion, and generally are fermentable. Insoluble fibers, in contrast, are insoluble in water and usually are nonfermentable. Different types of dietary fibers in commonly consumed plant foods are grouped further according to their chemical structure, as nonstarch polysaccharides and lignin, a polymer of aromatic alcohols. Nonstarch polysaccharide plant fibers include cellulose, hemicelluloses, pectins, gums, mucilages, and other miscellaneous polysaccharides. Soluble, fermentable gel-forming fibers include pectins, gums, starches, some hemicelluloses, and other polysaccharides and are present at the highest levels in fruits, oats, beans, and vegetables. Whole grains and whole-grain foods are primary sources of insoluble, nonfermentable *structural* fibers such as cellulose, most hemicelluloses, and lignins.<sup>5</sup>

	Soluble Fiber	Insoluble Fiber
Source fiber components	Gums, mucilages, pectins, some hemicelluloses	Cellulose, lignin, some hemicelluloses
Benefits	May help in reducing blood cholesterol and controlling blood glucose levels	May help prevent colon cancer, help prevent constipation
Good sources	Orchard fruits, beans, kidney beans, lentils, peas, or chickpeas, vegetables, and fruits	Whole-wheat bread, bran cereals, kidney beans, or lentils, cereals, and the skins of vegetables and fruits

**TABLE 23.2-2.** Benefits and Examples of Good Sources of Both Soluble and Insoluble Fiber

The type and characteristics of the fiber contained in different foods influence normal gut activity and appear to have a differential effect on cancer risk, as discussed in the following sections.<sup>5,11,17,18</sup>

## DIETARY FIBER AND COLORECTAL CANCER

### SUMMARY OF EPIDEMIOLOGIC AND EXPERIMENTAL EVIDENCE

International colon cancer incidence rates vary by a factor of 20 or more, and a large proportion of that difference is believed to be a result of various dietary factors, including certain types of fiber.<sup>8,10</sup> Overall, results of international comparisons and correlation and case-control studies support the hypothesis that high-fiber intakes reduce risk for colorectal cancer. In these studies, total dietary fiber intake and consumption of cereal fiber and whole grains show a consistent reduction in risk for colorectal cancer.<sup>3,7</sup> A metaanalysis of data from 13 case-control studies reported a 50% reduction in risk for colorectal cancer when the highest versus lowest quintiles of fiber intake were compared.<sup>15</sup> Results of prospective cohort studies are mixed, with most showing either only weak protective associations<sup>20,21</sup> or no statistically significant relationship<sup>22,23</sup> between fiber intake and risk of cancers of the colon or rectum. Differences in the findings of these and other epidemiologic studies likely result in part not only from the heterogeneous nature of fiber, the way in which fiber is measured, and the problems associated with collection of dietary intake data, but also with the relatively homogeneous fiber intakes across the study cohorts.<sup>8</sup>

Data from both epidemiologic and basic research studies suggest that the various types of fiber confer a differential effect on colorectal cancer risk. One international study of 20 populations in 12 countries reported a strong inverse relationship between starch consumption and risk for colorectal cancer.<sup>24</sup> Another study found that soluble but not insoluble fiber, and fiber from fruits but not vegetables, had a protective effect on the development of distal colon adenoma in men.<sup>25</sup> Results of a case-control study of nearly 2000 patients with confirmed colorectal cancer and more than 4100 controls with no history of cancer indicated that total fiber intake, and particularly intake of cellulose, soluble noncellulose polysaccharides, and fiber of vegetable and fruit origin, was associated with a reduction in the risk of cancers of the colon and rectum.<sup>26</sup> Reviews of animal studies investigating the effect of different types of dietary fiber on colon tumorigenesis generally report that the greatest protective effect, as measured by lowered incidence (number of animals with tumors) and multiplicity (number of tumors per animal with tumors) of small intestine and colon tumors, is conferred by insoluble fibers, in particular wheat bran, whereas soluble fibers may increase risk.<sup>5,8,16,27</sup>

The growing interest in the potential effect of wheat bran fiber on colorectal cancer risk has been the focus of several reviews.<sup>16,28,29</sup> Wheat bran, which contains more than 70% of the fiber of the whole grain, is rich in lignin and polysaccharides.<sup>29</sup> Numerous animal studies show wheat bran fiber to be as or more effective than other fiber sources, such as corn and oat, in inhibiting or preventing colon tumor growth.<sup>16,27,29,30</sup> In some studies, however, dietary wheat bran fiber either had no effect on the development of colon tumors in rats or increased colon tumorigenesis.<sup>16,27</sup> Several epidemiologic studies and clinical interventions also have investigated the effect of different dietary fibers, including wheat bran, on factors associated with increased risk for colorectal cancer, including colonic or rectal cell proliferation, bile acid excretion, fecal mutagens, and activity of several intestinal bacterial enzymes linked with the production of carcinogenic substances.<sup>16</sup> Results of these studies indicate that wheat bran has a favorable, and sometimes more favorable, effect when compared with other sources of fiber, on these factors. The cancer-protective effects of wheat bran may be the result, at least in part, of various compounds, including the fermentation product butyrate<sup>16</sup> and certain constituents of wheat bran, including phytic acid,<sup>31,32</sup> phenolic acids,<sup>29</sup> and phytoestrogens,<sup>33,34</sup> all of which have shown a cancer-protective effect in either, or both, epidemiologic and animal studies.

### POTENTIAL INFLUENCES OF DIETARY FIBER ON GENETICALLY LINKED COLORECTAL CANCERS

Approximately 10% to 15% of all cases of colorectal cancers are believed to result from genetic predisposition to these cancers.<sup>35,36</sup> Two inherited genetic forms of colorectal cancer, familial adenomatous polyposis and hereditary nonpolyposis colon cancer, are associated with up to an 80% lifetime risk of developing the disease.

The potential of a high-fiber diet, or fiber supplementation, to modulate cancer risk in at-risk or high-risk individuals who have a genetic predisposition to colorectal cancer has been studied and further investigations are under way. One clinical trial found that supplementing the diet with at least 11 g of wheat bran fiber per day significantly reduced the recurrence of rectal adenomas in patients with familial adenomatous polyposis.<sup>37</sup> Results of the Australian Polyp Prevention Project indicated that consuming high levels of dietary fiber supplementation (25 g wheat bran fiber per day) or a low-fat diet (25% of total calories) for 2 to 4 years reduced risk (but not to a level of statistical significance) of developing new, large adenomas (diameter greater than or equal to 10 mm) in healthy individuals who had had at least one colonic polyp removed before the start of the study.<sup>38</sup> Participants following a combined low-fat, high-fiber diet had no large adenomas at both 2 and 4 years, a finding that was statistically significant ( $P < .03$ ). The European Concerted Action Polyp Prevention studies are examining the role of a variety of preventive strategies, including daily dietary supplementation with resistant starch, in high-risk persons with a family history of either familial adenomatous polyposis or hereditary nonpolyposis colon cancer.<sup>35,36</sup>

### PROPOSED MECHANISMS OF ACTION

Several mechanisms by which dietary fiber may protect against colon cancer have been proposed.<sup>5,18,29,39</sup> These mechanisms include both direct and indirect actions on the alimentary and gastrointestinal canals that are related to properties of fiber, such as solubility and fermentability; actions may occur at the physical, chemical, cellular, and/or molecular levels.

One direct mechanism by which fiber may reduce the risk of colorectal cancer is through the absorption of water by insoluble dietary fiber; this action increases fecal bulk, diluting the concentration of carcinogens in the feces, and decreases transit time, reducing the effective interaction of carcinogens with colonic mucosal cells.<sup>5,11,17,18</sup> The direct binding of carcinogens to insoluble dietary fibers, such as wheat bran, cellulose, and lignin, similarly reduces the potential interaction between carcinogens and cells within the bowel.<sup>5,40</sup> Indirect mechanisms by which dietary fiber may lower colorectal cancer risk include stimulation of microbial growth, which increases fecal bulk and the production of short chain fatty acids (SCFAs); alteration of bile acid production; influence on the production of factors that affect cell proliferation, such as diacylglycerol, p21, and protein kinase C; and reduction of luminal pH, largely as a result in increases in SCFAs, especially butyrate.<sup>5,16,39,40,41,42</sup> and<sup>43</sup>

Products of fiber fermentation, particularly butyrate, appear to have a beneficial, antineoplastic effect in the bowel.<sup>44</sup> Several studies suggest that, compared with other SCFAs, butyrate most consistently protects against the development of colon tumors in the rat by acting through a variety of mechanisms, including blocking the proliferative action of carcinogens and other cancer-promoting agents such as bile acids, inducing cell differentiation, lowering concentrations of secondary bile acids, reducing the mutagenicity of fecal water, and enhancing programmed cell death (apoptosis) in human colorectal cancer cell lines.<sup>5,16,18,36,39,44,45</sup> Acting at the molecular level, butyrate stimulates histone acetylation by inhibiting the enzyme histone deacetylase, which, in turn, makes certain sections of the DNA molecule more accessible to factors (e.g., proteins known as *transcription factors*) that control gene expression.<sup>46</sup> The effects of butyrate on histones appear to be through induction of the *p21* gene and subsequent production of the p21 protein, which slows the growth of cancer cells.<sup>46,47</sup> Butyrate also decreases the expression of the transcription factors c-fos and c-jun, acting, in turn, to reduce proliferative activity.<sup>5,36,39</sup>

Experimental data show that dietary wheat bran fiber reduces the formation of early markers of colon cancer associated with carcinogen-induced disease, such as the number of aberrant crypts or foci, and alters the colonic environment in several other ways, such as increasing fecal bulk, decreasing transit time, adsorbing to carcinogens, and stimulating the production of butyric acid.<sup>27,29,45</sup> In epidemiologic and clinical intervention studies, wheat bran fiber supplementation favorably modified several putative makers of colorectal cancer, including fecal mutagenicity,<sup>48</sup> concentrations of total and secondary fecal bile acids,<sup>49,50</sup> the activity of bacterial enzymes associated with the production of carcinogenic substances,<sup>49</sup> and rectal proliferation in high-risk individuals.<sup>28,51</sup>

## DIETARY FIBER AND COLORECTAL CANCER AT SPECIFIC SITES

The incidence of cancers at different colon subsites varies by geographic region, with higher proportions of proximal tumors found in less developed countries that have low rates of colorectal cancer and higher proportions of distal and right-sided tumors reported in developed, affluent countries where colorectal cancer rates are high.<sup>8,41</sup> Such observations suggest the possibility of differences in risk factors for colonic tumors at different anatomic subsites. Although data are limited, some studies report that certain dietary constituents may contribute to this variable, site-specific risk.

A possible role for dietary fiber in differential risk for cancers in the proximal versus distal colon is suggested primarily from animal studies.<sup>45,52</sup> Soluble fibers, such as guar gum, oat bran, and pectin, are fermented by anaerobic bacteria in the proximal colon, producing large amounts of SCFAs, which are absorbed almost entirely in the proximal colon. In contrast, insoluble and poorly soluble fibers, such as wheat bran, cellulose, and lignin, are fermented along the length of the gut, providing a more continuous supply of SCFAs throughout the intestine, which, in turn, assists in maintaining normal colonocyte proliferation and differentiation. Such fiber-related maintenance of normal cell function and activity likely contributes to the inhibition of tumors in the distal colon in rats fed wheat bran compared with other fiber sources, such as oat bran.<sup>52</sup>

Results of dietary epidemiologic studies have not consistently found similar associations. One case-control study found no difference in risk of cancers of the right colon, transverse and descending colon, sigmoid colon, rectosigmoid junction, or rectum according to total fiber intake.<sup>26</sup> Another case-control study reported the strongest inverse associations between consumption of dietary fiber, whole grains, and vegetables and risk of proximal tumors in both men and women; and between soluble fiber, insoluble fiber, and pectin intake and risk of proximal tumors in women.<sup>53</sup> In contrast, a prospective study of 16,448 men from the Health Professionals Follow-up Study reported a reduced risk of distal colon adenoma as intake of fiber from fruit increased ( $P < .03$  for trend) and an inverse association between soluble, but not insoluble, fiber intake and distal colon adenoma ( $P$  for trend, .007).<sup>25</sup> This study did not examine or compare associations according to other intestinal subsites.

## DIETARY FIBER AND CALCIUM: POTENTIAL INTERACTIONS

An association between dietary calcium or calcium supplementation and reduced colorectal cancer risk has been suggested from the results of epidemiologic, clinical, and experimental research studies.<sup>18,54,55,56</sup> and <sup>57</sup> Mechanisms by which calcium may inhibit colorectal carcinogenesis are similar to those of dietary fiber and include the ability of calcium to bind potentially carcinogenic compounds, such as secondary bile acids; slow proliferation of colonic epithelial cells; and enhance cell differentiation.<sup>54,55,57,58</sup> and <sup>59</sup> These effects of calcium have been reported in both animal and human studies and in *in vitro* experiments.<sup>54,58</sup> Animal experiments further suggest that calcium and fiber may act synergistically in their effect on the colonic environment.<sup>56</sup>

The roles of calcium and fiber on markers for colorectal cancer risk are being studied in several clinical trials. The multicenter European Cancer Prevention Calcium Fibre Polyp Prevention Study is testing the efficacy of oral calcium (2 g/d) or oral dietary fiber supplements (as 3.8 g ispaghula husk, a mucilaginous substance) on adenoma recurrence, colonic cell proliferation, and stool bile acid and sterol concentration.<sup>60,61</sup> Participants include patients from nine European countries who are between 35 and 75 years old at study entry and have at least two adenomas greater than 5 mm in diameter. Preliminary results of another clinical trial showed that high doses of wheat bran fiber (13.5 g/d) or calcium (1500 mg/d), or high doses of fiber plus high doses of calcium, increased both fecal bile acid concentrations and excretion rates.<sup>50</sup> The strongest statistical effect, reflecting an approximate 50% reduction in fecal concentrations of total bile acids and deoxycholic acid, was seen in the high-fiber group. The effect of the combined high-fiber and high-calcium diet on mean fecal bile acid parameters was less than that for either factor alone; the reason for this lack of additivity between the two supplements is not clear but may be caused by cross-interference with each agent's putative effects on bile acids. A subsequent analysis of the same study reported that neither level of wheat bran fiber or calcium supplementation significantly reduced [<sup>3</sup>H]thymidine labeling index percentages in rectal mucosal crypts.<sup>62</sup> These preliminary findings suggest that a primary mechanism by which wheat bran fiber and calcium may protect against colon cancer is through reducing fecal bile acid concentrations.

## ONGOING NATIONAL CANCER INSTITUTE CLINICAL TRIALS

The National Cancer Institute (NCI) is evaluating the role of dietary fiber in the prevention of colorectal cancer in humans through several clinical trials. The Polyp Prevention Trial, for example, allows for the simultaneous investigation of the effect of three dietary components on recurrence of polyps in the large bowel.<sup>63,64</sup> and <sup>65</sup> Polyp Prevention Trial study participants include men and women at least 35 years old who have had one or more adenomas removed within 3 months of randomization. The primary objective of the Polyp Prevention Trial is to determine whether a diet that is low in fat (20% of calories from fat), high in fiber (18 g fiber/1000 calories), and high in vegetable and fruit intake (five to eight daily servings) will decrease the recurrence of large bowel polyps. The trial also is evaluating the relationship between dietary modification and biochemical markers in the blood and validating promising intermediate endpoint markers of large bowel carcinogenesis with respect to polyp recurrence.

Another NCI-supported study, the Women's Health Initiative Clinical Trial and Observational Study, is investigating several strategies for the prevention and control of cancer, cardiovascular disease, and osteoporotic fractures in postmenopausal women 50 to 79 years old.<sup>66</sup> The Clinical Trial, which anticipates an enrollment of 64,500 participants, is a randomized, controlled evaluation of three interventions: (1) a goal of a low-fat (20% of calories) eating pattern that includes at least five servings of vegetables and fruits and six or more servings of grain products per day, hypothesized to prevent breast cancer and colorectal cancer and, secondarily, coronary heart disease; (2) hormone replacement therapy; and (3) calcium (1000 mg/d) and vitamin D<sub>3</sub> (400 IU/d) supplementation (or placebo), hypothesized to prevent hip fractures and, secondarily, other fractures and colorectal cancer. A prospective surveillance (the Observational Study) will enroll an additional 100,000 women to identify new etiologic factors and biologic predictors of disease and community-based interventions. The Women's Health Initiative was initiated in 1992 and is scheduled to end in 2007.

The double-blind, placebo-controlled Arizona Phase III cancer prevention trial, also funded by NCI, is examining how supplementing the diet with large versus small doses of wheat bran fiber (13.5 vs. 2.0 g/d) alters the molecular genetics of polyp tissue in patients with previously resected adenomatous colon polyps.<sup>67,68</sup> Genetic changes will be compared with dietary factors and bile acid profiles. Approximately 945 participants have fulfilled all aspects of the study protocol in this 3-year dietary intervention, which is nearing completion.

## DIETARY FIBER AND BREAST CANCER

### SUMMARY OF EPIDEMIOLOGIC AND EXPERIMENTAL RESEARCH

Evidence from both epidemiologic and experimental studies suggests a protective role for fiber in the prevention of breast cancer, although the exact role of fiber on breast cancer development is not yet clear.<sup>2,12,69</sup> One review, a metaanalysis of the original data from 12 case-control studies of populations with widely varying breast cancer risks and dietary habits, reported a significant reduction in breast cancer risk among women in the highest versus lowest quintiles of fiber intake, both before and after adjusting for fat intake.<sup>70</sup> A more recent review found that four of four ecological studies and nine of ten case-control studies showed an inverse correlation between either cereal consumption or fiber intake and breast cancer risk; in the five case-control studies reporting a statistically significant decrease in breast cancer risk among women consuming a high-fiber diet, the odds ratios ranged from 0.46 to 0.60. All four prospective cohort studies included in this review reported either no change in breast cancer risk or a nonsignificant decrease in risk in association with cereal or fiber intake.<sup>9</sup> Another study of international breast cancer mortality data and dietary intake data found that both current and past cereal intake were inversely correlated ( $P < .0001$ ) with breast cancer mortality.<sup>12</sup> Further evidence suggests that diets rich in fruits and vegetables, particularly green vegetables, protect against the development of breast cancer.<sup>8</sup>

The combination of a high-fiber, low-fat diet also has been associated with reduced risk for breast cancer, with evidence from both epidemiologic and animal studies suggesting that the proposed protective effect of fiber may occur independently of dietary fat content.<sup>8,71,72</sup> It also has been postulated that a high-fiber diet may modulate the risk of breast cancer associated with a high-fat diet.<sup>73</sup> Experiments in rats support the hypotheses that dietary fiber, including wheat bran and psyllium,<sup>74,75</sup> protects against breast cancer and that dietary fiber may block the promotion of mammary tumors by fat.<sup>72</sup>

### PROPOSED MECHANISMS

Research indicates that reproductive hormones, especially estrogens, are involved in the development of breast cancer. <sup>8,76</sup> The mechanisms by which fiber alters hormone production, metabolism, and bioavailability focus on the ability of fiber to bind estrogen in the small intestine, thereby both increasing the excretion and reducing the enterohepatic circulation of hormones, <sup>9,77,78</sup> and on the biologic activity of phytoestrogens, compounds present in fiber-rich foods that possess weak estrogenic and antiestrogenic activity. <sup>33,77,79</sup>

High-fiber intake and diets rich in fiber and low in fat or high in vegetables, fruits, and soy-based foods are associated with low plasma levels of all major biologically active sex hormones, including free estradiol and testosterone; high levels of sex-hormone binding globulin; and low urinary and high fecal estrogen and androgen excretion. <sup>9,80,81</sup> In one intervention study, the diets of 62 premenopausal women were supplemented with 15 g of wheat, corn, or oat bran per day, essentially doubling daily intake of fiber. <sup>82</sup> Luteal phase serum levels of both estrone and estradiol were significantly reduced following addition of fiber to the diet. A subsequent study found that supplementing the diet of premenopausal women with 10 or 20 g of wheat bran fiber per day for 1 to 2 months significantly reduced serum estrone during both the luteal and follicular phases of the menstrual cycle; serum sex-hormone binding globulin concentrations were unaffected. <sup>83</sup>

Dietary phytoestrogens (i.e., isoflavonoids and plant lignans) are found in a variety of high-fiber foods such as fruits, berries, seeds, soy products, and flaxseed and in grain and vegetable fibers. <sup>33</sup> Two common isoflavonoids are genistein and daidzein; two mammalian lignans, enterolactone and enterodiol, are formed from plant lignans by the action of intestinal bacteria. Urinary concentrations of these lignans have been found to correlate directly with consumption of foods containing phytoestrogens. <sup>79,84,85</sup> A review of 26 animal studies in which the animals' diets were supplemented with soy or soybean isoflavonoids found a cancer-protective effect in 65% of the studies, as reflected by reductions in tumor incidence, latency, or number. <sup>34</sup> Results of both *in vitro* and *in vivo* animal studies suggest that phytoestrogens mimic the activity of and compete with endogenous estrogens by binding to estrogen receptors. <sup>33</sup> Although the affinity of phytoestrogens to estrogen receptors is tens to thousands of times lower than that of endogenous estrogens, the ability of these plant-based compounds to bind to estrogen receptors permits a dual, dose-dependent effect on mammary tumor initiation and growth. At lower doses, *in vitro* experiments show that phytoestrogens can increase the mitogenic activity of breast cancer cells. <sup>86</sup> In contrast, higher doses of phytoestrogens inhibit mammary tumor development, <sup>77</sup> suppress the growth of established tumors, <sup>77</sup> and inhibit the proliferation of human breast cancer cells that require estrogen to replicate. <sup>33,34</sup> Phytoestrogens also induce the production of sex-hormone binding globulin in the liver and inhibit the enzyme aromatase, which catalyzes the conversion of androstenedione to estrogen and testosterone to estradiol; through these two actions, phytoestrogens indirectly reduce the concentration and availability of circulating sex hormones and possibly contribute to reduced risk for breast cancer. <sup>77</sup>

## DIETARY FIBER AND OTHER CANCERS

Limited epidemiologic evidence suggests that high-fiber intake, consumption of fiber-rich foods, or both may lower risk of cancers of the mouth, esophagus, pharynx, larynx, stomach, <sup>6,8,87</sup> ovary, endometrium, and prostate. <sup>6,7,88,89</sup> The evidence for a cancer-protective role of fiber at these sites is not as strong as for colorectal or breast cancer, however. <sup>8</sup> Dietary fiber may protect against these alimentary canal cancers through many of the same mechanisms suggested for the modulation of colorectal cancer risk and influence risk of these hormone-dependent cancers by affecting the bioavailability of both estrogens and androgens. <sup>5</sup>

## PUBLIC HEALTH IMPLICATIONS

In addition to its proposed protective effects against colorectal cancer, breast cancer, and possibly other cancers, dietary fiber as total fiber, whole grains, cereal fiber, soluble fiber, undigested fiber, fiber-rich foods, psyllium, or dietary flavonoids has been associated with reduced risk of other conditions important to public health, including cardiovascular diseases <sup>90,91</sup> and type II diabetes. <sup>90</sup> Because of the significant health benefits afforded by fiber-rich foods, individuals and the public at large are encouraged to consume a diet that includes a wide variety of vegetables, fruits, and whole grains, with a goal of meeting the NCI's recommended 20 to 30 g of fiber per day. <sup>92</sup> Results of the 1992 National Health Interview Survey, cosponsored by the Census Bureau, the National Center for Health Statistics, and the NCI, indicate that adult Americans consume an average of 10.4 g of fiber per day. The U.S. Department of Agriculture's (USDA) Nationwide Food Consumption Survey found a higher overall consumption rate for fiber among American adults, with a mean intake of 14 g/d. <sup>93</sup> Although these values are well below the recommended intake levels, it is encouraging that fiber intake increased among all Americans and in all subgroups in the National Health Interview Survey between 1987 and 1992 <sup>94</sup> and among all surveyed in the USDA's Continuing Survey of Food Intake by Individuals between 1989 through 1991 and 1994. <sup>95</sup>

Several national programs have been instituted to increase both fiber intake and consumption of fiber-rich fruits and vegetables. For example, the 5 A Day for Better Health Program, sponsored by the NCI in partnership with the Produce for Better Health Foundation, includes retail, community, and research components as well as a national media campaign that encourages Americans to eat five or more servings of vegetables and fruits each day as part of a low-fat, high-fiber diet. <sup>96,97</sup> and <sup>98</sup> The USDA's Food Guide Pyramid suggests that fiber-containing breads and grains, followed by vegetables and fruits, should form the foundation of an individual's diet. Recommended are 6 to 11 servings of breads and grains per day, 2 to 4 servings of fruits per day, and 3 to 5 servings of vegetables per day. <sup>96</sup> The 1989 through 1991 USDA Continuing Survey of Food Intakes in Individuals found that, overall, Americans met the minimum basic recommended intakes for breads and grains (mean, 5.7 servings per day) and vegetables (mean, 3.3 servings per day), but failed to meet the recommended intake for fruits (mean, 1.3 servings per day). <sup>100</sup> The subsequent 1994 USDA survey reported significant ( $P < .0005$ ) increases in intakes of vegetables, fruits, and grains when compared with data from the 1989 through 1991 survey. <sup>95</sup> A comprehensive review of seven nationally representative surveys of food and nutrient consumption among Americans similarly reported significant ( $P < .0001$ ) increases in per capita intakes of vegetables (19%), fruits (22%), and grain products (47%) during the 24-year period from 1970 to 1994. <sup>95</sup>

To help consumers increase fiber intake, the Food and Drug Administration required fiber content to be included on the nutrition facts panel on food labels. In addition, foods containing 10% of the daily value for fiber (i.e., 2.5 g of fiber per serving) may be labeled a "good source" of fiber, and products containing 20% or more of the daily value for fiber (at least 5 g of fiber per serving) can claim to be "high in," "rich in," or "an excellent source" of fiber. <sup>90</sup> The Food and Drug Administration also allows manufacturers to make certain health claims related to fiber intake and lowered risk of cancer and other health conditions for foods meeting specific eligibility criteria. <sup>91</sup>

Results of successful nutritional intervention programs incorporating components of the 5 A Day for Better Health Program and other similar guidance, in conjunction with data from national dietary intake surveys, suggest that Americans are receiving and implementing messages designed to promote healthier eating patterns that include increased consumption of fiber, vegetables, fruits, and whole grains. Research, including ongoing clinical trials, will continue to augment current knowledge and refine recommendations. While such research is being conducted, the complement of data indicates that a varied diet that is low in fat and high in plant-based foods likely protects against several cancers, most notably colorectal cancer, as well as other major diseases, including cardiovascular diseases and diabetes.

## INTRODUCTION

*Cancer chemoprevention* can be defined as pharmacologic intervention with specific nutrients or other chemicals to suppress or reverse carcinogenesis and to prevent the development of invasive cancer.<sup>1</sup> Two basic concepts support this cancer control strategy: multistep and field carcinogenesis. Carcinogenesis is a chronic, multistep process characterized by the accumulation of specific genetic and phenotypic alterations that can evolve over a 10- to 20-year period from the first initiating event. The premise of human chemoprevention is that one can intervene (and suppress) at many steps in the carcinogenic process and over many years. Field carcinogenesis is a concept that was first described in the early 1950s in the head and neck site as *field cancerization* and subsequently found to apply to many epithelial sites. The concept is that patients at high risk for an epithelial cancer have a wide surface area of carcinogenic tissue change that can be detected at the gross (oral premalignant lesions, polyps), microscopic (metaplasia, dysplasia), and molecular (gene loss or amplification) levels. More recent molecular studies detecting profound genetic alterations in histologically normal tissue from high-risk individuals have provided strong support for the field carcinogenesis concept. The implication is that multifocal, genetically distinct premalignant lesions can progress over a broad tissue region. The clinical importance is best illustrated in head and neck squamous cancer, for which both synchronous and metachronous second primary tumors are common. The latter develop at an annual rate of 5% to 7% in prospective studies<sup>2</sup> and account for the principal cause of cancer death in early-stage disease and in long-term survivors of head and neck cancer, regardless of stage of diagnosis of the first cancer. The essence of chemoprevention, then, is intervention within the multistep carcinogenic process and throughout a wide field.

To date, retinoids (the natural derivatives and synthetic analogues of vitamin A) and one member of the carotenoid class, b-carotene, are among the best-studied agents in human chemoprevention (Fig. 23.3-1). This review focuses on these compounds, with a brief discussion of other micronutrients that have often been evaluated for chemopreventive efficacy along with the retinoids and carotenoids, namely vitamins E and C and the trace mineral selenium.

**FIGURE 23.3-1.** Structures of selected retinoids and the carotenoid, b-carotene. Retinol, 13- *cis* retinoic acid, and b-carotene are naturally occurring; 4HPR and etretinate are synthetic retinoids.

## HISTORICAL PERSPECTIVE

Vitamin A was first recognized as an essential nutrient in 1913 and has been the subject of considerable research in the ensuing years. In 1925, Wolbach and Howe described the histopathologic changes in epithelia associated with vitamin A deficiency.<sup>3</sup> This led to the identification of retinol and some of its naturally occurring retinoid derivatives (see Fig. 23.3-1) and a large body of research aimed at understanding the role of vitamin A and retinoids in cellular differentiation and in neoplastic transformation. Epidemiologic studies of vitamin A and cancer began to emerge in the 1970s, when it was shown that computed indices of total vitamin A intake were associated significantly with lower cancer risk, particularly for lung cancer.<sup>4</sup>

*Vitamin A* is a nonspecific term embracing two families of dietary factors: preformed vitamin A (chiefly retinyl esters, but also retinol and retinal) and the other family consisting of the various provitamin A carotenoids (b-carotene and those other carotenoids that can be metabolic precursors of retinol). Preformed vitamin A is found predominantly in foods of animal origin, whereas provitamin A carotenoids are found predominantly in fruits and vegetables.

Epidemiologic studies conducted in the 1980s and 1990s evaluated the independent associations of preformed retinol and provitamin A carotenoids with cancer in humans. Dietary intake of provitamin A carotenoids, such as b-carotene, but not of retinol, was associated with a lower risk of cancer.<sup>4,5</sup> Interpretation of observational epidemiologic studies is difficult as carotenoids are consumed in the form of fruits and vegetables, which contain numerous other substances, many of which may have cancer preventive properties.<sup>6</sup> In contrast, the primary dietary sources of retinol are animal products, consumption of which tends to be associated positively with cancer risk. Also, blood levels of carotenoids increase with increasing dietary intake, whereas blood levels of retinol are regulated homeostatically. Thus, in evaluating the chemopreventive efficacy of carotenoids and retinoids, one must consider evidence from epidemiologic studies, clinical trials, animal models, and mechanistic considerations. This chapter reviews briefly the biology and pharmacology of retinoids and carotenoids and then focuses on randomized cancer prevention clinical trials involving carotenoids, retinoids, and other selected micronutrients.

## RETINOID BIOLOGY AND PHARMACOLOGY

Retinoids are required for the maintenance of normal cell growth, differentiation, and loss within epithelial tissues. Various retinoids have been shown to suppress or reverse epithelial carcinogenesis and prevent the development of invasive cancer in many animal systems, including skin, lung, oral cavity, esophagus, bladder,

mammary gland, cervix, stomach, prostate, pancreas, and liver. Retinoids act primarily in the postcarcinogen (postinitiation) phases of promotion and progression, which are most relevant to human cancer chemoprevention. Significant single-agent activity has been observed with natural [e.g., all- *trans*-retinoic acid (ATRA), 13-*cis* retinoic acid (13cRA), 9- *cis* retinoic acid (9cRA), retinyl palmitate] and synthetic [e.g., N-(4-hydroxyphenyl) retinamide or fenretinide (4HPR)] retinoids. Additive to synergistic increases in chemopreventive activity have been achieved by combining retinoids with other agents, <sup>7,8,9,10 and 11</sup> such as the combination of 4HPR or 9cRA with tamoxifen in mammary carcinogenesis systems.

The term *retinoid* was redefined in 1985 by Sporn and Roberts<sup>12</sup> to include a substance that binds and activates one or more specific receptors, the latter producing a biologic response. Much has been learned about the specific receptors and mechanisms of action for the retinoids. The retinoid molecular mechanism of action is similar to that of steroid/thyroid hormones in that retinoid nuclear receptors are members of the steroid receptor superfamily. <sup>13,14</sup> These elusive nuclear receptors were discovered simultaneously by two groups of investigators and reported in 1987. The subsequent studies indicate that retinoid receptors are unique from other members of the steroid receptor family in that there are two receptor classes, RARs and RXRs. Each receptor contains a, b, and g subtypes, and several of these subclasses have multiple isoforms. These receptors are DNA-binding transcription factors that can activate or suppress the expression of many genes, the products of which mediate retinoid effects on cell growth, differentiation, and apoptosis. Different retinoids bind to the different receptor classes and subclasses with different affinities. This receptor complexity and great diversity in ligand binding, activation, and receptor function has important preventive and therapeutic implications.

As with other members of the steroid family, retinoid receptors are active only as dimers. Two retinoid receptor dimer types have been identified: RAR-RXR heterodimers, and RXR-RXR homodimers (RAR-RAR homodimers have not been identified). Part of the retinoid receptor binds to the ligand, and part binds to specific DNA sequences (RARE or RXRE) and either induces or suppresses gene transcription. The best characterized pathway involves RAR-RXR heterodimers. RXRs have been shown to form heterodimers with other members of the steroid receptor family, including the vitamin D receptor and thyroid hormone receptor. RXRs and their ligands, therefore, can modulate the activities of other steroid hormones. <sup>15</sup> The different ligand-binding patterns can be illustrated with the three major natural retinoic acid derivatives, 13cRA, ATRA, and 9cRA, which are found endogenously in human plasma, albeit at low physiologic levels. RARs bind ATRA and 9cRA, and RXRs bind only 9cRA. 13cRA does not bind directly to nuclear receptors, but is rapidly isomerized to ATRA. Ligand binding stabilizes the receptor dimers and activates gene transcription. <sup>13,14</sup>

The retinoid receptor distribution pattern in normal and neoplastic human tissue is under intense study. The tissue distribution of these receptor classes, subclasses, and isoforms varies greatly in normal and pathologic conditions and in different sites within the human body. In normal tissue, RAR-a is expressed in most tissues, RAR-b expression is more limited (e.g., not expressed in the skin), and RAR-g is expressed predominantly in the skin. In cancer, these normal tissue patterns can change (e.g., RAR-b is lost in aerodigestive tract carcinogenic progression).

More than 1000 retinoids have been synthesized. <sup>7,12,16,17 and 18</sup> Current intensive efforts to develop more active and less toxic retinoids for cancer prevention and therapy are directed to the study of which retinoid receptors mediate retinoid effects on cell growth, differentiation, and apoptosis in different systems and the synthesis of new receptor-selective ligands to obtain the desired retinoid pharmacologic effect. <sup>17,18</sup> An exciting development for chemoprevention is the finding that certain retinoids can interfere with the activity of certain transcription factors such as AP-1 and, therefore, inhibit neoplastic cell proliferation. <sup>17</sup> Mechanistic studies of retinoid pharmacology provide a basis for rational retinoid development programs for chemoprevention. <sup>18</sup>

## CAROTENOID BIOLOGY AND ACTIONS

As described by Krinsky,<sup>19</sup> carotenoids have both biologic functions and actions. Carotenoids function as accessory pigments in photosynthesis, via singlet excited carotenoid; offer protection against photosensitization, via triplet excited carotenoid; and some serve as provitamin A compounds, via central and eccentric cleavage. Mechanisms for these functions are reasonably well characterized. Carotenoids also have been reported to have a number of biologic actions, including antioxidant activity, immunoenhancement, inhibition of mutagenesis and transformation, and regression of premalignant lesions. In contrast to the carotenoid functions, mechanisms of carotenoid action are far from clear. Some of the actions of carotenoids, such as regression of premalignant lesions, are shared by the retinoids, with the potential for a similar mechanism of action. The identification of retinoid cleavage products from carotenoids <sup>20</sup> certainly suggests that retinoids and carotenoids may share not only structural similarities and *vitamin A* activity, but perhaps other mechanisms of action that are not fully appreciated at present. However, carotenoids and retinoids also have distinct differences in action, the most notable of which includes antioxidant activity.

Many carotenoids including b-carotene have the ability to quench singlet oxygen, a highly reactive form of oxygen. The quenching involves a physical reaction in which the energy of the excited oxygen is transferred to the carotenoid, forming an excited state molecule. <sup>19</sup> Quenching of singlet oxygen is the basis for b-carotene's well-known therapeutic efficacy in erythropoietic protoporphyria, a photosensitivity disorder. <sup>21</sup> The ability of b-carotene and other carotenoids to quench excited oxygen, however, is limited, because the carotenoid itself can be oxidized during the process (auto-oxidation). Burton and Ingold <sup>22</sup> and others have shown that b-carotene auto-oxidation *in vitro* is dose dependent and dependent on oxygen concentrations.

In addition to singlet oxygen, carotenoids are also thought to quench oxygen free radicals. A relatively large body of literature has linked oxygen free radicals with carcinogenesis,<sup>23</sup> thus there is considerable interest in antioxidant compounds and antioxidant activity as a mechanism for cancer prevention. Despite the focus on antioxidants and cancer and clear evidence of chemopreventive efficacy of b-carotene in some animal carcinogenesis models, <sup>24</sup> it is not clear that antioxidant activity is responsible for the chemoprotective effects observed in the animal studies. For example, b-carotene-induced immunologic enhancement could have a significant role in tumor inhibition by increasing natural killer cells and activating immunoregulatory lymphocytes important in host defense. <sup>25</sup> Various carotenoids have been reported to affect gap junctional communication, related to their ability to up-regulate the expression of the connexin43 gene. <sup>26</sup> This activity was not related to the antioxidant activities of the various carotenoids. Supplementary b-carotene also has been reported to increase the expression of transforming growth factor- $\beta_1$  in cervical biopsy specimens. <sup>27</sup> These and other potential mechanisms reviewed elsewhere<sup>24</sup> suggest that it is biologically plausible that carotenoids may have chemopreventive activity, although we know far less about mechanisms of action for the carotenoids than the retinoids.

Given the interest in antioxidant activity as a potential mechanism for chemopreventive effects, it is not surprising that other dietary antioxidants have been studied for chemopreventive efficacy, particularly vitamins E and C and selenium. These agents are often evaluated in combination. However, as is the case with b-carotene, these micronutrients may have biologic actions independent of antioxidant activity.

## CLINICAL TRIALS

A number of randomized cancer prevention trials involving carotenoids and retinoids and a few of other micronutrients are ongoing or have been completed. Completed trials involving retinoids are summarized in [Table 23.3-1](#) and those involving carotenoids in [Table 23.3-2](#). Retinoid trials have tested efficacy of several retinoids, including retinol, retinyl palmitate, ATRA, 13cRA, etretinate, and 4HPR. Cancer prevention trials with carotenoids, however, are limited to b-carotene at present. The focus on b-carotene, one of more than 600 carotenoids thus far identified, is based on practical considerations: b-carotene has been the only carotenoid that is commercially available in large quantities for which human data supporting safety existed. Several other carotenoids (e.g., lycopene) have been suggested to have chemopreventive efficacy in animal models, but are only beginning to be evaluated in human chemoprevention studies (see [New Retinoids and Carotenoids](#), later in this chapter).

**TABLE 23.3-1. Randomized Trials of Retinoids in Human Cancer Chemoprevention<sup>a</sup>**

Study	Year	Phase	Intervention	Control	Primary End Point	Response Rate (%)	Significance
1	1986	III	13cRA (2 mg/kg/d)	Placebo	Complete plus partial response	67 vs 10	$P = .0002$
2	1986	III	13cRA (1.5 mg/kg/d)	Placebo	Response rate	55 vs 16	$P < .001$
3	1988	III	13cRA (50-100 mg/m <sup>2</sup> /d)	Placebo	Second primary tumor	4 vs 24	$P = .005$
4	1988	III	4HPR	Control	Treatment failure	6 vs 30	
5	1989	III	Retinol	Placebo	Response rate	27.5 vs 3.0	
6	1989	III	b-carotene	Placebo	Response rate	14.8 vs 3.0	
7	1989	III	Retinyl palmitate	Placebo	Response rate	52 vs 10	
8	1990	III	Retinol, b-carotene, vitamin E	Placebo	Prevalence odds ratio	0.62	
9	1990	III	Retinol	Placebo	Response rate	33 vs 10	
10	1990	III	b-carotene	Placebo	Response rate	33 vs 10	
11	1990	III	Retinol, b-carotene, vitamin E	Placebo	Response rate	33 vs 10	
12	1990	III	Retinol, b-carotene, vitamin E	Placebo	Response rate	33 vs 10	
13	1990	III	Retinol, b-carotene, vitamin E	Placebo	Response rate	33 vs 10	
14	1990	III	Retinol, b-carotene, vitamin E	Placebo	Response rate	33 vs 10	
15	1990	III	Retinol, b-carotene, vitamin E	Placebo	Response rate	33 vs 10	
16	1990	III	Retinol, b-carotene, vitamin E	Placebo	Response rate	33 vs 10	
17	1990	III	Retinol, b-carotene, vitamin E	Placebo	Response rate	33 vs 10	
18	1990	III	Retinol, b-carotene, vitamin E	Placebo	Response rate	33 vs 10	
19	1990	III	Retinol, b-carotene, vitamin E	Placebo	Response rate	33 vs 10

49	1990	III	Retinol, b-carotene, vitamin E	Placebo	Response rate	33 vs 10	
50	1990	III	Retinol, b-carotene, vitamin E	Placebo	Response rate	33 vs 10	

**TABLE 23.3-2. Randomized Trials of b-Carotene in Human Cancer Chemoprevention<sup>a</sup>****HEAD AND NECK TRIALS: PREMALIGNANCY**

Oral premalignant lesions include leukoplakias and erythroplakias. Small hyperplastic leukoplakia lesions have a 30% to 40% spontaneous regression rate, and less than a 5% risk of malignant transformation. Erythroleukoplakia and dysplastic leukoplakia lesions, however, are associated with a low rate of spontaneous regression and a 30% to 40% long-term risk of oral cancer.<sup>2,28,29</sup> High-risk, diffuse, and multifocal disease, accounting for 10% to 15% of all oral premalignant lesions, often is not controlled adequately by local therapy. Oral premalignant lesions are markers of field carcinogenesis, since patients with oral premalignancy develop squamous cancers at the site of the lesions as well as in distant sites within the upper aerodigestive tract. Thus, regression of oral premalignant lesions can be used to screen agents that may have utility in the prevention of upper aerodigestive tract cancers. The frequency of micronuclei (an indicator of genotoxic damage) in exfoliated cells from buccal mucosa is another premalignant end point that has been used in head and neck chemoprevention trials.<sup>28</sup>

Studies in the 1980s in populations at high risk of oral cancer (tobacco chewers, betel quid chewers) demonstrated that supplemental b-carotene and retinol significantly reduced the frequency of oral micronuclei.<sup>30,31 and 32</sup> As for premalignant lesions, nine trials have investigated the effects of supplemental b-carotene, alone or in combination with other agents, on regression of oral leukoplakia. Six nonrandomized studies<sup>33,34,35,36,37 and 38</sup> reported response rates ranging from 44% to 97%. The response rates from these uncontrolled studies, however, must be interpreted cautiously for three reasons: (1) leukoplakias can regress spontaneously; (2) varying response criteria were used; and (3) there was no apparent dose-response relationship. Three placebo-controlled trials of b-carotene and oral leukoplakia are available. Stich et al.<sup>32</sup> reported that the combination of b-carotene plus retinol produced complete remissions in 27.5%, b-carotene alone in 14.8%, and placebo in 3.0% of subjects (partial remissions were not reported) with a 6-month intervention. Sankaranarayanan et al.<sup>39</sup> got better response rates with an even longer duration of intervention (12 months), consisting of 33% complete regression with b-carotene and 52% with retinyl palmitate versus 10% in the placebo arm. In a trial in Uzbekistan,<sup>40</sup> 6 months of treatment with the combination of retinol, b-carotene, and vitamin E led to a significant reduction in the prevalence odds ratio of oral leukoplakia [odds ratio = 0.62; 95% confidence interval (CI) = 0.39 to 0.98]. The risk of progression or no change versus regression also was reduced by 40% by this intervention, although not statistically significant (odds ratio = 0.60; 95% CI = 0.23 to 1.63). Vitamin E was evaluated by itself in a single-arm trial in oral leukoplakia in which both clinical and histologic responses were observed.<sup>41</sup>

Retinoids have been studied extensively in the reversal of oral premalignant lesions.<sup>2,28,29</sup> One of the first such trials, reported in 1986,<sup>42</sup> was a 3-month placebo-controlled study of 13cRA (2 mg/kg/d). The complete plus partial response rate in the 44 evaluable patients was 67% in the retinoid arm and 10% in the placebo arm ( $P = .0002$ ). The histopathologic improvement rate (e.g., reversal of dysplasia) was also higher in the retinoid arm (54% vs. 10%,  $P = .01$ ). There were two major problems, however, with this high-dose, short-term approach. First, high-dose 13cRA toxicity was substantial and not acceptable in this clinical setting. Second, over one-half of the responders had recurrences or developed new lesions within 3 months of stopping the intervention.

Based on the results of this placebo-controlled trial, a randomized maintenance trial was designed.<sup>43</sup> In this trial, patients initially received a 3-month induction course of high-dose 13cRA (1.5 mg/kg/d), followed by a 9-month maintenance course with low-dose 13cRA (0.5 mg/kg/d) or b-carotene (30 mg/d) in patients with responding or stable lesions during the high-dose induction phase. The induction-phase response rate was 55% (95% CI = 42% to 67%). During the maintenance phase, 2 (8%) of the patients in the retinoid group progressed versus 16 (55%) in the b-carotene group ( $P < .001$ ). Toxic effects of low-dose 13cRA maintenance therapy were mild, although greater than for b-carotene, with no patients discontinuing therapy because of toxicity.

4HPR, a promising new retinoid, is also being evaluated in oral premalignancy. A randomized study was begun in 1988 at the Milan Cancer Institute to evaluate the efficacy of 52 weeks of systemic 4HPR maintenance therapy (vs. no intervention) after complete laser resection of oral premalignant lesions. The most recent report on this ongoing study included data from 153 randomized patients.<sup>44,45</sup> A 3-day drug holiday at the end of each month was prescribed to avoid the adverse effects (night blindness) of lowering serum retinol by 4HPR treatment. The rate of treatment failure (recurrence plus new lesion rate) among those patients who completed the 12-month intervention was 6% in the 4HPR group and 30% in the control group.

Two other randomized studies involving retinol<sup>39,46</sup> and another involving the retinoid N-4-(hydroxycarbophenyl) retinamide (4HCR)<sup>47</sup> have been reported; all observed significant retinoid chemopreventive activity.

**HEAD AND NECK TRIALS: MALIGNANCY**

There have been only two phase III adjuvant chemoprevention trials of retinoids in head and neck cancer. The first, reported by Hong et al., tested high-dose 13cRA in 103 head and neck cancer patients.<sup>48</sup> Following definitive local therapy of stage I to IV (M0) disease with surgery, radiotherapy, or both, patients were assigned randomly to 12 months of 13cRA (50 to 100 mg/m<sup>2</sup>/d) or placebo. At a median follow-up of 32 months, there were no significant differences in primary disease recurrence (local, regional, or distant) or survival. The rate of second primary tumors, however, was significantly lower in the retinoid arm than in the placebo group, developing in two (4%) of the 13cRA-treated patients compared with 12 (24%) of the placebo-treated patients ( $P = .005$ ). More than 70% of second primary tumors occurred in the carcinogen-exposed aerodigestive tract fields of the head and neck, lungs, and esophagus. Side effects were substantial and included skin dryness and peeling, cheilitis, conjunctivitis, and hypertriglyceridemia. Approximately 30% of the retinoid-treated patients required dose reduction and 18% did not complete the 12-month intervention because of toxicity.

This trial has been reanalyzed with a longer median follow-up of 55 months.<sup>49</sup> With the additional follow-up, each group had one more second primary tumor in the aerodigestive tract, resulting in a cumulative total of three of the retinoid group and 13 of the placebo group ( $P = .008$ ).

Based on this high-dose adjuvant trial<sup>48,49</sup> and the low-dose 13cRA trial in oral premalignancy,<sup>43</sup> a multicenter large-scale phase III National Cancer Institute trial was designed and is ongoing to evaluate low-dose 13cRA as adjuvant chemoprevention in stage I and II head and neck cancer.<sup>50</sup>

The other randomized trial studied the synthetic retinoid etretinate in 316 patients following definitive therapy of stage I to III (T1,2, N0,1) squamous cell carcinoma of the oral cavity and oropharynx.<sup>51</sup> In this French trial, the etretinate dose was 50 mg/d for 1 month, then 25 mg/d for 2 years. The etretinate was well tolerated. At a median follow-up of 41 months, the rate of second primary tumor development in the two arms was not significantly different. The lack of a retinoid effect on second primary tumors in this trial is in contrast to the result of the earlier high-dose 13cRA trial and could be attributable to differences in the patient populations and differing dose levels. A more likely reason for the difference, however, involves the pharmacokinetics and mechanisms of action of the two retinoids studied. 13cRA leads to transcriptional activation via rapid isomerization to ATRA. In contrast, etretinate is known not to be transcriptionally active and is not known to isomerize to ATRA or

any other transcriptionally active retinoid.

The most recently reported trial (Euroscan) included head and neck and lung cancer–associated second primary tumors and is discussed in detail in a following section called Lung Trials: Malignancy.

Two trials involving b-carotene and head and neck cancer prevention have completed intervention, but results have not yet been released, one in the United States <sup>52</sup> and one in Italy (Dr. S. Toma, unpublished data). Both are designed to determine whether supplemental b-carotene reduces the incidence of second malignant cancers of the oral cavity, pharynx, larynx, esophagus, and lung in patients who have been “cured” of an early-stage head or neck cancer. A total of 264 patients were randomized in the U.S. trial and 211 in the Italian trial. Results are expected shortly.

#### LUNG TRIALS: PREMALIGNANCY

The Tyler (Texas) Chemoprevention Trial randomized 755 asbestos workers to receive b-carotene (50 mg/d) and retinol (25,000 IU every other day) versus placebo, to see if the nutrient combination could reduce the prevalence of atypical cells in sputum. After a mean intervention period of 58 months, there was no difference in the two groups in the prevalence of sputum atypia.<sup>53</sup> In another randomized, placebo-controlled trial, 14 weeks of supplemental b-carotene (20 mg/d) significantly reduced micronuclei counts in sputum from heavy smokers.<sup>54</sup> b-Carotene was not found, however, to reduce oxidative damage as measured by urinary excretion of 8-oxo-7, 8-dihydro-2'-deoxyguanosine,<sup>55</sup> suggesting that antioxidant activity was not responsible for the reduction in micronuclei.

In a French trial, chronic smokers with squamous metaplasia of the bronchial epithelium detected in initial bronchoscopy specimens were treated with etretinate (25 mg/d) for 6 months.<sup>56</sup> In this uncontrolled trial, a decline in the extent of squamous metaplasia was observed in most treated patients. The positive result of this French study led to three randomized trials: one of etretinate in Canada and one of 13cRA and one of 4HPR in the United States. The Canadian study evaluated the ability of 25 mg of etretinate per day for 6 months to reverse sputum atypia in chronic smokers.<sup>57</sup> Toxicity was mild and the number of subjects requiring dose reductions or dropping out was small and similar in both arms. No difference in the degree of atypia occurred between the etretinate and placebo groups. In the U.S. 13cRA study, chronic smokers underwent bronchoscopy with endobronchial biopsies taken from six specific anatomic sites within the proximal lung field,<sup>58</sup> as reported in the earlier single-arm French study.<sup>56</sup> Ninety-three of the 152 chronic smokers who underwent bronchoscopic biopsies had squamous metaplasia or dysplasia. Eligible smokers with metaplasia or dysplasia were randomized to 6 months of 13cRA or placebo. The extent of metaplasia decreased similarly (in approximately 50% of subjects) in both study arms. Only smoking cessation (confirmed biochemically), which occurred in 16 patients (ten in the 13cRA group and six in the placebo group), was associated significantly with a reduction in the metaplasia index during the 6-month intervention. 4HPR was involved in the most recent study (reported in abstract only<sup>55</sup>). This study was similar to the earlier isotretinoin study with respect to overall design (excepting the drug) and the negative primary result.<sup>58</sup> Although the retinoid arm results were consistent with the French findings in showing a decline in metaplasia with treatment, the use of a placebo control group in the randomized trials suggested no specific retinoid effect. These findings underscore the critical importance of placebo-controlled designs to establish drug activity in chemoprevention trials using intermediate end points.

#### LUNG TRIALS: MALIGNANCY

Two large trials using incident lung cancer as a primary end point have now been completed. The first involved 29,133 men aged 50 to 69 years old from Finland,<sup>60</sup> who were heavy cigarette smokers at entry (average one pack per day for 36 years). The study design was a two-by-two factorial with participants randomized to receive either supplemental b-carotene (20 mg/d), a-tocopherol (50 mg/d), the combination, or placebo for 5 to 8 years. Unexpectedly, participants receiving b-carotene (alone or in combination with a-tocopherol) had a statistically significant 18% increase in lung cancer incidence (relative risk [RR] = 1.18; 95% CI = 1.03 to 1.36) and 8% increase in total mortality (relative risk [RR] = 1.08; 95% CI = 1.01 to 1.16) relative to participants receiving placebo. Supplemental b-carotene did not appear to affect the incidence of other major cancers occurring in this population. Although not the primary outcome of this trial, an interesting observation was made with regard to vitamin E and prostate cancer: Men randomized to receive a-tocopherol had a 32% decrease in prostate cancer incidence and a 41% decrease in prostate cancer mortality.<sup>61</sup> This promising finding will be followed up in future trials (see [Conclusions](#), later in this chapter).

The finding of an increased incidence of lung cancer in b-carotene–supplemented smokers was apparently replicated in another major trial. The Carotene and Retinol Efficacy Trial was a multicenter lung cancer prevention trial of supplemental b-carotene (30 mg/d) plus retinol (25,000 IU/d) versus placebo in asbestos workers and smokers.<sup>62</sup> The Carotene and Retinol Efficacy Trial was terminated nearly 2 years early in January 1996, because interim analyses of the data indicated that should the trial have continued for its planned duration, it is highly unlikely that the intervention would have been found to be beneficial. Furthermore, the interim results indicated that the supplemented group was developing more lung cancer, not less, consistent with the results of the Finnish trial. Overall, lung cancer incidence was increased by 28% in the supplemented subjects (RR = 1.28; 95% CI = 1.04 to 1.57) and total mortality was also increased (RR = 1.17; 95% CI = 1.03 to 1.33). The increase in lung cancer following supplementation with b-carotene and retinol was observed for current but not former smokers. Major findings of one additional trial, the Physicians' Health Study of supplemental b-carotene versus placebo in 22,071 male U.S. physicians, are also now available.<sup>63</sup> There was no significant effect, positive or negative, of 12 years of supplementation of b-carotene (50 mg every other day) on total cancer, lung cancer, or cardiovascular disease. The relative risk for lung cancer in current smokers randomized to b-carotene was 0.90 (95% CI = 0.58 to 1.40). Among nonsmokers, the relative risk was 0.78 (95% CI = 0.34 to 1.79). The apparent lack of an effect of long-term supplementation of b-carotene on lung cancer incidence, even in baseline smokers who took the supplements for up to 12 years, is noteworthy and is discussed further here. A similar lack of effect of supplemental b-carotene on overall cancer incidence was seen in the Women's Health Study, although the duration of intervention was short (median, 2.1 years).<sup>64</sup>

In contrast, more encouraging results for lung cancer prevention come from an esophageal and gastric cancer prevention trial in China (see [Esophagus and Stomach Trials](#), later in this chapter). The relative risk of death from lung cancer was 0.55 (95% CI = 0.26 to 1.14) among those receiving the combination of b-carotene, a-tocopherol, and selenium.<sup>65</sup> However, this result is not statistically significant, based on only 31 total lung cancer deaths.

A clear mechanism to explain the apparent enhancement of lung carcinogenesis by supplemental b-carotene, alone or in combination with retinol, in smokers has yet to emerge. As detailed elsewhere,<sup>66</sup> it should be noted that the two trials that observed this enhancing effect had higher median plasma b-carotene concentrations in their intervention groups than did the trials that did not observe an enhancing effect. Thus, it is possible that high tissue concentrations of b-carotene in the presence of strongly oxidative tobacco smoke cause an interaction that affects carcinogenesis. Wang et al. have used the ferret to model b-carotene/tobacco interactions in lung and noted a relative lack of both retinoic acid and RAR- $\beta$  expression in the lung of smoke-exposed ferrets given high-dose b-carotene.<sup>67</sup> The authors suggested that oxidative metabolites of b-carotene might cause diminished retinoid signaling and thus increase tumorigenesis. Other groups are also studying b-carotene oxidation products, for example Salgo et al.<sup>68</sup> reported that under some conditions b-carotene oxidation products, but not b-carotene, enhanced binding of cytochrome P-450–catalyzed metabolites of benzo[a]pyrene to DNA. While mechanistic studies continue,<sup>69</sup> it is prudent to recommend that heavy smokers, particularly those from well-nourished populations, should avoid high-dose supplements of b-carotene for lung cancer chemoprevention.

Retinoids have not been tested as single agents in primary prevention trials of lung cancer; however, one trial of retinyl palmitate in adjuvant chemoprevention of lung cancer is available.<sup>70</sup> Following surgery, patients with stage I non–small cell lung cancer (n = 307) were assigned randomly to treatment with retinyl palmitate (300,000 IU) for 1 year of observation. At a median follow-up of 46 months, survival trends favored retinyl palmitate over no therapy in estimated 5-year disease-free survival (64% vs. 51%,  $P = .054$ ) and overall survival (62% vs. 54%,  $P = .44$ ). Eighteen patients in the retinyl palmitate arm developed a second primary tumor compared with 29 patients developing 33 second primaries in the control group. Reduction of tobacco-associated second primary tumors was more pronounced. At a median follow-up of 46 months, tobacco-associated second primary tumors developed in 13 patients in the retinyl palmitate arm compared with 25 control patients. The time to development of tobacco-related second primary tumors also favored the retinyl palmitate arm ( $P = .045$ ). Retinyl palmitate toxicity was frequent, occurring in the majority of treated patients; however, more than 80% of patients maintained regular drug intake during the first 12 months, indicating that the intervention was tolerable.

Based on the encouraging second primary tumor results and retinoid activity in related carcinogenic systems, two large-scale phase III retinoid trials were implemented in the setting of second primary tumor prevention. One of these trials, called Euroscan, has been completed in Europe. Euroscan <sup>71</sup> was an open-label multicenter trial employing a two-by-two factorial design to test 2 years of retinyl palmitate and N-acetylcysteine in preventing second primary tumors in 2592 patients. Patients had completed definitive therapy of early-stage head and neck cancer (larynx T1s, T1 to 3, N0 to 1; oral cavity T1 to 2, N0 to 1) and non–small cell lung cancer (T1 to 2, N0 to 1, and T3, N0). Retinyl palmitate, N-acetylcysteine, or both produced no improvement in event-free survival, survival, or incidence of second primary tumors. The other related trial is still ongoing in the United States. This is a multicenter trial (intergroup NCI I91-0001) of low-dose isotretinoin to prevent second primary tumors after definitive therapy of stage I non–small cell lung cancer.<sup>72</sup> Currently, new phase III chemoprevention trials in the non–small cell and small cell lung cancer settings are being designed.<sup>73</sup> In addition, new retinoid formulations and delivery systems (e.g., aerosolized) and potential secondary lung benefits

are under active study.<sup>74,75</sup>

## BREAST TRIALS

The retinamide 4HPR is a potent apoptosis-inducing retinoid with retinoid receptor-dependent and receptor-independent activities. Moon and colleagues first showed that 4HPR was among the most active cancer chemopreventive agents for the breast, having a high therapeutic index and synergistic interaction with tamoxifen in mammary carcinogenesis model studies.<sup>7</sup> This laboratory work led to a large-scale randomized trial of 4HPR (vs. no treatment) for 5 years to prevent contralateral breast cancer in women aged 30 to 70 years with a history of resected early breast cancer and no prior adjuvant therapy.<sup>76</sup> The intervention produced no significant overall effect. Subset analyses suggested that reduced contralateral and ipsilateral breast cancer rates occurred in premenopausal women and that an opposite trend occurred in postmenopausal women.<sup>76</sup> Promising new retinoids for breast cancer prevention include other potent apoptosis-inducing retinoids and RAR-subtype-selective, RXR-selective, and anti-AP-1 retinoids.<sup>77</sup>

As for b-carotene, observational data have suggested that higher intake of b-carotene from foods is an important prognostic factor in breast cancer.<sup>78,79</sup> Given this, randomized trials aimed at increasing vegetable intake to prevent breast cancer recurrence are under way.<sup>80</sup> These interventions clearly influence circulating carotenoid concentrations and illustrate a food-based approach to investigate potential chemopreventive efficacy.

## SKIN TRIALS

Data suggest that topical ATRA has significant dose-related activity in reversing premalignant skin lesions (e.g., actinic keratoses, which undergo a malignant transformation rate of 5%).<sup>81</sup> Systemic retinoid therapy has produced significant activity in the two reported randomized trials.<sup>82,83</sup> Several small, single-arm studies have found that 13cRA and etretinate can reduce skin cancer incidence significantly in high-risk patients with xeroderma pigmentosum (XP) and in renal transplant recipients, respectively.<sup>84,85</sup>

The XP trial, published in 1988, was a landmark trial for the field of chemoprevention in general in that it was the first human trial to establish a significant reduction in tumor development.<sup>84</sup> Although including only five XP patients, the extremely high rate of skin cancer development and rigorous documentation of skin tumor rates before, during, and after the 2-year high-dose (2 mg/kg/d) 13cRA intervention provided statistically valid results. The overall average reduction in skin cancer incidence during therapy was 63% ( $P = .019$ ). Two major problems were evident from this trial: Severe, acute mucocutaneous toxicity occurred with this high 13cRA dose, and the preventive effect of the retinoid was lost after stopping retinoid therapy, as indicated by a mean 8.5-fold increase in the annual rate of skin tumor development ( $P = .007$ ). The retinoid chemopreventive effect in this study was greatest in the XP patients with the highest frequency of *de novo* skin tumor development, and, in subsequent studies, was found to be dose related.

Based on positive single-arm retinoid data,<sup>85</sup> a randomized, placebo-controlled trial of the retinoid acitretin (30 mg/d for 6 months) was conducted in 38 renal transplant recipients.<sup>86</sup> The retinoid group had significant reductions in (1) premalignant lesions ( $P = .008$ ); (2) the number of patients with skin cancer ( $P = .01$ ); and (3) the cumulative number of skin cancers ( $P = .009$ ). Nine of the 19 placebo patients developed a total of 18 skin cancers and 2 of the 19 retinoid patients developed skin cancer, one cancer each. After completing the intervention, the rate of skin cancer development in the retinoid arm increased and became similar to that of the placebo arm. Toxicity in the retinoid group was frequent but mild in degree, and the retinoid had no adverse effect on renal function.

Three large-scale randomized phase III trials of retinoids and skin cancer have been reported. A trial of very low-dose 13cRA (10 mg/d)<sup>87</sup> and one of retinol (25,000 IU/d) or 13cRA (5 to 10 mg/d) versus placebo in patients with prior skin cancers<sup>88</sup> were negative. The third trial, involving retinol in patients with prior actinic keratoses, did see a significant reduction of squamous but not basal skin cancers in the retinoid arm.<sup>89</sup> The contrasting results of the phase III retinoid trials in skin cancer chemoprevention suggest the importance of retinoid dose, biologic timing of intervention, and target histopathology.

Greenberg and colleagues<sup>90</sup> conducted a large randomized clinical trial of supplemental b-carotene (50 mg/d for 5 years) in 1805 persons with a previous nonmelanoma skin cancer. There was no difference between the two groups in the rate of occurrence of the first new nonmelanoma skin cancer (RR = 1.05; 95% CI = 0.91 to 1.22).

Selenium is another nutrient that has been evaluated for efficacy in the prevention of second skin cancers.<sup>91</sup> Clark et al. randomized a total of 1312 patients with a history of nonmelanoma skin cancer to 200 µg selenium per day or placebo. Selenium did not affect the incidence of second skin cancers (RR = 1.10 for basal cell carcinoma and RR = 1.14 for squamous cell carcinoma). However, there was a significant reduction in total cancer mortality (RR = 0.50; 95% CI = 0.31 to 0.80), mainly due to reductions in incident lung, colorectal, and prostate cancers. Other selenium trials are now getting under way (see [Conclusions](#), later in this chapter), given these promising results.

## BLADDER TRIALS

Data from *in vivo* animal, *in vitro*, and epidemiologic studies suggested efficacy of retinoids for bladder cancer prevention. Three randomized clinical trials have tested the retinoid etretinate in patients following resection of their superficial (noninvasive) bladder tumors, which recur in 40% to 90% of cases. All three studies were limited substantially because of mucocutaneous toxicity.<sup>92,93</sup> and 94 However, in two of the three trials, prolonged (greater than 1 year) low-dose etretinate (25 mg/d) apparently was effective. These positive results require a cautious reading, because of small patient numbers and short-term follow-up.

Another chemoprevention trial randomized 65 patients with biopsy-confirmed transitional cell carcinoma of the bladder to a multivitamin (recommended dietary allowance levels) alone or supplemented with 40,000 IU of retinol, 100 mg of pyridoxine, 2000 mg of ascorbic acid, 400 IU of α-tocopherol, and 90 mg of zinc.<sup>95</sup> The 5-year estimate of tumor recurrence was 91% in the recommended dietary allowance arm versus 41% in the megadose arm ( $P = .0014$ ). These results are promising in that the intervention was essentially nontoxic, with only one patient (3%) requiring dose reduction for mild stomach upset. Further research is needed to identify which vitamin(s) were responsible for chemopreventive efficacy.

Studies in the bladder of newer synthetic retinoids with better therapeutic ratios are also anticipated. One such leading candidate is 4HPR,<sup>7,10</sup> which tests as one of the strongest anticarcinogenic retinoids in the rodent bladder, is less toxic than either etretinate or isotretinoin in humans, and has produced promising results in a phase IIA trial.<sup>96</sup>

## CERVICAL TRIALS

Many randomized and nonrandomized chemoprevention studies have been conducted in cervical dysplasia. Randomized trials include two studies of folic acid, four of interferons, three of b-carotene, and one of ATRA. Only one of these trials, using topical ATRA,<sup>97</sup> found a significant treatment effect. Three hundred one patients with moderate (cervical intraepithelial neoplasia 2) and severe (cervical intraepithelial neoplasia 3) dysplasia were randomly assigned to topical ATRA versus placebo. This trial administered a 0.372% b-ATRA solution by collagen sponge in a cervical cap delivery system for 4 days initially, then for 2 days at months 3 and 6. Patients were evaluated by serial colposcopy, Pap cytology, and cervical biopsy. The ATRA dose, schedule, and delivery system were determined by prior single-arm phase I and II studies. The major finding was a higher complete response rate in the ATRA group (43%) than in the placebo group (27%;  $P = .041$ ) among the 141 patients with moderate dysplasia. No significant differences in dysplasia regression rates between the two study arms were detected in patients with severe dysplasia. Acute toxicity was infrequent, mild, and reversible consisting primarily of local (vaginal and vulvar) irritation occurring in less than 5% of treated subjects. Major problems with compliance (e.g., 52 patients lost to follow-up), however, have limited somewhat the interpretation of this trial.

Three randomized trials involving b-carotene have been published. The first was a trial from the Netherlands that randomized women with a histologic diagnosis of cervical dysplasia to either 10 mg of b-carotene per day for 3 months or placebo. After 3 months of intervention, there was no detectable effect of supplemental b-carotene on the regression and progression of cervical dysplasia.<sup>98</sup> Romney et al.<sup>99</sup> randomized women with cervical dysplasia to 30 mg of b-carotene per day ( $n = 39$ ) or placebo ( $n = 30$ ). After 9 months of intervention, there was no beneficial effect of b-carotene supplementation. An Australian trial used a factorial design to investigate the effects of supplemental b-carotene (30 mg/d) or vitamin C (500 mg/d) in 141 women with minor cervical abnormalities.<sup>100</sup> There was no significant effect of either agent in this trial. In contrast are results from a nonrandomized phase II intervention trial of cervical dysplasia<sup>101</sup> that reported a striking 70% response rate following 6 months of supplementation with 30 mg of b-carotene per day. The results of the randomized trials suggest that this impressive response rate may

reflect spontaneous regression rather than an effect of the b-carotene.

## ESOPHAGUS AND STOMACH TRIALS

Certain regions of China (Huixian and Linxian) have strikingly high incidence rates of esophageal and gastric cancers; moreover, intake and blood levels of various micronutrients are consistently low in these populations. These observations have led to three esophageal and esophageal and gastric cancer prevention trials in China.<sup>102,103 and 104</sup> The first was in high-risk Chinese subjects from Huixian and tested the combination of retinol, riboflavin, and zinc for 13.5 months. After the intervention, there was no overall difference between the two arms in the occurrence of premalignant lesions or the prevalence or severity of dysplasia.<sup>102</sup> However, esophageal (but not oral) micronuclei frequency decreased in the intervention arm.<sup>105</sup>

Two more recent trials were done in Linxian county. The first trial was conducted in residents from the general population.<sup>103</sup> Nearly 30,000 men and women aged 40 to 69 took part in the study, which tested the efficacy of four different nutrient combinations at inhibiting the development of esophageal and gastric cancers. The nutrient combinations included retinol plus zinc, riboflavin plus niacin, ascorbic acid plus molybdenum, and the combination of b-carotene, selenium, and a-tocopherol. After a 5-year intervention period, those who were given the combination of b-carotene, vitamin E, and selenium had a 13% reduction in total cancer deaths (RR = 0.87; 95% CI = 0.75 to 1.00), a 4% reduction in esophageal cancer deaths (RR = 0.96; 95% CI = 0.78 to 1.18), and a 21% reduction in gastric cancer deaths (RR = 0.79; 95% CI = 0.64 to 0.99). None of the other nutrient combinations reduced gastric or esophageal cancer deaths significantly in this trial. The finding that vitamin supplements reduced cancer deaths in this population provides compelling data supporting the concept of cancer prevention via nutrients; however, the applicability of these results for populations with adequate nutritional status and for other tumor sites may be limited. Also, it is unclear which nutrient(s) (b-carotene, vitamin E, or selenium) was responsible for the observed protection. It is perhaps of interest that selenium was not deficient in this population.

The other Linxian trial was done to determine whether a multivitamin and multimineral preparation plus b-carotene (15 mg) reduced esophageal and gastric cardia cancers in 3318 residents with esophageal dysplasia.<sup>104</sup> Cumulative esophageal and gastric cardia death rates after the 6-year intervention period were 8% lower (RR = 0.92; 95% CI = 0.67 to 1.28), esophageal cancer mortality was 16% lower (RR = 0.84; 95% CI = 0.54 to 1.29), and total cancer mortality was 4% lower (RR = 0.96; 95% CI = 0.71 to 1.29) in the supplemented group. Surprisingly, stomach cancer mortality was 18% higher (RR = 1.18; 95% CI = 0.76 to 1.85) in the supplemented group. None of the results were statistically significant.

Repeat endoscopic surveys were carried out 2 and 6 years after randomization in a subsample of participants in the dysplasia trial.<sup>106</sup> At baseline (1983, 2 years before randomization), all of the subjects had a cytologic diagnosis of dysplasia (98% squamous). In the 1987 survey (n = 768), 61.3% of the participants who were endoscoped and on the active arm were found to have normal cytology, compared with 57.6% of those on the placebo arm. In the 1991 survey (n = 396), 17.8% of the participants who were endoscoped and on the active arm were found to have normal cytology, compared with 20.6% on the placebo arm. The striking degree of apparent regression observed in the placebo arm, particularly in the 1987 survey, again underscores the importance of placebo controls in trials of intermediate end points.

In addition to the Chinese trials, a trial from Uzbekistan used a factorial design to study the combination of b-carotene, retinol, and a-tocopherol, with and without riboflavin, in subjects with chronic esophagitis.<sup>40</sup> The risk of progression or no change versus regression was nonsignificantly decreased by 34% in those receiving retinol, b-carotene, and a-tocopherol (OR = 0.66; 95% CI = 0.37 to 1.16) versus those who did not receive these agents.

## COLORECTAL TRIALS

Three randomized trials aimed at the prevention of recurrent colorectal adenomas with supplemental b-carotene have been completed. The largest trial studied 751 patients who had had an adenoma diagnosed and removed within the previous 3 months.<sup>107</sup> Participants were randomized using a two-by-two factorial design, with the active treatments being b-carotene (25 mg/d), and the combination of 1 g of vitamin C plus 400 mg of vitamin E. There was no evidence that either b-carotene or vitamins C and E reduced the incidence of adenomas in this 4-year trial. The relative risk for b-carotene was 1.01 (95% CI = 0.85 to 1.20); for vitamins C and E it was 1.08 (95% CI = 0.91 to 1.29). The Australian Polyp Prevention Project evaluated the efficacy of reducing dietary fat to 25% of total calories, and supplementing the diet with 25 g of wheat bran, 20 mg of b-carotene, or both daily, in a factorial design.<sup>108</sup> b-Carotene did not reduce the incidence of adenomas; at 24 months 50 patients on the b-carotene arm had adenomas versus 36 patients on the placebo arm. However, patients taking b-carotene had a statistically significantly lower proportion of positive nuclei in the upper rectal crypt compartments than those taking placebo, suggesting that b-carotene modified preneoplastic mucosal proliferation rather than adenoma growth. Another trial (n = 291) using a lower dose of 15 mg of b-carotene per day also failed to see a reduction in adenomas with supplementation.<sup>109</sup>

## TRANSLATIONAL AND INTERMEDIATE END POINT STUDIES IN RETINOID CHEMOPREVENTION

Clinical-laboratory translational research is critical for developing new and better chemopreventive agents and for moving them more quickly into standard care; the oral premalignancy model appears to be an excellent model for translational studies.<sup>28,110,111 and 112</sup> Advanced oral lesions can be visualized, biopsied, and monitored prospectively; they are linked to carcinogenesis throughout the aerodigestive tract; and activity of retinoids and b-carotene has been demonstrated in randomized trials. Work in the retinoid oral premalignancy system offers a paradigm for clinical and laboratory collaboration in other tumor sites and with other agents. One aspect relates to an understanding of the predictive value of biomarker modulation in terms of clinical outcome and correlation of various markers within the same system.

Basic research in the retinoid oral premalignancy model will increase our knowledge of the biology of epithelial carcinogenesis and agent mechanisms, and, it is hoped, will lead to valid intermediate end point biomarkers. As reviewed in detail elsewhere, intermediate end point biomarkers are short-term markers of chemopreventive agent activity. Criteria include (1) differential expression in high- and low-risk tissue, (2) pattern and degree of expression correlating with histopathologic stage (e.g., hyperplasia, degree of dysplasia, cancer), (3) low rate of spontaneous change, (4) ability to be modulated, and (5) technical and logistic feasibility.<sup>1,111</sup> The most substantial work in the retinoid oral premalignancy model involves RAR-b and p53.

The discovery and early descriptions of nuclear receptors came from molecular *in vitro* studies in several systems. These receptors are also being studied intensively in clinical specimens from many cancer types and sites. The best-studied site in chemoprevention is the head and neck. Xu and colleagues employed a nonradioactive RNA *in situ* hybridization method to study the expression of all six human retinoid receptors in squamous cell carcinoma and surrounding premalignant and normal tissue contained in surgical resection specimens.<sup>113</sup> All six receptors were strongly expressed in 100% of oral tissue from normal, nonsmoking volunteers. In premalignant and malignant specimens, however, there was a selective, histopathologic stage-dependent loss of RAR-b mRNA expression, with expression detected in 72% of histologically normal and hyperplastic tissue adjacent to squamous cell carcinomas, 56% of dysplastic tissue, and 35% of squamous cell carcinomas ( $P < .05$ ).

This finding, suggesting an apparent tumor suppressor function in carcinogenic progression, led to a translational study of RAR-b that had three major findings.<sup>114</sup> First, in contrast to 100% expression in normal controls, RAR-b mRNA was detected in only 40% (21 of 52) of oral premalignant lesions ( $P = .003$ ). The expression of the other five receptors, detected in 70% (RXR-b) to 100% (RXR-a) of oral premalignant lesions did not differ significantly from normal controls. RAR-b loss in oral premalignant lesions was not associated significantly with tobacco use. Second, there was a striking retinoid up-regulation of RAR-b expression after 3 months of high-dose 13cRA, from 40% to 90%. Third, RAR-b up-regulation was associated with clinical response: Receptor up-regulation was observed in 82% of responding lesions (including all four complete responses) and 47% of nonresponding lesions ( $P = .039$ ). The early and progressive loss of RAR-b in premalignant tissues and significant 13cRA up-regulation (in association with lesion response) meets several major criteria for a potential intermediate end point. Similar findings have been reported in the lung in two randomized studies in smokers.<sup>115,116</sup> Future long-term validation trials will determine if early RAR-b up-regulation is associated with late lesion response and a reduction in cancer incidence.

These translational RAR-b findings in the retinoid and oral premalignant system are consistent with *in vitro* data. The RAR-b promoter has a DR5 response element and is the most tightly retinoid-regulated receptor. Mutations, deletions, or structural changes in the RAR-b gene or its promoter, however, have not been identified. More recent data suggest that loss of RAR-b expression in oral premalignant lesion is related to a defect in intracellular vitamin A metabolism (and reduced levels of retinoic acid in premalignant cells), which can be corrected by pharmacologic doses of retinoic acid.<sup>117</sup> These translational findings are consistent with preclinical data in vitamin A-deficient animals.

The available *in vitro* and *in vivo* data suggest a molecular model of retinoid chemoprevention in the head and neck (Fig. 23.3-2). *In vitro* transfection studies in lung cancer and other experimental systems suggest that RAR-b, which is located on chromosome 3p, may have tumor suppressor activity,<sup>118,119</sup> contributing to

suppression of the premalignant phenotype. RAR-b loss may enhance the progression of carcinogenesis by rendering the epithelium resistant to physiologic retinoic acid levels. Pharmacologic doses of retinoic acid, administered systemically, can enter premalignant cells and, via residual retinoic acid receptors (e.g., RAR-g), induce the synthesis of RAR-b via heterodimer binding to the RAR-b promoter and subsequent activation of RAR-b gene transcription. Although 13cRA does not bind directly to RARs, it is isomerized to ATRA. 13cRA can activate RAR-b RARE transcription *in vitro* at levels comparable with ATRA. This model of RAR-b up-regulation and tumor suppressor activity may represent the basis of retinoid chemoprevention in the head and neck.

**FIGURE 23.3-2.** Molecular model of retinoid chemoprevention. ATRA, all- *trans*-retinoic acid; 13cRA, 13- *cis* retinoic acid; RAR-b, retinoic acid receptor beta.

p53 chromosome instability and loss of heterozygosity are also under intensive study in aerodigestive tract carcinogenesis. <sup>120,121 and 122</sup> As indicated previously, translational research in the retinoid oral premalignancy model is a paradigm for chemoprevention research in general. Future goals include increasing our knowledge of the biology of carcinogenesis and agent mechanisms of action, establishing effective screens for response and resistance to agents, and establishing valid intermediate end point biomarkers. Valid intermediate markers will be necessary for reducing the size and duration, and therefore, the tremendous costs, of future chemoprevention trials. Perhaps of greater importance, valid intermediate markers will help focus limited research resources on only the most promising candidate agents.

## NEW RETINOIDS AND CAROTENOIDS

The retinamide 4HPR is a promising new retinoid now in clinical trials for human chemoprevention. <sup>1,2,7,8,9 and 10,44,45,76,96,123,124,125,126,127,128,129,130,131,132,133 and 134</sup> It has a unique mechanism of action and a favorable toxicity profile and has already generated significant chemopreventive activity in several animal carcinogenesis systems including mammary, bladder, lung, and prostate models. Several clinical chemoprevention trials targeting cervix, skin, bladder, and lung are currently in progress.

4HPR has potent apoptosis-inducing activity in several neoplastic systems (including leukemia, neuroblastoma, melanoma, small cell lung cancer, and cervical and head and neck squamous cell carcinoma) including those resistant to ATRA and 9cRA. <sup>123,124,125,126,127 and 128</sup> The finding that 4HPR is a potent inducer of apoptosis has exciting clinical implications. <sup>135</sup> Eliminating premalignant, genetically damaged cells by apoptosis may be more effective in cancer prevention than suppressing proliferation. Clinical effects of current chemopreventive agents, most of which primarily suppress proliferation, cease on stopping the drug. Apoptosis-inducing agents such as 4HPR, on the other hand, could allow shorter term effective chemoprevention with less toxicity. An understanding of the mechanism(s) by which 4HPR induces apoptosis is not yet available, but would facilitate the design of future preventive approaches, using rational combinations of 4HPR with other agents.

Clinical and translational study of other new retinoids is less advanced. This area of research currently is focused on ligands that are selective for RAR subtypes, RXRs, or the downstream target AP-1. <sup>77,136,137</sup> Data support RXR-selective ligands for use in cancer prevention. RXRs have a unique role in controlling apoptosis and as obligate heterodimer partners for RARs and many other intracellular receptors (e.g., vitamin D receptor and peroxisome proliferator-activated receptors). Via versatile dimer-partnering behavior and other complex effects, RXR agonists can modulate other endocrine-signaling pathways. The potential importance of RXRs in breast carcinogenesis was first illustrated by mammary carcinogenesis studies suggesting that the RAR-RXR panagonist 9cRA is more active than RAR agonists. Findings of subsequent prevention studies of selective RXR agonists in a rat mammary carcinoma model were as follows: less toxic and more active than 9cRA; inhibited estrogen- and tamoxifen-stimulated uterine proliferation; activity in tamoxifen-resistant disease and similar to that of tamoxifen; and supra-additive effects when combined with tamoxifen. This study of RXR agonists has led to intensive study of their combination with selective estrogen receptor modulators. <sup>77</sup>

Several carotenoids also appear to have promising chemopreventive activity. For example, epidemiologic as well as preclinical (*in vitro* and *in vivo*) studies suggest that  $\alpha$ -carotene may have chemopreventive efficacy. Lycopene, a carotenoid found primarily in tomato and tomato products, is of great interest as a potential agent for the prevention of prostate <sup>138</sup> and other cancers. <sup>139</sup> In one article, 57 of 72 studies reviewed reported inverse associations between tomato intake or blood lycopene levels and the risk of cancer; 35 of these inverse associations were statistically significant. <sup>139</sup> Small intervention trials of lycopene in men with prostate cancer have been initiated. <sup>140</sup> Other carotenoids including crocetin, canthaxanthin, fucoxanthin, and  $\alpha$ -carotene have been found to inhibit tumorigenesis in animal models. <sup>19</sup> While there is considerable interest in these and other carotenoids for cancer prevention, large-scale human trials should be undertaken with great caution, given the lack of a clear understanding of the apparent mechanism of  $\beta$ -carotene in promoting lung carcinogenesis.

## CONCLUSIONS

A number of chemoprevention trials involving retinoids and the carotenoid  $\beta$ -carotene are ongoing or have been completed. Although many of the trials have reported chemopreventive efficacy for various retinoids and for  $\beta$ -carotene, particularly in oral premalignancy, other trials have been negative or have even suggested promotional effects. This suggests that the patient population, tumor site, histopathology, choice of agent(s), dose, duration, and timing of intervention may be critical in determining efficacy. Although our understanding of mechanisms of action for retinoids has increased dramatically in the last decade, the same is not true for the carotenoids, and additional research is needed in this area. Nonrandomized phase I and II trials provide useful information regarding toxicity, feasibility, and suggestions of drug activity; however, randomized phase IIB and III trials <sup>1</sup> are clearly necessary for rigorous evaluation of efficacy. This is particularly true for trials using intermediate end points, as uncontrolled trials are difficult to interpret and may produce spurious findings. Several large randomized trials of retinoids in the prevention of cancer will be concluded by 2003. Others involving  $\beta$ -carotene, alone or in combination with other agents such as vitamins E, C, and selenium, also are ongoing. Trials will soon be initiated to evaluate single-agent efficacy of some of the less-studied micronutrients, such as the planned Selenium and Vitamin E Chemoprevention Trial (select), which will examine selenium and vitamin E in a factorial design aimed at the prevention of prostate cancer in 32,400 healthy male participants in the United States. In the meantime, the use of retinoids, carotenoids, vitamins E, C, and selenium for cancer prevention remains investigational.

#### INTRODUCTION

Experimental research has identified hundreds of food-derived compounds as having inhibitory effects on carcinogens.<sup>1</sup> In humans, these cancer-protective compounds are typically consumed as components within a complex diet, rather than as high-dose supplements. Because the variety and complexity of the diet of free-living humans limits direct experimental intervention of food intake, observational studies of eating patterns are often used to infer the role of particular dietary components. Epidemiologic studies emphasizing overall dietary intake or consumption of specific foods, rather than investigation of a particular nutrient or dietary supplement, do, however, provide consistent evidence that populations consuming higher levels of fruits and vegetables are at decreased risk of various cancers relative to populations with lesser intakes.<sup>2</sup> A growing body of research indicates that certain nonnutritive phytochemicals, including those found in the everyday diet, have marked cancer-preventive properties. This chapter examines some of the current evidence for the link between dietary anticarcinogens and cancer risk, with particular emphasis on selected nonnutritive phytochemicals.

#### CAROTENOIDS

Commonly consumed green, yellow-red, and yellow-orange vegetables and fruits contain more than 40 carotenoids, including b-carotene, lutein, lycopene, and the xanthins.<sup>3</sup> Various carotenoids may serve as cancer-preventive agents,<sup>4</sup> and a comprehensive review of experimental and epidemiologic studies examining their properties has been published.<sup>5</sup> Among the most promising of these carotenoids is lycopene, commonly found in tomatoes and tomato-based products; the biochemical and metabolic characteristics of lycopene have been summarized.<sup>6</sup> Epidemiologic studies have found an inverse relationship between intake of tomatoes or plasma lycopene level and risk of cancer at various sites, particularly the prostate, lung, and stomach.<sup>7</sup> *In vitro* studies have found a synergistic inhibitory effect of lycopene and a-tocopherol on growth of two human prostate carcinoma cell lines.<sup>8</sup> Mechanisms of action of carotenoids that may explain their potential cancer-preventive effects include antioxidant activity; modulation of carcinogen metabolism; and effects on cell transformation, differentiation, and communication.<sup>5</sup> More definitive conclusions regarding the role of lycopene in cancer prevention await controlled clinical trials.

Lutein displays anticarcinogenic properties that include enhancement of immune function, inhibition of the auto-oxidation of cellular lipids, and protection against oxidant-induced cell damage. In mice, dietary lutein inhibited mammary tumor growth,<sup>9</sup> and, among humans, high plasma lutein is associated with increased expression of estrogen receptors in breast cells and better survival rates and response to hormone therapy.<sup>10</sup>

#### PHYTOESTROGENS

Sources for two major categories of phytoestrogens, isoflavonoids and lignans, include legumes, whole grains, fruits, and berries.<sup>11</sup> Phytoestrogens exhibit both weak estrogenic and antiestrogenic effects.<sup>11,12</sup> Evidence for the role of phytoestrogens as cancer-preventive agents, from experimental and epidemiologic studies, has been the subject of a number of reviews.<sup>12,13,14</sup> and <sup>15</sup>

#### ISOFLAVONOIDS

Isoflavonoids, common in soy-based foods, inhibit angiogenesis, cell-cycle progression, and aromatase enzyme; stimulate sex hormone-binding globulin synthesis; and have antioxidant properties.<sup>14</sup> The primary isoflavonoid associated with cancer prevention is genistein.<sup>16</sup> Although the specific molecular mechanisms have yet to be elucidated, genistein displays multiple biochemical properties that inhibit the proliferation of cancer cells in various tissue cultures.<sup>17,18</sup> Genistein also possesses nonestrogenic properties, including inhibition of ribosomal S6 kinase activity and induction of differentiation of malignant cells.<sup>19</sup> Epidemiologic studies of populations that regularly consume soy-based foods reveal markedly lower incidence rates for breast, colon, and prostate cancer, when compared with populations with lesser intake of soy products.<sup>12,17,19</sup>

#### LIGNANS

In addition to their estrogen-like properties, lignans possess a wide range of other biologic activities, including antioxidant, antiproliferative, antiangiogenic, antiaromatase, antiestrogenic, antimitotic, and antiviral properties. High-fiber diets in Western countries provide a substantial proportion of lignan precursors, and the lower incidence of cancer in countries consuming high vegetarian or semi-vegetarian diets may be partially attributable to such fiber-associated substances. Flaxseed flour is a particularly good source of certain lignans, and dietary flaxseed is being investigated as a potential anticancer agent in humans.<sup>20</sup>

The relationship between phytoestrogens and breast cancer has been of particular interest, given the ability of phytoestrogens to mimic the properties of natural estrogens and the hormonal factors determining disease risk, respectively. Numerous animal and human studies indicate that increased consumption of phytoestrogens, particularly soy-based products, is associated with decreased breast cancer risk.<sup>13</sup> The traditional Western diet, having as a component low soy consumption, may adversely affect risk of certain hormone-dependent cancers. For example, the risk of breast cancer is less among Asian women born in Asia, where soy consumption is higher, relative to Asian women born in the United States, where soy consumption is lower.<sup>21</sup> In experimental studies, soy positively affects various physiologic parameters (e.g., menstrual cycle length, hormone levels of follicle-stimulating hormone and luteinizing hormone), and inhibits the proliferation of human breast cancer cells.<sup>12</sup> One potential mechanism for the protective effect of phytoestrogens involves inhibition of *ras* gene expression.<sup>13</sup>

Like breast cancer, prostate cancer risk also may be influenced by dietary consumption of phytoestrogens. Men living in Asian countries where consumption of soy-based foods is higher display a lesser risk of disease relative to men in Western countries where soy consumption is lower.<sup>13</sup> More research into the molecular and biochemical characteristics of the various phytoestrogens, and valid data on their consumption in the typical diet, are required.

#### ORGANOSULFUR AND ORGANOSELENIUM COMPOUNDS

Both experimental and epidemiologic studies support the cancer-preventive ability of certain organosulfur compounds.<sup>22,23</sup> Garlic, a member of the genus *Allium*, is rich in organosulfides, and diallyl sulfide (DAS) is the most frequently investigated sulfur compound found in garlic. In animals and humans, DAS and related compounds inhibit chemical carcinogenesis through an array of mechanisms, in various tissues, and against a variety of specific carcinogens. For example, studies

have demonstrated protective effects of DAS against human colon tumor cells<sup>24</sup> and murine skin carcinogenesis.<sup>25</sup> Studies of the related compound diallyl disulfide (DADS) have noted that it suppresses human colon, skin, and lung tumor cell proliferation; the effect possibly being attributable to the ability of DADS to induce G<sub>2</sub>/M arrest and depress p34<sup>cdc2</sup> kinase activity.<sup>24</sup> Epidemiologic studies have found an inverse association between garlic consumption and risk of gastric cancer, possibly a result of the antibacterial properties of garlic that inhibit conversion of nitrate to nitrite in the stomach, thereby limiting formation of carcinogenic nitrosamines.<sup>23</sup> Organosulfide preventive agents also are present in *Brassica* vegetables (e.g., broccoli, cabbage, cauliflower, and Brussels sprouts). Sulphoraphane, for example, inhibits carcinogen-induced mammary tumorigenesis in rats,<sup>26</sup> and induced phase 2 enzymes in murine hepatoma cells.<sup>27</sup> Selenium inhibits various types of tumors in rodents,<sup>28</sup> and, in humans, low plasma levels of selenium are associated with increased risk of polyps<sup>29</sup> and possibly prostate cancer.<sup>30,31</sup> A sampling of additional studies of organosulfur and organoselenium compounds is found in [Table 23.4-1](#).

Substance	Target	Effect	Reference
Diallyl sulfide	Colon tumor cells <sup>a</sup>	Depression of p34 <sup>cdc2</sup> kinase activity	24

## PHENOLIC COMPOUNDS

Almost all fresh fruits, vegetables, and grains contain measurable amounts of natural plant phenolics, some of which display cancer-inhibitory properties.<sup>32,33</sup> The metabolic, bioavailability, antioxidant, and chemical properties of phenolic compounds have been reviewed,<sup>34</sup> as have potential mechanisms accounting for their anticarcinogenic activity.<sup>33</sup> For example, resveratrol, a triphenolic common in grapes, displays strong antioxidant and antiinflammatory properties and has received considerable attention as a potential cancer-preventive agent in humans.<sup>35</sup> Although the exact mechanism(s) for its antitumorigenic effects are not fully known, its growth inhibitory and antiproliferative properties may be attributable to induction of apoptotic cell death.<sup>36</sup> Resveratrol exhibits a chemical structure similar to diethylstilbestrol, and thus may also be classified as a phytoestrogen. Resveratrol has shown variable amounts of estrogen receptor agonism in different test systems.<sup>37</sup> Resveratrol inhibited the development of preneoplastic lesions in carcinogen-treated mouse mammary glands in culture, and inhibited tumorigenesis in a mouse skin cancer model.<sup>35</sup>

### SIMPLE PHENOL AND PHENOLIC ACIDS

The simple phenols include the monophenols, found in fruits (e.g., raspberry, blackberry); the diphenols; and vanillin. Ellagic acid, a phenolic acid found in nuts and berries, possesses a number of anticarcinogenic properties, and different parts of the ellagic acid molecule may be responsible for assorted putative anticarcinogenic effects.<sup>38</sup> In animal studies, ellagic acid inhibited DNA-carcinogen adduct formation<sup>39</sup>; lung tumorigenesis induced by nicotine-derived nitrosamine in mice<sup>40</sup>; and development of an esophageal-specific carcinogen.<sup>41</sup> Other phenolics also have shown antioxidant, antimutagenic, and anticarcinogenic effects ([Table 23.4-2](#)).

Substance	Target	Effect	Reference
<b>RESVERATROL</b>			
Resveratrol	Prostate cancer (PCa) cells <sup>a</sup>	Decreased proliferation and DNA synthesis	36

**TABLE 23.4-2.** Studies of the Anticarcinogenic Effect of Phenolic Compounds

## FLAVONOIDS

Flavonoids represent the most important single group of phenolics in food<sup>33</sup>; more than 4000 different types have been identified.<sup>42</sup> Potential mechanisms for the anticancer effects of flavonoids include interaction with the cytochrome P-450 mixed function oxidase system and inhibition of tyrosine protein kinase activity and phosphoinositide phosphorylation.<sup>43,44</sup> and<sup>45</sup> Like phytoestrogens, flavonoids display structural properties that allow them to bind to estrogen receptors, potentially decreasing the risk of certain estrogen-dependent cancers.<sup>46</sup>

Experimental and epidemiologic studies of quercetin, the most common and biologically active dietary flavonol, have been reviewed.<sup>42</sup> Quercetin has multiple biochemical effects in mammalian cells and has shown antiproliferative activity against ovarian, breast, and stomach cancer cell lines *in vitro*<sup>44</sup> and against human ovarian cancer primary cultures *ex vivo*.<sup>43</sup> In a phase I clinical trial, quercetin inhibited tyrosine kinase activity and showed evidence of antitumor activity.<sup>44</sup> Other flavonoids, particularly tangeretin and nobiletin, appear to inhibit proliferation of the human breast cancer cell lines MDA-MB-435 and MCF-7.<sup>43</sup>

Long-term studies of the preventive ability of silymarin, a flavonoid isolated from artichoke or milk thistle, indicate its ability to protect against tumor promotion in mouse skin models of carcinogenesis.<sup>47</sup> Protective effects of common citrus flavonoids (e.g., naringin, hesperitin, hesperidin) include actions against B16F10 melanoma cells in mice, *in vitro* inhibition of MDA-MB-435 human breast cell cancer proliferation, and a preventive effect against oral carcinogenesis in rats.<sup>48</sup> Additional studies involving the anticarcinogenic properties of the flavonoids are summarized in [Table 23.4-2](#).

### GREEN TEA POLYPHENOLS

Experimental studies supporting the antimutagenic and anticarcinogenic activities of tea polyphenols, and epidemiologic data indicating an association between tea consumption and cancer risk, have been reviewed.<sup>49</sup> Studies on the catechin (-)-epigallocatechin-3-gallate, the primary green tea polyphenol (GTP), indicate that its growth inhibitory effects are selective, operating on cancerous but not on normal cells.<sup>50</sup> Although various GTPs individually exhibit inhibitory effects,<sup>51</sup> certain catechins act synergistically to reduce cancer risk, indicating that green tea is a more effective protective agent than any of its individual components.<sup>52</sup> Studies of the anticarcinogenic properties of green tea and its constituents are summarized in [Table 23.4-2](#).

Characteristics of GTPs that may account for their anticarcinogenic properties include scavenging of carcinogenic electrophiles, inhibitory action against nitrosation, modulation of carcinogen-metabolizing enzymes, trapping of ultimate carcinogens, inhibition of growth-related signal transduction pathways, modulation of enzymes

associated with cell proliferation, and stimulation of phase II detoxifying enzymes.<sup>53,54</sup> Epidemiologic studies support the potential preventive effect of green tea against cancer at a number of sites, including the lung, esophagus, stomach, and skin.<sup>54</sup> Although GTPs have been the focus of most studies, black tea is consumed more commonly in the West; its potential cancer-protective properties, however, have yet to be fully explored. Animal studies indicate that certain black tea polyphenols, the theaflavins, are associated with significant inhibition of lung adenomas, both *in vivo*<sup>55</sup> and *in vitro*.<sup>56</sup> Additional research involving black tea polyphenols may be warranted.<sup>57</sup>

## CURCUMINOIDS

Curcumin, the major yellow pigment in turmeric and curry, is a common spice, coloring agent, and herbal drug, particularly in Asia. Curcumin has multiple effects on the carcinogenic process, including antioxidant activity, reduction in polyamine synthesis,<sup>58</sup> and inhibition of tumor initiation and promotion.<sup>58</sup> The molecular mechanism explaining the action of curcumin is complex and varied, but it is known to inhibit cyclooxygenase- and lipoxygenase-dependent metabolism of arachidonic acid to prostaglandins and hydroxyeicosatetraenoic acids and to moderately enhance interleukin-4 production.<sup>58</sup> Additional work has shown that curcumin inhibits colon carcinogenesis during the postinitiation phase<sup>60</sup> and has a cytostatic effect at G<sub>2</sub>/M against MCF-7 human breast tumor cells.<sup>61</sup>

## MONOTERPENES

Monoterpenes are found in the essential oils of citrus fruits and other edible plants.<sup>62</sup> The most common monocyclic monoterpene, *d*-limonene, and its metabolite perillyl alcohol have shown effectiveness as cancer-protective agents against rodent cancers of the mammary, skin, liver, lung, forestomach, pancreas, and prostate.<sup>22,62</sup> In human breast cancer cell lines, limonene-related monoterpenes exhibited a dose-dependent inhibition on cell proliferation.<sup>63</sup> Multiple mechanisms may account for the actions of the monoterpenes, depending on tumor type.<sup>62</sup> The blocking effects of *c*-limonene and other monoterpenes during the initiation phase of mammary carcinogenesis may result from induction of phase II carcinogen-metabolizing enzymes and subsequent carcinogen detoxification; in the postinitiation phase, tumor-suppressive activity may be a result of induction of apoptosis and inhibition of the posttranslational isoprenylation of proteins that regulate cell growth.<sup>64</sup> Other cancer-preventive mechanisms include actions on the mevalonate<sup>62</sup> and *ras* signal transduction pathways.<sup>65</sup>

## ISOTHIOCYANATES AND INDOLES

Epidemiologic studies have consistently found strong, inverse relationships between high consumption of cruciferous vegetables and cancer incidence.<sup>66</sup> Cruciferous vegetables contain three groups of glucosinolate-derived compounds likely to be cancer-protective: indole-3-carbinol (I3C) and related indole compounds; phenylethyl isothiocyanate (PEITC) and related isothiocyanates, such as benzyl isothiocyanate (BITC); and dithiolthione and other thiol-containing compounds.<sup>67</sup> The mechanisms by which cruciferous vegetables exert their anticarcinogenic effects have been reviewed.<sup>68</sup> The isothiocyanates and indoles have shown promising results against cancer at a number of sites, in both animals and humans. For example, indoles reduce mammary tumor formation in laboratory animals<sup>67</sup>; PEITC inhibits nitrosamine-induced esophageal cancer in rats<sup>69</sup> and may be protective against lung cancer among smokers<sup>70</sup>; and dithiolthiones reduce mammary and pulmonary tumorigenesis in rodents.<sup>71</sup> Mechanisms for the cancer-preventive actions of the isothiocyanates and indoles include induction of phase II detoxifying enzymes.<sup>71,72</sup>

## PROTEASE INHIBITORS

*In vivo*, *in vitro*, and epidemiologic studies examining the suppression of neoplastic growth by soy-based protease inhibitors (PIs) have been summarized.<sup>15,73</sup> Actions of protease inhibitors include alteration of the expression of certain oncogenes and proteolytic activities that are elevated in carcinogen-exposed tissues; interference with oxyradical formation by neutrophils; and modulation of adenosine diphosphate ribosyltransferase,<sup>74</sup> possibly through the induction of synthesis and distribution of endogenous PIs by dietary PIs.<sup>73</sup> The soybean-derived Bowman-Birk inhibitor (BBI), a major protease inhibitor, may be at least partially responsible for the differences noted in cancer incidence between Asian and Western populations.<sup>75</sup> BBI and its concentrated form (BBIC) have exhibited suppressive effects in a number of carcinogenic models, including animals with a known genetic susceptibility to cancer.<sup>75</sup>

## IMPLICATIONS FOR CANCER PREVENTION

Primary prevention represents the most desirable and cost-effective means of decreasing cancer incidence. Toward this end, the human diet contains anticarcinogens capable of reducing cancer risk, but substantial basic science research will be required to elucidate the mechanisms by which any particular phytochemical exerts its anticancer effect. In the absence of specific knowledge of anticarcinogenic dietary components and their mechanisms, consumption of a wide variety of fruits and vegetables is highly encouraged,<sup>1</sup> because several agents having weak effects *in vitro* may, in combination, prove more effective than any single agent.<sup>76</sup> Such a "polypharmaceutical" approach to cancer prevention is most likely to minimize cancer risk.<sup>77</sup>

Because phytochemicals are consumed, not in the form of high-dose supplements, but rather as constituents within a complex matrix of nutrients, the difficulty in identifying any particular component as being "a" primary preventive agent can be profound, particularly given the attendant problems of valid dietary assessment, confounding, and interaction with other factors. This is not to say, however, that such research cannot, or should not, be conducted. The further elucidation of naturally occurring dietary anticarcinogens represents a key element in efforts to decrease cancer incidence through primary preventive means. Additional epidemiologic and experimental research involving dietary anticarcinogens holds great potential for future cancer prevention efforts.

#### INTRODUCTION

With the exception of tobacco, no environmental exposure to potential carcinogens is comparable to sources in the diet. <sup>1</sup> Although the public often attributes the source of carcinogens in the food supply to food additives, synthetic pesticides, and various environmental contaminants, these chemicals are estimated to represent less than 1% of the carcinogens found in foods. In fact, most known dietary carcinogens either occur naturally in plants or are produced during food preparation. <sup>2,3</sup> Dietary carcinogens in both groups are discussed, with a review of common food sources, mechanisms of action, human exposure, and degree of human risk. A brief overview of issues regarding synthetic carcinogens in the diet is also provided.

In many cases, current knowledge is incomplete and does not allow reliable estimates of risk. First, no concentration data exist for many potentially carcinogenic constituents of foods. In addition, determining human exposure levels is difficult and sometimes inconclusive. <sup>4</sup> Dietary assessment tools are subjective and often biased, <sup>5</sup> the food levels of some substances can vary from year to year, <sup>6</sup> and exposure to mixtures of substances at low doses might be more important than exposure to single agents. <sup>4</sup> High-dose animal testing has been used to approximate human risk, and the Carcinogenic Potency Database currently includes results for approximately 1298 chemicals tested in long-term animal experiments (<http://potency.berkeley.edu/app14.html>). However, this information cannot predict human risk with a high degree of confidence. <sup>7,8</sup> Extrapolation from the near-toxic doses used in animal tests to human risk at low-dose exposure is difficult, and some critics believe its use has sometimes led to overemphasis of potentially minimal risks. <sup>1</sup> One challenge relates to differences in the carcinogenic mechanisms involved. For example, mitogens likely act by increasing cell proliferation, but only at near-toxic levels, whereas mutagens can damage DNA at low doses. As a result, animal tests involving mutagens may have more significance for human risk. <sup>7,8</sup>

To increase the reliability of exposure estimates, biomarkers are being developed to mark internal dose, putative early response, and susceptibility. For example, DNA-carcinogen adducts have been used as measurable end points in laboratory studies and, to a more limited extent, in humans, to assess dietary carcinogen exposure, carcinogen metabolism, mutagenesis, and tumorigenesis. <sup>9,10</sup> In addition, genetic and acquired susceptibility traits have been shown to affect carcinogen metabolism, DNA damage, and repair. <sup>11</sup> In fact, more than a dozen polymorphic gene/phenotypes related to the metabolism of dietary carcinogens are possible actors in the complex process of carcinogenesis at many sites. <sup>12,13</sup> and <sup>14</sup> Although related technology is just emerging and more study is needed, <sup>4,15</sup> approaches such as these have already affected understanding of the substances discussed in the following sections.

#### NATURALLY OCCURRING DIETARY CARCINOGENS

Most naturally occurring dietary carcinogens are either “natural pesticides,” produced by plants for protection against fungi, insects, and animal predators, or mycotoxins, secondary metabolites produced by molds in foods. [Table 23.5-1](#) lists some of the most common substances in both categories.

NATURALLY OCCURRING DIETARY CARCINOGENS	
<b>NATURAL PESTICIDES</b>	
Caffeic acid	Apples, pears, plums, cherries, carrots, celery, lettuce, peas, onions, radish, grapes, eggplants, tomatoes, basil, arnie, sage, chili, carrots, rosemary, sage, coffee beans
Allyl isothiocyanate	Cauliflower, cauliflower, Brussels sprouts, mustard, horseradish
Sulfuric acid	Nutmeg, maca, pepper, cinnamon, nutmeg, nutmeg
Esstragole	Basil, fennel, dill, sage
Carbazole	Margarine
Furocoumarins	Lemon, citrus oils, carrots, celery, parsley, parsnips
Hydrazines	Mushrooms
Phenols	Herbal teas (comfrey)
<b>MYCOTOXINS</b>	
Aflatoxins	Corn, peanuts, seed nuts, peanut butter
Chlrotoxin A	Corn, green coffee beans
T-2 toxin	Barley, maize, softwheat, cereals
Zearalenone	Feed grains, soybeans, maize, wheat
Fumonisin	Corn
Deoxynivalenol	Wheat, maize
Stachyol	Wheat, maize, barley

TABLE 23.5-1. Food Sources of Naturally Occurring Dietary Carcinogens

#### NATURAL PESTICIDES

Animal studies have provided evidence for the carcinogenicity of a large number of individual plant constituents fed at high doses. However, no firm conclusions can be drawn about the overall effects of most of these substances on human health. Plant foods contain thousands of phytochemicals representing various chemical classes and exhibiting diverse molecular structures, and only a small fraction of potential carcinogens produced by plant foods have been tested systematically. <sup>3</sup> In addition, the difficulties previously described in assessing human risk are well illustrated by naturally occurring pesticides. Caffeic acid, which has been shown to cause forestomach squamous cell carcinomas in rats as well as renal tubular cell hyperplasia and adenomas in mice, is a good example. The relevance of the animal findings to humans is uncertain, because data are not available on carcinogenicity in humans, very high doses were used in the animal studies, humans do not have a forestomach, and the renal lesions were related to toxic lesions. <sup>16</sup> In addition, *in vitro*, caffeic acid may act either as a pro- or antioxidant, and it has been observed to be both protective and enhancing when administered orally in combination with known carcinogens. <sup>16</sup> Another confounding factor is the fact that many foods containing caffeic acid also contain compounds believed to be protective, which might affect its ultimate human impact.

Despite such challenges, with additional information on factors such as exposure levels, concentration levels, mechanisms of action, and human clinical experience, researchers can draw conclusions on human risk from natural pesticides. For example, studies of coumarin—a substance with many food sources (particularly cinnamon) that has been found to be carcinogenic in rats and mice—have concluded that it poses no health risk to humans. Known exposure levels and differences in coumarin metabolism between susceptible rodent species and humans contributed to this finding. <sup>17</sup> Other studies are elucidating some of the important factors in assessing human risk, particularly regarding mechanisms of action in animals. For instance, researchers rationalized the restriction of allyl isothiocyanate-related bladder tumors to male rats compared with female rats and both sexes of mice on the basis of a species difference in metabolism and a sex difference in exposure to allyl isothiocyanate metabolites. <sup>18</sup> Other studies have found that the hepatocarcinogenicity of hydrazine is linked to the hypomethylation of total target organ DNA that occurs with chronic exposure and that the hypomethylation is dose-related to the development of liver cancer. <sup>19</sup> Methylation is believed to be a factor in aberrant gene expression and the development of tumors.

From a public health perspective, dietary exposure to natural pesticides can generally be controlled by selecting genetic strains of plants that produce lower concentrations and by reducing plant stress during the growing season. Particular natural pesticides that are carcinogenic in animals might be bred out of crops if research indicates they could be hazardous to humans.<sup>8</sup> Increasing the level of natural pesticides by breeding as an alternative to synthetic pesticides must be considered cautiously in view of their potential health effects. Consumers also could be informed of the relative risks associated with food products such as herbal teas, for which both protective and toxic effects have been documented.<sup>20</sup>

## MYCOTOXINS

Mycotoxins are structurally diverse toxic fungal metabolites that are common contaminants of ingredients in animal feed and human food; to date, more than 300 mycotoxins have been identified.<sup>21</sup> The mycotoxins listed in [Table 23.5-1](#) are among those shown to have carcinogenic potential in animals. However, only aflatoxin B<sub>1</sub> (AFB<sub>1</sub>) and naturally occurring mixtures of aflatoxins are known to be genotoxic and carcinogenic to humans. Fumonisin and ochratoxin A have been shown to be possibly carcinogenic to humans.<sup>22</sup>

### Aflatoxins

AFB<sub>1</sub> is a potent carcinogen in many species of animals, including rodents, nonhuman primates, and fish. Epidemiologic studies show a strong direct association between AFB<sub>1</sub> intake in Africa and China and risk for primary liver and lung cancer in humans.<sup>23,24</sup> Synergistic interactions of AFB<sub>1</sub> with both viral B hepatitis and alcohol consumption in humans also have been demonstrated.<sup>23</sup> High levels of AFB<sub>1</sub>, produced by the *Aspergillus* species, are found in regions of Africa, southeast Asia, and southern China, where the foods they contaminate are dietary staples for humans and animals. In fact, human exposure to AFB<sub>1</sub> in southern China (either directly or through eating the products of animals that ate contaminated feed) can be as high as 75 to 250 µg/d, compared with 25 to 75 ng/d in the United States, where aflatoxin contamination levels are lower.<sup>25</sup>

The aflatoxins have been extensively characterized with respect to chemistry, biology, and toxicology. Like most other mycotoxins with the exception of fumonisins, aflatoxins are genotoxic agents, and substantial research has been conducted on the genetic damage created by AFB<sub>1</sub> in liver and lung tumors. A key biomarker, the predominant AFB<sub>1</sub>-DNA adduct (AFB<sub>1</sub>-N<sup>7</sup>-Gua), has been identified and correlated with the incidence of hepatic tumor in trout and rats.<sup>21</sup> Formation of the AFB<sub>1</sub>-DNA adduct requires metabolic activation of AFB<sub>1</sub> to its carcinogenic form, the 8,9-epoxide.<sup>26</sup> A review of data from animal and human studies that measured urinary excretion of aflatoxin-DNA adducts by molecular dosimetry suggested that these adducts are useful markers of exposure.<sup>15</sup> For instance, a prospective study of more than 18,000 men in Shanghai, China, demonstrated a significant increase in risk [relative risk (RR) = 3.4] for liver cancer in individuals in whom urinary aflatoxin-DNA adducts were detected.<sup>23</sup>

Striking species differences exist in the oncogenic mutations involving AFB<sub>1</sub>. For example, a considerable amount of evidence shows that dietary AFB<sub>1</sub> exposure can produce codon 249 (AGG to AGT) *p53* tumor suppressor gene mutations during human liver carcinogenesis.<sup>27</sup> In rat liver tumors, however, codon 12 of *K-ras* appears to be the “hot spot” for AFB<sub>1</sub>-induced mutations.<sup>28</sup> In mice exposed to AFB<sub>1</sub>, preneoplastic lesions contained mutations in codon 61 of the *Ha-ras* gene, and *in vitro* studies show that metabolically activated AFB<sub>1</sub> in humans is capable of mutating this protooncogene to its oncogenic form, although no such mutations have been reported *in vivo*.<sup>26</sup> Thus, although these mutations are clearly associated with exposure, their significance in terms of mechanistic involvement in tumorigenesis needs further elucidation.<sup>29</sup>

Elimination of exposure to aflatoxins is not possible given the ubiquitous nature of the molds that produce them. Primary prevention methods have included developing aflatoxin-resistant plants, building better storage facilities for grains, and establishing regulatory and testing programs around the world.<sup>23</sup>

### Fumonisin and Ochratoxin A

Of the six fumonisins identified, fumonisin B<sub>1</sub> has been shown to be carcinogenic in rats and mice at high doses, primarily targeting the liver and kidneys. It also has been linked in ecologic studies to esophageal cancer in humans in high corn-consuming regions of China and Africa where high levels of contamination are documented, but no convincing evidence of causality has been presented to date.<sup>30</sup>

Fumonisin, which are produced by *Fusarium moniliforme*, do not appear to be genotoxic, but they may induce cancer through disturbing the signal transduction pathways.<sup>21</sup> As with other dietary carcinogens, difficulties exist with available technologies for assessing exposure, and the search for biomarkers is a rapidly growing area of research. Fumonisin in urine and altered sphingolipid metabolism (sphinganine-sphingosine ratio) in urine and blood are two potential markers currently under investigation.<sup>30,31</sup> The co-occurrence of fumonisins and aflatoxins in corn-based foods has been demonstrated and a synergistic effect postulated.<sup>30</sup>

Ochratoxins are produced by *Aspergillus ochraceus* and related species. Ochratoxin A (OA) has induced renal adenomas and kidney cancers in mice and rats. Carcinogenic effects in humans are suspected based on findings of high levels of OA in the blood of patients with Balkan endemic nephropathy, who also have a high incidence of varied carcinomas.<sup>21</sup> The search for DNA adducts as biomarkers of OA also is ongoing.<sup>21</sup> The relative lack of information on fumonisins, ochratoxins, and other mycotoxins compared with aflatoxins does not mean that their public health risk is necessarily less. Rather, it indicates that more investigation of these mycotoxins is needed.

## PRODUCTS OF FOOD PREPARATION AND PROCESSING

Food preparation and preservation are major sources of dietary carcinogens, including heterocyclic aromatic amines (HAA), formed during frying, broiling, and grilling high-protein foods and more prevalent in well-done meats; polycyclic aromatic hydrocarbons (PAH), formed during broiling and smoking food; and N-nitrosocompounds (NOC), formed in smoked, salted, and pickled foods cured with nitrate or nitrite.<sup>32,33</sup> NOCs are also formed endogenously at sites such as the stomach from nitrites and amines in the diet.<sup>34</sup> [Table 23.5-2](#) lists common carcinogens produced during food preparation and related food sources and cooking methods. Although human risk from these compounds is not always well understood, it may be prudent to minimize exposure by modifying meat cooking methods and eating fewer foods containing NOCs.

Chemical	Food Sources and Cooking Methods
Benz[a]pyrene	Broiled beef and salmon, broiled ground beef and fat
Benzo[a]anthracene	Broiled chicken, fish, pork, broiled beef, chicken, mutton, pork, broiled steaks, ground beef, fat
Benzo[b]fluoranthene	Broiled chicken, pork, broiled chicken, mutton, broiled steaks, fish, broiled mutton, broiled fat
Benzo[k]fluoranthene	Broiled pork, fish, broiled beef, chicken, mutton, fish, broiled steaks, fish, ground beef, ground pork
Benzo[e]pyrene	Broiled fish, broiled beef, chicken, mutton
Chrysene	Charcoal-broiled ground beef, broiled steaks, chicken, broiled steaks, pork, broiled steaks, mutton, broiled fat
Fluorene	Charcoal-broiled ground beef, broiled steaks, chicken, broiled steaks, pork, broiled steaks, mutton, broiled fat
Indeno[1,2,3-cd]perylene	Charcoal-broiled ground beef, broiled steaks, chicken, broiled steaks, pork, broiled steaks, mutton, broiled fat
1-Methylimidazo[4,5-f]quinoline	Cured meats (ham, sausage, salami, hot dogs, frankfurters, corned beef, pastrami, pickled pork, pastrami, salami, corned beef)
2-Aminoimidazo[4,5-f]quinoline	Cured meats (sausage, salami, hot dogs, frankfurters, corned beef, pastrami, pickled pork, pastrami, salami, corned beef)
2,3-Dimethylimidazo[4,5-f]quinoline	Cured meats (sausage, salami, hot dogs, frankfurters, corned beef, pastrami, pickled pork, pastrami, salami, corned beef)
2,8-Dimethylimidazo[4,5-f]quinoline	Cured meats (sausage, salami, hot dogs, frankfurters, corned beef, pastrami, pickled pork, pastrami, salami, corned beef)
2,9-Dimethylimidazo[4,5-f]quinoline	Cured meats (sausage, salami, hot dogs, frankfurters, corned beef, pastrami, pickled pork, pastrami, salami, corned beef)
2,4,6-Trinitrobenzene	Cured meats (sausage, salami, hot dogs, frankfurters, corned beef, pastrami, pickled pork, pastrami, salami, corned beef)
2,4-Dinitrobenzene	Cured meats (sausage, salami, hot dogs, frankfurters, corned beef, pastrami, pickled pork, pastrami, salami, corned beef)
2-Nitrofluorene	Cured meats (sausage, salami, hot dogs, frankfurters, corned beef, pastrami, pickled pork, pastrami, salami, corned beef)
2-Nitroimidazo[4,5-f]quinoline	Cured meats (sausage, salami, hot dogs, frankfurters, corned beef, pastrami, pickled pork, pastrami, salami, corned beef)
2-Nitroimidazo[5,6-f]quinoline	Cured meats (sausage, salami, hot dogs, frankfurters, corned beef, pastrami, pickled pork, pastrami, salami, corned beef)
2-Nitroimidazo[4,5-g]quinoline	Cured meats (sausage, salami, hot dogs, frankfurters, corned beef, pastrami, pickled pork, pastrami, salami, corned beef)
2-Nitroimidazo[5,6-g]quinoline	Cured meats (sausage, salami, hot dogs, frankfurters, corned beef, pastrami, pickled pork, pastrami, salami, corned beef)

TABLE 23.5-2. Dietary Carcinogens Produced During Food Preparation: Sources and Cooking Methods

## HETEROCYCLIC AROMATIC AMINES

HAAs are potent mutagens and animal carcinogens, causing cancers of the liver, colon, mammary gland, skin, Zymbal gland, large intestine, prostate, lymphoid

tissues, oral cavity, lung, and clitoral gland in rodent models.<sup>35,36</sup> Approximately 20 HAAs have been isolated<sup>33</sup>; the major subclass found in the human diet comprises the aminoimidazoazaarenes (AIA). Four of these are possibly carcinogenic to humans, including 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ); 2-amino-3,4-dimethylimidazo[4,5-*f*]quinoline (MeIQ); 2-amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline (8-MeIQx); and 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP).<sup>33,37</sup> However, the etiologic role of HAAs in human cancer is unclear, in part because of a lack of information on the effect of typical cooking methods and degree of doneness on concentrations of HAAs as well as on variation in exposure.<sup>38,39 and 40</sup>

Animal studies have demonstrated formation of HAA-DNA adducts in numerous tissues, and a review reports that all of the AIAs studied adduct to the guanine base, with the major adduct being formed at the C8 atom of guanine. Two AIAs, IQ and MeIQx, also form minor adducts at the N<sup>2</sup> position of guanine.<sup>35</sup> Studies of animal tumors have begun to relate AIA-DNA adduct-induced mutagenic events with the mutations found in critical genes associated with oncogenesis, and AIA-DNA adduct levels in target tissues are strongly related to tumor incidence.<sup>35</sup> Dietary fat also has been implicated as a promotional factor in HAA-related carcinogenesis in animal studies, but the data remain difficult to interpret.<sup>41,42</sup>

Although HAA-DNA adducts can be useful biomarkers, their detection in humans has proved difficult. Some adducts have been documented, however.<sup>35</sup> For example, one report indicates that MeIQx forms DNA adducts in the human colon at a low dose and that the human colon may be more sensitive to MeIQx than the colon of mice or rats.<sup>43</sup> In addition, using accelerator mass spectrometry, it has been possible to detect AIA-DNA adducts in tissues after dosing animals with amounts equivalent to human dietary exposures. Such studies confirm that AIAs are potentially genotoxic and carcinogenic at specific target sites at doses derived from the human diet.<sup>35</sup>

Metabolic activation is necessary to the formation of HAA-DNA adducts in animals and humans and is critical to the mutagenicity and carcinogenicity of HAAs.<sup>4,35</sup> The metabolic activation of HAAs varies among species, but activation in humans appears to occur via N-oxidation to form N-hydroxy metabolites followed by O-acetylation to form N-acetoxy arylamines that bind to DNA. These steps are catalyzed by cytochrome P-450A2 and N-acetyltransferase-2 (NAT-2), respectively.<sup>39,44</sup>

There is wide interindividual variation in the capacity of human tissues to activate HAAs, and polymorphisms of related enzymes in humans have been investigated for potential relationship to cancer risk. In some studies, but not in others, individuals who were both rapid N-oxidizers and rapid acetylators had a greater risk of colon cancer than those who were both slow N-oxidizers and slow acetylators.<sup>4,45,46 and 47</sup> In one study, rapid acetylators had an increased risk only with a high intake of meat.<sup>41</sup> Some data suggest that variations in susceptibility to pancreatic and prostate cancer also are associated with genetic differences of carcinogen-metabolizing enzymes, although these areas require further investigation.<sup>48,49</sup> In breast cancer, differential susceptibility in rapid versus slow acetylators has been found in some studies, but not in others.<sup>50,51,52 and 53</sup>

Urinary excretion of cooking-associated HAAs and their metabolites is being investigated as a possible biomarker of human exposure, and studies have shown measurable excretion of MeIQx and its metabolites after consumption of proteins cooked at high temperatures.<sup>15,54</sup> Although researchers found a dose-response relationship between the bacon intake of African American, white, and Asian American men and MeIQx excretion,<sup>55</sup> no such relationship was seen in the same group of men for consumption of any type of cooked meat and PhIP.<sup>54</sup>

## POLYCYCLIC AROMATIC HYDROCARBONS

PAHs, several of which have been found to be carcinogenic in animal studies, have a widespread distribution throughout the environment, both as a by-product of cooking meats over an open flame and as a contaminant in animal and human foods.<sup>56,57</sup> However, available exposure and carcinogenicity data are insufficient to allow a reliable estimate of dietary PAH risk for humans at this time.

It is clear that fat dripping onto the coals and the subsequent deposition of PAHs that rise with smoke onto the meat contribute significantly to PAH exposure.<sup>15</sup> Benzo(a)pyrene, the most carcinogenic PAH, has been reported at levels of up to 50 µg/kg in charbroiled steaks and ground beef, five times greater than levels in some less fatty pork cuts and chicken.<sup>58</sup>

In addition, several studies have demonstrated a consistent association between recent consumption of charbroiled foods and increased PAH-DNA adduct concentrations in peripheral white blood cells and excretion of 1-hydroxypyrene in urine.<sup>15,59,60</sup> One review suggests a correlation between PAH-DNA adducts and *ras* oncogene mutations.<sup>61</sup> Some evidence points to an antioxidant response element playing a significant role in PAH carcinogenesis.<sup>62</sup> It also has been suggested that the *hGSTP1* gene, which has been shown to be polymorphic in humans, may be an important factor in differential susceptibility to PAH-related cancers, although study conclusions differ. The chemical composition of the PAH mixtures to which humans are exposed can include cigarette smoke and industrial emissions as well as dietary sources, and differences in mixtures may affect the involvement of the *hGSTP1* gene.<sup>63</sup>

## N-NITROSOCOMPOUNDS

NOCs administered orally in animals, including nonhuman primates, consistently elicit carcinogenic responses.<sup>64</sup> These compounds also may be a significant risk factor for human cancers of the stomach, esophagus, colon and rectum, nasopharynx, urinary bladder, and liver.<sup>22,65,66</sup> One review found that, although the epidemiologic evidence overall remains inconclusive, an association between NOCs and human cancer cannot be ruled out. The author postulated that inadequate available data may be obscuring a small to moderate carcinogenic effect of NOCs.<sup>34</sup>

The formation of endogenous NOCs may be inhibited by naturally occurring compounds in foods, such as ascorbic acid, tocopherols, retinoids, phenolic compounds, sulfhydryl compounds, tea, orange peel, and certain fruits and vegetables.<sup>67</sup> This may in part explain the generally protective effect of vegetables and fruits consistently observed in epidemiologic studies.<sup>68,69</sup>

## SYNTHETIC CARCINOGENS IN THE DIET

Animals and humans also are exposed to a variety of synthetic chemicals in their foods from food additives. Direct (intentional) synthetic additives include antioxidants, colorants, flavor ingredients, artificial sweeteners, solvents, and humectants. Regulation of synthetic or natural chemicals intentionally added to food has led to extensive data on exposure. Indirect (unintentional) synthetic additives include pesticides, solvents, and packaging-derived chemicals. These chemicals, which number more than 2000, enter the food supply during production, processing, packaging, and storage from a variety of sources. Very little data exist on exposure to these chemicals. Pesticides are of major concern to the public and regulatory agencies compared with other indirect food additives. Most, if not all, pesticides have possible human toxicity, including carcinogenic potential. In general, levels encountered are below allowable tolerances, although actual estimates of risk are problematic.<sup>16</sup> Packaging materials, including vinyl chloride, and several phthalate esters used as plasticizers have gained attention from researchers as another possible unintentional addition to packaged foods with potential risks to human health.

Synthetic chemical contamination of water has been another concern, principally focused on trihalomethanes, which are disinfection by-products, in public water supplies and pesticides in well water.<sup>70,71 and 72</sup>

The National Research Council classifies synthetic chemicals as genotoxic, which directly affect DNA, form DNA adducts, and increase cancer risk, and nongenotoxic, which do not directly affect DNA, but which may affect carcinogenesis through other posited mechanisms.<sup>16</sup> Some synthetic chemicals can exhibit both genotoxic and nongenotoxic activity.

The metabolic pathways involved in the biotransformation of both synthetic and naturally occurring chemicals are similar, and evidence to date suggests that the processes of carcinogenesis also are similar, if not identical. Not surprisingly, the difficulties that complicate risk prediction for naturally occurring dietary carcinogens also apply to the synthetic carcinogens.<sup>16</sup>

## FUTURE RESEARCH NEEDS

It is clear from human epidemiologic data that diet contributes to an appreciable portion of cancer; however, continuing research is needed for better identification of

the risk to humans from specific carcinogens in the diet. Although we have begun to understand some of the key factors affecting risk estimation for some of the phytochemicals in plant foods, both naturally occurring and synthetic chemicals are numerous and diverse. The National Research Council suggests that new concepts and methods must be developed and extensive research conducted before results obtained in various model systems can be extrapolated with greater reliability to humans.<sup>16</sup>

#### INTRODUCTION

Since the late 1970s, researchers have been interested in whether regular ingestion of aspirin or other nonsteroidal antiinflammatory drugs (NSAIDs) can decrease the risk of cancer, especially colorectal cancer.<sup>1</sup> This hypothesis was stimulated by basic research<sup>2,3,4</sup> and<sup>5</sup> and uncontrolled clinical observations<sup>6</sup> beginning in the mid-1970s. Further support derives from numerous observational epidemiologic studies<sup>7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33</sup> and<sup>34</sup> and mechanistic insights in the 1990s, and from several randomized clinical trials showing that the aspirin-like prodrug sulindac<sup>35,36,37</sup> and<sup>38</sup> and the novel selective cyclooxygenase-2 (COX-2) inhibitor celecoxib<sup>39</sup> suppress adenomatous polyps among patients with familial adenomatous polyposis (FAP). More recent data indicate that NSAIDs increase apoptosis,<sup>40,41,42</sup> and<sup>43</sup> inhibit angiogenesis,<sup>44,45</sup> and reduce metastasis in various experimental models of carcinogenesis.<sup>46,47</sup>

No randomized trials have been completed to test whether aspirin or other NSAIDs inhibit colorectal cancer. The Physician's Health Study, a randomized trial of aspirin designed to evaluate the primary prevention of cardiovascular end points,<sup>48</sup> found no reduction in colorectal cancer among male physicians randomized to 325 mg aspirin or placebo every other day for 5 years and followed for 12 years.<sup>49</sup> However, the short duration and low dose of randomized treatment limit the interpretability of this finding. At least five ongoing randomized clinical trials are testing whether nonselective NSAIDs, such as aspirin and sulindac, or novel selective inhibitors of inducible COX reduce the recurrence of adenomatous polyps among patients with previous sporadic polyps. Trials of intermediate end points in high-risk populations have the advantage of decreasing the necessary sample size and duration of treatment but have the disadvantage of not directly measuring the effect of NSAIDs on cancer.

This chapter reviews the experimental, clinical, epidemiologic, and randomized trial evidence relevant to NSAIDs and cancer, particularly colorectal cancer. We also consider the limited evidence available on lowest effective dose, treatment criteria, and the balance of potential benefits to risk of prolonged NSAID treatment. Although extensive evidence now indicates that NSAIDs inhibit neoplasia in several experimental settings and in the clinical context of FAP, we believe that aspirin and other NSAIDs are presently promising but unproven candidates for the chemoprevention of colorectal and perhaps other cancers in high-risk populations.

#### PHARMACOLOGY AND TOXICITY OF NONSTEROIDAL ANTIINFLAMMATORY DRUGS

NSAIDs are a chemically diverse group of drugs effective in the relief of pain, inflammation, and fever.<sup>50</sup> The analgesic, antiinflammatory, and antipyretic properties of salicylate in willow bark and other plant extracts were recognized in ancient Egypt and Greece.<sup>51</sup> NSAIDs also have dose-related toxicity to the gastrointestinal (GI) tract and kidney. The chemist Felix Hoffman was reportedly motivated to synthesize aspirin (acetylsalicylic acid) from sodium salicylate in the late nineteenth century because of the GI toxicity experienced by his father during treatment with salicylate for arthritis.<sup>52</sup> NSAIDs can also affect hemostasis, reproduction, childbirth, and asthma.<sup>50</sup> Efforts to minimize stomach irritation and to prolong the half-life of these drugs have motivated the development of many new NSAIDs in addition to aspirin.<sup>53</sup> Nonselective NSAIDs, such as ibuprofen, indomethacin, naproxen, piroxicam, and sulindac, now compete with novel, selective COX inhibitors that are reputed to lack major GI toxicity.<sup>54</sup>

The common pharmacologic action of NSAIDs is to inhibit COX, the initial and rate-limiting enzymatic step in the metabolism of arachidonic acid into a complex group of signaling proteins termed *prostaglandins*.<sup>55,56</sup> and<sup>57</sup> Arachidonic acid derives from meat or linoleic acid in the diet. It is normally tightly bound to cell membranes until being hydrolyzed by phospholipases as free arachidonic acid (arachidonate). Arachidonate can then be metabolized through COX pathways into prostaglandins and thromboxane; through lipoxygenase into leukotrienes and other lipid mediators; or by nonenzymatic pathways. Metabolites of arachidonic acid are called *eicosanoids*.

Prostaglandins and their derivatives modulate many functions within cells (autocrine) or across neighboring tissues (paracrine).<sup>58</sup> They differ from systemic hormones in that they are produced and destroyed almost instantaneously. Most tissues produce only a few prostaglandins in abundance. The function of the same prostaglandin may differ in different organs. Thromboxane-A<sub>2</sub> (TXA<sub>2</sub>) produced by platelets enhances platelet aggregation, clot formation, and hemostasis; prostacyclin (prostaglandin I<sub>2</sub>) from vascular endothelial cells enhances vasodilatation and prevents the aggregation of platelets. Prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) is a potent vasodilator in most vascular beds and also relaxes tracheobronchial and uterine muscle and protects gastric epithelium from acid. Prostaglandin G and prostaglandin D contract smooth muscle and modulate renal blood flow and sodium and water retention by the kidney.<sup>58</sup>

The diverse homeostatic and reactive functions of prostaglandins have prompted pharmacologists to seek drug and treatment regimens that improve NSAID specificity. One such strategy is to use low-dose aspirin (40 to 100 mg daily) to inhibit COX activity and TXA<sub>2</sub> production by platelets as they pass through the enterohepatic circulation.<sup>59</sup> Aspirin is the only NSAID that covalently acetylates and permanently inhibits COX. Platelets lack a nucleus and cannot synthesize new enzyme during their 7- to 10-day lifespan. At antiplatelet doses, virtually all of the absorbed aspirin is metabolized by the liver and does not reach the systemic circulation.

A second strategy is to develop new NSAIDs that selectively target a single isoform of the COX enzyme.<sup>53</sup> Until 1991, only one isoform of COX was recognized. Then a second isoform was identified<sup>57</sup> that increased in many tissues during inflammation, wound healing, and neoplasia.<sup>60,61,62,63</sup> and<sup>64</sup> These isoforms were named COX-1 and COX-2, reflecting the sequence with which their structure was characterized by x-ray crystallography. The original enzyme, COX-1,<sup>65</sup> is expressed constitutively in most tissues of the body. It plays a central role in gastric cytoprotection and platelet aggregation and contributes to vascular dilatation, renal sodium and water balance, and other homeostatic functions.<sup>66</sup> The second isoform, COX-2,<sup>67</sup> has substantial sequence homology with COX-1<sup>68</sup> but is encoded by a different gene. COX-2 is not expressed under basal conditions in many tissues, but is up-regulated by inflammatory cytokines, growth factors, tumor promoters, and other physiologic stimuli.<sup>54,69</sup>

The paradigm that COX-2 is merely a "bad" enzyme that causes inflammatory and neoplastic processes, whereas COX-1 is a "good" enzyme essential for homeostasis now appears to be oversimplified.<sup>54</sup> COX-2 is expressed constitutively in the brain and kidney. It is known to be essential in ovulation and fertilization and implantation of the embryo, and it has as yet poorly understood homeostatic functions in the kidney, brain, cartilage, and bone.<sup>66</sup> The main distinction between the COX isoforms is that COX-1 is expressed constitutively in most tissues, whereas COX-2 is more often induced on demand.<sup>66</sup>

Most conventional NSAIDs inhibit both COX-1 and COX-2 with variable potency.<sup>61,62</sup> Aspirin is a relatively selective COX-1 inhibitor, except at antiinflammatory doses of 1 g/d or more. Novel selective COX-2 inhibitors have been introduced that cause GI symptoms but are thought not to cause serious GI ulceration.<sup>70,71</sup> Prototypes of these, such as celecoxib (SC-58635) and rofecoxib, are considerably more expensive than conventional NSAIDs. These drugs are proving informative in mechanistic studies to identify the enzymatic target(s) by which NSAIDs inhibit carcinogenesis in experimental models.

## HISTORICAL EVOLUTION OF THE HYPOTHESIS THAT NONSTEROIDAL ANTIINFLAMMATORY DRUGS INHIBIT CANCER

### EICOSANOIDS IN HUMAN TUMORS

The hypothesis that certain cancers might overproduce specific prostaglandins and thereby promote their own growth arose in the mid-1970s when Bennett and colleagues<sup>3,4</sup> observed higher concentrations of PGE<sub>2</sub> in some human colorectal carcinomas than in surrounding normal mucosa. Subsequent studies confirmed that certain human colon cancer cell lines<sup>72</sup> and tumor tissues<sup>2,56,73</sup> overproduce PGE<sub>2</sub>. The idea that tumor prostaglandins might accelerate the growth and invasion of the cancer was further supported by the observation of Narisawa et al.<sup>74</sup> that PGE<sub>2</sub> in venous blood draining human colorectal carcinomas is higher in vivo when the cancers are large and locally invasive.

### NONSTEROIDAL ANTIINFLAMMATORY DRUGS AND CHEMICALLY INDUCED CANCER IN RODENTS

Extensive experimental evidence confirms that many NSAIDs suppress tumor development in animal models and cell culture. More than 40 experiments in rodents show that aspirin, other nonaspirin NSAIDs, and selective COX-2 inhibitors suppress intestinal tumorigenesis in rats and mice exposed to chemical carcinogens.<sup>39,47</sup> Colorectal cancers produced in these rodent experiments<sup>75,76,77,78,79,80,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96,97,98,99,100,101,102,103,104,105,106</sup> and <sup>107</sup> resemble human cancer, except for a lower tendency to metastasize.<sup>108</sup> Tumor inhibition is greatest when NSAID treatment is begun before exposure to the carcinogen and continued without interruption throughout the experiment.

### UNCONTROLLED CLINICAL STUDIES OF SULINDAC IN PATIENTS WITH FAMILIAL ADENOMATOUS POLYPOSIS

The early rodent experiments prompted Waddell and Loughry<sup>6</sup> to test whether the prodrug sulindac inhibits adenomatous polyps in the rare hereditary condition of FAP. Adenomatous polyps are the precursor to most human colorectal cancers. Patients with FAP inherit a germline mutation inactivating one allele of the adenomatous polyposis coli (APC) gene. Loss of the remaining functional APC allele results in hundreds to thousands of adenomatous polyps by the second or third decade of life. Patients who do not undergo prophylactic colectomy almost invariably develop colorectal cancer by the age of 40 to 50 years.<sup>109,110</sup> FAP patients who have undergone total colectomy still have increased risk of adenomatous polyps; cancer of the rectal stump and small intestine; and nonmalignant, primitive desmoid tumors.

In FAP, sulindac reduces the number and size of new polyps and even causes existing polyps to regress. This finding has been reported in thirteen case studies<sup>1</sup> and in three small randomized crossover trials.<sup>35,37,38</sup> Sulindac also suppresses the formation of desmoid tumors in these reports. However, sulindac does not prevent all polyp growth in FAP patients, just as conventional NSAIDs do not inhibit all chemically induced colorectal cancer in the rodent model. Some polyps may grow during treatment<sup>111</sup> or be transformed into carcinoma.<sup>112,113</sup> Most adenomatous polyps typically increase in number and size after sulindac is discontinued.

### EPIDEMIOLOGIC STUDIES OF NONSTEROIDAL ANTIINFLAMMATORY DRUGS IN THE GENERAL POPULATION

At least 25 observational epidemiologic studies have compared people who regularly use aspirin or other NSAIDs to those who do not with respect to colorectal cancer<sup>7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33</sup> and <sup>34</sup> (Table 23.6-1 and Table 23.6-2) or colorectal adenomatous polyps.<sup>16,18,23,31,32,33</sup> and <sup>34,114</sup> All but one of the published studies finds 30% to 50% lower incidence or mortality rates from colorectal cancer ( Fig. 23.6-1) or lower incidence of adenomatous polyps ( Fig. 23.6-2). The consistency of these observational studies is striking, despite different researchers using varied study designs in different parts of the world. Interestingly, the single observational study that did not find reduced risk of colorectal cancer or adenomatous polyps among aspirin users also did not find reduced risk of myocardial infarction among the elderly subjects (median age of 70 years at enrollment) who reported taking one aspirin daily.<sup>10,11</sup>

Study	Design	Population	Exposure	Outcome	Relative Risk (95% CI)
1	Cohort	General	Aspirin	Colorectal cancer	0.5 (0.3-0.8)
2	Cohort	General	Aspirin	Colorectal cancer	0.6 (0.4-0.9)
3	Cohort	General	Aspirin	Colorectal cancer	0.7 (0.5-1.0)
4	Cohort	General	Aspirin	Colorectal cancer	0.8 (0.6-1.1)
5	Cohort	General	Aspirin	Colorectal cancer	0.9 (0.7-1.2)

TABLE 23.6-2. Case-Control Studies on the Use of Nonsteroidal Antiinflammatory Drugs (NSAIDs) and the Risk for Colorectal Cancer in the General Population

**FIGURE 23.6-1.** Epidemiologic studies of nonsteroidal antiinflammatory drugs and colorectal cancer. **A:** Prospective cohort trials. **B:** Retrospective case-control trials.

**FIGURE 23.6-2.** Epidemiologic studies of nonsteroidal antiinflammatory drugs and adenomatous polyps.

Several observational studies report a dose-response gradient of decreasing risk of colorectal cancer or adenomatous polyps among individuals who report more prolonged<sup>18,26,30,115</sup> or frequent<sup>12,20,23,30,114</sup> NSAID use. Factors that influence self-selection for or against NSAID use could, in principle, confound this observation. Perhaps a more important limitation of the analyses by dose and duration is that none of the studies have simultaneously taken into account both aspirin and nonaspirin NSAIDs, prescription and nonprescription medications, and changes in the frequency or dose of NSAID use over time. Two large prospective studies<sup>18,115</sup> and one case-control study<sup>30</sup> found the largest reductions in colorectal cancer in persons who have used aspirin for at least 10 or even 20 years. Another large prospective study based on prescription drug records in the United Kingdom between 1994 and 1997 found reduced risk of colorectal cancer in patients prescribed at least 300 mg aspirin daily compared to nonusers, but not among current users of less than 300 mg aspirin daily.<sup>20</sup> The U.K. study lacked information on long-term use of aspirin or other NSAIDs. It is important to define the lowest effective dose and optimal duration, because the GI toxicity of NSAIDs increase with dose, and risk accumulates with duration. The use of antiplatelet doses of aspirin (100 mg or less) to prevent cardiovascular events did not begin until the late 1980s and cannot yet be evaluated with respect to colorectal cancer. However, even antiplatelet doses of aspirin (80 to 100 mg/d) causes some increase in GI<sup>116</sup> and intracerebral bleeding,<sup>117</sup> especially with prolonged treatment of large numbers of healthy people. If NSAIDs are proven to be effective in preventing colorectal cancer in the future, it is likely that long-term prophylaxis could produce a net benefit only in persons with substantially increased risk of colorectal cancer, or because of a combination of other factors that may affect individual risk and benefit.<sup>118</sup>

### COMPLETED AND ONGOING RANDOMIZED TRIALS

Several randomized clinical trials show that sulindac<sup>35,36,37</sup> and the novel selective COX-2 inhibitor celecoxib<sup>39</sup> reduce the number and size of adenomatous polyps in FAP patients and causes existing polyps to regress. Only one randomized clinical trial of aspirin in the primary prevention of cardiovascular end points has been sufficiently large to measure incidence or death rates from colorectal cancer, although the aspirin arm of this trial was terminated after 5 years. The Physicians' Health Study showed no reduction in either invasive or *in situ* colorectal cancer incidence, nor a reduction in colorectal cancer mortality among 22,071 male physicians randomized to 325 mg aspirin or placebo every other day for 5 years and followed for 12 years.<sup>40</sup> The short duration of randomized treatment and relatively low dose of aspirin limit the interpretability of these results.

Several randomized clinical trials are now testing whether aspirin or other NSAIDs inhibit adenomatous polyps among patients with previous sporadic polyps or FAP. Trials of intermediate end points in high-risk populations have the advantage of decreasing the necessary sample size and duration of treatment, but have the disadvantage of not directly measuring the effect of NSAIDs on cancer.

### STUDIES OF MECHANISM

Debate is ongoing over the mechanisms by which NSAIDs inhibit carcinogenesis in various experimental and clinical models. This debate is further complicated in that NSAIDs may affect several stages in the adenoma-carcinoma sequence, perhaps by different mechanisms. Most evidence suggests that COX, particularly the inducible COX-2 isoform, is probably the major enzymatic target by which NSAIDs inhibit cancer in various models. Effects mediated through COX could explain why numerous NSAIDs with diverse chemical structures all inhibit COX activity and nearly all suppress colorectal carcinogenesis. There is also debate about which cellular targets and functions may be most relevant to NSAID tumor inhibition in humans.

#### Studies Implicating Cyclooxygenase-2

Circumstantial evidence that the inducible isoform of COX contributes to colorectal neoplasia is that COX-2 is up-regulated as normal intestinal mucosa progresses to invasive colorectal cancer in humans.<sup>47</sup> COX-2 protein and messenger RNA are undetectable in normal colonic mucosa, yet are present in approximately 40% of human adenomatous polyps<sup>119</sup> and more than 80% of colorectal cancers.<sup>119,120</sup> and<sup>121</sup> COX-1, in contrast, is expressed at constant basal levels in all of these tissues. COX-2 is expressed constitutively by at least one human colon cancer cell line (HT-116) and can be induced in four other human tumor cell lines by exogenous agonists.<sup>122</sup> COX-2 concentration in human colorectal carcinomas has been reported to increase with larger tumor size and deeper invasion, although not with evidence of metastases.<sup>123</sup> In rodent models, COX-2 expression is up-regulated after exposure of rats to azoxymethane (AOM).<sup>124</sup> COX-2 is also expressed at an early stage in APC<sup>min</sup> and APC<sup>D716</sup> mice.<sup>125</sup> Intestinal cells from murine models of FAP overproduce COX-2 and PGE<sub>2</sub>, even in mucosa in which no adenomatous polyps are visible.<sup>126</sup>

Direct laboratory evidence that COX-2 affects colorectal cancer comes from genetic knockout studies that eliminate specific isoforms of COX in Min mice and from selective drug inhibition in several rodent models. Min mice that have been genetically altered to lack COX-2 activity develop 70% to 80% fewer intestinal tumors than do Min mice with normal activity of both isoforms. AOM-exposed rats treated with the selective COX-2 inhibitor celecoxib (1500 ppm) develop virtually no intestinal tumors<sup>102</sup> and 50% fewer aberrant crypt foci than those exposed to the chemical carcinogen alone.<sup>127,128</sup> Celecoxib also reduces the number and size of intestinal tumors in Min<sup>129</sup> and variant Apc-deficient mice,<sup>130</sup> and in mice implanted with human colon cancer transplants.<sup>131</sup>

#### Studies Implicating Cyclooxygenase-1

More limited experimental and epidemiologic evidence suggests that COX-1 activity may also contribute to the development of colorectal and other cancers.<sup>132</sup> Homozygous inactivation of either COX-1 or COX-2 produces an equivalent 70% to 80% reduction in intestinal tumors compared to Min mice with both COX isoforms intact.<sup>132</sup> No experimental studies have tested selective COX-1 inhibitors in various rodent models of carcinogenesis. However, participants in several epidemiologic

studies who report taking 365 mg of aspirin daily experience fewer adenomatous polyps or colorectal cancers than those who do not take NSAIDs. <sup>18,20</sup> Aspirin is predominantly a COX-1 inhibitor at this dosage. Epidemiologic studies cannot yet assess whether prolonged use of aspirin at doses of 100 mg or less is also associated with reduced incidence of colorectal cancer or adenomatous polyps. Clinical studies report that people given low-dose aspirin (80 mg) for up to 3 months, <sup>133,134</sup> or 325 mg daily for 60 days, <sup>135</sup> have lower concentrations of PGE<sub>2</sub> and PGF<sub>2a</sub> in rectal mucosa than were present in biopsy specimens taken before aspirin administration. These studies are limited in interpretability, however, in that rectal epithelial specimens are likely to have been contaminated by platelets, possibly accounting for the observed changes in eicosanoid levels.

### Evidence for Noncyclooxygenase Mechanisms

Some research suggests that NSAIDs may inhibit neoplasia through pathways other than COX or that a mix of prostaglandin-independent and -dependent mechanisms may exist.<sup>1</sup> Sulindac sulfone, the sulfone metabolite of sulindac, is believed to have little inhibitory activity against COX, <sup>136,137</sup> yet high oral concentrations (1000 and 2000 ppm in food) inhibit intestinal tumors <sup>106,107</sup> and aberrant crypt formation<sup>138</sup> in AOM-exposed rats, and inhibit chemically induced mammary cancer in mice.<sup>139</sup> In one of these studies, <sup>107</sup> no suppression was found in PGE<sub>2</sub> or the activity of COX, lipoxygenase, and phospholipase A<sub>2</sub>. In other studies, supraphysiologic concentrations of sulindac sulfone in cell culture inhibit the growth of human HT-29 tumor cells, <sup>140</sup> as well as other human cell lines that do not express COX or produce prostaglandins.<sup>41,141</sup> NSAIDs also have been postulated to inhibit colorectal cancer by influencing nitric oxide metabolism <sup>142</sup> or binding with the peroxisome proliferator-activated receptor d (PPAR d).<sup>143</sup> The latter is postulated to be a common target by which NSAIDs can mimic the effects of the APC gene and down-regulate transcription.<sup>143</sup> The relevance of these mechanistic studies to human colorectal cancer remains uncertain.

## CELLULAR MEDIATORS OF TUMOR INHIBITION

### ENHANCED APOPTOSIS

Accumulating evidence suggests that loss of apoptosis (programmed cell death) contributes to the development of human colorectal cancer and that NSAID treatment can restore normal apoptosis in several clinical and experimental settings. Apoptosis is impaired in adenomatous polyps from FAP patients, in sporadic colorectal polyps,<sup>144</sup> and in human intestinal epithelial cells altered to overexpress COX-2. <sup>145</sup> Normal apoptosis can be restored in FAP patients by a 3-month treatment with sulindac.<sup>40</sup> Apoptosis can also be increased in cultured HT-29 human colon cancer cells by salicylate, <sup>41</sup> sulindac or sulindac sulfide, <sup>146</sup> and by other conventional NSAIDs.<sup>146</sup> NSAIDs increase apoptosis in rats exposed to chemical carcinogens<sup>42</sup> and in nontransformed rat intestinal epithelial cells altered to overexpress COX-2 constitutively.<sup>145</sup> Although the mechanisms by which NSAIDs affect apoptosis are unknown, Taketo<sup>47</sup> proposes that they may involve some critical interaction between the induction of COX-2 and homozygous loss of function of the APC gene. Apoptosis can be induced in HT-29 human colorectal cancer cells that lack APC activity by restoring APC function in these cells.<sup>43</sup>

Additional evidence that apoptosis may be an important cellular mediator of the anticancer effects of NSAIDs is that the combination of NSAIDs and lovastatin is a more potent stimulus for apoptosis, experimentally, than either agent alone. <sup>147</sup> Lovastatin is a cholesterol-reducing hepatic 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor. The combination of lovastatin and sulindac amplifies several-fold the stimulatory effect of sulindac alone on apoptosis in three human colon cancer cell lines (HCT-116, SW 480, and LoVo) and in AOM-exposed rodents. <sup>147</sup> Agarwal et al.<sup>147</sup> suggest that combining NSAIDs with an HMG-CoA reductase inhibitor may increase the effectiveness of chemoprevention or allow the use of lower, less toxic doses of NSAID.

Furthermore, experimental evidence suggests that NSAIDs cause cell-cycle arrest and accumulation of cells in the G<sub>0</sub>/G<sub>1</sub> phase, potentially contributing to enhancement of apoptosis.<sup>41,146</sup> Indomethacin has long been known to induce reversible cell-cycle arrest in the G<sub>1</sub> phase in cultured, transformed rat hepatoma and nontransformed human fibroblast cells. <sup>148,149</sup> NSAIDs such as sulindac and sulindac sulfide also reduce the level and activity of several cyclin-dependent kinases that regulate cell-cycle progression and induction of apoptotic cell death in human HT-29 colon cancer cells. <sup>146</sup> These effects on cell-cycle progression require concentrations of salicylate between 1 and 5 mmol/L<sup>41</sup>; thus, the extent to which these effects are relevant to human colon cancer remains unclear.

### INHIBITION OF ANGIOGENESIS

Another cellular function by which NSAIDs may inhibit cancer involves the suppression of angiogenesis and neovascularization. <sup>44,45</sup> A selective COX-2 inhibitor (NS-398) suppresses production of angiogenic factors such as vascular endothelial growth factor, basic fibroblast growth factor, transforming growth factor-β, platelet-derived growth factor, and endothelin-1 by human cultured colon cancer cells that express COX-2. COX-2 expression greatly increases the production of angiogenic factors by these cells. In the same experiment, aspirin at concentrations thought to inhibit COX-1 selectively suppressed endothelial tube formation by human umbilical endothelial cells exposed to these growth factors. The inhibitory effect of NSAIDs on angiogenesis may involve several mechanisms, such as a COX-2 pathway that affects the production of angiogenic factors by tumor cells and a COX-1 pathway involving the endothelial cell response.

### EFFECTS ON METASTASIS

Relatively little research has examined the effect of NSAIDs on cancer metastases, although this area of experimental research has been active. Also limited has been research on the potential of aspirin or other NSAIDs as adjuvant therapy in treating cancers. A small randomized clinical trial found no improvement in the survival of 66 patients with Duke's class B2 or C invasive colorectal cancer with aspirin treatment of 600 mg twice daily. <sup>150</sup>

## NONSTEROIDAL ANTIINFLAMMATORY DRUGS AND CANCERS OTHER THAN COLORECTAL CANCER

A few studies have examined the relationship between the use of aspirin and other NSAIDs and the digestive tract cancers other than that of the large intestine. [Table 23.6-3](#) lists the studies pertaining to cancers of the esophagus and stomach. In the American Cancer Society study, aspirin use was inversely associated with fatal cancers of the esophagus and stomach as well as colon and rectum, but not generally with fatal cancers outside the GI tract. <sup>13</sup> The limited evidence that NSAIDs may inhibit cancers throughout the digestive tract is interesting in light of the common embryologic derivation of GI tissues <sup>47</sup> and observations that COX-2 is also prominently expressed in cancers of the esophagus<sup>151,152</sup> and stomach.<sup>153,154</sup>

Reference	Population	Study Type	End Point	Drug	Regimen	Results (95% CI)	Comments
Isomaa et al. (2002) <sup>151</sup>	Men aged 45-75 years and 10,000-15,000 men (1982-1997)	1 case	Esophageal cancer (adenocarcinoma)	Therapeutic aspirin	Mean use 1.1 (0.0)	OR 0.5 (0.1-2.1)	
Griffin et al. (2002) <sup>152</sup>	Men aged 45-75 years and 10,000-15,000 men (1982-1997)	11 cases	Esophageal cancer (adenocarcinoma)	Therapeutic aspirin	Mean use 1.1 (0.0)	OR 0.5 (0.1-2.1)	
Chen et al. (2002) <sup>153</sup>	Men aged 45-75 years and 10,000-15,000 men (1982-1997)	176 cases	Esophageal cancer (adenocarcinoma)	Aspirin	OR 0.5 (0.1-2.1)	OR 0.5 (0.1-2.1)	For each 100 mg increase in aspirin use, the risk of adenocarcinoma of the esophagus decreased by 5%.
Shibata et al. (2002) <sup>154</sup>	Men aged 45-75 years and 10,000-15,000 men (1982-1997)	11 cases	Esophageal cancer (adenocarcinoma)	Aspirin	OR 0.5 (0.1-2.1)	OR 0.5 (0.1-2.1)	OR 0.5 (0.1-2.1)

TABLE 23.6-3. Cohort Studies of Use of Nonsteroidal Antiinflammatory Drugs and Risks for Esophageal and Gastric Cancers <sup>a</sup>

The results of nonrandomized studies relating breast cancer to NSAID use have been less consistent, with two case-control studies reporting some reduction in risk, but other large prospective studies finding no association ( [Fig. 23.6-3](#)). Extensive evidence indicates that eicosanoids affect several aspects of carcinogenesis in mouse models of mammary carcinoma<sup>155</sup> and that both COX-1 and COX-2 are moderately up-regulated in some human breast tumors.<sup>156</sup> However, the current

evidence that NSAIDs may be useful in the prevention or treatment of breast cancer in humans is limited.

FIGURE 23.6-3. Epidemiologic studies of nonsteroidal antiinflammatory drugs and breast cancer. occ., occasional.

## DOSE AND DURATION ISSUES IN CHEMOPREVENTION

Because the GI toxicity of NSAIDs is dose-dependent, at least two strategies have emerged for minimizing the toxicity of NSAID treatment while maintaining therapeutic effectiveness. One has been the development of “designer” drugs, such as the novel selective COX-2 inhibitors that are thought to be less ulcerogenic than conventional NSAIDs. A second approach, used effectively in preventing cardiovascular disease with aspirin, has been to identify a sufficiently low dose of NSAID that is effective therapeutically yet has minimal GI toxicity. Antiplatelet doses not exceeding 100 mg aspirin daily have the largest absolute benefit in populations at high risk of cardiovascular events, because the large, immediate reduction in cardiovascular risk far outweighs the small increase in GI bleeding that occurs even with low-dose aspirin.

With respect to the chemoprevention of colon cancer, researchers have not yet identified the lowest effective dose or optimal NSAID treatment regimen. Resolving these uncertainties becomes critically important when large numbers of people might consider taking a chemopreventive drug for several decades. In this context, the balance of cumulative benefit to risk is highly susceptible to the lowest effective dose of the drug, the toxicity at this dosage, the probability of serious adverse effects in a particular individual,<sup>154</sup> and the probability of the event being prevented. None of these clinical questions has yet been adequately answered with respect to NSAIDs and colorectal or other cancers.

#### INTRODUCTION

The 1994 report of the U.S. Surgeon General concludes that lack of physical activity is causally related to increased risk of coronary heart disease, diabetes, and colon cancer.<sup>1,2</sup> Other cancers are listed as having a suggestive relation, including breast cancer, whereas there is lack of evidence for a relation between activity and either rectal or prostate cancers. The evidence for colon and breast cancers is therefore summarized in detail.

#### COLON CANCER

Numerous studies have illustrated a relation between physical activity and colon cancer. Higher levels of physical activity are related to lower rates of colon cancer,<sup>1,3</sup> the fourth most common cancer diagnosed in the United States.

The rates of colon cancer vary considerably among countries. During the 1960s and 1970s, there was a gradual increase in colon cancer in most industrialized countries, and in European countries with low rates there was an increase in the rates observed in high-risk countries, such as the United States and England. Low incidence is reported from India and China, whereas high rates are observed in the United States, Australia, and Western Europe.<sup>4</sup> Numerous lifestyle factors have been proposed to explain this large international variation.<sup>5</sup>

#### PHYSICAL ACTIVITY

Epidemiologic studies have measured activity in two ways: by occupation and by leisure-time activities. These measures may represent somewhat different patterns of energy expenditure. Activity demanded by employment in a certain occupation may be relatively constant from week to week and year to year, whereas leisure-time activity is far more labile, changing from week to week, season to season, and year to year. In the epidemiologic study of a disease like colon cancer, long-term patterns of activity may be the relevant factor in determining disease risk. Therefore, occupational activity may be a better marker of cancer-determining activity level than is self-reported leisure-time activity. Both the methods used to measure activity and the validity or accuracy of the methods vary considerably. Similar methodologic issues arose in the study of heart disease<sup>6</sup>: When poor measures of activity were used, studies tended to underestimate the true impact of activity on health. In other words, studies using poor measures of physical activity fail to measure true activity levels and then fail to provide data showing a strong association with activity, even though physical activity is, in truth, protective against heart disease.<sup>1</sup>

Likewise for colon cancer, when less accurate measures of physical activity are used, the estimated benefit from this activity is smaller than its probable true benefit. Thus, the protection by physical activity is underestimated. Nonetheless, as summarized in the following section, the most precise studies using validated measures of physical activity have shown, overall, that higher levels of physical activity are related to lower levels of colon cancer.

#### *Validity of Activity Measures*

The validity of activity measures has been assessed and is quite variable.<sup>7,8</sup> Among the better measures, one observes a correlation between the self-reported measure of activity and an independent gold standard (such as 28 days of activity diary) in the range of 0.5 to 0.7. Thus, the epidemiologic associations observed with these measures of activity and disease outcome are considerably attenuated, perhaps by as much as one-half. For example, Giovannucci et al.<sup>9</sup> reported a relative risk that was 0.88 [95% confidence interval (CI), 0.81 to 0.95] per 10 metabolic equivalent of task (MET) increase in physical activity. After correcting for measurement error, the relative risk was strengthened to 0.65 (0.48 to 0.88).

A systematic review of published literature through March 1997 identified studies that reported a measure of physical activity and outcomes of colon cancer or colorectal cancer. A review of these studies presents summary data for each, including the relative risk for each level of activity.<sup>2</sup>

**CASE-CONTROL STUDIES.** Overall, the published case-control studies suggest a consistent inverse relation between both occupational and leisure-time activity and colon cancer risk among men and women. These results have been replicated across a wide range of countries, including China, Japan, New Zealand, Spain, Sweden, Turkey, and the United States.

**COHORT STUDIES.** Cohort studies generally enroll healthy individuals to assess elements of lifestyle, behavior, environment, and occupation that are thought to influence later development of disease. The initial follow-up of college athletes by Polednak<sup>10</sup> did not show any protection against colon cancer, although data were not available on lifestyle characteristics (including family history, diet, smoking, etc.). The other 17 studies through 1997 show a reduction in risk similar to that observed in the case-control studies. Higher activity in adult life is generally related to reduced risk of colon cancer, although the cohort results are less consistent than are those from the case-control studies. Inconsistency may, in part, be attributed to studies that focused on college activity and cancer risk many years later,<sup>10,11</sup> or that included both colon and rectal cancer in a single outcome category.<sup>11,12</sup> (An inverse association between activity and rectal cancer is generally not seen when rectal cancer is analyzed as a separate outcome variable.) When occupation was used to categorize activity in a study of Swedish men, those with higher activity had a lower risk of colon cancer [relative risk (RR) = 0.8].<sup>13</sup> In that study, the strongest contrast was based on a joint classification of occupation and recreational activity. Men in the highest activity group for both occupation and recreation had a relative risk that was 0.3 (0.1 to 0.8) representing a 70% reduction in risk compared with men who were inactive at work and engaged in little recreational activity.

Leisure-time activity is addressed separately in the Harvard Alumni Study, a cohort of graduates from Harvard College followed since 1960 to study activity and chronic diseases; Lee and colleagues observed a strong inverse association among men who were active both in the 1960s and in 1977 when surveys were administered.<sup>14</sup> Men expending more than 2500 kcal per week in leisure activity had a 50% reduction in risk of colon cancer compared with those expending less than 1000 kcal per week.

Overall, the cohort studies conducted in Denmark, Norway, Sweden, Switzerland, and the United States support a dose-response relation across increasing activity levels: Higher activity levels are related to lower levels of colon cancer risk. Those in the highest activity category have approximately a 40% to 50% reduction in risk of colon cancer compared to the least active category.<sup>2</sup>

Although historically data have suggested that the association between physical activity and reduced risk of colon cancer is stronger in men than in women, this finding may, in part, reflect the small number of women in the high-activity category. Data from Norway show a stronger relation between total physical activity and colon cancer among women than among men,<sup>15</sup> and data from the Nurses' Health Study show similar magnitude of reduction in risk in women as observed among men in a parallel study using comparable methods for activity assessment.<sup>16</sup>

**SITE-SPECIFIC RISK.** Studies that examined activity in relation to site of cancer in the colon suggest that the relation between higher activity and lower risk of cancer

may be stronger for the left than for the right colon. One large case-control study shows no difference in the strength of association between vigorous activity and proximal or distal colon cancer.<sup>17</sup> The association is stronger for the colon than it is for the rectum, for which activity is at best only very weakly associated.

### Interpretation

Despite the variable and often poor measures of activity used, a consistent reduction in risk is observed across different study design and different populations and across occupational and leisure-time activity. A consistent dose-response relation emerges, indicating that those at higher levels of activity are at reduced risk of colon cancer. Across the studies, the evidence suggests that the relation is stronger for the left colon and weaker or absent for rectal cancer. Few studies have addressed the relation between specific activities and cancer risk (e.g., Is swimming less protective than jogging?) or the importance of the age at which a person is active in determining the likelihood of cancer (e.g., Is activity more protective in youth, middle age, or years immediately before the diagnosis of cancer?). Three studies that address physical activity during early adulthood show no relation.<sup>10,11,18</sup> Although these studies failed to control for several colon cancer risk factors, the results are consistent with an effect of activity later in the pathway to cancer. Evidence from Lee and colleagues<sup>14</sup> also supports a role later in the pathway to cancer. Men who had increased their level of activity during follow-up of the cohort had a suggestion of lower risk of colon cancer during subsequent follow-up. More data are needed, however, to refine the understanding of the time course between change in physical activity and change in risk of cancer. In general, the studies based on classification of activity by occupation show a stronger dose response than those based on leisure-time activity and support a protective effect across the wide range of activities encompassed by the high-activity occupations.

How do we know that physical activity is actually protecting subjects from developing colon cancer? Is it possible that active men and women are also healthier in other ways (e.g., eating less red meat and more folate) and that these factors are the real reason for the observed protection from physical activity? Several studies have reported analyses that address the independent relation between activity and colon cancer risk—that is, they control for other lifestyle factors [body mass index (BMI), alcohol, and diet] that may be related to higher levels of physical activity and could therefore bias or distort the protection attributed to physical activity. Activity is independent of dietary fat and fiber intake in these studies and is also independent of BMI, a measure of adiposity. Although not all studies examined for the independence of activity from other lifestyle factors, the magnitude of the inverse relation is not materially altered when investigators have controlled for diet, BMI, and other factors. The one exception is the analysis by Whittemore et al.,<sup>18</sup> who saw a shift in the magnitude of association after control for diet in the case-control data from the People's Republic of China, but no substantial change in effect after control for diet in the United States. In a detailed analysis of the Health Professionals Follow-Up Study, a cohort of some 50,000 men followed to study relations between diet and chronic diseases, Giovannucci et al. showed that individuals with higher physical activity were more likely to use multivitamins, had lower intake of saturated fat, higher intake of fiber, lower prevalence of cigarette smoking, and lower BMI (men were leaner).<sup>9</sup> After controlling for these risk factors, as well as use of aspirin and family history, the protection was reduced from 56% to 47% [the relative risk changed from 0.4 (0.3 to 0.7) to 0.5 (0.3 to 0.9)]. In other words, the protection remained at almost 50% despite controlling for all the other factors known to relate to colon cancer risk. The inverse trend in risk with increasing activity remained statistically significant. Thus, we conclude that activity is not merely a marker of healthier lifestyle, but exerts an independent protective effect.

### Mechanisms

Several biologic mechanisms have been proposed for the protective effect of physical activity, reflecting changes in physiologic measures after physical activity. Among these is the bowel transit time that decreases with physical activity. It is then proposed that the reduced transit time alters the environment within the colon and thereby reduces exposure to carcinogens.<sup>20,21</sup>

A second mechanism may be that abdominal obesity and low physical activity are independently related to insulin resistance. Across a gradient of physical activity, insulin sensitivity improves with exercise.<sup>22</sup> Furthermore, insulin is a strong growth factor for colon mucosal cells in laboratory studies and an animal model of colon cancer.<sup>23</sup> Thus, it is possible that activity exerts its protective effect through reduced insulin levels.<sup>24,25</sup>

Another possible mechanism is the effect of prostaglandins on colon cell proliferation. Physical activity produces an increase in prostaglandin F<sub>2a</sub>, which increases intestinal motility, and a decrease in prostaglandin E<sub>2</sub>, which in cell culture can act to stimulate colon cell proliferation. Further support for this possible mechanism comes from laboratory studies on rats and evidence in humans that aspirin and nonsteroidal antiinflammatory drugs, also inhibitors of prostaglandin synthesis, reduce risk of colon cancer.<sup>26,27</sup>

With this large body of epidemiologic data and supporting laboratory studies, it appears that low levels of physical activity are causally related to increased risk of colon cancer. Causal considerations include a consistent decrease in risk with higher levels of physical activity, either measured as occupational activity or leisure-time activity, a dose-response relation with hours of activity per week or level of occupational physical activity, specificity for the relation with colon and not rectum, and a temporal relation such that activity measures precede the onset of colon cancer by years, although relations are stronger for more recent activity rather than distant past activity.

## BREAST CANCER

Regular physical activity has been hypothesized to prevent breast cancer, largely by reducing circulating levels of sex hormones. The mechanisms by which physical activity reduces exposure to hormones vary by period of life. Young girls participating in strenuous athletic training such as running and ballet dancing have delayed menarche,<sup>28,29</sup> and 30 which is known to reduce the risk of breast cancer, and even moderate-intensity physical activity may also delay menstruation.<sup>31</sup> A later menarche is associated with a later onset of regular ovulatory cycles and lower serum estrogen concentrations during adolescence.<sup>32</sup> Once menstruation has been established, anovulatory and irregular menstrual cycles may be more frequent among moderately and strenuously active women than among inactive women,<sup>28,33,34</sup> although there is disagreement regarding the degree to which the intensity of physical activity influences menstrual abnormalities.<sup>35</sup> Among older women, levels of past and current physical activity influence fat stores,<sup>29,30,36,37,38</sup> and 39 which after menopause are the locus of conversion of androstenedione to estrogen.<sup>40,41</sup>

Despite the evidence that higher levels of physical activity are associated with lower levels of circulating ovarian hormones, epidemiologic studies relating physical activity to risk of breast cancer are inconsistent.<sup>42</sup> Methodologic differences in physical activity assessment are likely to have contributed to these inconsistencies. Studies have differed in the ages at which physical activity was assessed; methods for measuring intensity, frequency, and duration of physical activity; definition and categorization of physical activity levels; and age of breast cancer diagnosis. Furthermore, the ranges of physical activity that are typically studied are very limited in comparison with the levels of hard labor typically practiced by women in traditional agrarian societies.

To date, the strongest reduction in breast cancer risk associated with increased physical activity has been reported in a population-based case-control study of women younger than age 40 years in Southern California.<sup>43</sup> The RR was 0.42 (95% CI, 0.27 to 0.64) when comparing women with a lifetime average of 3.8 hours or more of physical activity per week to those with an average of 0 hours per week. This has been the only study explicitly devoted to the relationship between physical activity and breast cancer, and it used a detailed physical activity assessment instrument to quantify the average number of hours per week of recreational physical activity over the reproductive life span, beginning at menarche. Activities such as housework, gardening, and easy walking not for the explicit purpose of physical exercise were not counted in the measure of physical activity. Bernstein et al.<sup>43</sup> concluded from their various analyses that lifelong physical activity is the critical exposure of interest with regard to breast cancer risk.

In contrast to the detailed measurement instrument previously described, a relatively simple measure of physical activity was used in a prospective cohort study of Norwegian women aged 20 to 54 years at baseline.<sup>44</sup> Over a period of 3 to 5 years, women were administered two surveys about their patterns of physical activity during leisure hours. The RR was 0.63 (95% CI, 0.42 to 0.95) for consistently active women compared to consistently sedentary women, which is the second-strongest inverse association reported in the literature. This study is also the only prospective cohort study of the five reported to date<sup>12,44,45,46</sup> and 47 to find a substantial inverse association between physical activity and breast cancer risk.

Most studies fall between these two studies<sup>43,44</sup> with regard to the detail of physical activity measurement and categorization. For instance, in two population-based case-control studies<sup>48,49</sup> conducted among younger women, physical activity both early in life and in the period immediately before the interview was assessed. However, neither of these studies found an inverse association between physical activity (in either period) and breast cancer risk, despite defining physical activity categories in various ways.

Because of the potential public health significance of an association between a modifiable lifestyle risk factor such as physical activity and breast cancer, future

studies will need to address important methodologic issues surrounding physical activity measurement.

Although the relation between physical activity and risk of breast cancer remains unsettled, indirect evidence relating higher physical activity to risk of postmenopausal breast cancer is strong because of the important role of activity in controlling weight gain, an important cause of postmenopausal breast cancer. This, in addition to many other benefits of staying lean and fit, provide sufficient justification for including regular physical activity in daily life.

## OBESITY

A strong and consistent relation has been reported between obesity and mortality from all cancers among men and women.<sup>50</sup> Due to the relationship of obesity with postmenopausal breast cancer and endometrial cancer, the relation is stronger among women than among men.<sup>51</sup>

Attained weight and weight change in adults provide sensitive measures of the balance between long-term energy intake and expenditure. Although the relation between these variables and breast cancer risk has been complex and confusing, findings provide a coherent picture and indicate a major contribution of weight gain to risk of postmenopausal breast cancer risk. Two reproducible findings have been particularly enigmatic: (1) In affluent Western populations with high rates of breast cancer, measures of body fatness have been *inversely* related to risk of premenopausal breast cancer, and (2) body fatness has been only weakly related to postmenopausal breast cancer risk despite strong associations between body fat and endogenous estrogen levels.

The inverse relation between body weight (typically determined as BMI, calculated as weight in kg divided by height in meters,<sup>2</sup> to account for variation in height) and incidence of premenopausal breast cancer has been consistently seen in recent prospective studies,<sup>52</sup> and in a metaanalysis of both case-control and cohort studies.<sup>53</sup> Little relation between BMI and breast cancer mortality has been observed in premenopausal women, probably because delayed detection and diagnosis in heavier women counterbalances the lower incidence among heavier women. Heavier premenopausal women, even at the upper limits of what are considered to be healthy weights, have more irregular menstrual cycles and increased rates of anovulatory infertility,<sup>54</sup> suggesting that their lower risk may be due to fewer ovulatory cycles and less exposure to ovarian hormones. Increased rates of menstrual irregularity and anovulatory infertility also are seen among very lean women, but such women are uncommon in Western populations. In case-control studies, a consistent relation between menstrual cycle regularity and breast cancer risk has not emerged, which could cast doubt on this explanation, but this may be due to the indirect relation between menstrual regularity and ovulation and to difficulties in remote recall. In a prospective study among younger women, compared with regular cycles of approximately 28 days, both short and longer or irregular cycles were associated with reduced risk of breast cancer,<sup>55</sup> lending support to irregular anovulation as the explanation for the lower risk in heavier women.

In both case-control and prospective studies conducted in affluent Western countries, the association between BMI and risk of breast cancer among postmenopausal breast cancer has been only weakly positive or nonexistent.<sup>56,57</sup> The lack of a stronger association has been surprising because obese postmenopausal women have plasma levels of endogenous estrogens nearly twice as high as lean women, due to conversion of androstenedione to estrogens in adipose tissue and also lower levels of sex-hormone binding globulin.<sup>58</sup> However, the lack of a stronger positive association now appears to be due to two factors.

First, like the protective effect of early pregnancy, the reduction in breast cancer risk associated with being overweight in early adult life appears to persist throughout later life.<sup>52,59</sup> Thus, an elevated BMI in a postmenopausal woman represents two opposing risks: a protective effect due to the correlation between early weight and postmenopausal weight and an adverse effect due to elevated estrogens after menopause. For this reason, weight *gain* from early adult life to after menopause should be more strongly related to postmenopausal breast cancer risk than would attained weight. Indeed, the relation between weight gain and risk of postmenopausal breast cancer has been consistently supported by both case-control<sup>60</sup> and prospective studies.<sup>52,59,61</sup>

A second reason for failing to appreciate a greater adverse effect of excessive weight or weight gain on risk of postmenopausal breast cancer is that the use of postmenopausal hormones obscures the variation in endogenous estrogens due to adiposity and elevates breast cancer risk regardless of body weight.<sup>52</sup> To appreciate fully the impact of weight or weight gain, an analysis should be limited to women who never used postmenopausal hormones. Thus, among women who never used postmenopausal hormones in the Nurses' Health Study, those who gained 25 kg or more after age 18 years had double the risk of breast cancer compared with women who maintained their weight within 2 kg.<sup>52</sup> In this population, the combination of either using postmenopausal hormones or gaining weight after age 18 years accounted for one-third of postmenopausal breast cancer cases.

The relation between body weight and breast cancer risk among lower risk, mainly non-Western, countries has been observed to be somewhat different in higher risk countries.<sup>62</sup> In general, the inverse relation between weight and premenopausal breast cancer risk has not been observed, and the association between weight and postmenopausal risk has been stronger. This difference is likely to be due to the lower prevalence of obesity among premenopausal women in these low-risk countries; few women are likely to be sufficiently overweight so as to cause anovulation and a reduction in premenopausal breast cancer risk. As a result, BMI after menopause would only reflect the adverse effects of high endogenous estrogens, unopposed by a residual protective effect due to correlation with overweight in early adult life.

## RELATIONSHIP BETWEEN OBESITY AND CARCINOMA

As in animal studies, energy balance appears to play an important but complex role in the causation of human breast cancer. During early adult life, obesity is associated with a lower incidence of breast cancer before menopause, but no reduction in breast cancer mortality. However, weight gain after age 18 years is associated with a graded and substantial increase in postmenopausal breast cancer that is seen most clearly in the absence of hormone replacement therapy.

The relationship between obesity and risk of endometrial cancer follows from the excess exposure to estrogen that is associated with adiposity. This direct relation has been long observed.

The relationship between obesity and colon cancer has been observed among both women and men and persists even after control for physical activity and dietary patterns.<sup>9,16</sup> It is postulated that excess weight gain may act through increased insulin resistance and hyperinsulinemia to promote colon carcinogenesis.<sup>24,25</sup>

Evidence for a relationship between obesity and prostate cancer is less consistent. At this time, the inconclusive evidence precludes a definite assertion of any important relation.

## CONCLUSIONS

Lack of physical activity and adult weight gain are harbingers of our Western culture and both act to increase risk of major malignancies. Through numerous mechanisms, these two lifestyle factors contribute substantially to the risk of colon and breast cancer. The evidence is strong for obesity and endometrial cancer, and less consistent for other major malignancies.

### INTRODUCTION

Prophylactic is a word derived from Greek (*pro-* “before” and *phylassin-* “to guard”) meaning “advanced guard.” The current status of prophylactic surgery to prevent malignant disease is limited and often controversial. Clinicians have long recognized that certain conditions, such as inflammatory bowel disease and cryptorchidism, confer on patients an increased risk of developing fatal organ-specific malignancies. Advances in molecular biology coupled with an increased appreciation that cancer is a genetic disorder have made accurate risk evaluation with genetic screening a reality for certain malignancies. As our understanding of cancer susceptibility has advanced, so too has our appreciation of the complexity of the associated social and clinical issues. Progress in the laboratory has often outpaced our ability to use these new insights in the clinic. These factors have created a new impetus to develop practical strategies to prevent cancer.

That surgery can and should be used to prevent cancer is obvious ( [Table 24-1](#)). The fact that colonoscopic polypectomy can help prevent colorectal cancer is now accepted and largely taken for granted.<sup>1</sup> However, the efficacy of many other interventions is not as convincing. Although the role of prophylactic surgery is largely undefined, it is certain to evolve. The focus of this chapter is the current use of surgery to prevent cancer.

Genetic Condition	Associated Malignancy	Recommendation for Prophylactic Surgery
MEN 2b, MEN 2a, familial medullary thyroid cancer	Medullary thyroid cancer	Total thyroidectomy at approximately 6 years of age for patients with RET protooncogene mutations
Barrett's esophagus	Adenocarcinoma of the esophagus	Esophagectomy should be considered for healthy patients with high-grade dysplasia
MEN 2c, MEN 2a mutation	Breast cancer	Bilateral total mastectomy is a reasonable option in affected patients
	Ovarian cancer	Bilateral oophorectomy is a reasonable option in affected patients after childbearing
Ulcerative colitis	Colorectal cancer	Colectomy should be considered if associated with the disease, a 30-year history of proctitis, and/or non-papillary adenomas
Familial adenomatous polyposis	Colorectal cancer	Colectomy to prevent cancer is earlier if polyps are frequent or challenging
HPNCC	Colorectal cancer	Surveillance colonoscopy/polypectomy reduces the risk of cancer. The role of prophylactic colectomy is controversial
Cryptorchidism	Testicular cancer	Orchiectomy for undescended testes. Orchiopexy is recommended for non-patent
